## Abstract

Tipping points occur in many real-world systems, at which the system shifts suddenly from one state to another. The ability to predict the occurrence of tipping points from time series data remains an outstanding challenge and a major interest in a broad range of research fields. Particularly, the widely used methods based on bifurcation theory are neither reliable in prediction accuracy nor applicable for irregularly-sampled time series which are commonly observed from real-world systems. Here we address this challenge by developing a deep learning algorithm for predicting the occurrence of tipping points in untrained systems, by exploiting information about normal forms. Our algorithm not only outperforms traditional methods for regularly-sampled model time series but also achieves accurate predictions for irregularly-sampled model time series and empirical time series. Our ability to predict tipping points for complex systems paves the way for mitigation risks, prevention of catastrophic failures, and restoration of degraded systems, with broad applications in social science, engineering, and biology.

## Introduction

Many real-world systems, ranging from biological systems to climate systems and financial systems, can experience sudden shifts between states at critical thresholds which are so-called tipping points, for example, the epileptic seizures(1), abrupt shifts in ocean circulation(2, 3) and systemic market crashes(4). Accurately predicting tipping points before they occur has many important applications, including making strategies to prevent disease outbreak, avoiding disasters induced by climate change and designing robust financial systems. However, due to the complexity of various real-world systems, it is a challenge task to invent an effective tool to predict the occurrence of tipping points(5, 6).

A classical mathematical tool to understand tipping points is bifurcation theory which focuses on how dynamical systems undergo sudden qualitative changes as a parameter crosses a threshold(7). There are basically two classes of methods based on bifurcation theory to deal with tipping points prediction. The first class of methods is using lag-1 autocorrelation which is based on “critical slowing down”, a paramount clue of whether a tipping point is approached(5, 8). Such methods are widely used in various complex systems, including degenerate fingerprinting(9), BB method(10) and ROSA(11). The second class of methods is using dynamical eigenvalue (DEV)(12) which is based on Takens embedding theorem(13). Yet, the success of the existing methods based on bifurcation theory are impaired by two fundamental limitations. First, these methods are not applicable for irregularly-sampled time series data which are commonly observed from various scientific fields, such as geoscientific measurements(14, 15), medical observations(16) and biological systems(17). Second, the performance of existing methods based on bifurcation theory in prediction accuracy is affected by several approximations used in these methods. One such approximation is that only the first-order term of the dynamical systems is considered

in these methods while the impact of the higher-order terms is ignored. However, the higher-order terms become significant for prediction when a tipping point is approached(18) (see Supplementary Information section 1 for details). Besides, in the approximation of fast-slow systems(19), the delay on the bifurcation-tipping due to the changing rate of the bifurcation parameter is ignored(20, 21) (see Supplementary Information section 2.1 and 2.2 for details).

Recent studies show that some machine learning based techniques have been used as effective early warning signals of tipping points by learning generic features of bifurcation(18, 22–24). However, they can not be used for predicting where the tipping points occur. A machine learning framework based on reservoir computing has been developed for tipping points prediction(25–27). But this algorithm is only effective for nonlinear dynamical systems with chaotic attractors and requires a large amount of data from phase space for training.

To circumvent above limitations of existing methods for tipping points prediction, we develop a deep learning (DL) algorithm based on 2D CNN-LSTM architecture. This DL algorithm only requires the time series of the state and that of the bifurcation parameter from a single variable of a system. The 2D CNN layer is used to extract local features from the time series of the state and that of the bifurcation parameter. Then the LSTM layer is used to identify long-term dependencies from the sequences of local features for tipping points prediction. We assume that the DL algorithm can detect features that emerge in time series prior to a tipping point, such as the features of the recovery rate in normal forms, which are associated with the occurrence of tipping points. We apply the DL algorithm to predict the occurrence of tipping points in systems it was not trained on. Our DL algorithm is applicable to both regularly-sampled and irregularly-sampled time series. We first test this DL algorithm on regularly-sampled time series generated by the models from ecology(28–30) and climatology(31–34). The DL algorithm outperforms traditional methods in prediction accuracy for regularly-sampled model time series. We further validate our DL algorithm on irregularly-sampled time series generated by the same models and two other models from neuroscience with hysteresis phenomena(35, 36). Finally, we validate our DL algorithm in irregularly-sampled empirical data from microbiology(37), thermoacoustics(20) and paleoclimatology(38). In this work, we show that our DL algorithm is effective in dealing with dynamical systems exhibiting fold, Hopf and transcritical bifurcation. We anticipate that our DL algorithm may also be applicable to dynamical systems exhibiting other bifurcation types.

## Results

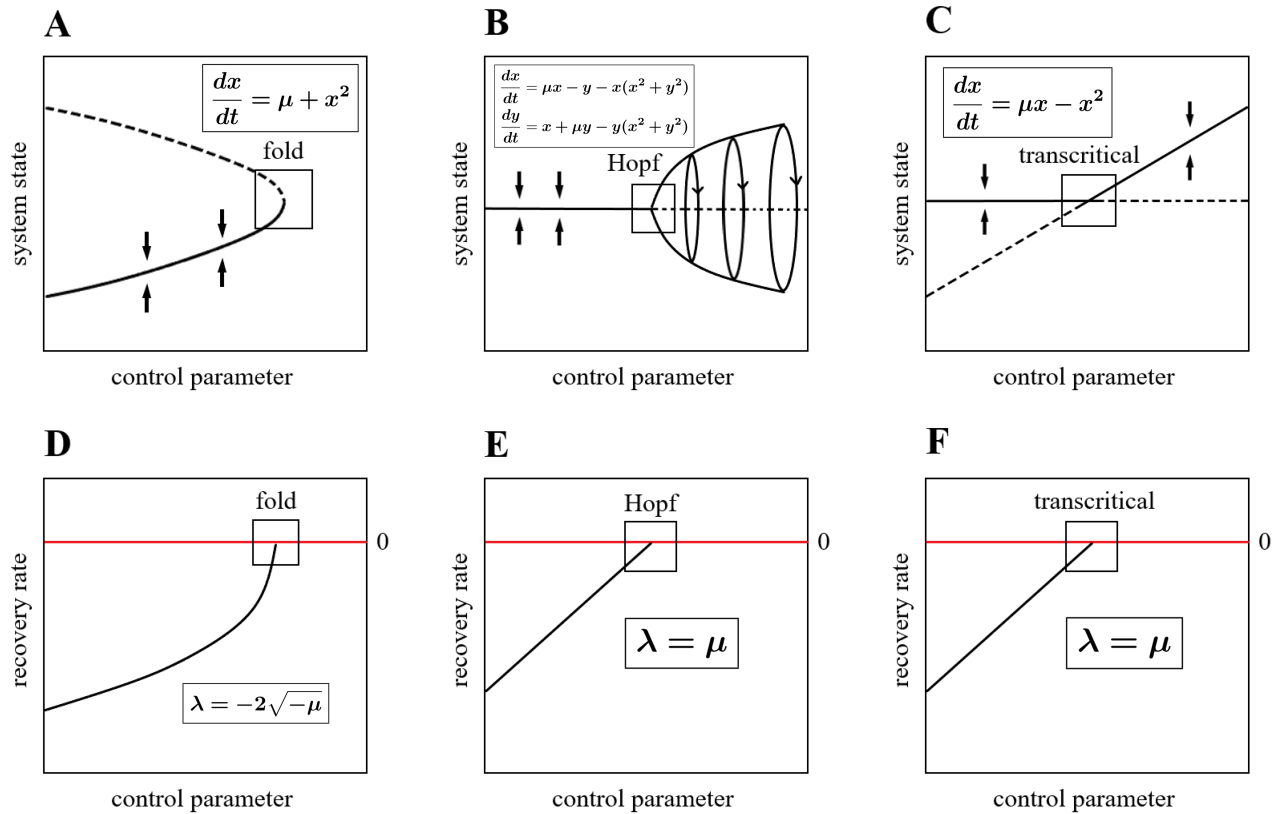

### Bifurcation theory

The bifurcation theory is a classical and widely used mathematical tool to understand tipping points. According to the center manifold theorem(7), as a high-dimensional dynamical system approaches a bifurcation, its dynamics converges to a lower-dimensional space which exhibits dynamics topologically equivalent to those of the normal form of that bifurcation(7). Here we focused on codimension-one bifurcations in continuous-time dynamical systems, including the fold, Hopf, and transcritical bifurcation. Many tipping points of complex systems from the nature and the society are initiated by these three types of bifurcation(18, 39). The normal forms of fold, Hopf, and transcritical bifurcation are shown in Fig. 1 A-C respectively.

Suppose  $dx/dt = f(x, \mu(t))$  has quasi-static attractor  $x^*(\mu)$  where  $\mu$  is the bifurcation parameter. Then the recovery rate is defined as the maximal real part of the eigenvalues of the Jacobian matrix when  $x = x^*(\mu)$  in an  $n$ -dimensional dynamical system(40, 41)

$$\lambda = \max(\operatorname{Re}(\operatorname{eigvals}(\left[ \begin{array}{ccc} \frac{\partial f_1}{\partial x_1} & \frac{\partial f_1}{\partial x_2} & \cdots & \frac{\partial f_1}{\partial x_n} \\ \frac{\partial f_2}{\partial x_1} & \frac{\partial f_2}{\partial x_2} & \cdots & \frac{\partial f_2}{\partial x_n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial f_n}{\partial x_1} & \frac{\partial f_n}{\partial x_2} & \cdots & \frac{\partial f_n}{\partial x_n} \end{array} \right]_{x=x^*(\mu)}))),$$

where *eigvals* refers to the operation of computing eigenvalue and *Re* refers to the operation of taking the real part. Note that when the recovery rate of a system shifts from negative value to positive value, the bifurcation occurs(7). In other words, if we know the relation between the recovery rate of a system and the bifurcation parameter, we can easily identify the tipping point for this system. It is also worth noting that the relation between the recovery rate and the bifurcation parameter is the same for the systems of the same bifurcation type in normal forms, as shown in Fig. 1 D-F respectively. We assume that our DL algorithm can detect features of the recovery rate for the system by training it on a training set generated from a sufficiently diverse library of possible dynamical systems with fold, Hopf and transcritical bifurcation. Then the DL algorithm can be used to predict the tipping points where the recovery rate becomes zero based on the detected relation between the recovery rate and the bifurcation parameter of the system. Note that we only focus on dynamical systems exhibiting fold, Hopf and transcritical bifurcation in this paper. In order to predict tipping points of other bifurcation types, we can expand the training library by including simulated data exhibiting those dynamics.

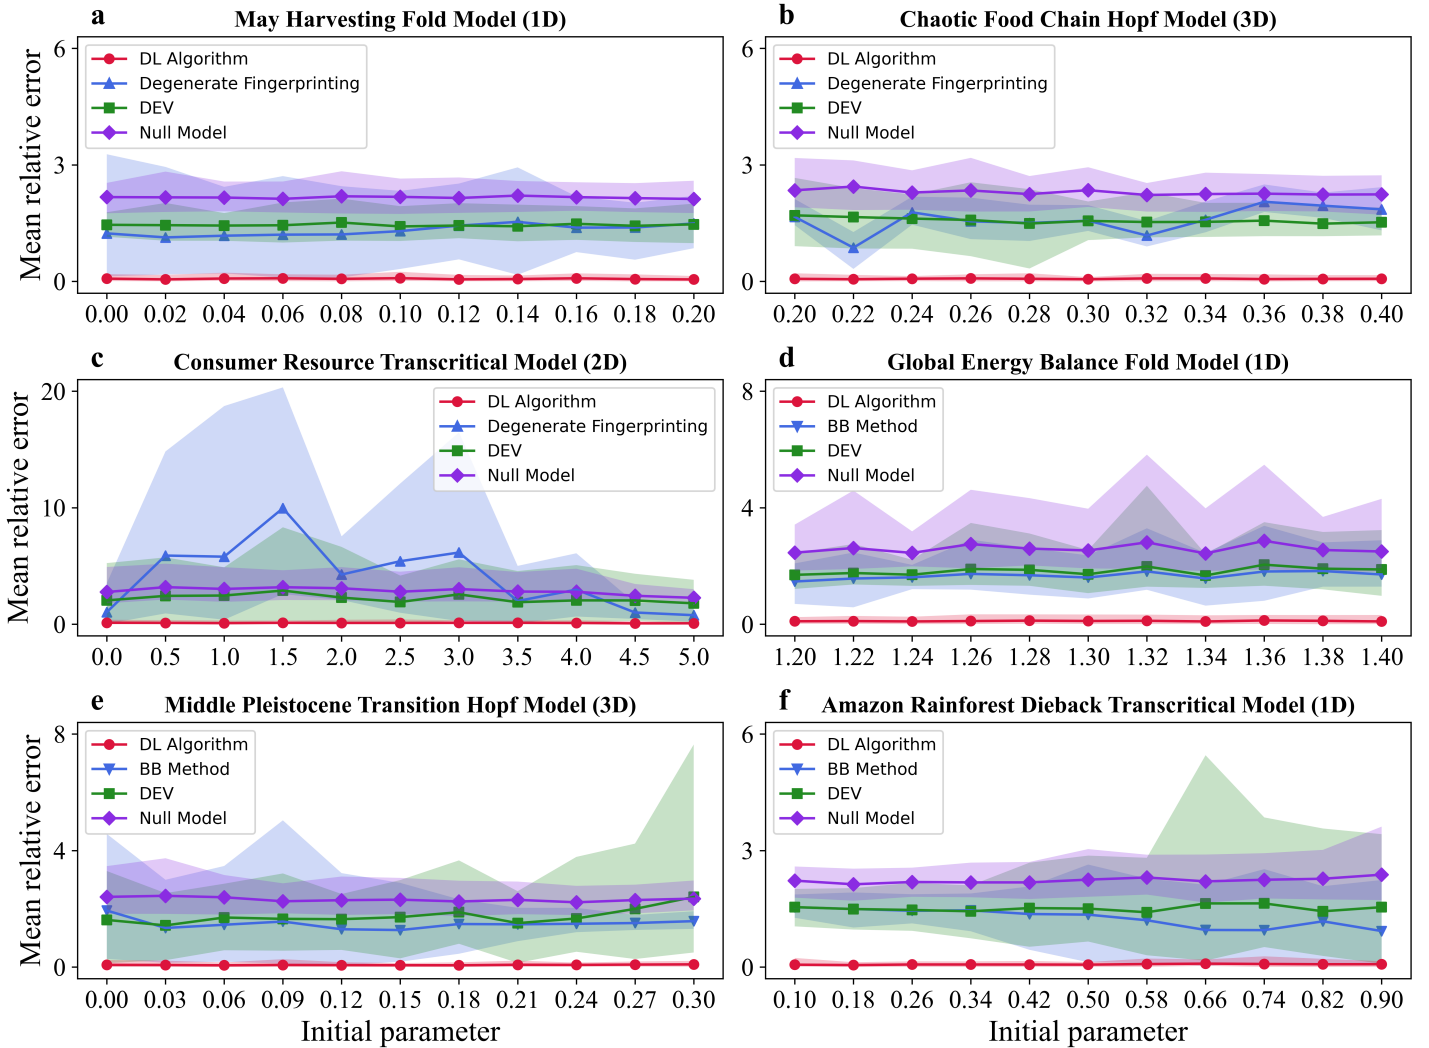

**Fig.1** (A-C) The normal forms of fold, (supercritical) Hopf, and transcritical bifurcation where bifurcation occurs at  $\mu = 0$  (hollow square). Their mathematical expressions are inside the boxes within the corresponding figures. (D-F) The recovery rate  $\lambda$  of the normal forms for the fold, (supercritical) Hopf, and transcritical bifurcation as a function of the control parameter  $\mu$ , their function expressions are inside the boxes within the corresponding figures. Bifurcation occurs when the recovery rate  $\lambda$  reaches zero (hollow square).

## Performance of DL algorithm on model time series

We applied the DL model on regularly-sampled time series generated from three ecological models with white noise and three climate models with red noise. We generated test data with 11 different initial values of the bifurcation parameter for each model and 50 test time series for each initial value of the bifurcation parameter. To evaluate the performance of DL algorithm, we measured the relative error(25) of tipping points prediction for each of the 50 test time series associated with every initial value of the bifurcation parameter. The performance of DL algorithm is evaluated by the mean relative error of tipping points prediction, which is averaged over the 50 measurements of the relative error of tipping points prediction for each initial value of the bifurcation parameter. We first compared

