

Measurement of t -channel production of single top quarks and antiquarks in pp collisions at 13 TeV using the full ATLAS Run 2 data sample

The ATLAS Collaboration

The production of single top quarks and top antiquarks via the t -channel exchange of a virtual W boson is measured in proton–proton collisions at a centre-of-mass energy of 13 TeV at the LHC using 140 fb^{-1} of ATLAS data. The total cross-sections are determined to be $\sigma(tq) = 137_{-8}^{+8} \text{ pb}$ and $\sigma(\bar{t}q) = 84_{-5}^{+6} \text{ pb}$ for top-quark and top-antiquark production, respectively. The combined cross-section is found to be $\sigma(tq + \bar{t}q) = 221_{-13}^{+13} \text{ pb}$ and the cross-section ratio is $R_t = \sigma(tq)/\sigma(\bar{t}q) = 1.636_{-0.034}^{+0.036}$. The predictions at next-to-next-to-leading-order in quantum chromodynamics are in good agreement with these measurements. The predicted value of R_t using different sets of parton distribution functions is compared with the measured value, demonstrating the potential to further constrain the functions when using this result in global fits. The measured cross-sections are interpreted in an effective field theory approach, setting limits at the 95% confidence level on the strength of a four-quark operator and an operator coupling the third quark generation to the Higgs boson doublet: $-0.37 < C_{Qq}^{3,1}/\Lambda^2 < 0.06$ and $-0.87 < C_{\phi Q}^3/\Lambda^2 < 1.42$. The constraint $|V_{tb}| > 0.95$ at the 95% confidence level is derived from the measured value of $\sigma(tq + \bar{t}q)$. In a more general approach, pairs of CKM matrix elements involving top quarks are simultaneously constrained, leading to confidence contours in the corresponding two-dimensional parameter spaces.

1 Introduction

During the 2015–2018 period of operation, known as Run 2, the Large Hadron Collider (LHC) [1] provided proton–proton (pp) collisions at a centre-of-mass energy of $\sqrt{s} = 13$ TeV, giving the collider experiments access to a previously unexplored kinematic range. By measuring top-quark production at this energy scale with high precision, theoretical predictions based on the Standard Model (SM) can be tested and deviations that might result from energy-dependent non-SM couplings can be searched for. Top quarks are produced singly in weak charged-current interactions. The dominant single-top-quark production process at the LHC is characterised by the t -channel exchange of a virtual W boson. Figure 1 depicts example Feynman diagrams of this process at leading order (LO) in perturbation theory. A light quark from one of the colliding protons interacts with a b -quark from another proton by exchanging a virtual W boson. Since the valence u -quark density of the proton is about twice as high as the valence d -quark density, the production cross-section of single top quarks, $\sigma(tq)$, is expected to be higher than the cross-section of top-antiquark production, $\sigma(\bar{t}q)$.

Figure 1: Example Feynman diagrams of (a) single top-quark and (b) single top-antiquark production via the t -channel exchange of a virtual W boson at LO in perturbation theory.

This document presents cross-section measurements of tq and $\bar{t}q$ production using the full data sample recorded with the ATLAS detector [2] during Run 2 of the LHC, corresponding to an integrated luminosity of 140 fb^{-1} . Separate measurements of tq and $\bar{t}q$ production provide sensitivity to the parton distribution functions (PDFs) of u - and d -quarks [3], exploiting the different initial states of the two processes shown in Figure 1. In addition, the combined cross-section $\sigma(tq + \bar{t}q)$ and the cross-section ratio $R_t = \sigma(tq)/\sigma(\bar{t}q)$ are measured. The ratio R_t has better precision than the individual cross-sections because of partial cancellations of common uncertainties. The measurements presented here supersede the results obtained by an ATLAS analysis of early Run 2 data corresponding to an integrated luminosity of 3.2 fb^{-1} [4], significantly improving the precision due to a larger data sample, better detector calibration, the use of more advanced object reconstruction [5, 6], and an improved statistical analysis based on profile maximum-likelihood fits which fully exploit the statistical power of the data sample. This analysis also features an improved treatment of systematic uncertainties related to the modelling of the hard partonic collision and the subsequent hadronisation with event generator programs based on the Monte Carlo (MC) method. The measurements are compared with fixed-order predictions made at next-to-next-to-leading-order (NNLO) in quantum chromodynamics (QCD). The measurement of R_t , in particular, is compared with predictions based on different PDFs.

