The NA60 experiment at the CERN SPS has studied dimuon production in 158A GeV In-In collisions. The strong excess of pairs above the known sources found in the complete mass region 0.2 < M < 2.6 GeV has previously been interpreted as them alradiation. We now present rst results on the associated angular distributions. Using the Collins-Soper reference frame, the structure function parameters , and are measured to be zero, and the projected distributions in polar and azim uth angles are found to be uniform. The absence of any polarization is consistent with the interpretation of the excess dimuons as therm alradiation from a random ized system.

Lepton pairs are a particularly attractive observable to study the hot and dense matter created in highenergy nuclear collisions. Their continuous em ission, undisturbed by nal-state interactions, probes the entire space-time evolution of the reball, including the early phases with the conjectured QCD phase transitions of chiral symmetry restoration and parton decon nement. To the extent that the bulk constituents of the expanding m atter (hadrons and partons) equilibrate, the direct lepton pairs generated by them are commonly referred to as 'therm al radiation'. Our previous work has indicated 'therm al' dilepton production to be largely mediated for M < 1 G eV by + annihilation via the strongly broadened vector m = 1, and for M > 1 G eV by partonic processes like qq annihilation [2, 3]. The two dilepton variables basically explored in this work were mass M and transversem om entum pr, where the correlations between the two were decisive in bearing out the nature of the em ission sources in the two mass regions [2, 3].

Further inform ation on the production mechanism and the distribution of the annihilating particles, com plementary to that from M and p_T , can be obtained from the study of dilepton angular distributions. This Letter presents the rst measurement of full dilepton angular distributions in the eld of high-energy nuclear collisions. It is restricted to the mass region M < 1 G eV, due to the lack of su cient statistics for M > 1 G eV. The question asked is simple: can one get direct experimental insight

into whether the radiating matter is therm alized?

H istorically, the interest in angular distributions of continuum lepton pairs was mostly motivated by the study of the D rell-Y an mechanism, following in particular the insight that the 'na ve'QED interpretation [4] had to be signi cantly modi ed due to QCD e ects [5, 6, 7, 8]. The di erential decay angular distribution in the rest frame of the virtual photon with respect to a suitably chosen set of axes, ignoring the rest mass of the leptons, can quite generally be written as

$$\frac{1}{d}\frac{d}{d}$$
 / (1 + \cos^2 + $\sin^2 \cos + \frac{1}{2}\sin^2 \cos^2$) (1)

The angular dependence on polar angle and azim uth angle dates back to [9], but the speci c coe cients ,

and , the 'structure function' parameters, follow the nom enclature in e.g. [8,10]. They are directly related to the helicity structure functions W_i de ned in [6], and in particular to the spin density matrix R_{ij} of the virtual photon , them ain object of the spin analysis [7,10,11]. We have chosen here the Collins-Soper (CS) reference frame [5], where the quantization axis z is de ned as the bisector between the beam and negative target momenta p_{Deam} and p_{target} , which de ne the reaction plane. The polar angle is then the angle between the momentum of the positive muon p_{+} and the z axis, which de ne the reaction between the reaction and the decay planes. How ever, the

FIG.1: Isolation of an excess above the electrom agnetic decays of neutralm esons (see text). O pen charm still contained.

particular choice of the fram e is not really relevant here, since the determ ination of the full set of coe cients , and allows to compute them in any other fram e by a simple transform ation [8]. This would not apply if only the cos distribution would be measured.

In principle, the dilepton angular distributions can be anisotropic, with all structure function parameters ;; 🗧 0 [5, 6, 7, 8, 10]. Even for spinless particles in the initial state like in +annihilation, the param eters can still have any value \neq 0, since the spin density matrix of the virtual photon also receives contributions from orbital angular m om entum [12]. Very elem entary exam ples are qq and + annihilation along the beam direction for $p_T = 0$. Here = = 0 and = +1 for qq (like low est order DY [4]) and = 1 for +[12], corresponding to transverse and longitudinal polarization of the virtual photon, respectively. However, a com pletely random orientation of annihilating partons or pions in 3 dimensions (but not in 2 [11]) would lead to ;; = 0 [11, 12, 13], and that is the case of prime interest here.