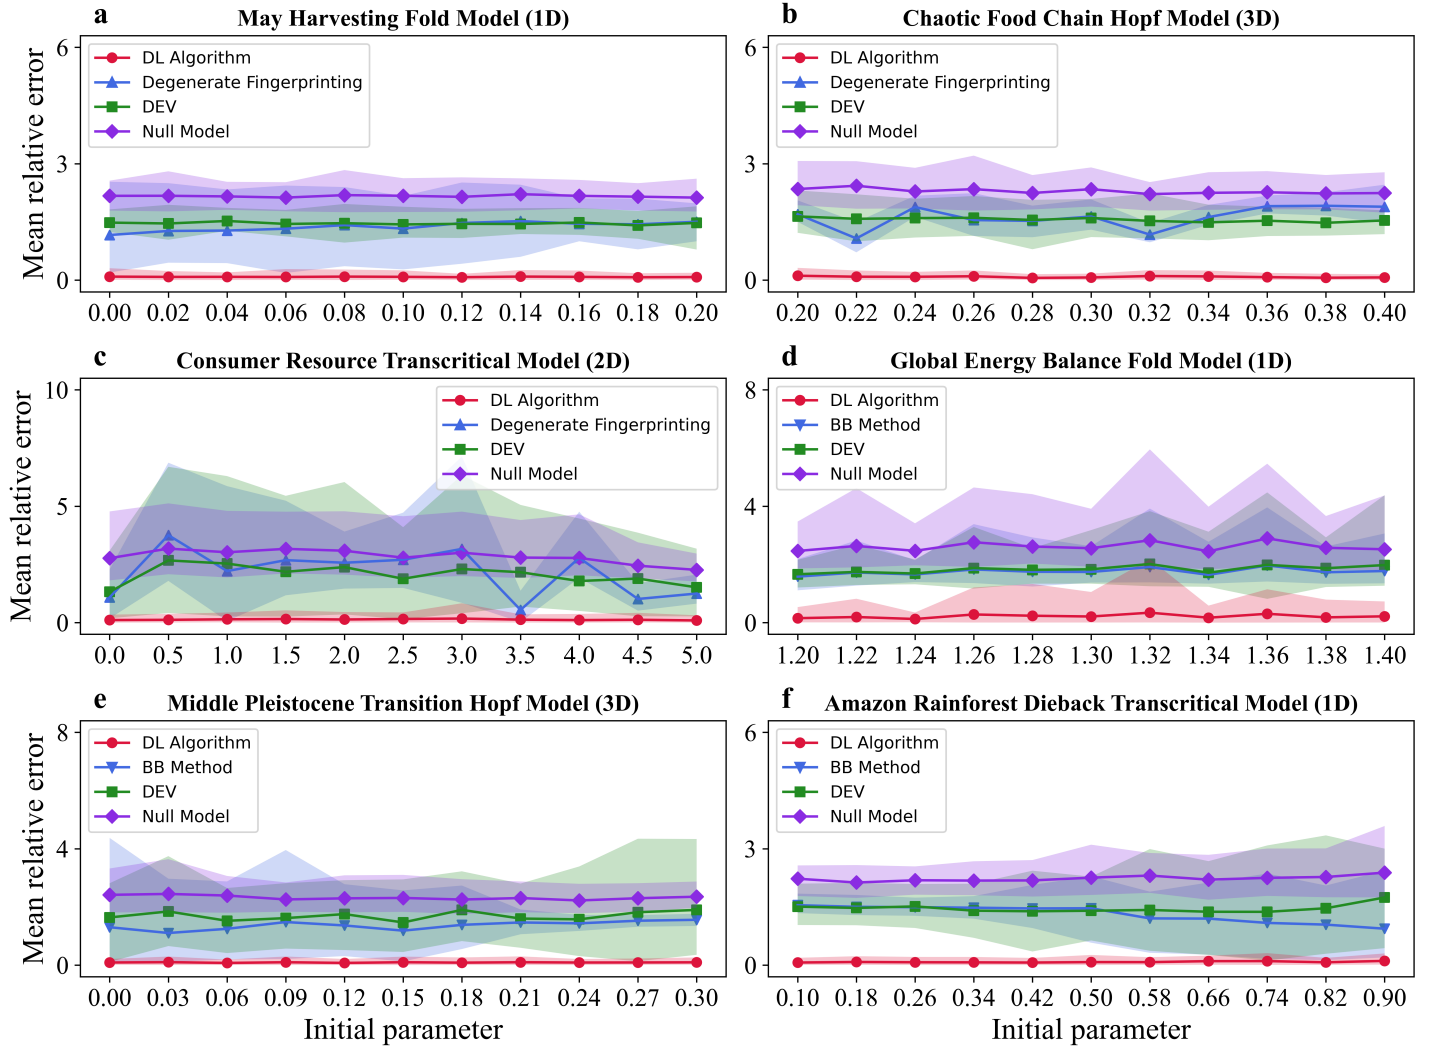

the results of DL algorithm with those of degenerate fingerprinting(9), DEV(12) and null model in three ecological models with white noise which exhibit fold, Hopf and transcritical bifurcations respectively. Then we compared the results of DL algorithm with those of BB method(10), DEV(12) and null model in three climate models with red noise which exhibit fold, Hopf and transcritical bifurcations respectively. As Fig. 2 shows, the DL algorithm outperforms the other competing algorithms for all initial values of each model. Moreover, the DL algorithm exhibits smaller fluctuations of relative error of tipping points prediction than the other competing algorithms for each initial value and exhibits smaller fluctuations of the mean relative error of tipping points prediction than the other competing algorithms across different initial values. Our results suggest that the DL algorithm is more robust against different initial values of the bifurcation parameter than competing algorithms.

**Fig.2** We tested the DL model on regularly-sampled model time series with 11 initial values of bifurcation parameter. Here the mean relative error of tipping points prediction is plotted as a function of initial parameter. The area covered by the polyline represents the 90% confidence interval for the relative error of tipping points prediction. (a-c) We compared the DL algorithm (red lines) with degenerate fingerprinting (blue lines), DEV (green lines) and null model (purple lines) on three ecological model time series with white noise. These model time series undergo fold, Hopf, and transcritical bifurcation, occurring at 0.268, 0.480, and 5.882, respectively. (d-f) The DL algorithm (red lines) is compared with BB method (blue lines), DEV (green lines) and null model (purple lines) on three climate model time series with red noise. These model time series undergo fold, Hopf, and transcritical bifurcation, occurring at 0.962, 0.355, and  $-0.005$ , respectively.

We further tested the DL model on irregularly-sampled time series from the above six models. It is worth noting that the above competing algorithms are not applicable for irregularly-sampled time series. Therefore, we used linear interpolation to transform these irregularly-sampled time series into equidistant data. This allows us to use the competing algorithms of degenerate fingerprinting, BB method and DEV for detecting early warning

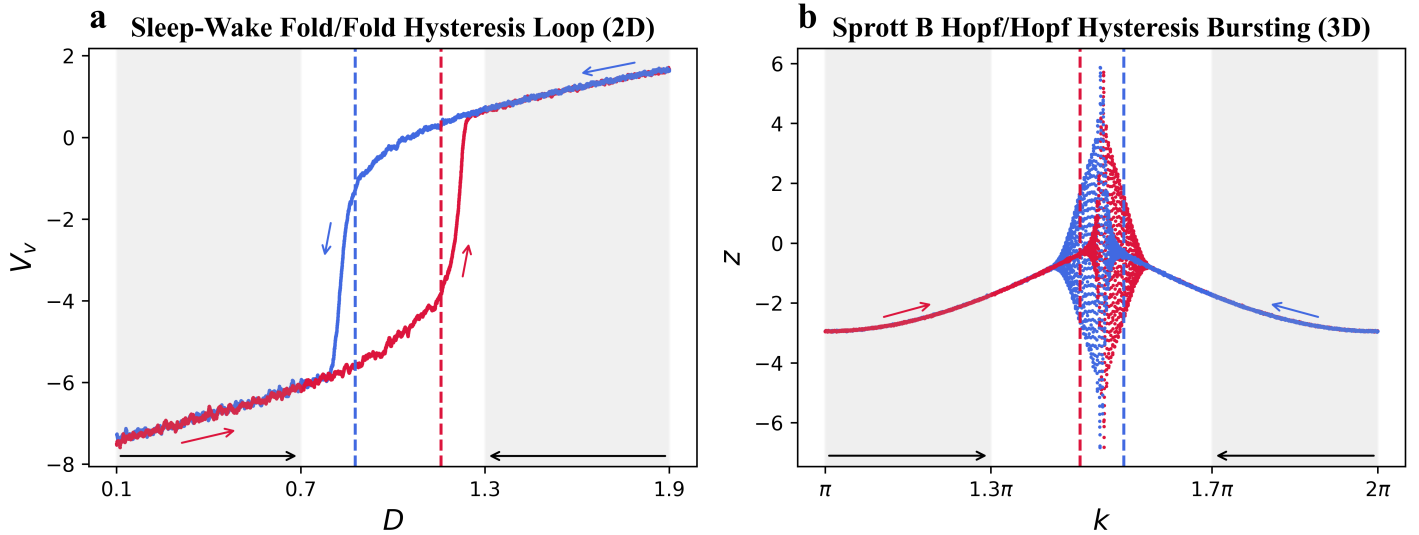

signals on reconstructed model time series(42). The null model is also applied as a competing algorithm. From Fig. 3, we find that DL algorithm outperforms the other competing algorithms for all initial values of each model. Moreover, our results suggest that the DL algorithm is more robust against different initial values of the bifurcation parameter than competing algorithms.

**Fig.3** We tested the DL model on irregularly-sampled model time series with 11 initial values of bifurcation parameter. Here the mean relative error of tipping points prediction is plotted as a function of initial parameter. The area covered by the polyline represents 90% confidence interval for the relative error of tipping points prediction. (a-c) We compared the DL algorithm (red lines) with degenerate fingerprinting (blue lines), DEV (green lines) and null model (purple lines) on three ecological model time series with white noise. (d-f) The DL algorithm (red lines) is compared with BB method (blue lines), DEV (green lines) and null model (purple lines) on three climate model time series with red noise. We used linear interpolation to transform these irregularly-sampled time series into equidistant data so that they are suitable for degenerate fingerprinting, BB method and DEV.

We then tested the DL model on irregularly-sampled time series from the ascending arousal system with a fold/fold hysteresis loop. We conducted an irregular sampling of 400 points within the bifurcation parameter intervals of  $[0.1, 0.7]$  and  $[1.3, 1.9]$  (bifurcation parameter decreases in this interval) respectively. We applied the DL model on these irregularly-sampled time series and predicted that the tipping points occur at 1.157 and 0.877 with relative errors of tipping points prediction of 0.84% and 1.49% respectively, as shown in Fig. 4 (a). Similarly, we tested the DL model on irregularly-sampled time series from the Sprott B system with a Hopf/Hopf-hysteresis bursting. We irregularly sampled 400 points from the bifurcation parameter intervals of  $[\pi, 1.3\pi]$  and  $[1.7\pi, 2\pi]$  (bifurcation parameter decreases in this interval) respectively. We applied the DL model on these irregularly-sampled time series and predicted that the tipping points occur at  $1.461\pi$  and  $1.540\pi$  with relative errors of

tipping points prediction of 0.05% and 0.81% respectively, as shown in Fig. 4 (b). Our results suggest that the DL algorithm is effective for tipping point prediction in theoretical models with hysteresis phenomenon.

**Fig.4** The performance of the DL algorithm in predicting transitions of irregularly-sampled time series generated by theoretical models exhibiting hysteresis. The red and blue curves illustrate the time series forced by increasing and decreasing bifurcation parameter respectively, while the grey area denotes the range of time series data used for prediction. (a) In the case of the sleep-wake system, a fold/fold hysteresis loop is observed at  $D = 1.152$  and  $D = 0.883$ . The predicted tipping points are  $1.157$  (red dashed line) and  $0.877$  (blue dashed line) respectively. (b) For the Sprott B system, a Hopf/Hopf hysteresis bursting occurs at  $k = 1.461\pi$  and  $k = 1.539\pi$ . The predicted tipping points are  $1.461\pi$  (red dashed line) and  $1.540\pi$  (blue dashed line) respectively.

## Performance of DL algorithm on empirical time series

We tested the DL model on three empirical examples, including a cyanobacteria microcosm experiment under light stress(37), a physical experiment of voice oscillation during heat(20) and metallic elements concentration in sediment cores collected from the eastern Mediterranean Sea(38). For each empirical system, we applied the DL model to four irregularly-sampled time series, each containing 400 data points, across different parameter ranges. Then we used linear interpolation to transform these irregularly-sampled records to time series with equidistant data. This allows us to use the competing algorithms of degenerate fingerprinting, BB method and DEV for detecting early warning signals on reconstructed empirical records(42). Note that the first two empirical examples from ecology and physics are subject to white noise while the third empirical example from paleoclimatology is subject to red noise(43). Therefore, we applied degenerate fingerprinting to the first two empirical examples and BB method to the third empirical example. We compared the results of the DL algorithm with those of four competing algorithms, including degenerate fingerprinting, BB method, DEV and null model.

In the cyanobacteria microcosm experiment under light stress, the photo-inhibition drives a cyanobacterial population, measured by light attenuation coefficient, towards a tipping point with fold bifurcation when a critical threshold of light irradiance is approached(37). To validate our DL algorithm, we applied the DL model to the empirical time series sampled in four periods which are from day 1 to day 16, from day 1.5 to day 16.5, from day 2 to day 17 and from day 2.5 to day 17.5 respectively. The corresponding range of bifurcation parameter of light irradiance for the four periods is from  $477$  to  $845\mu\text{mol photons m}^{-2}\text{s}^{-1}$ , from  $488.5$  to  $856.5\mu\text{mol photons m}^{-2}\text{s}^{-1}$ , from  $500$  to  $868\mu\text{mol photons m}^{-2}\text{s}^{-1}$ , and from  $511.5$  to  $879.5\mu\text{mol photons m}^{-2}\text{s}^{-1}$  respectively. The corresponding tipping points predicted by the DL model are  $1088.5\mu\text{mol photons m}^{-2}\text{s}^{-1}$ ,  $1090.9\mu\text{mol photons m}^{-2}\text{s}^{-1}$ ,  $1088.2\mu\text{mol photons m}^{-2}\text{s}^{-1}$ , and  $1090.4\mu\text{mol photons m}^{-2}\text{s}^{-1}$  respectively, which are all very close to  $1091\mu\text{mol photons m}^{-2}\text{s}^{-1}$ , the true value of the tipping point. From Fig. 5 A1-A4, we find that the DL algorithm outperforms the other competing algorithms in all cases. These results suggest the robustness of the DL algorithm

in tipping points prediction against different light irradiance intervals.

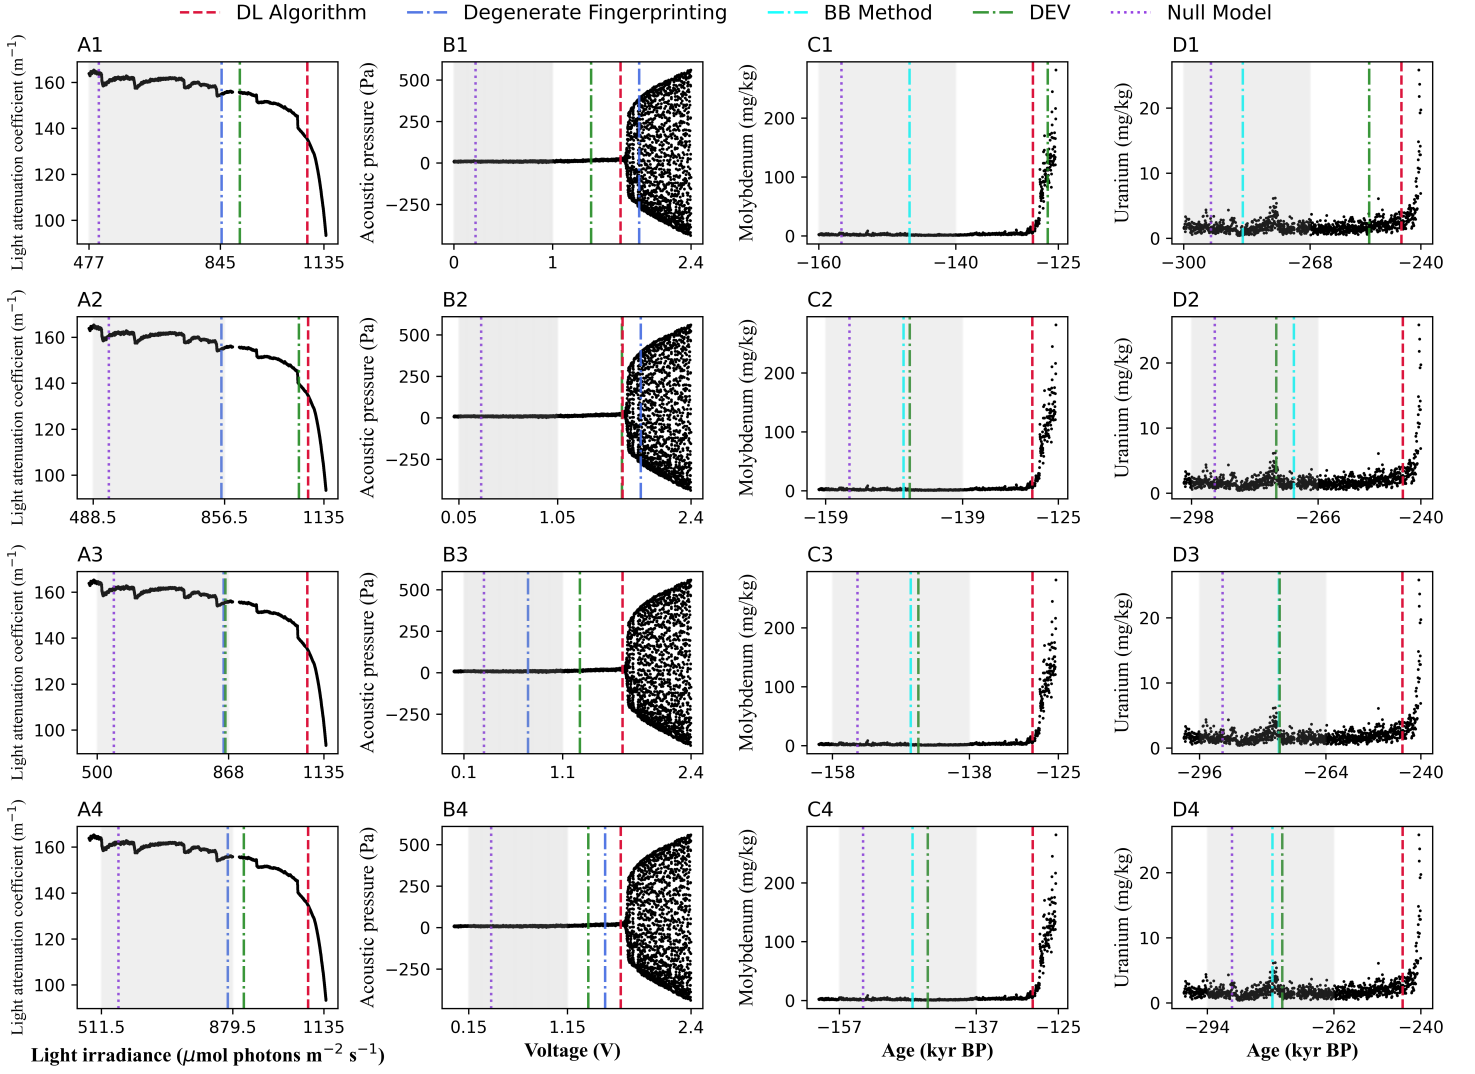

The second empirical data we analyzed is the thermoacoustic system. The state of the thermoacoustic system is measured by acoustic pressure. The thermoacoustic system undergoes a Hopf bifurcation from a non-oscillatory to an oscillatory state with increasing voltage(24, 44–46). It has also been demonstrated that the transition to high amplitude limit cycle oscillations occurs later for faster changing rate of voltage, which can be explained by rate-delayed tipping(20, 21). In order to verify the robustness of DL algorithm in tipping points prediction against different changing rates of voltage, we applied the DL model to empirical time series under three voltage changing rates (20mV/s, 40mV/s, 60mV/s) within the bifurcation parameter voltage ranges from 0 to 1 V, from 0.05 to 1.05 V, from 0.1 to 1.1 V and from 0.15 to 1.15V respectively. From Fig. 5 B1-B4, we find that the DL algorithm outperforms the other competing algorithms in predicting the tipping points, where the acoustic pressure starts to oscillate, for various voltage intervals of empirical data under the voltage changing rate of 20mV/s. We further test these algorithms for different changing rates of voltage as shown in Supplementary Fig. 16, which suggest the DL algorithms also shows best performance among all these algorithms. These results suggest that the DL algorithm is robust against various voltage intervals and changing rates of voltage.

The third empirical data is the concentration of metallic elements in sediment cores collected from the eastern Mediterranean Sea. The concentration of metallic elements changes rapidly due to the transition between oxic and anoxic states occurred regularly in this region. The bifurcation types of these transitions have been uncovered by previous study(18). We studied the Mo concentration in sediment cores and the U concentration in sediment cores collected in different periods of time, which are from 160 to 125 ka BP and from 300 to 240 ka BP respectively. We lacked information on the bifurcation parameter series data in this example, therefore we used age as a substitute for the bifurcation parameter. Since the Mo concentration in sediment cores undergoes fold bifurcation, we applied the DL model on this data within four age intervals, from 160 to 140 ka BP, from 159 to 139 ka BP, from 158 to 138 ka BP and from 157 to 137 ka BP respectively. However, the U concentration in sediment cores undergoes transcritical bifurcation. We applied the DL model on this data within four age intervals, from 300 to 268 ka BP, from 298 to 266 ka BP, from 296 to 264 ka BP and from 294 to 262 ka BP respectively. We find that the DL algorithm outperforms the other competing algorithms in predicting tipping points where the concentration of metallic elements Mo or U in sediment cores change dramatically for various age intervals of empirical data as shown in Fig. 5 C1-C4 and Fig. 5 D1-D4. These results also suggest the robustness of the DL algorithm in tipping points prediction against various age intervals.