The measurements are further interpreted in the context of effective field theory (EFT) to constrain the

Wilson coefficients associated with the four-quark operator $O_{Qq}^{3,1}$ and the operator $O_{\phi Q}^3$ that couples the third quark generation to the Higgs boson doublet. Both operators potentially contribute to t -channel single top-quark production in extensions of the SM. Existing limits on the coefficient of $O_{Qq}^{3,1}$ [7–9] are based on the combination of published measurements and do not account for reconstruction effects on EFT signal events, while the analysis presented here employs simulated signal samples and involves template fits to observed distributions. The operator $O_{\phi Q}^3$ features the same Lorentz structure as the Wtb vertex in the SM and limits on this operator are thus obtained from the measured value of $\sigma(tq + \bar{t}q)$. Another interpretation sets limits on the coupling strengths of Wtq vertices, constraining the products of a left-handed form factor f_{LV} and the absolute values of the Cabibbo–Kobayashi–Maskawa (CKM) matrix elements V_{tb} , V_{ts} and V_{td} . The form factor scales the cross-section of tq production with f_{LV}^2 , but leaves the Lorentz structure of the Wtq vertices unchanged; and thus the event kinematics remain unchanged. The SM has $f_{LV} = 1$.

The event selection of the analysis targets tq and $\bar{t}q$ events with leptonically decaying W bosons. Consequently, either one isolated electron or muon and high missing transverse momentum are required. In addition, there must be exactly two hadronic jets with high transverse momentum. Exactly one of these jets must be identified as originating from a b -quark and is hence labelled as a b -tagged jet, while the second jet is preferentially produced in the forward direction at high absolute values of pseudorapidity. The main background processes are top-quark–antiquark ($t\bar{t}$) pair production and $W+b\bar{b}$ production. Two other single top-quark production processes are also relevant: the associated production of a W boson and a top quark (tW production) and the production of $t\bar{b}$ or $\bar{t}b$ via the s -channel exchange of a virtual W boson. The selected signal and background events are further separated by constructing discriminants with an artificial neural network (NN). The output distributions of the NN are used in a maximum-likelihood fit to determine the signal yields and measure $\sigma(tq)$, $\sigma(\bar{t}q)$, $\sigma(tq + \bar{t}q)$, and R_t .

The CMS Collaboration measured tq and $\bar{t}q$ production at $\sqrt{s} = 13$ TeV using a partial Run 2 data sample, determining the total cross-sections [10], various differential cross-sections [11], and measuring CKM matrix elements [12].

2 The ATLAS detector

The ATLAS detector covers nearly the entire solid angle around the collision point.¹ It consists of an inner tracking detector surrounded by a thin superconducting solenoid, electromagnetic and hadronic calorimeters, and a muon spectrometer incorporating three large superconducting toroidal magnets.

The inner-detector system (ID) is immersed in a 2 T axial magnetic field and provides charged-particle tracking in the range of $|\eta| < 2.5$. The high-granularity silicon pixel detector covers the vertex region and typically provides four measurements per track, the first hit normally being in the insertable B-layer installed before Run 2 [13, 14]. It is followed by the silicon microstrip tracker, which usually provides eight measurements per track. These silicon detectors are complemented by the transition radiation tracker (TRT), which enables radially extended track reconstruction up to $|\eta| = 2.0$. The TRT also provides electron identification information based on the fraction of hits (typically 30 in total) above a higher energy-deposit threshold corresponding to transition radiation.

¹ ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector and the z -axis along the beam pipe. The x -axis points from the IP to the centre of the LHC ring, and the y -axis points upwards. Cylindrical coordinates (r, ϕ) are used in the transverse plane, ϕ being the azimuthal angle around the z -axis. The pseudorapidity is defined in terms of the polar angle θ as $\eta = -\ln \tan(\theta/2)$. Angular distance is measured in units of $\Delta R \equiv \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2}$.