D etails of the NA 60 apparatus are contained in [3, 14]. The data sam ple for 158A G eV In-In collisions is the sam e as used in [1, 2], and the di erent analysis steps follow the sam e sequence: assessment of the combinatorial background from and K decays by a mixed-event technique, assessment of the fake-matches (associations of m uons to non-m uon vertex tracks in the Sipixel telescope), isolation of the dim uon excess by subtraction of the known m eson decay sources and charm from the net opposite-sign sam ple, and nally correction for acceptance and pair e ciency. All steps are now done independently in each $\left[\frac{dN}{d\cos d}\right]_{ij}$ bin. The binning is varied depending on the goal, thereby assuring that the results

are stable with respect to the bin widths chosen.

The assessment of the two background sources and open charm is extensively discussed in the ref. [3]. The centrality-integrated net mass spectrum after background subtraction is shown in Fig. 1 together with the contributions from neutralm eson decays: the 2-body decays of the _, ! and _ resonances, and the D alitz decays of the , and !. The data clearly exceed the sum of the decay sources. The excess dim uons are isolated by subtracting them from the total (except for the), based solely on local criteria [1, 2]. The excess for M < 1GeV is interpreted as the strongly broadened which is continuously regenerated by + annihilation [1,2]. Two adjacent mass windows indicated in Fig. 1 are used for the subsequent angular distribution analysis: the like region 0.6 < M < 0.9, and the low-m asstail 0.4 < M < 0.6GeV. To exclude the region of the low -m $_{\rm T}$ rise seen for all m asses [2], a transverse m om entum cut of $p_T > 0.6$ G eV is applied, leaving about 54000 excess pairs in the two mass windows. The subtracted data for the ! and , about 73000 pairs, are subject to the sam e further analysis steps as the excess data and are used for com parison.

The correction for the acceptance of the NA 60 apparatus requires, in principle, a 5-dimensional grid in M – p_T -y-cos – space. To avoid large statistical errors in low-acceptance bins, the correction is performed in 2-dim.cos – space, using them easured data for M, p_T [2] and y [15] as an input to the M onte C arbo (M C) simulation of the cos – acceptance matrix. The sensitivity of the nalresults to variations of this M- p_T -y input has been checked, and the e ects are found to be considerably smaller than the statistical errors of the results. The M C simulations were done in an overlay mode with real data to include the e ects of pair reconstruction e ciencies. The product acceptance e ciency is illustrated in

FIG. 2: Spectrom eter acceptance as a function of the two angular variables joos jand j j.

FIG. 3: Polar angle distributions of excess dileptons and of the vector m esons ! and

Fig. 2 for 0.6 < M < 0.9 G eV and $p_T > 0.6 \text{ G eV}$. The rapidity coverage is 3.2 < y < 4.2 (+ $0.3 < y_{cm} < +1.3$).

The results on the angular distributions have been analysed in three di erent ways, distinguished by the m ethod and the associated statistical/system atic errors. In the rst and most rigorous method (1), the 3 structure function parameters , and are extracted from a simultaneous t of the 2-dimensional data on the basis of Eq.(1), using a 6 6 m atrix in the range $0.6 < \cos < +0.6$ (bin width 0.2) and $0.75 < \cos < 0.75$ (bin width 0.25). The restrictions in range are enforced by regions of very low acceptance in the 2-dim ensional acceptance matrix, masked in the projections of Fig. 2. The tvalues are sum marized in Table I for all 4 cases, the two excess mass windows, the ! and the . Within errors, they are all compatible with zero. It is reassuring to see that this is also true for , as expected for a symmetric collision system at midrapidity on the basis of sym m etry considerations [11].