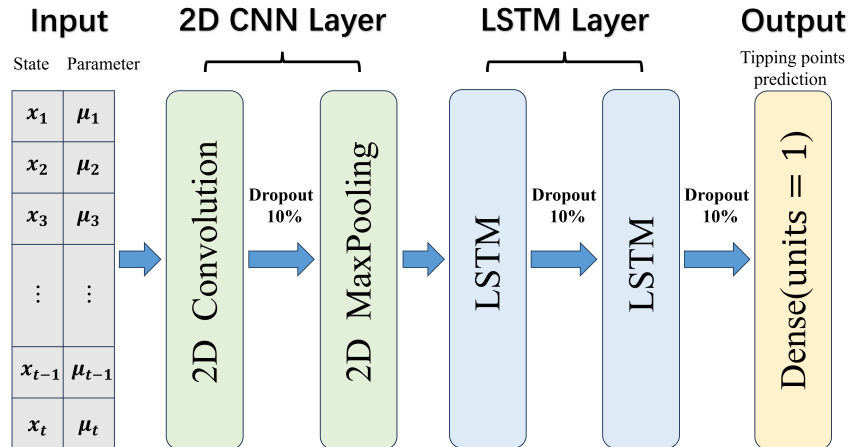

## Discussion

Predicting the occurrence of tipping points based on time series is a challenging problem. In this work, we develop a deep learning algorithm that exploits information of normal form from the training systems for tipping points prediction. This algorithm can deal with both regularly-sampled and irregularly-sampled time series. Our results show that the DL algorithm not only outperforms traditional methods in the accuracy of tipping points prediction for regularly-sampled time series, but also achieve accurate prediction for irregularly-sampled time series. Our results pave the way to make effective strategies to prevent and prepare tipping points from various real-world systems(47).

There are three major advantages of our work. First, traditional methods for tipping points prediction can only deal with regularly-sampled time series(9–12). However, the DL algorithm used in this paper can deal with both regularly-sampled time series and irregularly-sampled time series. This is because the bifurcation parameter series input into the 2D CNN layer contains the information about the sequence of distance between adjacent points, which is used for tipping points prediction. Second, the effect of rate-delayed tipping has been ignored in previous methods for tipping points prediction(9–12). This is due to the limitations of the theory of fast-slow systems used in previous methods. However, we consider the effect of rate-delayed tipping in our work and label

**Fig.5** The performance of DL algorithm in predicting tipping points on irregularly-sampled empirical time series. Grey region represents the range of empirical time series used for prediction. (A1-A4) Cyanobacterial population undergoes a fold bifurcation, which is measured by light attenuation coefficient. (B1-B4) The thermoacoustic system undergoes a Hopf bifurcation under the 20mV/s changing rate of the control parameter voltage. (C1-C4) The eastern Mediterranean Sea experienced an anoxic event, it exhibited a fold bifurcation, which was measured using the concentration of Mo in sediment cores. (D1-D4) The eastern Mediterranean Sea experienced another anoxia event, characterized by a transcritical bifurcation, which was measured using the concentration of U in sediment cores. We compared the performance of the DL algorithm (red dashed lines) with degenerate fingerprinting (blue dash-dot lines), BB method (cyan dash-dot lines), DEV (green dash-dot lines) and null model (purple dotted lines). We used linear interpolation to transform these irregularly-sampled time series into equidistant data so that they are suitable for degenerate fingerprinting, BB method and DEV.

**Fig.6** The 2D CNN-LSTM architecture. The 2D convolutional kernel processes state series and bifurcation parameter series into one-dimensional local feature series. These features are then subjected to local max pooling, followed by analysis using an LSTM layer. Finally, the features processed by the LSTM are mapped to the prediction of tipping point, through a fully connected layer.

the data by using the fact that the quasi-static attractor loses stability at the occurrence of tipping points in our training set (see Methods for details). The DL algorithm trained with such labels is robust against different changing rates of bifurcation parameter (Supplementary Fig. 16). Third, previous methods for tipping points prediction require test data that includes samples taken near the tipping points where pronounced early warning signals are present, particularly for the bifurcation theory based methods(9, 12). However, most of the time series from our experiments were sampled beyond a certain distance from the tipping points, leading to the unsuccessful performance of these algorithms in predicting tipping points shown in this paper. The DL algorithm, in contrast, can accurately identify the location where the tipping points occur with various distance between the end of the time series and the tipping points.

Most previous methods require full information of all interacting variables in the dynamical systems for predicting tipping points, such as the time series of interacting variables(9, 48). However, this information is often not available especially for large systems. Therefore, it is often not feasible to use those methods for predicting tipping points of real-world systems. In this work, we use time series of only a single variable in the dynamical system as prior information for predicting tipping points. Such time series is commonly available from real-world systems, because it is very likely that only one or few variables in the systems are measured(12). The theoretical foundation of our algorithm lies in Takens embedding theorem(13). Specifically, the time series of a single variable preserves dynamical information of the entire system, which can provide sufficient information for tipping points prediction.

Our work raises several problems worthy of future pursuit. First, we have studied the situation of local codimension-one bifurcations in continuous-time dynamical systems in this paper. For future work, we can focus on tipping points prediction in discrete-time dynamical systems, such as period-doubling bifurcation(7) which arise naturally in physiology(49, 50) and ecology(51). It would be interesting to develop a method that can deal with both regularly-sampled and irregularly-sampled time series for systems with period-doubling bifurcation. Second, it would be interesting to investigate tipping points prediction in systems with other types of bifurcation, such as codimension-two bifurcation and global bifurcation(7). Yet, tipping points prediction in systems with codimension-two bifurcation and global bifurcation are more challenging than that in systems with codimension-one bifurcation. Third, one can develop interpretable machine learning models for tipping points prediction by combing dynamical system theory with neural networks(52–56), which offer an avenue for making safe and reliable high-stakes decisions for policy makers(57).

## Methods

### Generation of training data for the DL algorithm

We construct two-dimensional dynamical systems of the following form which are used to generate the training data based on simulation(18)

$$\begin{aligned}\frac{dx}{dt} &= \sum_{i=1}^{10} a_i p_i(x, y) \\ \frac{dy}{dt} &= \sum_{i=1}^{10} b_i p_i(x, y),\end{aligned}\tag{1}$$

where  $x$  and  $y$  are state variables,  $p(x, y)$  is a vector containing all polynomials in  $x$  and  $y$  from zero up to third order

$$p(x, y) = (1, x, y, x^2, xy, y^2, x^3, x^2y, xy^2, y^3),$$

$p_i(x, y)$  is the  $i$ -th component of  $p(x, y)$ .  $a_i$  and  $b_i$  are parameters randomly drawn from standard normal distribution, and then, half of these parameters are selected at random and set to zero. The parameters for the

cubic terms are set to the negative of their absolute values to encourage models with bounded solutions. Since our training data is required to contain representation of all possible dynamics that may occur in the study time series data, we generate models with different sets of parameter values in Eqs. 1 until a required number of each type of bifurcation (fold, Hopf, or transcritical) has been discovered. We add white or red noise to these models to simulate training data for the DL algorithm.

After a model is generated, we perform numerical simulation of this model with 10,000 time steps from a randomly drawn initial condition and test whether the system converges to an equilibrium point. The odeint function from the Python package Scipy(58) is applied in the numerical simulation with a step size of 0.01. The criteria that we used to determine the convergence is that the maximum difference between the final 10 points in numerical simulation is less than  $10^{-8}$ . The convergence is required in order to search for bifurcations which occur at non-hyperbolic equilibria(7). The models that do not converge are discarded. For the models that converge, we apply AUTO-07P(59) to identify bifurcations along the equilibrium branch by either increasing or decreasing each nonzero parameter. For each bifurcation identified, we first set the initial condition with the value of the equilibrium of the model and a burn-in period of 100 units of time. Then we run simulations of the model with noise and obtain the quasi-static attractor time series with noise and bifurcation parameter time series which are used for training. We also run simulations of the same model without noise and obtain the corresponding quasi-static attractor time series and bifurcation parameter time series which are used for calculating the recovery rate  $\lambda$  to locate the bifurcation point where  $\lambda$  changes from negative value to positive value,

$$\lambda = \max(\operatorname{Re}(\operatorname{eigvals}(\left[ \begin{array}{cc} \frac{\partial(\sum_{i=1}^{10} a_i p_i(x,y))}{\partial x}}{\frac{\partial(\sum_{i=1}^{10} b_i p_i(x,y))}{\partial x}} & \frac{\partial(\sum_{i=1}^{10} a_i p_i(x,y))}{\partial y}}{\frac{\partial(\sum_{i=1}^{10} b_i p_i(x,y))}{\partial y}} \end{array} \right]_{(x,y)=(x^*,y^*)})))). \quad (2)$$

The simulations of the models with noise are based on the Euler Maruyama method(60) with a step size of 0.01 and the simulations of the models without noise are based on Euler method(61) with the same step size.

For each model where a bifurcation is identified, we perform five independent simulations of the model with varying bifurcation parameter from its initial value to a terminal value beyond the bifurcation point given by AUTO-07P. In these five simulations, we set the changing rate of the bifurcation parameter to remain constant within each simulation where the changing rate of the bifurcation parameter is the change in the bifurcation parameter per unit time with a step size of 0.01, but vary across different simulations. The ratio of each changing rate of the bifurcation parameter to the smallest changing rate of the bifurcation parameter in these five simulations is drawn from 1, 2, ..., 10. The nonzero changing rate of the bifurcation parameter can lead to the delay in the occurrence of tipping points, which is called rate-delayed tipping(20, 21). Due to rate-delayed tipping, the theoretical bifurcation point given by AUTO-07P is not the accurate location of the tipping point. Therefore, we identify the location of the tipping point by the recovery rate (Eq. 2) and use this identified tipping point as the training label for our supervised deep learning training process (Supplementary Information section 2.3). If no tipping point is detected in a simulation, this simulated data will be discarded. Otherwise, we randomly and irregularly sample  $l_s$  points from quasi-static attractor time series with noise which is simulated by the variable  $x$  of the model and corresponding bifurcation parameter time series between the initial value and the tipping point, where  $l_s$  is drawn from *Uniform*(505, 1000). Then we select the first 500 points as training data. The obtained training data can make DL algorithm to learn the features of recovery rate from time series data with different changing rates of parameter and varying distances between the end of the time series and the tipping points.

Here we train deep learning algorithm on datasets with white and red noise. The white noise in simulation has the amplitude drawn from a triangular distribution centered at 0.01 with upper and lower bounds 0.0125 and 0.0075 respectively while the red noise is modeled by AR(1) process in which the lag-1 autoregressive coefficient is between -1 and 1. It is worth noting that the simulations shift to new regime before the bifurcation point due to the noise(62, 63). Since the location of this premature transition is stochastic, we still use the location where the quasi-static attractor without noise loses stability as the training label for DL algorithm even it is not accurate.

We mathematically illustrate how slight perturbation causes bifurcation to occur earlier and its stochasticity in Supplementary Information section 6.

## DL algorithm architecture and training

In this paper we use the 2D CNN-LSTM DL algorithm(64, 65). The 2D CNN-LSTM architecture is shown in Fig. 6. We use a train/validation/test split of 0.95/0.04/0.01 for the DL algorithm, and MSE as the loss function to minimize the difference between the real tipping points (training labels) and the predictions. The DL algorithm is trained on 300,000 instances for 200 epoches. We train ten neural networks and report the performance of the DL algorithm averaged over them. The hyperparameters of the DL model are tuned through random search, and we present the optimal hyperparameters of the DL model in Supplementary Table 1.

Before training our DL algorithm, there are several preprocessing matters(66). The quasi-static attractor time series with noise are detrended using Lowess smoothing with a span of 0.2 to obtain the residual time series used for training. Besides, in order to obtain the robustness of DL algorithm on time series of various lengths, we zero out the left side of the residual time series and corresponding bifurcation parameter time series, with the length drawn from  $Uniform(0, 250)$ . Due to the zeroing process, the DL algorithm can deal with time series even if it is a little short. After the zeroing process, each residual time series is normalized by dividing each time series data point by the average absolute value of the residuals across the non-zero part of the time series. In addition, each bifurcation parameter time series is also normalized: each data point in the time series minus the initial value of the bifurcation parameter time series, and then divided by the distance between the initial and final values of the bifurcation parameter time series, thereby mapping the bifurcation parameter time series to the interval of  $[0, 1]$ . The corresponding label, i.e., the tipping point, is normalized following the same procedure as the normalization of the data point in bifurcation parameter time series. Thus the relative distance of tipping point to the time series in the training set for the DL algorithm (calculated as the tipping points minus the final value of the bifurcation parameter time series, divided by the distance between the initial and final values of the bifurcation parameter time series) is between 0.01 and 2. In other words, the labels in the training set, after normalization, will fall within the interval of  $[1.01, 3]$ .

## Theoretical models used for testing

The simulation of theoretical models with noise is based on the Euler Maruyama method(60) with a step size of 0.01 ( $\delta t = 0.01$  units of time) unless otherwise stated. The amplitude of white noise  $\sigma$  is 0.01 while the red noise is modeled by AR(1) process in which the lag-1 autoregressive coefficient  $\phi$  is drawn from  $Uniform(-1, 1)$ . We fix the changing rate of the bifurcation parameter in each simulation of the same theoretical model to ensure that these simulations have the same bifurcation point. The bifurcation point of each simulation is the location where the recovery rate changes from negative value to positive value. Then we sample from these simulations to obtain regularly-sampled model time series and irregularly-sampled model time series for testing. The lengths of these model time series range from 250 to 500, and the relative distances of tipping points to these time series range from 0.01 to 2.

We apply the relative error  $\varepsilon$  of tipping points prediction to evaluate the performance of the DL algorithm, which is defined as

$$\varepsilon = \frac{|\hat{\mu}_c - \mu_c|}{|\mu_{end} - \mu_c|},$$

where  $\hat{\mu}_c$  is the predicted tipping point,  $\mu_c$  is the real tipping point,  $\mu_{end}$  is the value of bifurcation parameter for last point of the test time series.

### Theoretical models with white noise

To test the fold bifurcation with white noise, we use the May's harvesting model(28). This is given by

$$\frac{dx}{dt} = rx\left(1 - \frac{x}{k}\right) - \frac{hx^2}{s^2 + x^2} + \sigma\xi(t),$$

where  $x$  is biomass of some population,  $k$  is its carrying capacity,  $h$  is the harvesting rate,  $s$  characterizes the nonlinear dependence of harvesting output on current biomass,  $r$  is the intrinsic per capita growth rate of the population, and  $\xi(t)$  is a Gaussian white noise process. We use parameter values  $r = 1$ ,  $k = 1$ ,  $s = 0.1$  and  $h$  increases at a rate of  $6.25 \times 10^{-4}$ . We generate model time series by this equation from eleven initial values of  $h$ , which are 0, 0.02, 0.04, ..., 0.18, 0.2. In this configuration, a fold bifurcation occurs at  $h = 0.268$  (Supplementary Fig. 9).

To test the Hopf bifurcation with white noise, we use a three-species chaotic food chain model(29). This is given by

$$\begin{aligned}\frac{dr}{dt} &= r\left(1 - \frac{r}{k}\right) - \frac{x_c y_c c r}{r + r_0} + \sigma\xi_r(t), \\ \frac{dc}{dt} &= x_c c \left(\frac{y_c r}{r + r_0} - 1\right) - \frac{x_p y_p p c}{c + c_0} + \sigma\xi_c(t), \\ \frac{dp}{dt} &= x_p p \left(\frac{y_p c}{c + c_0} - 1\right) + \sigma\xi_p(t),\end{aligned}$$

where  $r$ ,  $c$ , and  $p$  are the population densities of the resource, consumer, and predator species, respectively.  $k$  is a parameter characterizing the environmental capacity of the resource species.  $x_c$ ,  $y_c$ ,  $x_p$ ,  $y_p$ ,  $r_0$ , and  $c_0$  are other parameters in the system.  $\xi_r(t)$ ,  $\xi_c(t)$  and  $\xi_p(t)$  are independent Gaussian white noise processes. For our simulations, we use parameter values  $x_c = 0.4$ ,  $y_c = 2.009$ ,  $x_p = 0.08$ ,  $y_p = 2.876$ ,  $r_0 = 0.16129$ ,  $c_0 = 0.5$  and  $k$  increases at a rate of  $1.54 \times 10^{-3}$ . We generate model time series by these equations from eleven initial values of  $k$ , which are 0.20, 0.22, 0.24, ..., 0.38, 0.40. In this configuration, a Hopf bifurcation occurs at  $k = 0.480$  (Supplementary Fig. 10).

To test the transcritical bifurcation with white noise, we use the Rozenzweig-MacArthur consumer-resource model(30). This is given by

$$\begin{aligned}\frac{dx}{dt} &= gx\left(1 - \frac{x}{k}\right) - \frac{axy}{1 + ahx} + \sigma\xi_x(t), \\ \frac{dy}{dt} &= \frac{eaxy}{1 + ahx} - my + \sigma\xi_y(t),\end{aligned}$$

where  $x$  and  $y$  are the population densities of the resource, consumer, respectively.  $g$  is the intrinsic per capita growth rate of  $x$ ,  $k$  is its carrying capacity,  $a$  is the attack rate of  $y$ ,  $e$  is the conversion factor,  $h$  is the handling time,  $m$  is the per capita consumer mortality rate,  $\xi_x(t)$  and  $\xi_y(t)$  are independent Gaussian white noise processes. We fix the parameter values  $r = 4$ ,  $k = 1.7$ ,  $e = 0.5$ ,  $h = 0.15$ ,  $m = 2$  and  $a$  increases at a rate of  $8.112 \times 10^{-3}$ . We generate model time series by these equations from eleven initial values of  $a$ , which are 0, 0.5, 1.0, ..., 4.5, 5.0. In this configuration, the system has a transcritical bifurcation at  $a = 5.882$  (Supplementary Fig. 11).