The calorimeter system covers the pseudorapidity range $|\eta| < 4.9$. Within the region $|\eta| < 3.2$, electromagnetic calorimetry is provided by barrel and endcap high-granularity lead/liquid-argon (LAr) calorimeters, with an additional thin LAr presampler covering $|\eta| < 1.8$ to correct for energy loss in material upstream of the calorimeters. Hadronic calorimetry is provided by the steel/scintillator-tile calorimeter, segmented into three barrel structures within $|\eta| < 1.7$, and two copper/LAr hadronic endcap calorimeters. The solid angle coverage is completed with forward copper/LAr and tungsten/LAr calorimeter modules optimised for electromagnetic and hadronic measurements respectively.

The muon spectrometer (MS) comprises separate trigger and high-precision tracking chambers measuring the deflection of muons in a magnetic field generated by superconducting air-core toroids. The field integral of the toroids ranges between 2.0 and 6.0 Tm across most of the detector. A set of precision chambers covers the region $|\eta| < 2.7$ with three layers of monitored drift tubes, complemented by cathode-strip chambers in the forward region, where the background is highest. The muon trigger system covers the range $|\eta| < 2.4$ with resistive-plate chambers in the barrel, and thin-gap chambers in the endcap regions. Interesting events are selected to be recorded by the first-level trigger system implemented in custom hardware, followed by selections made by algorithms implemented in software in the high-level trigger [15]. The first-level trigger accepts events from the 40 MHz bunch crossings at a rate below 100 kHz, that the high-level trigger further reduces to record events to disk at about 1 kHz.

An extensive software suite [16] is used in the reconstruction and analysis of real and simulated data, in detector operations, and in the trigger and data acquisition systems of the experiment.

3 Samples of data and simulated events

The analysis uses proton–proton (pp) collision data recorded with the ATLAS detector in the years 2015 to 2018 at a centre-of-mass energy of 13 TeV. After applying data-quality requirements [17], the data set corresponds to an integrated luminosity of 140.1 fb^{-1} with a relative uncertainty of 0.83% [18]. The LUCID-2 detector [19] was used for the primary luminosity measurements, complemented by measurements using the inner detector and calorimeters.

Events were selected online during data taking by single-electron or single-muon triggers [20, 21]. Multiple triggers were combined in a logical OR to increase the selection efficiency. The lowest-threshold triggers utilised isolation requirements for reducing the trigger rate. The isolated-lepton triggers had thresholds in transverse momentum (p_T) of 20 GeV for muons and 24 GeV for electrons in 2015 data, and 26 GeV for both lepton types in 2016, 2017 and 2018 data. They were complemented by other triggers with higher p_T thresholds but no isolation requirements to increase the trigger efficiency.

Sets of simulated events from signal and background processes were produced with MC-based event generator programs to model the physics processes. After event generation, the response of the ATLAS detector was simulated using the GEANT4 toolkit [22] with a full detector model [23] or a fast simulation [24, 25] which employed a parameterisation of the calorimeter response. The fast simulation was used for samples that were employed to evaluate systematic uncertainties associated with the event generators and for samples used for the EFT interpretation. To account for additional inelastic pp collisions in the same and neighbouring bunch crossings (pile-up), minimum-bias interactions were overlaid on the hard-scattering events at the level of simulated energy depositions. The minimum-bias events were simulated using PYTHIA 8.186 [26] with the A3 [27] set of tuned parameters and the NNPDF2.3LO PDF set [28]. The

resulting events were weighted to reproduce the observed pile-up distribution. The average number of interactions per bunch crossing during the entire data-taking period from 2015 to 2018 is 33.7.

Finally, the simulated events were reconstructed using the same software as applied to the collision data. Except for events of the multijet background, the same event selection requirements were applied and the selected events were passed through the same analysis chain. Corrections are applied to simulated events such that the lepton trigger and reconstruction efficiencies, jet energy calibration and b -tagging efficiency are in better agreement with the response observed in data. More details of the simulated event samples are provided in the following subsections.