In the second method (2), setting now = 0, the 2-dimensional acceptance-corrected data are projected onto either the jos jor the j jaxis, sum ming over the two signs. The polar angular distribution is obtained by integrating Eq.(1) over the azim uth angle ()

$$\frac{\mathrm{dN}}{\mathrm{d}\cos} = A_0 \left(1 + \cos^2\right); \tag{2}$$

while the azim uth angular distribution is obtained by integration over the polar angle (\cos)

$$\frac{dN}{d} = A_1 \left(1 + \frac{1}{3} + \frac{1}{3} \cos^2 \right)$$
(3)

The structure function parameters and can then be determ ined independently by 1-dimensional ts to the respective projections. The data of the polar angular distributions together with the t lines according to Eq.(2) are shown in Fig. 3 for all four cases, using now 8 bins in jos j (bin width 0.1). The distributions are seen to be uniform, and the t parameters, included in Table I, are again compatible with zero, within errors. To determ ine the parameter , (contained in Eq.(3)) is set to the measured value of . The t results for on the basis of Eq.(3), keeping the sm all num ber of bins used in m ethod 1, are again zero, within errors (see Table I).

In the third method (3), the inclusive measured distributions in cos and are analysed. A 1-dim ensional acceptance correction is applied in each case, determ ined by using (as now measured) uniform distributions in (for \cos) and in \cos (for) as an input to the M C \sin – ulations. The num ber of bins in jos jiskept, while that in j j is increased to 10 (bin width 0.3). The data for the azim uth angular distributions together with the t lines according to Eq.(3) are shown in Fig. 4. The distributions are again uniform, as are those for cos (not shown, since hardly distinguishable from Fig. 3). The resulting t param eters for and (taking account again) are included in Table I. As expected, the erof rors are sm aller than for the other two m ethods, but the values of and are still close to zero, within errors.

Figs. 3 and 4 also contain the system atic errors attached to the individual data points. They mainly arise from two sources. The subtraction of the combinatorial background, with relative uncertainties of 1% [1, 2, 3],

FIG. 4: A zim uth angle distributions of excess dileptons and of the vector m esons ! and .

leads to errors of 2-3% of the net data for the kinem atic selection used here. The subtraction of the meson decay sources causes (correlated) errors for the excess and the vector mesons ! and . W ith respect to the excess, they range from 4-6% up to 10-15% in the low-populated

TABLE I: Sum m ary of results for $p_T > 0.6~G~eV$ on the structure function parameters , and in the CS frame, extracted from three di erent m ethods (see text). The $^2=\!ndf$ of the ts varies between 0.8 and 1.2. For a cut $p_T > 1.0~G~eV$, the results are the same, within errors.

cos - matrix bins. This variation is well visible for the overall errors plotted in Figs. 3 and 4. A ssum ing, very conservatively, these errors to be uncorrelated from point to point, the (statistical) terrors for and quoted in Table I would increase by 15-20% if the system atic errors would be added in quadrature. Further con dence into the stability of the results is obtained from their independence of the methods and the bin widths used.

The global outcome from our analysis of dilepton angular distributions is straightforward: the structure function parameters , and are all zero within the statisticaland system atic errors, and the projected distributions in polar and azim uth angle are all uniform. This applies not only for the excess dileptons as anticipated if of therm alorigin, but also for the vector mesons ! and . W hile there m ay be a rather direct connection between the two ndings in nuclear collisions, it is of interest to note that the result of = 0 has been reported before for and ! production in p-p [16] and -C [17].

W e conclude, follow ing the prim ary motivation of this study, that the absence of any polarization is fully consistent with the interpretation of the observed excess dimuons as therm alradiation from a random ized system. W hile this is a necessary condition, it is not su cient. How ever, together with other features like the P lanck-like shape of the excess mass spectra [3, 18], the exponential shape of the m_T spectra [2, 18] and the global agreement with theoretical models both as to spectral shapes and absolute yields [3, 18], the therm al interpretation has become more plausible than ever before.

W e are grateful to 0 .N achtm ann for useful discussions.