### Theoretical models with red noise

To test the fold bifurcation with red noise, we use a climate model describing temperature of an ocean on a spherical planet subjected to radiative heating(31, 32) which can simulate a transition from a greenhouse to an icehouse Earth(42). The model is given by

$$\begin{aligned}\frac{dT}{dt} &= \frac{-e\rho T^4 + \frac{1}{4}uI_0(1 - a_p)}{c} + \eta(t), \\ \text{with } a_p &= a - bT,\end{aligned}$$

where  $T$  is the average temperature of ocean,  $u$  is relative intensity of solar radiation,  $e$  is effective emissivity,  $I_0$  is solar irradiance,  $c$  is a constant thermal inertia, and  $a_p$  is the planetary albedo. Parameters  $a$  and  $b$  define a linear feedback between ice and albedo variability and temperature.  $\eta(t)$  is a red noise process with lag-1 autoregressive coefficient  $\phi$ . We use  $e = 0.69$ ,  $I_0 = 71944000$ ,  $c = 10^8$ ,  $a = 2.8$ ,  $b = 0.009$ ,  $\rho = 0.03$ ,  $\delta t = 1$  time unit and  $u$  decreases at a rate of  $6 \times 10^{-7}$ . We generate model time series by this equation from eleven initial values of  $u$ , which are 1.4, 1.38, 1.36, ..., 1.22, 1.2. In this configuration, a fold bifurcation occurs at  $u = 0.962$  (Supplementary Fig. 12).

To test the Hopf bifurcation with red noise, we use the middle Pleistocene transition system(33), explaining the dynamics of glacial cycles, which is given by

$$\begin{aligned}\frac{dx}{dt} &= -x - y + \eta_x(t), \\ \frac{dy}{dt} &= -pz + uy + sz^2 - yz^2 + \eta_y(t), \\ \frac{dz}{dt} &= -q(x + z) + \eta_z(t),\end{aligned}$$

where  $x$  represents the global ice volume,  $y$  represents the atmospheric greenhouse gas concentration and  $z$  represents a deep ocean temperature. All variables are rescaled to dimensionless form,  $p = 1$ ,  $q = 1.2$ ,  $s = 0.8$  are parameters, and  $u$  increases at a rate of  $8.4 \times e^{-6}$ .  $\eta_x(t)$ ,  $\eta_y(t)$  and  $\eta_z(t)$  are independent red noise processes with lag-1 autoregressive coefficient  $\phi$ . We generate model time series by these equations from eleven initial values of  $u$ , which are 0, 0.03, 0.06, ..., 0.27, 0.3. In this configuration, a Hopf bifurcation occurs at  $u = 0.355$  (Supplementary Fig. 13).

To test the transcritical bifurcation with red noise, we use the simplified version of TRIFFID dynamic global vegetation model(34, 67). It can be used to simulate the dieback of the Amazon rainforest(67), which is mainly driven by climate change(68). The model is given by

$$\frac{dV}{dt} = PV^*(1 - V) - GV + \eta(t),$$

where  $V$  is equal to the broadleaf fraction,  $G$  is a disturbance coefficient (0.004/year) and  $V^*$  is either the value of  $V$  or 0.1 if  $V$  falls below 0.1.  $\eta(t)$  is a red noise process with lag-1 autoregressive coefficient  $\phi$ .  $P$  is the productivity, in dimensionless area fraction units, it decreases at a rate of  $2.4 \times 10^{-3}$ . We generate model time series by this equation from eleven initial values of  $P$ , which are 0.90, 0.82, 0.74, ..., 0.18, 0.10. A transcritical bifurcation occurs at  $P = -0.005$  in this configuration (Supplementary Fig. 14).

### Theoretical models with hysteresis phenomenon

We also test our DL model on irregularly-sampled model time series generated by two theoretical neuroscience models with white noise. These systems exhibit hysteresis, which suggests that when the bifurcation parameter changes in opposite directions, these system will undergoes sudden shifts at different bifurcation points. The ascending arousal system is modeled in terms of the neuronal populations and their interactions(35), which is given by

$$\begin{aligned}\tau_v \frac{dV_v}{dt} &= -V_v + v_{vm}Q_m + D + \sigma\xi_v(t), \\ \tau_m \frac{dV_m}{dt} &= -V_m + v_{ma}Q_a + v_{mv}Q_v + \sigma\xi_m(t).\end{aligned}$$

Each population  $j = v, a, m$ , where  $v$  is ventrolateral preoptic area,  $a$  is acetylcholine, and  $m$  is monoamines, has a mean cell body potential  $V_j$  relative to resting and a mean firing rate  $Q_j$ . The relation of  $Q_j$  to  $V_j$  is well described by  $Q_j = Q_{max}/[1 + \exp(-(V_j - \theta)/\sigma)]$ , where  $Q_{max}$  is the maximum possible rate, equals  $100\text{s}^{-1}$ . Besides,  $V_a$  is constant,  $\tau_j$  is the decay time for the neuromodulator expressed by group  $j$ , the  $v_{jk}$  weights

the input from population  $k$  to  $j$ ,  $\xi_v(t)$  and  $\xi_m(t)$  are independent Gaussian white noise processes. The model parameters are consistent with physiological and behavioral measures,  $\theta = 10\text{mV}$ ,  $\sigma = 3\text{mV}$ ,  $v_{ma}Q_a = 1\text{mV}$ ,  $v_{vm} = v_{mv} = -1.9\text{mVs}$  and  $\tau_m = \tau_v = 10\text{s}$ . In our simulations within the interval of  $[0.1, 1.9]$ , we force the parameter  $D$  to increase from 0.1 or decrease from 1.9 at a rate of  $1/7200\text{mV}$  per unit time. In this configuration, a fold/fold-hysteresis loop occurs at  $D = 1.153$  (in the increasing direction) and  $D = 0.883$  (in the decreasing direction) respectively.

Another system is Sprott B system(69) with a single excitation, which can be used for researching bursting oscillation in neuroscience(36). The model is given by

$$\begin{aligned}\frac{dx}{dt} &= a(y - x) + \sigma\xi_x(t), \\ \frac{dy}{dt} &= xz + \beta \cos(k) + \sigma\xi_y(t), \\ \frac{dz}{dt} &= b - xy + \sigma\xi_z(t),\end{aligned}$$

where  $a = 8$ ,  $b = 2.89$  and  $\beta = 5$ .  $\xi_x(t)$ ,  $\xi_y(t)$  and  $\xi_z(t)$  are independent Gaussian white noise processes. We force the parameter  $k$  to increase from  $\pi$  or decrease from  $2\pi$  at a rate of  $\pi \times 10^{-3}$  within the interval of  $[\pi, 2\pi]$ . A Hopf/Hopf-hysteresis bursting occurs at  $k = 1.461\pi$  (in the increasing direction) and  $k = 1.539\pi$  (in the decreasing direction) respectively in this configuration.

## Empirical systems used for testing

In this work, we use three empirical examples in the fields of microbiology, thermoacoustics, and paleoclimatology to evaluate the performance of the DL algorithm.

In the first example, photo-inhibition drives cyanobacterial population to a fold bifurcation when a critical light level is exceeded(37). In this system, bifurcation parameter light irradiance starts at  $477\mu\text{mol photons m}^{-2}\text{s}^{-1}$  and is increased in steps of  $23\mu\text{mol photons m}^{-2}\text{s}^{-1}$  each day. The time series includes 7,784 data points spanning overall 28.86 days with time interval equal to 0.0035 day (5 min).

The second example is a thermoacoustic system where positive feedback between the unsteady heat release rate fluctuations and the acoustic field in the confinement can result in a transition to high amplitude limit cycle oscillations(46). Induja et al.(20) conduct experiments in a thermoacoustic system exhibiting Hopf bifurcation. They pass several constant mass flow rates of air through a horizontal Rijke tube which consists of an electrically heated wire mesh in a rectangular duct and increase the voltage applied across the wire mesh to attain the transition to thermoacoustic instability. In such case, they observe that the occurrence of Hopf bifurcation depends on the changing rate of control parameter. We select three experimental sets for our study with the bifurcation parameter of voltage increasing at rates of 20 mV/s, 40 mV/s, and 60 mV/s. The voltage is ranging from 0V to 2.4V. The corresponding time series data consists of 1,200,000, 600,000, and 400,000 data points, respectively.

The third example is the concentration of metallic elements in sediment cores collected using a piston corer at  $33^\circ 18.1' \text{N}$ ,  $33^\circ 23.7' \text{E}$ , 1760 m water depth in the eastern Mediterranean Sea(38) where rapid transitions between oxic and anoxic states occurred regularly. Molybdenum (Mo) and uranium (U) are commonly used as key indicators for anoxic events, which signify past climatic or environmental changes that occurred during certain periods(70–72). Therefore, we select the time series of the concentration of Mo and U in sediment cores for our study. In the analysis of these empirical datasets, we assume that the bifurcation parameter of the system varies uniformly with time, such that age can be served as a substitute for this parameter. The time series of the concentration of Mo in sediment cores consists of 1,147 data points ranging from 160 ka BP to 125 ka BP while the time series of the concentration of U in sediment cores consists of 1,142 data points ranging from 300 ka BP to 240 ka BP.

## Comparison of DL algorithm with competing algorithms

For detecting early warning signals (EWS) in quasi-static attractor time series with white noise, H. Held and T. Kleinen(9) develop a technique called degenerate fingerprinting using PCA to approximate the critical mode, then estimating the lag-1 autoregressive coefficient of critical mode as an indicator (Supplementary Information section 4.1). Boettner and Boers(10, 73) propose an unbiased estimate of the lag-1 autoregressive coefficient for time series with red noise which we refer to as the BB method (Supplementary Information section 4.2). Florian Grziwotz et al.(12) introduce a EWS robust to limited level of noise, named dynamical eigenvalue (DEV), which is rooted in bifurcation theory of dynamical systems to estimate the dominant eigenvalue of the system (Supplementary Information section 4.3). After obtaining EWS through these three approaches, linear regression or nonlinear fit between EWS and bifurcation parameters is used to make an extrapolation to anticipate the occurrence of tipping points. Based on experimentation, we choose to fit a quadratic curve for extrapolation, which is proved to be more robust than linear regression.

It is worth noting that the required information of detecting early warning signals with degenerate fingerprinting is different from that with our DL algorithm. The degenerate fingerprinting requires information from all variables of the study system to approximate the critical mode, whereas our DL algorithm only requires data from one variable of the study system. Similarly, the DEV also requires data from one variable of the study system. Moreover, the BB method is designed for estimating the lag-1 autoregressive coefficient of one-dimensional system, whereas our DL algorithm is suitable for analyzing high-dimensional system. The DEV can also deal with high-dimensional system.

## Null Model

To create a new training set for null model, we shuffle the residual time series in the original training set, completely randomizing the order of data points in the residual time series, while keeping the bifurcation parameter time series unchanged. Then we use the 2D CNN-LSTM DL algorithm to train null model on this dataset. Following random search, the optimal hyperparameters of the null model are presented in Supplementary Table 1. We compare our DL model with this null model on model time series and empirical time series to validate that the DL algorithm has indeed extracted useful information from the data.

## Data availability

All the simulated datasets and the empirical datasets used to test the deep learning algorithm have been deposited in Github ([https://github.com/zhugchzo/dl\\_occurrence\\_tipping](https://github.com/zhugchzo/dl_occurrence_tipping)) and the training set used to train the deep learning algorithm have been deposited in Zenodo (<https://zenodo.org/records/12725553>).

## Code availability

Code and workflow to reproduce the analysis are available at the GitHub ([https://github.com/zhugchzo/dl\\_occurrence\\_tipping](https://github.com/zhugchzo/dl_occurrence_tipping)).

# 1 Critical slowing down

The local behavior of a dynamical system about an equilibrium can be well characterized by a linear approximation of the equations that dominate its dynamics. We illustrate this for a one-dimensional system  $dx/dt = f(x)$  with equilibrium  $x^*$ , which means  $f(x^*) = 0$ . The dynamics about equilibrium following a perturbation by  $\varepsilon$  satisfy

$$\begin{aligned} \frac{d(x^* + \varepsilon)}{dt} &= f(x^* + \varepsilon) = f(x^*) + \left. \frac{\partial f}{\partial x} \right|_{x=x^*} \varepsilon + \frac{1}{2} \left. \frac{\partial^2 f}{\partial x^2} \right|_{x=x^*} \varepsilon^2 + \dots \\ &= \lambda_1 \varepsilon + \lambda_2 \varepsilon^2 + \dots, \end{aligned} \quad (1)$$

where  $\lambda_1, \lambda_2, \dots$  are coefficients of the Taylor expansion, and  $\lambda_1$  is the dominant eigenvalue. The potential landscape of this system centered on  $x^*$  is given by

$$V(\varepsilon) = - \int f(x^* + \varepsilon) d\varepsilon = -\frac{1}{2} \lambda_1 \varepsilon^2 - \frac{1}{3} \lambda_2 \varepsilon^3 - \dots,$$

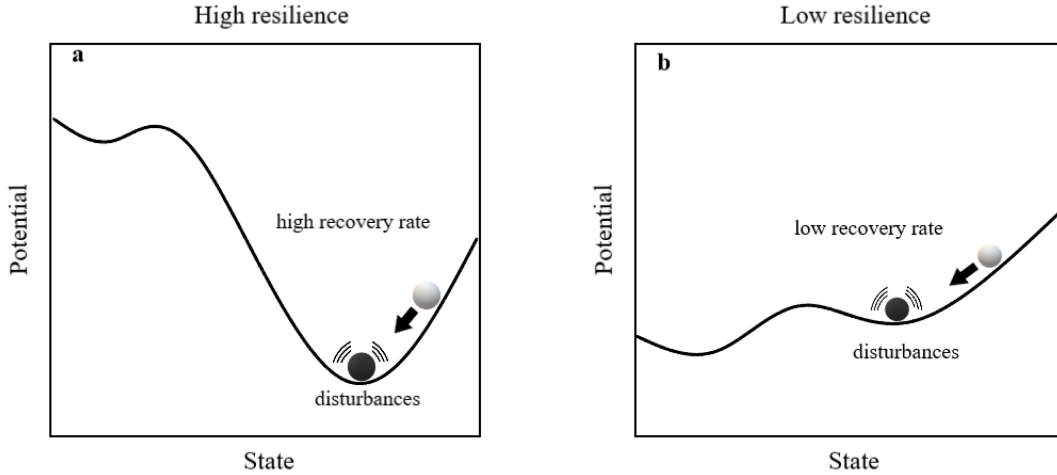

where the arbitrary integration constant has been dropped. For the slight perturbation  $\varepsilon$ , displacement from equilibrium  $x^*$  is small, we can linearize equation (1) by using a first-order Taylor expansion

$$\frac{d(x^* + \varepsilon)}{dt} = f(x^* + \varepsilon) \approx f(x^*) + \left. \frac{\partial f}{\partial x} \right|_{x=x^*} \varepsilon.$$

Therefore we have

$$f(x^*) + \frac{d\varepsilon}{dt} = f(x^*) + \lambda_1 \varepsilon \Rightarrow \frac{d\varepsilon}{dt} = \lambda_1 \varepsilon. \quad (2)$$

Equation (2) reflects the system's ability to return to the equilibrium after being perturbed, where  $\lambda_1$  is the recovery rate. The system has high resilience when it is far from the bifurcation point, and its state will rapidly return to equilibrium after deviating from it (Fig. S1. a). As a local bifurcation is approached,  $\lambda_1$  approaches 0 and the resilience of the system decreases, which is denoted as critical slowing down (Fig. S1. b).

**Supplementary Figure 1** The potential landscape of a system centered on its equilibrium. (a) The system has high resilience when it is far from the bifurcation point. (b) The system has low resilience when it is near the bifurcation point.

We will next illustrate how critical slowing down can lead to an increase in the lag-1 autocorrelation. From equation (2), we can solve the displacement  $\varepsilon_t$  from equilibrium  $x^*$ ,

$$\varepsilon_t = e^{\lambda_1 t} \Rightarrow x_t - x^* = e^{\lambda_1 t}.$$

Thus, the evolution of the system state over time can be described in a simple lag-1 autoregressive model:

$$\begin{aligned} x_{t+1} - x^* &= e^{\lambda_1(t+1)} + \sigma \xi_t = e^{\lambda_1} (x_t - x^*) + \sigma \xi_t \\ \Leftrightarrow y_{t+1} &= e^{\lambda_1} y_t + \sigma \xi_t = \alpha y_t + \sigma \xi_t, \end{aligned}$$

where  $y_t = x_t - x^*$ , is the deviation of the state variable  $x_t$  from the equilibrium  $x^*$ ,  $\xi_t$  is a random noise and  $\sigma$  is the standard deviation. As  $\lambda_1$  approaches zero,  $\alpha = e^{\lambda_1}$  approaches 1, leading to an increase in the lag-1 autocorrelation. When the lag-1 autoregressive coefficient  $\alpha$  reaches 1, a bifurcation occurs. Therefore, many methods based on the lag-1 autocorrelation of the system states, have been developed for tipping points prediction. For example, the degenerate fingerprinting and BB method are designed for predicting tipping points for systems driven by white noise and red noise respectively. Note that if the additive noise  $\xi_t$  is red noise with lag-1 autocorrelation, the lag-1 autocorrelation of the system state will be partially from the lag-1 autocorrelation of the red noise, which make the lag-1 autoregressive coefficient  $\alpha$  more difficult to estimate.

Then we will show the significance of high-order terms in dynamical systems close to a bifurcation point. As a system is far from a bifurcation point in a regime of small noise, the displacement  $\varepsilon$  from equilibrium is small. Thus in the simplified equation

$$\frac{d(x^* + \varepsilon)}{dt} = f(x^* + \varepsilon) \approx f(x^*) + \left. \frac{\partial f}{\partial x} \right|_{x=x^*} \varepsilon,$$

we can omit the higher-order terms and then simplify this dynamical system to equation (2). However, as a local bifurcation is approached, the recovery rate  $\lambda_1$  approaches 0 when critical slowing down occurs. This allows the noise to push the system farther from equilibrium which means  $\varepsilon$  increases. Therefore high-order terms become significant for the dynamics of the system.

## 2 Fast-slow systems and rate-delayed tipping

### 2.1 Fast-slow systems in critical transition

Consider a family of ordinary differential equations:

$$\frac{dx}{dt} = f(x, \mu), \quad (3)$$

where  $x \in R^m$  are phase space variables and  $\mu \in R^m$  are parameters. Since the critical transitions occur when a parameter evolves slowly until a tipping point, it is a natural way to include the parameters in the original differential equation. So the equation (3) can be written as

$$\begin{aligned} \frac{dx}{dt} &= f(x, \mu) \\ \frac{d\mu}{dt} &= 0. \end{aligned} \quad (4)$$

Then we add a slow evolution to  $\mu$  in equation (4)

$$\begin{aligned} \frac{dx}{dt} &= f(x, \mu) \\ \frac{d\mu}{dt} &= \epsilon g(x, \mu), \end{aligned} \quad (5)$$

where  $0 < \epsilon \ll 1$  is a small parameter and  $g$  is sufficiently smooth. In many cases, we can assume that the parameter dynamics is decoupled from phase space dynamics and  $g \equiv 1$ . The equations (5) form a fast-slow system where  $x \in R^m$  are the fast variables,  $\mu \in R^m$  are the slow variables and the parameter  $\epsilon$  characterizes the time scale separation.

When  $\epsilon g(x, \mu)$  is small, system (5) can be simplified to one-dimensional dynamical system (3) based on the theory of fast-slow systems. Therefore the effect of the changing rate of the parameter on the location of the critical transition will not be taken into account.