3.1 Simulation of $t\bar{t}$ and single-top-quark production

Samples of simulated events from $t\bar{t}$ and single-top-quark production were generated using the next-to-leading-order (NLO) matrix-element generator POWHEG Box v2 [29–35], setting the top-quark mass to $m_t = 172.5$ GeV. For $t\bar{t}$ and tW production as well as s -channel single-top-quark production ($t\bar{b}$ production) the NNPDF3.0_{NLO} PDF set [36] was used with the five-flavour scheme. Following a recommendation given in Ref. [35], single top-quark production in the t -channel (tq production) was simulated with the NNPDF3.0_{NLO_NF4} PDF set, which implements the four-flavour scheme. Parton showers, hadronisation, and the underlying event were modelled using PYTHIA 8.230 with the A14 [37] set of tuned parameters and the NNPDF2.3_{LO} PDF set. The POWHEG Box+PYTHIA generator setup applies a matching scheme to the modelling of hard emissions in the two programs. For $t\bar{t}$ production, the matrix-element-to-parton-shower matching is steered by the h_{damp} parameter, that controls the p_T of the first additional gluon emission beyond the LO Feynman diagram in the parton shower and therefore regulates the high- p_T emission against which the $t\bar{t}$ system recoils. Event generation was run with $h_{\text{damp}} = 1.5 \times m_t$ [38]. The renormalisation and factorisation scales were set dynamically on an event-by-event basis, namely to $\mu_r = \mu_f = \sqrt{m_t^2 + p_T^2(t)}$ for $t\bar{t}$ production and to $\mu_r = \mu_f = 4 \sqrt{m_b^2 + p_T^2(b)}$ for tq production, where $p_T(t)$ is the p_T of the top quark, m_b is the mass of the b -quark, and $p_T(b)$ is the p_T of the b -quark originating from the initial-state gluon that splits into a $b\bar{b}$ pair. The scale choice for tq production follows a recommendation in Ref. [35]. When generating tW events, the scales were set to $\mu_r = \mu_f = m_t$ and the diagram-removal scheme [39] was employed to treat the interference with $t\bar{t}$ production [38].

In the case of tq production, top-quark decays were modelled by MADSPIN [40, 41], while in the case of $t\bar{t}$, $t\bar{b}$ and tW production top-quark decays were handled by POWHEG Box directly. The decays of bottom and charm hadrons were simulated using the EVTGEN 1.6.0 program [42].

The sample of simulated $t\bar{t}$ events was normalised to a total cross-section of $\sigma(t\bar{t}) = 834 \pm 33$ pb (relative uncertainty: 4.0%), the value obtained from NNLO predictions from the TOP++ 2.0 program (see Ref. [43] and references therein), which includes the resummation of next-to-next-to-leading logarithmic (NNLL) soft-gluon terms. The predicted cross-sections of tq and $\bar{t}q$ production used to normalise the corresponding samples of simulated events are $\sigma(tq) = 134.2 \pm 2.2$ pb and $\sigma(\bar{t}q) = 80.0 \pm 1.6$ pb (relative uncertainties: 1.6% and 2.0%, respectively) and were calculated with the MCFM 10.1 program [44] at NNLO in QCD. The quoted uncertainties include the uncertainties related to a variation of μ_r and μ_f , the uncertainty in the PDFs and in the value of the strong coupling constant α_s . The scale uncertainty is determined by varying μ_r and μ_f independently up and down by a factor of two, whilst never allowing them to differ by a factor greater than two from each other. The combined PDF and α_s uncertainties were determined at the 68% confidence level (CL) according to the Hessian representation of the PDF4LHC21 PDF set [45]. The total

cross-section for $t\bar{b}$ production was computed at NLO in QCD with the HATHOR 2.1 program [46, 47] and the corresponding sample of simulated events was normalised to $\sigma(t\bar{b} + \bar{t}b) = 10.32 \pm 0.38$ pb (relative uncertainty: 3.7%). The cross-section used for normalising the tW sample is $\sigma(tW + \bar{t}W) = 79.3 \pm 2.9$ pb (relative uncertainty: 3.7%) [48]. All cross-section calculations assume $m_t = 172.5$ GeV.