### 2.2 Rate-delayed tipping

For dynamical system (5), if  $\epsilon g(x, \mu)$  is not sufficiently small, the changing rate of the bifurcation parameter  $\mu$  will cause a delay on the Bifurcation-tipping. Here is an example of the normal form of fold bifurcation where the bifurcation parameter  $\mu$  approaches the bifurcation point at a rate of  $r$ :

$$\frac{dx}{dt} = \mu + x^2 \quad (6)$$

$$\frac{d\mu}{dt} = r, \quad (7)$$

this dynamical system has a stable equilibrium branch  $x^2 = -\mu$  ( $x < 0$ ) if we only consider the equation (6). However, due to the nonzero changing rate of the bifurcation parameter described in equation (7), the expression of this equilibrium branch is not entirely precise. If we take the derivative of  $x^2 = -\mu$  with respect to  $t$  on both sides, we will obtain the following:

$$\begin{aligned} \frac{dx^2}{dt} &= 2x \frac{dx}{dt} = -\frac{d\mu}{dt} = -r \\ \Rightarrow \frac{dx}{dt} &= \frac{-r}{2x} = \mu + x^2 \\ \Rightarrow -\mu &= x^2 + \frac{r}{2x}. \end{aligned}$$

This implies that the trajectory of the quasi-static attractor  $x$  as it moves with the changing bifurcation parameter  $\mu$  is approximately governed by  $x^2 + \frac{r}{2x} = -\mu$ . Moreover, as the changing rate of  $\mu$  increases (larger  $r$

values), the trajectory of the quasi-static attractor  $x$  deviates farther from  $x^2 = -\mu$ . Here we set  $r$  to be 0, 0.5 and 1 respectively, and plot the graph of  $x^2 + \frac{r}{2x} = -\mu$ , as shown in Fig. S2. It can be observed that as  $r$  increases, the occurrence of the tipping points is progressively delayed comparing with the bifurcation point  $\mu = 0$ .

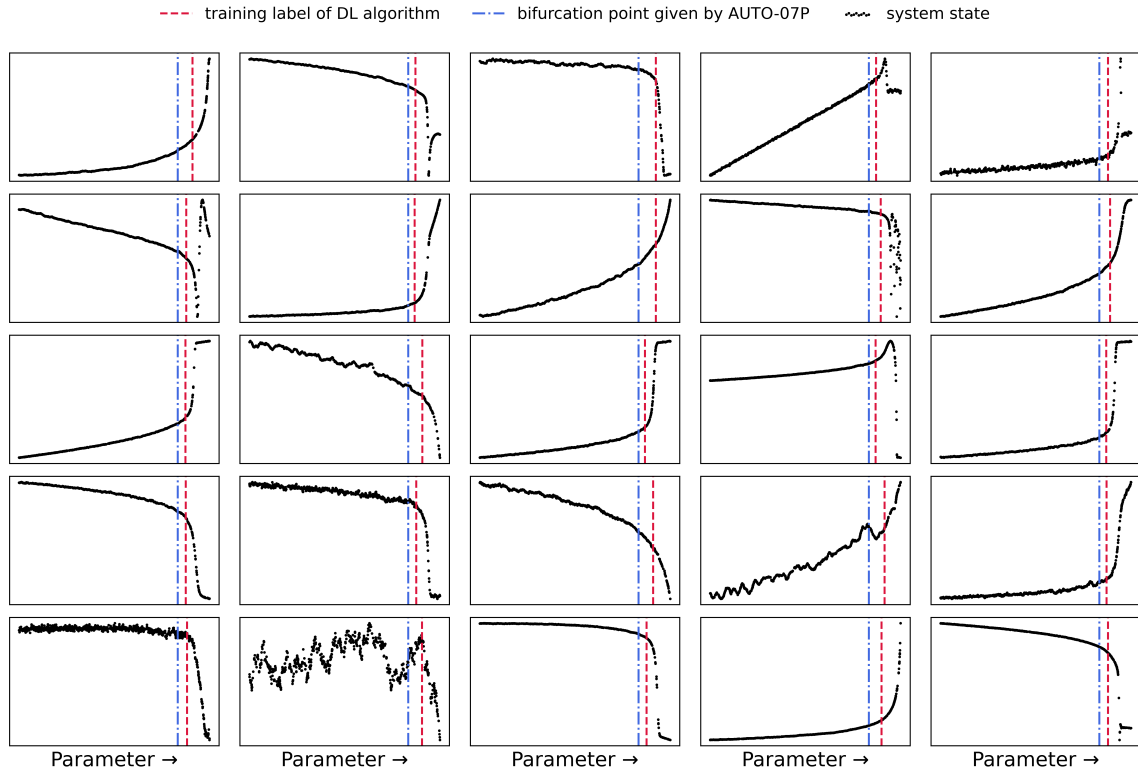

**Supplementary Figure 2** A rate-delayed tipping example of the normal form of fold bifurcation. The bifurcation occurs at  $\mu = 0$  in the normal form of fold bifurcation  $dx/dt = \mu + x^2$ . Solid lines represent stable equilibrium branches, while dashed lines represent unstable equilibrium branches.

### 2.3 Training labels of tipping points

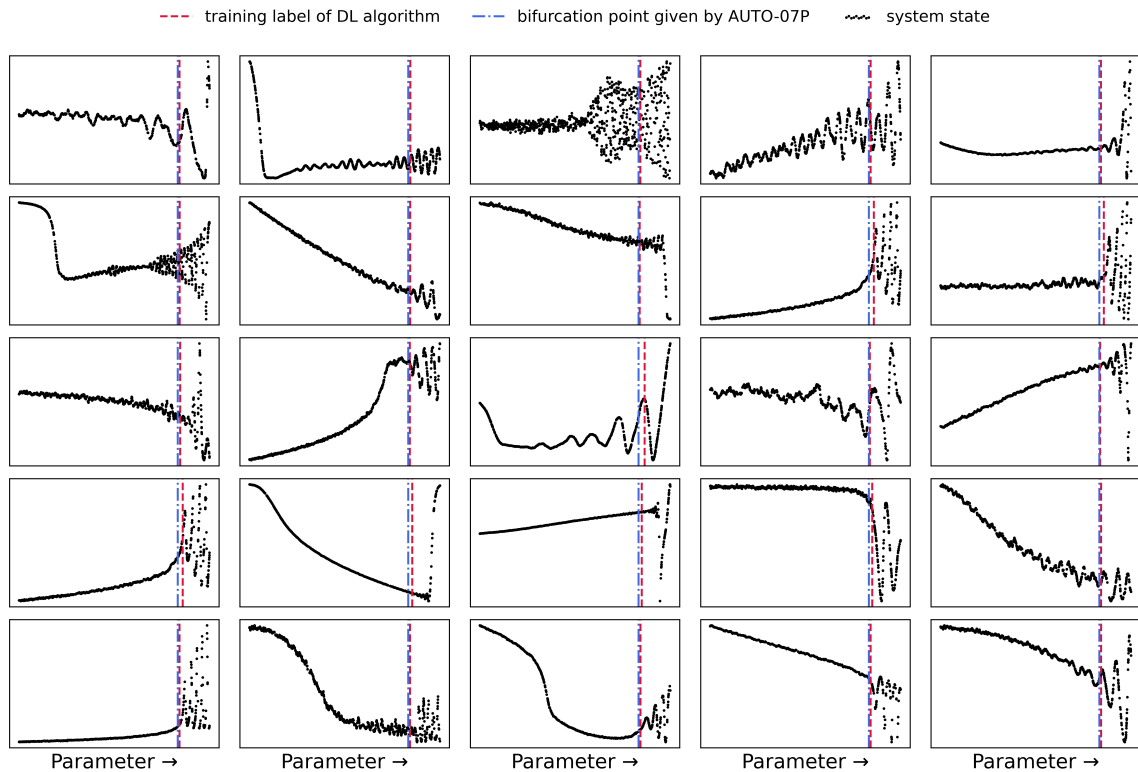

Due to the effect of rate-delayed tipping, the real tipping points of the simulated training time series have been delayed. As a result, we have not utilized the bifurcation points given by AUTO-07P as the training labels. Instead, we identify the location of the tipping points where the recovery rate changes from negative value to positive value and use them as training labels for tipping points. This location is where the quasi-static attractor loses stability. Here, we provide some examples in the training set to show the location of our training labels. For each bifurcation type, we plot figures of training time series that undergo tipping points, generated by 50 different systems with white noise. Half of the figures represent systems with an increasing parameter, while the other half represent systems with a decreasing parameter. Then we compare the tipping points given by AUTO-07P with those identified by the recovery rate. It can be observed that due to the effect of rate-delayed tipping, the tipping points identified by the recovery rate are more accurate, as shown in Fig. S3-S8.

### Rate-delayed Tipping in Fold Bifurcation (increased parameter)

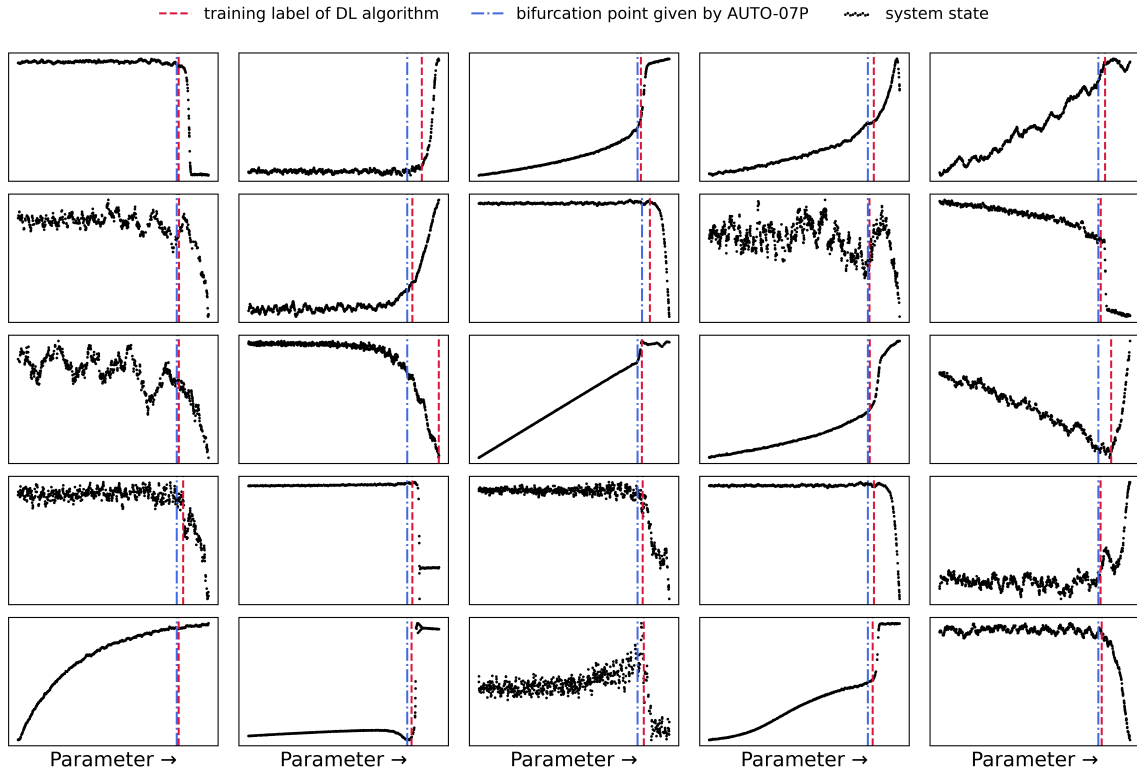

**Supplementary Figure 3** An example of 25 different time series with white noise in our training set, each going through a fold bifurcation, where the bifurcation parameter is increasing. The red dashed lines are the labels used to train our DL algorithm identified by the recovery rate, while the blue dash-dot lines are the bifurcation points given by AUTO-07P.

### Rate-delayed Tipping in Hopf Bifurcation (increased parameter)

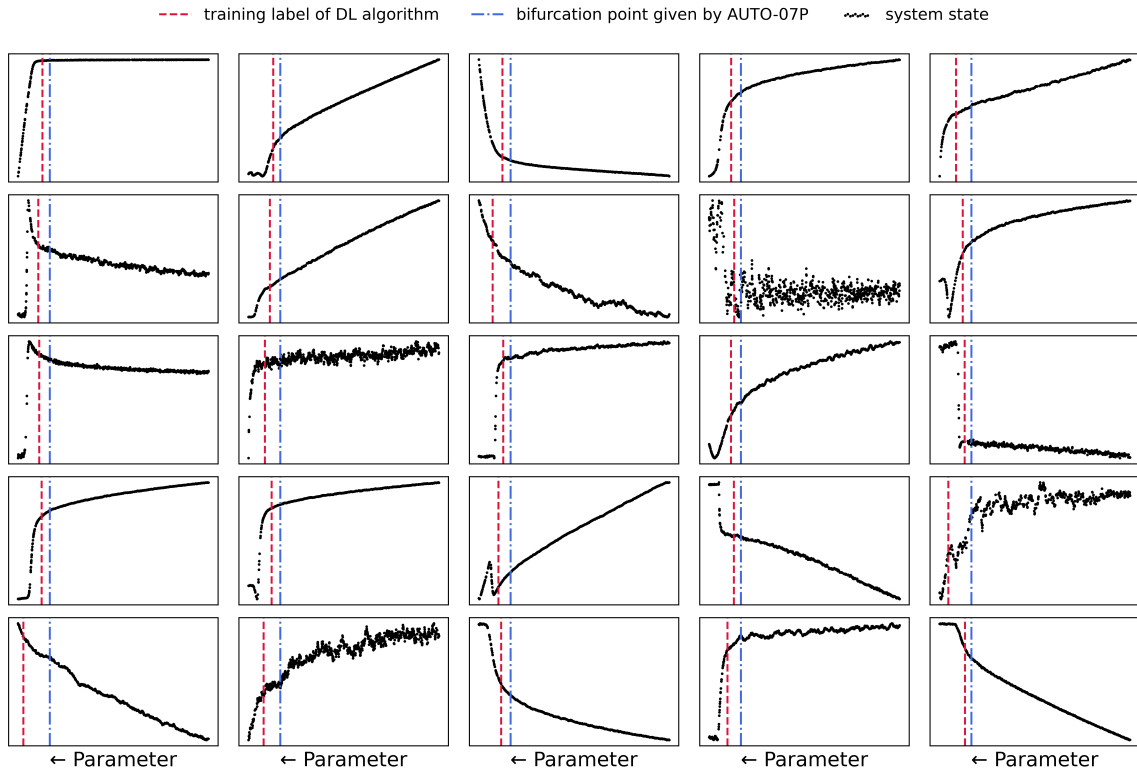

**Supplementary Figure 4** An example of 25 different time series with white noise in our training set, each going through a Hopf bifurcation, where the bifurcation parameter is increasing. The red dashed lines are the labels used to train our DL algorithm identified by the recovery rate, while the blue dash-dot lines are the bifurcation points given by AUTO-07P.

### Rate-delayed Tipping in Transcritical Bifurcation (increased parameter)

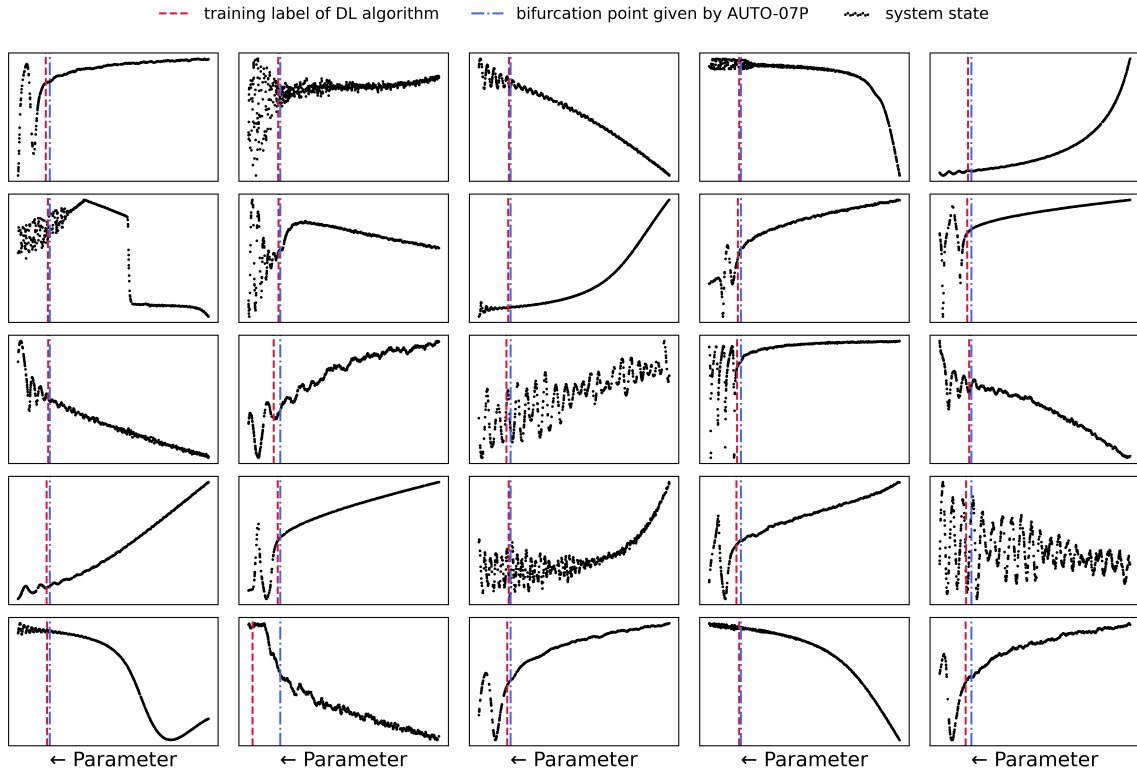

**Supplementary Figure 5** An example of 25 different time series with white noise in our training set, each going through a transcritical bifurcation, where the bifurcation parameter is increasing. The red dashed lines are the labels used to train our DL algorithm identified by the recovery rate, while the blue dash-dot lines are the bifurcation points given by AUTO-07P.

### Rate-delayed Tipping in Fold Bifurcation (decreased parameter)

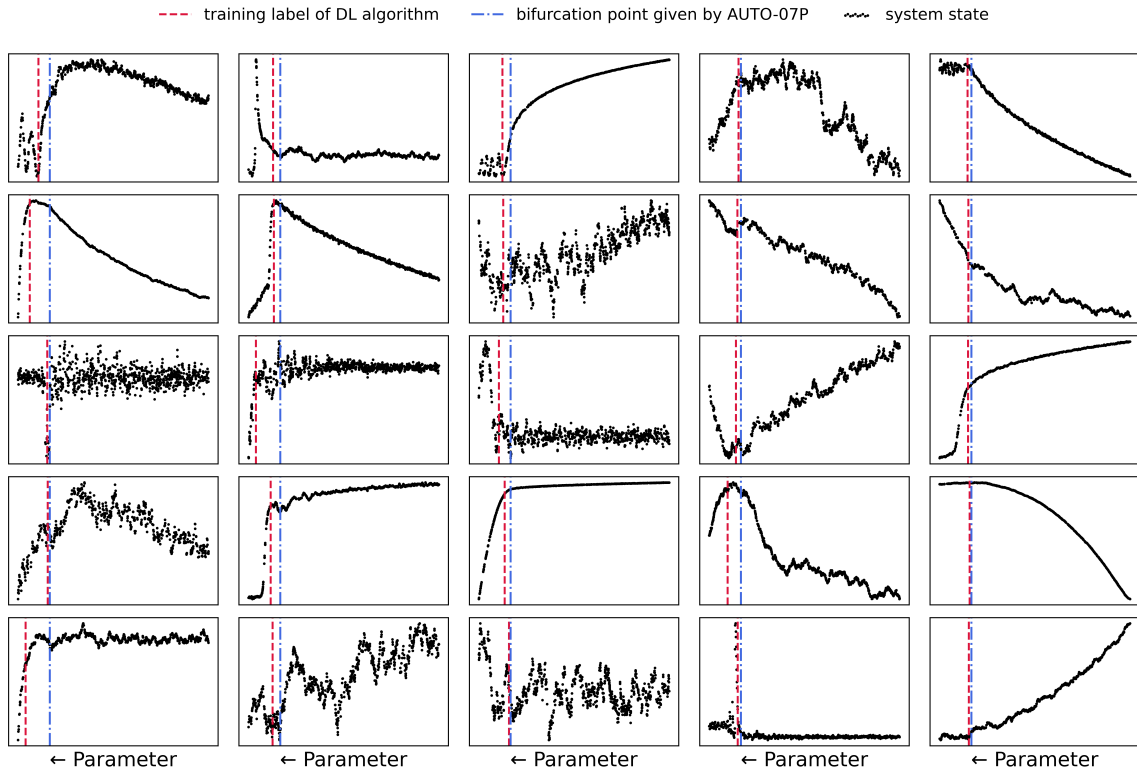

**Supplementary Figure 6** An example of 25 different time series with white noise in our training set, each going through a fold bifurcation, where the bifurcation parameter is decreasing. The red dashed lines are the labels used to train our DL algorithm identified by the recovery rate, while the blue dash-dot lines are the bifurcation points given by AUTO-07P.

### Rate-delayed Tipping in Hopf Bifurcation (decreased parameter)

**Supplementary Figure 7** An example of 25 different time series with white noise in our training set, each going through a Hopf bifurcation, where the bifurcation parameter is decreasing. The red dashed lines are the labels used to train our DL algorithm identified by the recovery rate, while the blue dash-dot lines are the bifurcation points given by AUTO-07P.

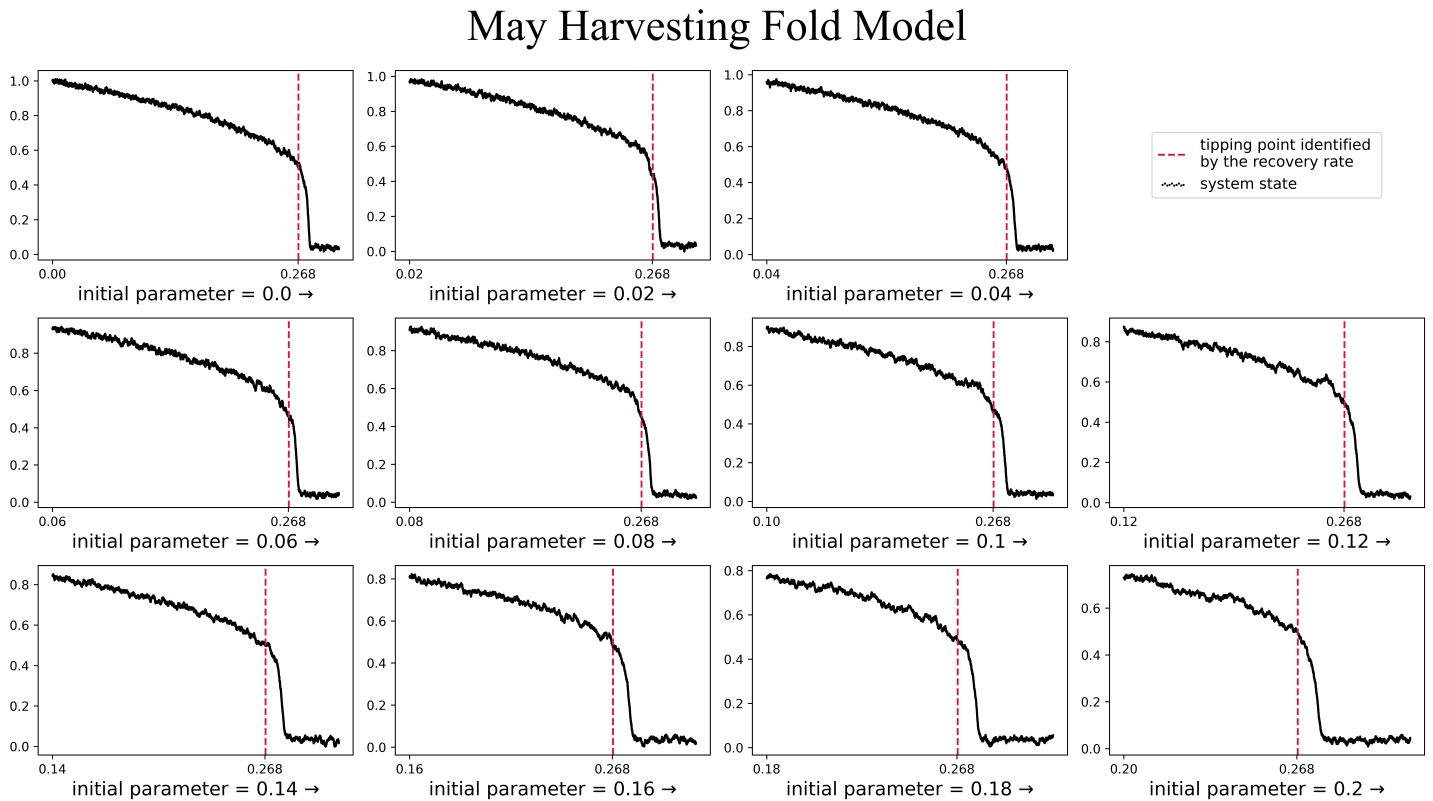

### Rate-delayed Tipping in Transcritical Bifurcation (decreased parameter)

**Supplementary Figure 8** An example of 25 different time series with white noise in our training set, each going through a transcritical bifurcation, where the bifurcation parameter is decreasing. The red dashed lines are the labels used to train our DL algorithm identified by the recovery rate, while the blue dash-dot lines are the bifurcation points given by AUTO-07P.

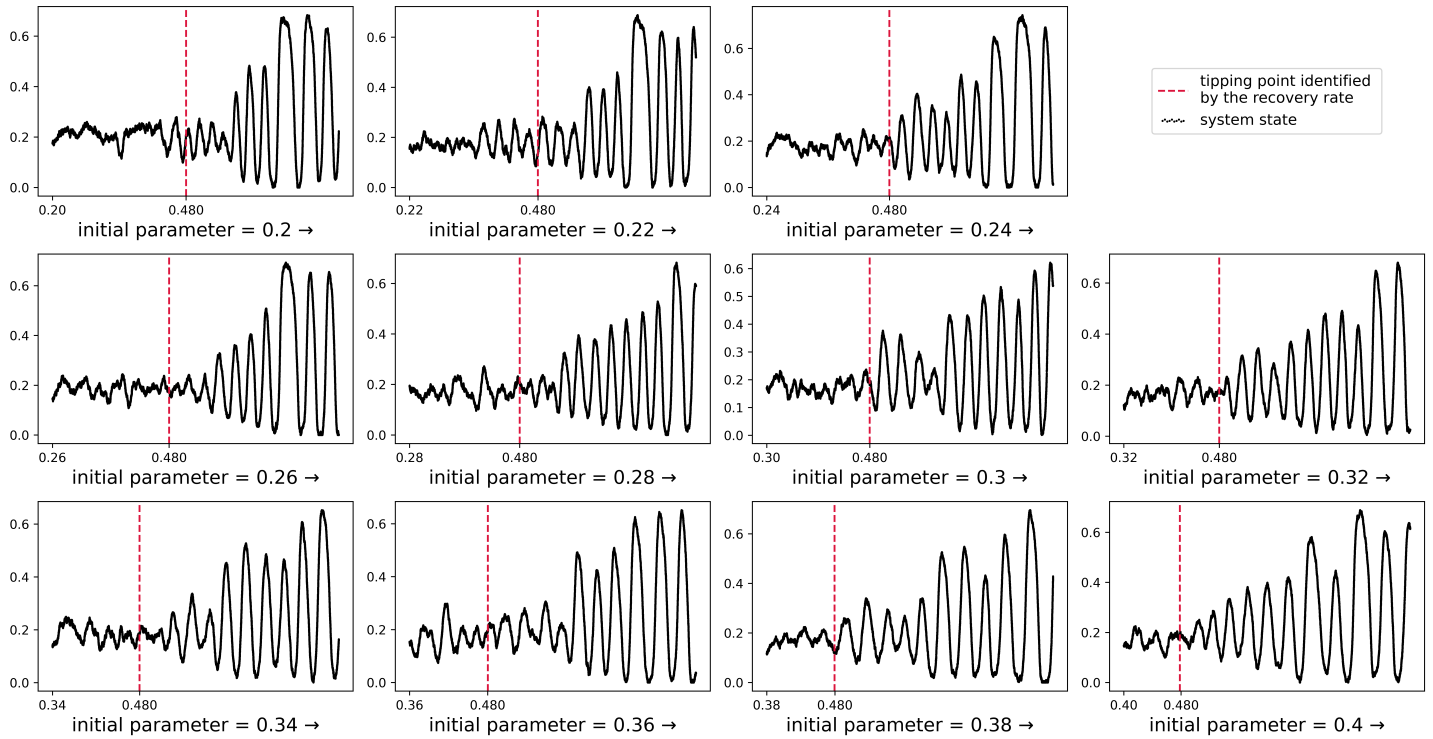

## 2.4 The ground truth of test model time series

Due to the effect of rate-delayed tipping, the real tipping points of test model time series generated by six theoretical models are delayed. Therefore, we use the fact that the quasi-static attractor loses stability at the occurrence of tipping points to obtain the ground truth of tipping points. The model time series generated by six theoretical models with noise and their ground truth of tipping points where the recovery rate changes from negative value to positive value are shown in Fig. S9-S14. Because we set the changing rate of the bifurcation parameter as a constant in simulations of each model, the occurrence of tipping points is the same for all time series generated by that model.

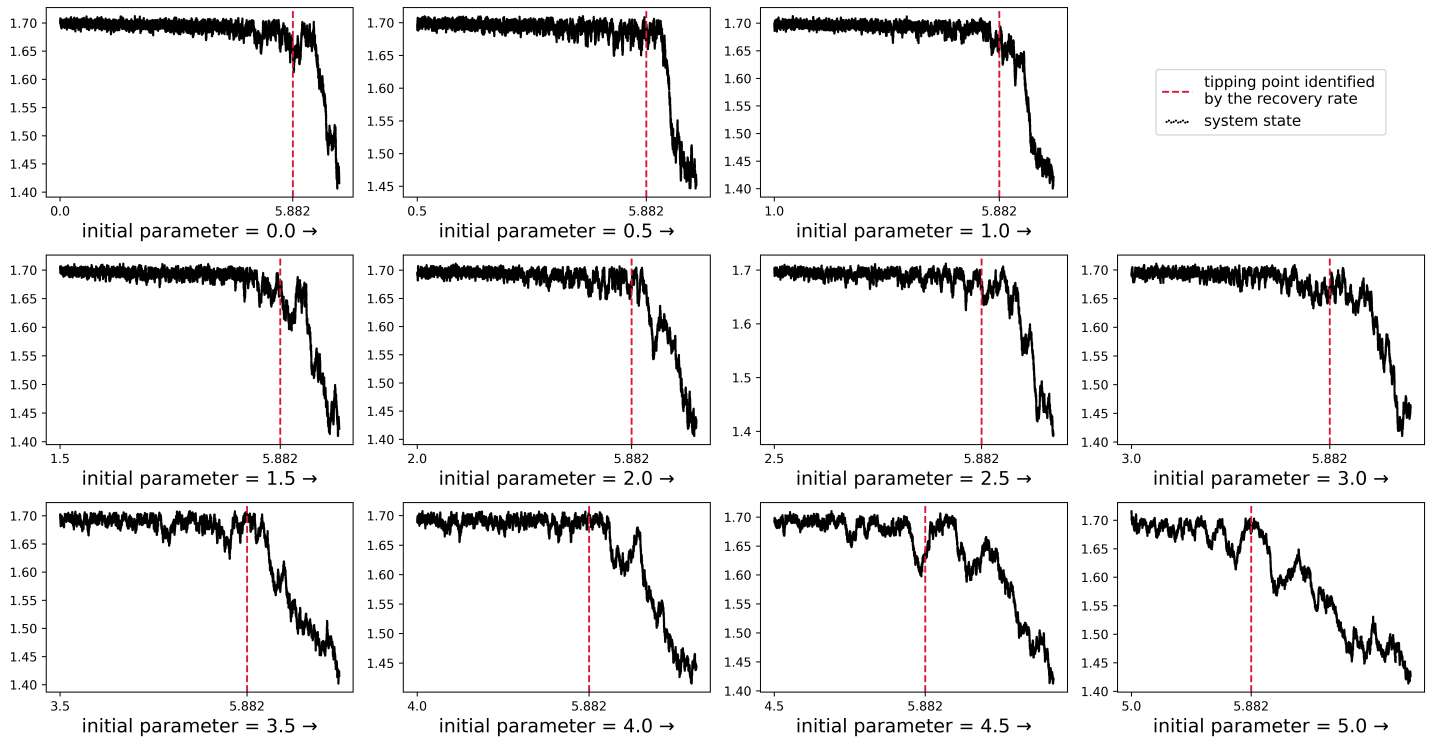

**Supplementary Figure 9** The time series undergo fold bifurcation generated by May's harvesting model with white noise. The simulations are forced by increasing bifurcation parameter from eleven initial values of 0, 0.02, 0.04, ..., 0.18, 0.2. The red dashed lines are the ground truth of tipping points identified by the recovery rate. A fold bifurcation occurs at 0.268.

## Chaotic Food Chain Hopf Model

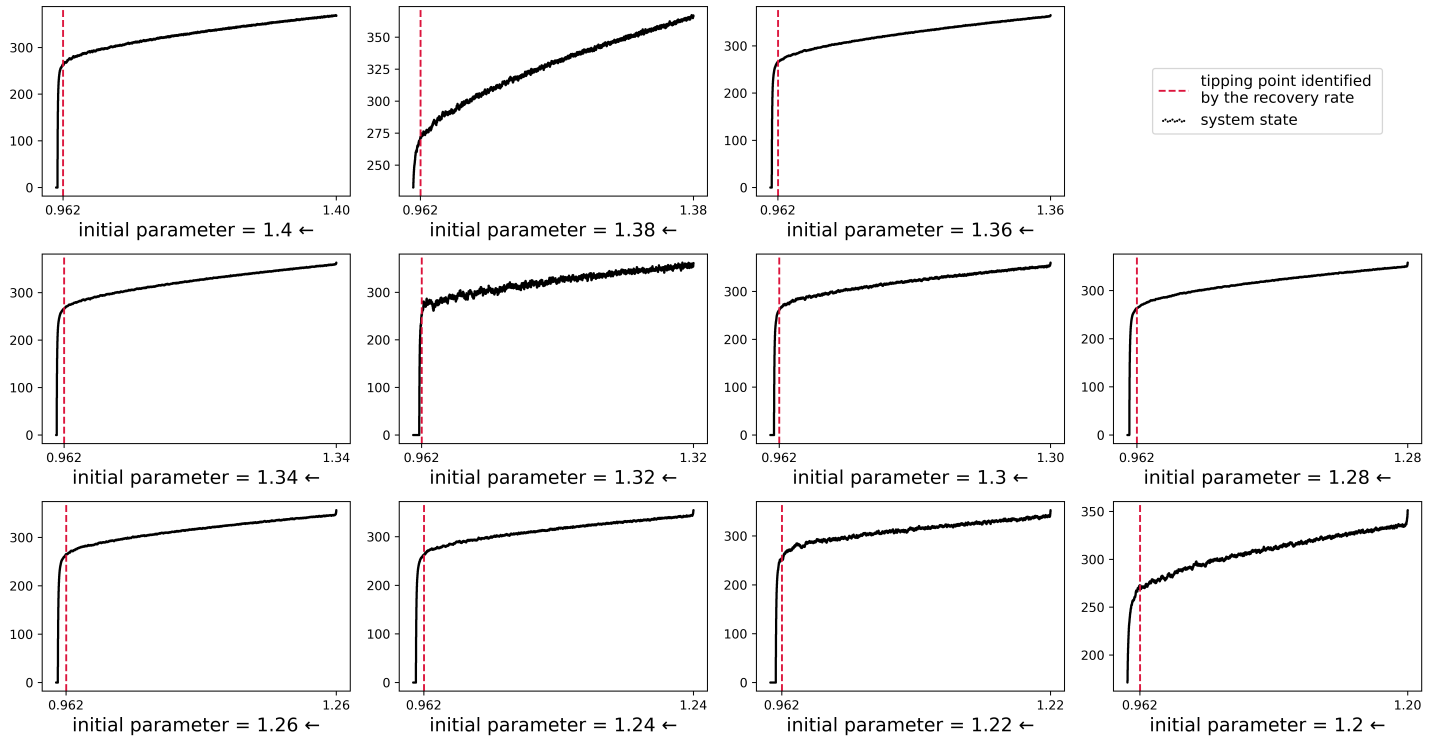

**Supplementary Figure 10** The time series undergo Hopf bifurcation generated by three-species chaotic food chain model with white noise. The simulations are forced by increasing bifurcation parameter from eleven initial values of 0.20, 0.22, 0.24, ..., 0.38, 0.40. The red dashed lines are the ground truth of tipping points identified by the recovery rate. A Hopf bifurcation occurs at 0.480.