3.2 Simulation of W +jets, Z +jets and diboson production

The production of W and Z bosons in association with jets, including heavy-flavour jets, was simulated with the SHERPA 2.2.1 generator [49]. In this setup, NLO-accurate matrix elements for up to two partons and LO-accurate matrix elements for up to four partons are calculated with the COMIX [50] and OPENLOOPS 1 [51–53] libraries. The default SHERPA parton shower [54] based on Catani–Seymour dipole factorisation and the cluster hadronisation model [55] were used. The generation employed the dedicated set of tuned parameters developed by the SHERPA authors and the NNPDF3.0_{NLO} PDF set.

The NLO matrix elements of a given jet multiplicity are matched to the parton shower using a colour-exact variant of the MC@NLO algorithm [56]. Different jet multiplicities are then merged into an inclusive sample using an improved CKKW matching procedure [57, 58] that is extended to NLO accuracy using the MEPS@NLO prescription [59]. The merging threshold was set to 20 GeV. The W +jets and Z +jets samples are normalised to NNLO predictions [60] of the total cross-sections, obtained with the FEWZ package [61].

After event generation and before detector simulation, the W +jets and Z +jets samples were subjected to hadron-flavour filters. Events in which at least one b -hadron is present were selected and form b -filtered samples. The production of a W boson in association with b -hadrons is dominated by processes in which a radiated high- p_T gluon splits into a $b\bar{b}$ pair. This class of background processes is thus called $W+b\bar{b}$ production. Samples with an applied c -filter were produced by vetoing events that pass the b -filter described above and requiring at least one c -hadron to be present. Two different classes of physics processes contribute to the c -filtered samples, flavour production via gluon splitting leading to $W+c\bar{c}$ and a second class of processes with a down-type quark and a gluon in the initial state, leading to the production of a single c -quark in the final state via $qg \rightarrow W+c$. To represent both classes of processes the associated production of a W boson and c -jets is denoted as $W+c(\bar{c})$ production. Generated events of W +jets production that remain after applying the b -filter and the c -filter as a veto constitute W +light-quark-jet production. The contribution of this process to the expected event yields is much smaller than the contributions of $W+b\bar{b}$ and $W+c(\bar{c})$ production due to the tight b -tagging requirement made, and therefore the W +light-quark-jet contribution is merged with the contribution of the $W+b\bar{b}$ process in the statistical analysis. The Z +jets samples are treated with the same hadron-flavour filtering scheme as the W +jets samples, leading to b -filtered, c -filtered and light-flavour samples. However, Z +jets production is a minor background in the analysis and therefore the flavour split is not used in the statistical analysis.

Samples of on-shell diboson production (WW , WZ and ZZ) were simulated with the same SHERPA setup as described above for W +jets and Z +jets production. The matrix elements considered contain all diagrams with four electroweak vertices and were calculated at NLO accuracy in QCD for up to one additional parton and at LO accuracy for up to three additional parton emissions. The diboson event samples are normalised to the total cross-sections provided by SHERPA.

3.3 Simulation and modelling of multijet production

Events featuring generic high- p_T multijet production may satisfy the event selection if a jet is misidentified as an electron or muon, or if real electrons or muons coming from hadron decays inside the jets satisfy the isolation requirements. The former are called *fake leptons*, the latter *non-prompt leptons*. In addition, non-prompt electrons occur as a result of photon conversions in the detector material. Multijet events with fake electrons or non-prompt electrons are modelled with a sample of simulated dijet events, while events with non-prompt muons are modelled with collision data, described in Section 4.2. The number of events with fake muons is negligible. The dijet event sample was generated using PYTHIA 8.186 with LO matrix elements for dijet production and interfaced to a p_T -ordered parton shower. The scales μ_r and μ_f were set to the square root of the geometric mean of the squared transverse masses of the two outgoing particles in the matrix element, $\mu_r = \mu_f = \sqrt{(p_{T,1}^2 + m_1^2)(p_{T,2}^2 + m_2^2)}$. At generator level, a filter was applied that required the existence of one particle-level jet with $p_T > 17$ GeV. The generation used the NNPDF2.3LO PDF set and the A14 set of tuned parameters. The generated sample of dijet events is used to model the kinematics of electron events of the multijet background when producing template distributions, while the rate of the multijet background is estimated in a data-driven way using dedicated control regions (CRs) described in Section 4.4.