## Consumer Resource Transcritical Model

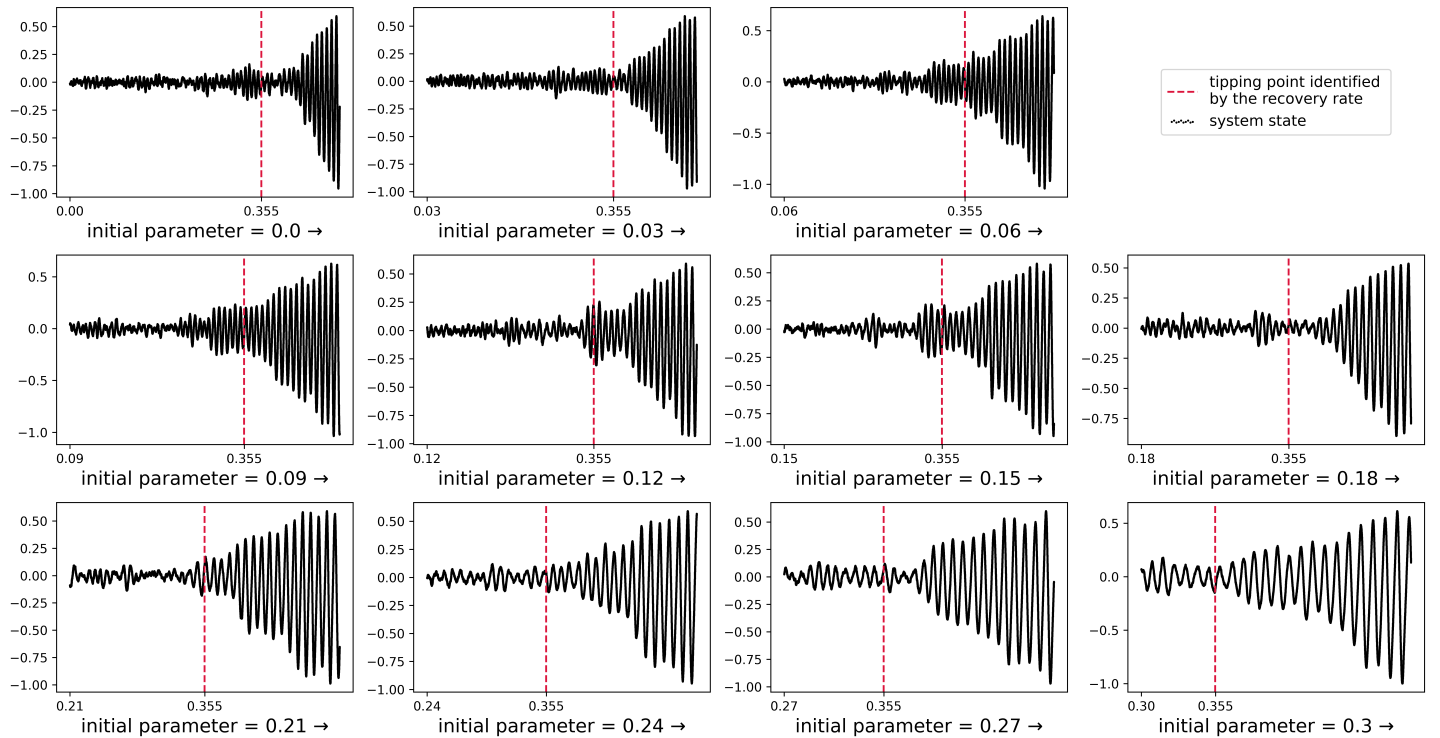

**Supplementary Figure 11** The time series undergo transcritical bifurcation generated by consumer-resource model with white noise. The simulations are forced by increasing bifurcation parameter from eleven initial values of 0, 0.5, 1.0, ..., 4.5, 5.0. The red dashed lines are the ground truth of tipping points identified by the recovery rate. A transcritical bifurcation occurs at 5.882.

## Global Energy Balance Fold Model

**Supplementary Figure 12** The time series undergo fold bifurcation generated by global energy balance model with red noise. The simulations are forced by decreasing bifurcation parameter from eleven initial values of 1.4, 1.38, 1.36, ..., 1.22, 1.2. The red dashed lines are the ground truth of tipping points identified by the recovery rate. A fold bifurcation occurs at 0.962.

## Middle Pleistocene Transition Hopf Model

**Supplementary Figure 13** The time series undergo Hopf bifurcation generated by middle Pleistocene transition model with red noise. The simulations are forced by increasing bifurcation parameter from eleven initial values of 0, 0.03, 0.06, ..., 0.27, 0.3. The red dashed lines are the ground truth of tipping points identified by the recovery rate. A Hopf bifurcation occurs at 0.355.

## Amazon Rainforest Dieback Transcritical Model

**Supplementary Figure 14** The time series undergo transcritical bifurcation generated by Amazon rainforest dieback model with red noise. The simulations are forced by decreasing bifurcation parameter from eleven initial values of 0.90, 0.82, 0.74, ..., 0.18, 0.10. The red dashed lines are the ground truth of tipping points identified by the recovery rate. A transcritical bifurcation occurs at  $-0.005$ .

### 3 Normal form

#### 3.1 The formula for the recovery rate in the normal form

The normal form of the fold bifurcation is

$$\frac{dx}{dt} = \mu + x^2,$$

which exhibits a stable equilibrium branch  $x^*(\mu) = -\sqrt{-\mu}$ . Therefore, we have the following relation between the recovery rate  $\lambda$  and the bifurcation parameter  $\mu$ ,

$$\begin{aligned}\lambda &= \left. \frac{\partial(\mu + x^2)}{\partial x} \right|_{x=x^*(\mu)} \\ &= 2x \Big|_{x=-\sqrt{-\mu}} \\ &= -2\sqrt{-\mu}.\end{aligned}$$

The normal form of the supercritical Hopf bifurcation is

$$\frac{dx}{dt} = \mu x - y - x(x^2 + y^2), \quad \frac{dy}{dt} = x + \mu y - y(x^2 + y^2),$$

which exhibits a stable equilibrium branch  $(x^*(\mu), y^*(\mu)) = (0, 0)$ . Therefore, we have the following relation between the recovery rate  $\lambda$  and the bifurcation parameter  $\mu$ ,

$$\begin{aligned}\lambda &= \max(\operatorname{Re}(\operatorname{eigvals}\left(\left[\begin{array}{cc} \frac{\partial(\mu x - y - x(x^2 + y^2))}{\partial x} & \frac{\partial(\mu x - y - x(x^2 + y^2))}{\partial y} \\ \frac{\partial(x + \mu y - y(x^2 + y^2))}{\partial x} & \frac{\partial(x + \mu y - y(x^2 + y^2))}{\partial y} \end{array}\right]_{(x,y)=(x^*(\mu), y^*(\mu))}\right))) \\ &= \max(\operatorname{Re}(\operatorname{eigvals}\left(\left[\begin{array}{cc} \mu - 3x^2 - y^2 & -1 - 2xy \\ 1 - 2xy & \mu - x^2 - 3y^2 \end{array}\right]_{(x,y)=(0,0)}\right))) \\ &= \max(\operatorname{Re}(\operatorname{eigvals}\left(\left[\begin{array}{cc} \mu & -1 \\ 1 & \mu \end{array}\right]\right))) \\ &= \max(\operatorname{Re}(\mu \pm i)) \\ &= \mu.\end{aligned}$$

The normal form of the subcritical Hopf bifurcation is

$$\frac{dx}{dt} = \mu x - y + x(x^2 + y^2), \quad \frac{dy}{dt} = x + \mu y + y(x^2 + y^2),$$

which exhibits a stable equilibrium branch  $(x^*(\mu), y^*(\mu)) = (0, 0)$ . Therefore, we have the following relation between the recovery rate  $\lambda$  and the bifurcation parameter  $\mu$ ,

$$\begin{aligned}\lambda &= \max(\operatorname{Re}(\operatorname{eigvals}\left(\left[\begin{array}{cc} \frac{\partial(\mu x - y + x(x^2 + y^2))}{\partial x} & \frac{\partial(\mu x - y + x(x^2 + y^2))}{\partial y} \\ \frac{\partial(x + \mu y + y(x^2 + y^2))}{\partial x} & \frac{\partial(x + \mu y + y(x^2 + y^2))}{\partial y} \end{array}\right]_{(x,y)=(x^*(\mu), y^*(\mu))}\right))) \\ &= \max(\operatorname{Re}(\operatorname{eigvals}\left(\left[\begin{array}{cc} \mu + 3x^2 + y^2 & -1 + 2xy \\ 1 + 2xy & \mu + x^2 + 3y^2 \end{array}\right]_{(x,y)=(0,0)}\right))) \\ &= \max(\operatorname{Re}(\operatorname{eigvals}\left(\left[\begin{array}{cc} \mu & -1 \\ 1 & \mu \end{array}\right]\right))) \\ &= \max(\operatorname{Re}(\mu \pm i)) \\ &= \mu.\end{aligned}$$

The normal form of the transcritical bifurcation is

$$\frac{dx}{dt} = \mu x - x^2,$$

which exhibits a stable equilibrium branch  $x^*(\mu) = 0$  when  $\mu$  increases from negative value to positive value or a stable equilibrium branch  $x^*(\mu) = \mu$  when  $\mu$  decreases from positive value to negative value. Therefore, the relation between the recovery rate  $\lambda$  and the bifurcation parameter  $\mu$  when  $\mu$  increases from negative value to positive value is:

$$\begin{aligned}\lambda &= \left. \frac{\partial(\mu x - x^2)}{\partial x} \right|_{x=x^*(\mu)} \\ &= \mu - 2x \Big|_{x=0} \\ &= \mu \quad (\mu < 0).\end{aligned}$$

The relation between the recovery rate  $\lambda$  and the bifurcation parameter  $\mu$  when  $\mu$  decreases from positive value to negative value is:

$$\begin{aligned}\lambda &= \left. \frac{\partial(\mu x - x^2)}{\partial x} \right|_{x=x^*(\mu)} \\ &= \mu - 2x \Big|_{x=\mu} \\ &= -\mu \quad (\mu > 0),\end{aligned}$$

which is equivalent to  $\lambda = \mu$  ( $\mu < 0$ ) when  $\mu$  increases from negative value to positive value.

### 3.2 Dimension reduction near a bifurcation

Here we demonstrate how to simplify the dynamics of an arbitrary  $n$ -dimensional dynamical system  $dX^n/dt = F(X^n, \mu)$  exhibiting a fold bifurcation to its normal form and derive the relation between the recovery rate  $\lambda$  and the bifurcation parameter  $\mu$  (1).

As an  $n$ -dimensional dynamical system  $dX^n/dt = F(X^n, \mu)$  approaches a bifurcation, its dynamics simplify to a one-dimensional dynamical system  $dx/dt = f(x, \mu)$  according to center manifold theorem. We examine the behavior of  $dx/dt = f(x, \mu)$  near the bifurcation at  $x = x^*$  and  $\mu = \mu_c$ . Taylor's expansion yields

$$\begin{aligned}\frac{dx}{dt} &= f(x, \mu) \\ &= f(x^*, \mu_c) + (x - x^*) \left. \frac{\partial f}{\partial x} \right|_{(x^*, \mu_c)} + (\mu - \mu_c) \left. \frac{\partial f}{\partial \mu} \right|_{(x^*, \mu_c)} + \frac{1}{2} (x - x^*)^2 \left. \frac{\partial^2 f}{\partial x^2} \right|_{(x^*, \mu_c)} + \dots,\end{aligned}$$

where the quadratic terms in  $(\mu - \mu_c)$  and cubic terms in  $(x - x^*)$  are neglected. Two terms in this equation vanish:  $f(x^*, \mu_c) = 0$  since  $x^*$  is a fixed point, and  $\left. \frac{\partial f}{\partial x} \right|_{(x^*, \mu_c)} = 0$  by the non-hyperbolicity of the fold bifurcation.

Thus, we have

$$\frac{dx}{dt} = a(\mu - \mu_c) + b(x - x^*)^2, \quad (8)$$

where  $a = \left. \frac{\partial f}{\partial \mu} \right|_{(x^*, \mu_c)}$ ,  $b = \frac{1}{2} \left. \frac{\partial^2 f}{\partial x^2} \right|_{(x^*, \mu_c)}$ , and for the transversality and non-degeneracy of fold bifurcation,  $\left. \frac{\partial f}{\partial \mu} \right|_{(x^*, \mu_c)} \neq 0$ ,  $\left. \frac{\partial^2 f}{\partial x^2} \right|_{(x^*, \mu_c)} \neq 0$  are satisfied. Thus, equation (8) agrees with the normal form of fold bifurcation  $dx/dt = \mu + x^2$ .

Since the equilibrium of the system (8) is  $x = x^* + \frac{1}{b} \sqrt{|a(\mu_c - \mu)|}$ , we can derive the relation between the recovery rate  $\lambda$  and the bifurcation parameter  $\mu$  in the following

$$\begin{aligned}\lambda &= \left. \frac{\partial}{\partial x} (a(\mu - \mu_c) + b(x - x^*)^2) \right|_{x=x^* + \frac{1}{b} \sqrt{|a(\mu_c - \mu)|}} \\ &= 2b(x - x^*) \Big|_{x=x^* + \frac{1}{b} \sqrt{|a(\mu_c - \mu)|}} \\ &= -2\sqrt{|ab(\mu_c - \mu)|}.\end{aligned}$$

This function is a translation and scaling transformation of the function  $\lambda = -2\sqrt{-\mu}$  which is the relation between the recovery rate  $\lambda$  and the bifurcation parameter  $\mu$  of the normal form of the fold bifurcation.

## 4 Competing algorithms

### 4.1 Degenerate fingerprinting

The degenerate fingerprinting(2) is applicable for tipping points prediction in high-dimensional dynamical systems with white noise. In the small-noise limit, the system's response to white noise can be approximated by the dynamics of linear modes. According to the theory of dynamical systems, one mode becomes unstable at any bifurcation which is called critical mode when the smallest decay rate  $\kappa$  of perturbation vanishes. The critical mode produces diverging variance  $\propto 1/\kappa$  as a bifurcation point is approached. Therefore, the critical mode can be approximated by leading principal component obtained by using principal component analysis (PCA) on high-dimensional time series data sampled from the system.

The vicinity to a bifurcation allows for a simplification in the time-domain. Suppose that the other modes have much larger decay rate  $\kappa_i$ , their dynamics can be lumped into the noise. Then we can pre-aggregate the leading principal component time-series into a time-discrete dynamics of fixed time-step  $\Delta t$  with  $\Delta t \gg 1/\kappa_i$ . If furthermore  $1/\kappa \gg \Delta t$ , the fluctuations of the critical mode can be modeled by a AR(1) process  $y_{t+\Delta t} = \phi y_t + \xi_t = e^{-\kappa \Delta t} y_t + \xi_t$ , where  $\xi_t$  is Gaussian white noise. Thus we can estimate the lag-1 autoregressive coefficient  $\phi$  from leading principal component time-series  $y_t$ .  $\phi$  is used to be indicator for predicting the occurrence of tipping points, when  $\phi$  reaches 1, we can predict that a bifurcation occurs.

### 4.2 BB method

The BB method(3) is designed for estimating the lag-1 autoregressive coefficient of a time series sampled from one-dimensional systems with red noise. Due to the Takens embedding theorem, it can be applicable to a time series from one dimension of a high-dimensional system. Thus we compare the BB method with our DL algorithm on a time series from one dimension of high-dimensional systems in the main text. The evolution of a one-dimensional time series of state  $x_t$  under the disturbance of red noise  $v_t$  over time can be modeled by

$$x_{t+1} = \varphi x_t + v_t, \quad v_{t+1} = \rho v_t + \epsilon_t, \quad \epsilon_t \sim N(0, 1),$$

which has the following statistical property:

$$AC(x_{t+1}, x_t) = \varphi_b = \frac{\varphi + \rho}{1 + \varphi\rho}. \quad (9)$$

where  $AC(x_{t+1}, x_t)$  is the lag-1 autoregressive coefficient of time series  $x_t$ . The unbiased least-squares estimator for  $\varphi_b$  is

$$\hat{\varphi}_b = \frac{\sum_{i=1}^n (x_i - \bar{x})(x_{i-1} - \bar{x})}{\sum_{i=1}^n (x_{i-1} - \bar{x})^2},$$

which only coincides with  $\varphi$  for the white-noise case  $\rho = 0$ . Since increasing  $\varphi$  is an early warning signal for critical transition but the increase in  $\rho$  leads to an increase in  $\varphi_b$ , thus  $\varphi_b$  is not an effective early warning signal for the critical transition under red noise. For the least-squares estimator for  $\rho$ ,

$$\hat{\rho}_b = \frac{\sum_{i=1}^n \hat{v}_i \hat{v}_{i-1}}{\sum_{i=1}^n \hat{v}_{i-1}^2}, \quad \hat{v}_i = x_{i+1} - \hat{\varphi}_b x_i,$$

we have the following convergence property

$$\rho_b = \varphi \rho \varphi_b. \quad (10)$$

Using the equations (9) and (10), we have

$$\varphi^2 - (\varphi_b + \rho_b)\varphi + \frac{\rho_b}{\varphi_b} = 0.$$

Thus the unbiased estimator  $\hat{\varphi}$  of  $\varphi$  for  $\varphi > \rho$  is given by

$$\hat{\varphi} = \frac{(\hat{\varphi}_b + \hat{\rho}_b) + \sqrt{(\hat{\varphi}_b + \hat{\rho}_b)^2 - 4\frac{\hat{\rho}_b}{\hat{\varphi}_b}}}{2},$$

and for  $\rho > \varphi$  is given by

$$\hat{\varphi} = \frac{(\hat{\varphi}_b + \hat{\rho}_b) - \sqrt{(\hat{\varphi}_b + \hat{\rho}_b)^2 - 4\frac{\hat{\rho}_b}{\hat{\varphi}_b}}}{2},$$

where

$$\hat{\varphi}_b = \frac{\sum_{i=1}^n (x_i - \bar{x})(x_{i-1} - \bar{x})}{\sum_{i=1}^n (x_{i-1} - \bar{x})^2}, \quad \hat{\rho}_b = \frac{\sum_{i=1}^n \hat{v}_i \hat{v}_{i-1}}{\sum_{i=1}^n \hat{v}_{i-1}^2}, \quad \hat{v}_i = x_{i+1} - \hat{\varphi}_b x_i.$$

The estimator  $\hat{\varphi}$  of  $\varphi$  is used to be an indicator for predicting the occurrence of tipping points. When  $\hat{\varphi}$  reaches 1, we can predict that a bifurcation occurs.

### 4.3 Dynamical eigenvalue

Based on the Takens embedding theorem, for a one-dimensional state time series  $\{x(t) \mid 1 \leq t \leq n\}$  from a  $d$ -dimensional dynamical system  $dy/dt = f(y)$ , one can employ state space reconstruction to find an embedding space  $X_t = [x(t), x(t - \tau), \dots, x(t - (E - 1)\tau)]$  of dimension  $E$  which is topologically equivalent to original state space. Here,  $\tau$  represents the time delay, and  $E > 2d + 1$ . Therefore, the dominant eigenvalue of the Jacobian matrix  $J$  of the reconstructed state space  $X_t$  can be utilized as an early warning signal for critical transition in high-dimensional systems. It only requires time series sampled from one dimension of the system to estimate this indicator, which is named dynamical eigenvalue (DEV)(4).

We set  $X_t = [x(t), x(t - \tau), \dots, x(t - (E - 1)\tau)]^T$ . Then at time  $t_a$ , we have  $X_{t_a+\tau} = JX_{t_a} + v$  where

$$X_{t_a+\tau} = JX_{t_a} + v \Rightarrow \begin{bmatrix} x(t_a + \tau) \\ x(t_a) \\ x(t_a - \tau) \\ \vdots \\ x(t_a - (E - 2)\tau) \end{bmatrix} = \begin{bmatrix} j_{11} & j_{12} & j_{13} & \cdots & j_{1E} \\ 1 & 0 & 0 & \cdots & 0 \\ 0 & 1 & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{bmatrix} \begin{bmatrix} x(t_a) \\ x(t_a - \tau) \\ x(t_a - 2\tau) \\ \vdots \\ x(t_a - (E - 1)\tau) \end{bmatrix} + \begin{bmatrix} v_1 \\ 0 \\ 0 \\ \vdots \\ 0 \end{bmatrix}.$$

Based on the S-map algorithm, matrix  $J$  of the parameters  $j_{11}, j_{12}, j_{13}, \dots, j_{1E}$  can be estimated as the associated S-map coefficients. Then we have

$$[j_{11}, j_{12}, j_{13}, \dots, j_{1E}]^T = A^{-1}B,$$

where  $A$  is an  $n \times E$  dimensional matrix ( $n$  is the number of observations in  $\{x(t) \mid 1 \leq t \leq n\}$ ), given by

$$A_{ij} = \omega(\|X_{t_i} - X_{t_a}\|^2)x(t_i - (j - 1)\tau), \quad (1 \leq i \leq n, 1 \leq j \leq E),$$

and  $B$  is an  $n$ -dimensional vector, given by

$$B_i = \omega(\|X_{t_i} - X_{t_a}\|^2)x(t_i + \tau), \quad (1 \leq i \leq n).$$

The weighting function  $\omega$  is defined by

$$\omega(u) = \exp\left(-\frac{\theta u}{\bar{u}}\right),$$

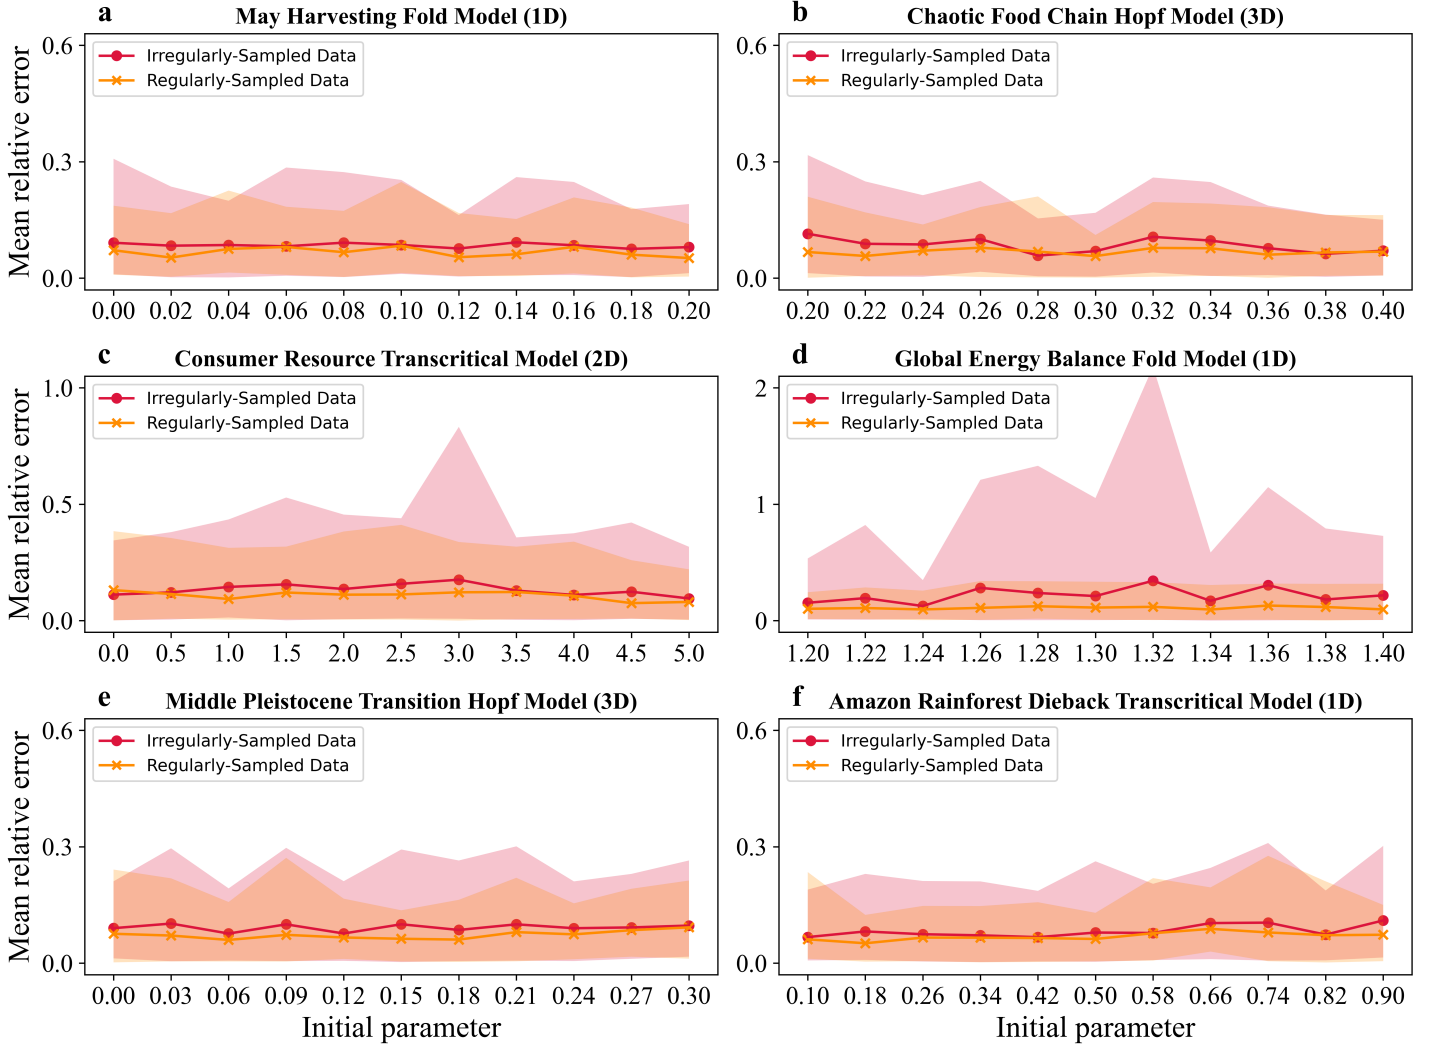

where  $\|\cdot\|$  denotes the Euclidean distance and  $\bar{u}$  is the average distance between  $X_{t_a}$  and all other vectors on the attractor. The weight is tuned by the nonlinear parameter  $\theta \geq 0$ .

Then we use the dominant eigenvalue  $\lambda$  of the Jacobian matrix  $J$  as the indicator for tipping points. When  $|\lambda|$  reaches 1, we can predict that a bifurcation occurs.

## 5 Robustness of DL algorithm

### 5.1 Robustness of DL algorithm against sampling methods

Here, we compared the performance of the DL algorithm on regularly-sampled and irregularly-sampled model time series, as respectively illustrated in Fig. 2 and Fig. 3 of the main text. We can find that the DL algorithm performs similarly on regularly-sampled and irregularly-sampled model time series for most cases (Fig. S15). The experimental results suggest the DL algorithm is robust against sampling methods.

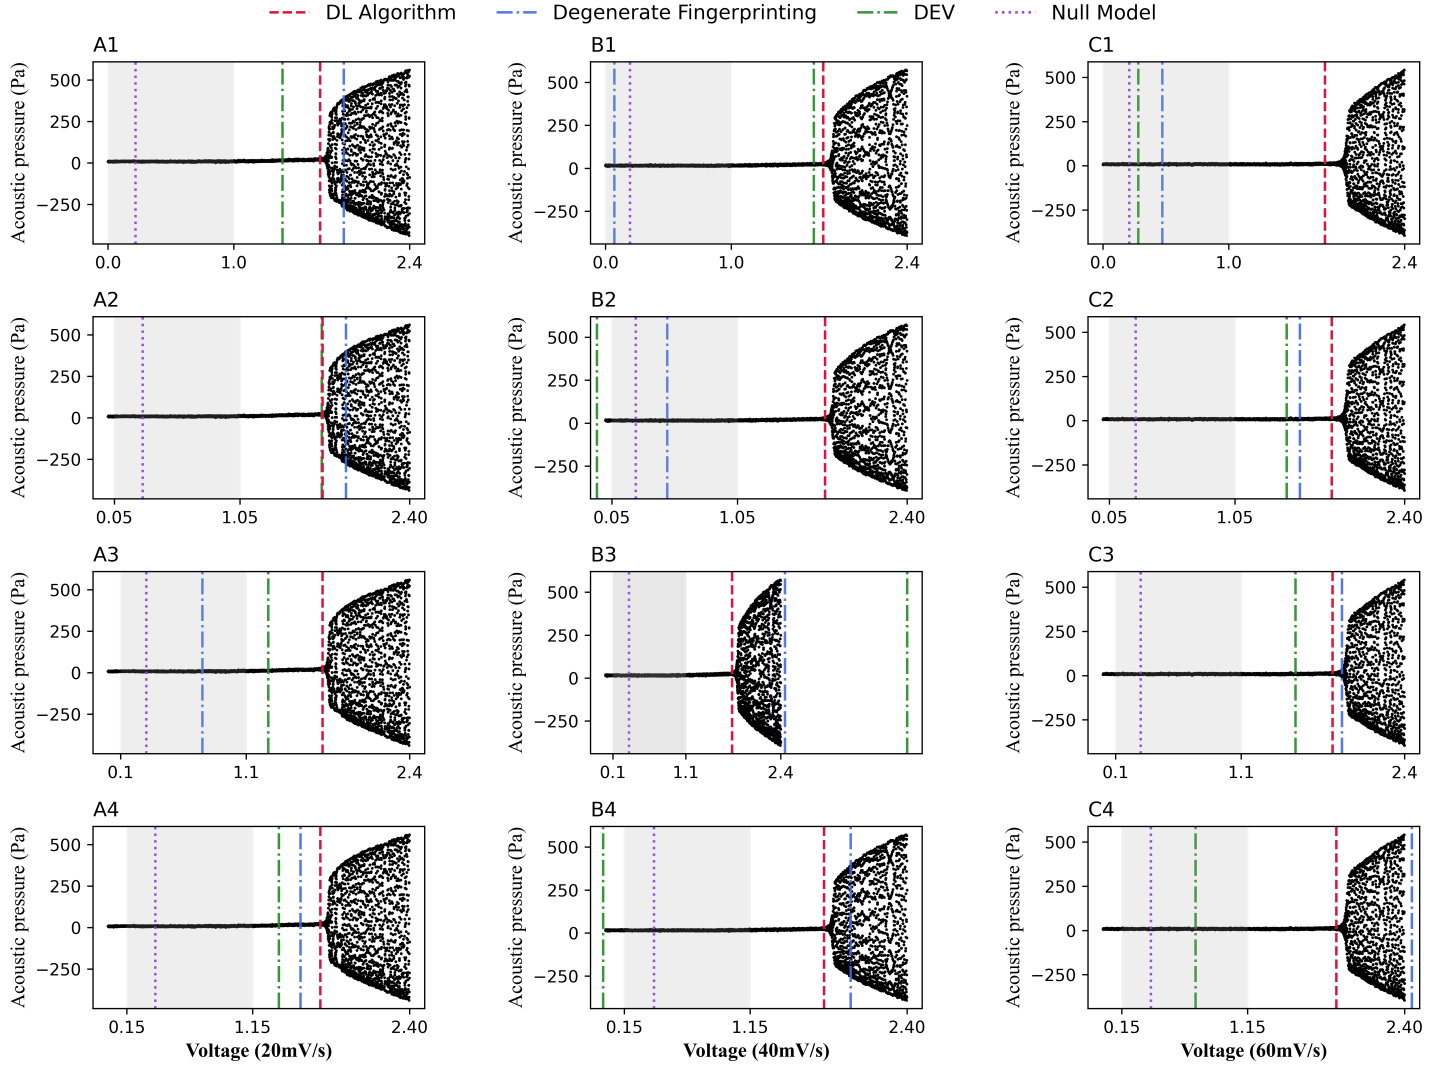

**Supplementary Figure 15** We compared performance of the DL algorithm on irregularly-sampled (red lines) and regularly-sampled model time series (orange lines) with 11 initial values of bifurcation parameter. Here the mean relative error of tipping points prediction is plotted as a function of initial parameter. The area covered by the polyline represents the 90% confidence interval for the relative error of tipping points prediction.

### 5.2 Robustness of DL algorithm against changing rate of bifurcation parameter

We applied the DL model to irregularly-sampled thermoacoustic time series under three voltage changing rates (20mV/s, 40mV/s, 60mV/s) within the bifurcation parameter voltage ranges from 0 to 1 V, from 0.05 to 1.05 V, from 0.1 to 1.1 V and from 0.15 to 1.15V respectively. Then we used linear interpolation to transform these irregularly-sampled records to time series with equidistant data. This allows us to use the competing algorithms of degenerate fingerprinting and DEV for detecting early warning signals on reconstructed thermoacoustic records.

We compared the results of the DL algorithm with those of competing algorithms, including degenerate fingerprinting, DEV and null model, as shown in Fig. S16.

**Supplementary Figure 16** The performance of DL algorithm in predicting tipping points on irregularly-sampled thermoacoustic time series. Grey region represents the range of empirical time series used for prediction. Different columns of this figure (A1-A4, B1-B4, C1-C4) represent the states of thermoacoustic systems under different changing rates of the bifurcation parameter voltage (20mV/s, 40mV/s, 60mV/s) as the bifurcation parameter increases. We compared the performance of the DL algorithm (red dashed lines) with degenerate fingerprinting (blue dash-dot lines), DEV (green dash-dot lines) and null model (purple dotted lines). We used linear interpolation to transform these irregularly-sampled time series into equidistant data so that they are suitable for degenerate fingerprinting and DEV.

## 6 Noise-induced premature bifurcation

In this section, we will introduce several bifurcation-related definitions and theorem. Based on this preliminary mathematical knowledge, we explain how slight noise induces premature bifurcation and the stochasticity of this phenomenon(5).

**Definition 1** (bifurcation). *The appearance of a topologically nonequivalent phase portrait under variation of parameters is called a bifurcation.*

**Definition 2** ( $n_-, n_0, n_+$ ). *Consider a continuous-time dynamical system defined by*

$$\frac{dx}{dt} = f(x), \quad x \in \mathbb{R}^n,$$

where  $f$  is smooth. Let  $x_0$  be an equilibrium of the system and let  $A$  denote the Jacobian matrix  $\frac{df}{dx}$  evaluated at  $x_0$ . Let  $n_-, n_0$  and  $n_+$  be the numbers of eigenvalues of  $A$  (counting multiplicities) with negative, zero and positive real part, respectively.

**Definition 3** (hyperbolic equilibrium). *An equilibrium is called hyperbolic if  $n_0 = 0$ .*

**Theorem 1.** *The phase portraits of system  $\frac{dx}{dt} = f(x)$  near two hyperbolic equilibria,  $x_0$  and  $y_0$ , are locally topologically equivalent if and only if these equilibria have the same number  $n_-, n_0$  and  $n_+$ .*

Here we mathematically investigate how the noise induces the premature bifurcation. We consider a system

$$\frac{dx}{dt} = f(x, \mu), \tag{11}$$

where  $f$  is a smooth function. We add stochastic perturbation  $\varepsilon g(x)$  ( $g$  is also smooth) to the system (11) and have the following system

$$\frac{dx}{dt} = f(x, \mu) + \varepsilon g(x). \tag{12}$$

As a system approaches a bifurcation, all the real parts of the eigenvalues of the Jacobian matrix at the equilibrium are less than zero. Thus, the equilibrium is hyperbolic. We assume  $x_0$  is a hyperbolic equilibrium of system (11) at  $\mu = \mu_0$ , and system (12) has an equilibrium  $x(\varepsilon)$  at  $\mu = \mu_0$ , such that  $x(0) = x_0$ . The equation defining equilibria of system (12) at  $\mu = \mu_0$  can be written as

$$F(x, \varepsilon) = f(x, \mu_0) + \varepsilon g(x) = 0,$$

with  $F(x_0, 0) = 0$ . We also have  $F_x(x_0, 0) = A_0$ , where  $A_0$  is the Jacobian matrix of system (11) at the equilibrium  $x_0$ , and because  $x_0$  is hyperbolic,  $|A_0| \neq 0$ . Thus, the Implicit Function Theorem guarantees the existence of a smooth function  $x = x(\varepsilon)$ ,  $x(0) = x_0$ , satisfying

$$F(x(\varepsilon), \varepsilon) = 0,$$

for  $\varepsilon \in (-\alpha(x_0), \alpha(x_0))$  (for small values of  $|\varepsilon|$ ). The Jacobian matrix of  $x(\varepsilon)$  in system (12),

$$A_\varepsilon = \left( \frac{df(x)}{dx} + \varepsilon \frac{dg(x)}{dx} \right) \Big|_{x=x(\varepsilon)},$$

which depends smoothly on  $\varepsilon$  and coincides with  $A_0$  in system (11) at  $\varepsilon = 0$ . Therefore, the  $n_-, n_0$  and  $n_+$  of  $A_\varepsilon$  equal that of  $A_0$  for all sufficiently small  $|\varepsilon|$ . Since  $x_0$  is a hyperbolic equilibrium, it follows that  $x_\varepsilon$  is also a hyperbolic equilibrium. According to *Theorem 1*, as  $\mu_0$  is far from the bifurcation point  $\mu_c$ , the phase portraits near the equilibria of system (12) are locally topologically equivalent under variation of  $\mu$  near  $\mu_0$ . However, as  $\mu_0$  is approaching  $\mu_c$ , the eigenvalue of  $A_0$  with the largest real part increasingly approaches the imaginary axis (the

condition for bifurcation occurs). This leads to the threshold of  $|\varepsilon|$  for  $A_\varepsilon$  and  $A_0$  to have the same  $n_-$ ,  $n_0$  and  $n_+$  is becoming increasingly smaller. Therefore, there may be a moment when the  $\varepsilon$  crosses the threshold, the  $n_-$ ,  $n_0$  and  $n_+$  of  $A_\varepsilon$  change. According to *Theorem 1*, a topologically nonequivalent phase portrait appears near the equilibrium of system (12), according to *Definition 1*, a bifurcation occurs in system (12). But all the real parts of the eigenvalues of the Jacobian matrix at the equilibrium of system (11) are still less than zero, i.e., system (11) is before bifurcation. Thus the bifurcation may occurs earlier in the system (12) with stochastic perturbation  $\varepsilon g(x)$  than in the system (11).

**Supplementary Table 1** The hyperparameters of the DL model and the null model.

Model Name	Learning Rate	CNN Filters	CNN Kernel Size	MaxPooling Size	LSTM1 Cells	LSTM2 Cells
DL model	0.01	60	(8,2)	(4,1)	40	60
Null model	0.005	50	(10,2)	(4,1)	50	50