3.4 Samples for the EFT and CKM interpretations

For interpreting the measurement in the framework of EFT, samples of tq (t -channel) and $t\bar{b}$ (s -channel) production were generated with MADGRAPH5_AMC@NLO 2.7.3 using the SMEFTatNLO-NLO model [62] with the five-flavour scheme and the NNPDF3.0NLO PDF set. The operator $O_{Qq}^{3,1}$ was activated, which introduces a four-quark contact interaction. Separate samples of simulated events were generated for each $C_{Qq}^{3,1}/\Lambda^2 \in \{-0.6, -0.2, 0.0, 0.4, 1.0\}$ for single top-quark and top-antiquark production. The setting $C_{Qq}^{3,1}/\Lambda^2 = 0.0$ corresponds to the SM. Each sample includes both tq and $t\bar{b}$ production. The SM production of the two processes is covered as well as the production via the four-quark operator $O_{Qq}^{3,1}$, and the interference of SM and non-SM amplitudes. The generated events were showered with PYTHIA 8.244 using the A14 set of tuned parameters and the NNPDF2.3LO PDF set. In these samples, the top-quark is assumed to decay to W^+b with a branching ratio of 100%.

The generalised CKM interpretation is based on samples of tq and $t\bar{q}$ events generated with MADGRAPH5_AMC@NLO 2.9.9 using the NNPDF3.0NLO PDF set. Eight samples were generated in which all different combinations of Wtq vertices with $q \in \{d, s, b\}$ are considered for the production and the decay vertex, except for the dominant mode that has a Wtb vertex on the production and the decay side. The four-flavour scheme was used for both samples in which the top quark originates from a b -quark. The other six samples were generated based on the five-flavour scheme. Parton showers were simulated with PYTHIA 8.307 using the A14 set of tuned parameters and the NNPDF2.3LO PDF set. The decay of top quarks was simulated with MADSPIN preserving all spin correlations, while W bosons coming from the top-quark decays were forced to decay leptonically. The samples are normalised to cross-sections calculated with MADGRAPH5_AMC@NLO assuming that the CKM matrix elements involved are equal to one, and were simulated with the full detector simulation.

The main background, $t\bar{t}$ production, also involves Wtq vertices when the top quark and antiquark decay. To facilitate a consistent treatment of the $t\bar{t}$ background eight additional samples were generated with POWHEG Box v2, implementing all combinations of Wtq decay vertices, except for the nominal channel that

involves two Wtb vertices. For the alternative samples, the parton shower was simulated with PYTHIA 8.307 using the A14 set of tuned parameters and the NNPDF2.3LO PDF set. The top-quark decay was handled with MADSPIN.

4 Object reconstruction and event selection

The partonic final state of the tq signal process comprises a charged lepton, a neutrino, a b -quark and a light quark (see Figure 1) and is reconstructed by identifying corresponding objects measured in the detector, such as electron and muon candidates, and hadronic jets. The presence of a high- p_T neutrino is indicated by large missing transverse momentum.

4.1 Object definitions

Events are required to have at least one vertex reconstructed from at least two ID tracks with transverse momenta of $p_T > 0.5$ GeV. The primary vertex of an event is defined as the vertex with the highest sum of p_T^2 over all associated ID tracks [63].

Electron candidates are reconstructed by matching a track in the ID to clusters of energy deposits in the electromagnetic calorimeter [64]. The pseudorapidity of clusters, η_{cluster} , is required to be in the range of $|\eta_{\text{cluster}}| < 2.47$. However, clusters are excluded if they are in the transition region $1.37 < |\eta_{\text{cluster}}| < 1.52$ between the barrel and endcap electromagnetic calorimeters. Electron candidates must have $p_T > 10$ GeV. A likelihood-based discriminant is constructed to simultaneously evaluate several properties of electron candidates, including shower shapes in the electromagnetic calorimeter, track quality, and the detection of transition radiation produced in the TRT. By placing a requirement on the discriminant, the selection of true electrons is enhanced, while photon conversions and hadrons misidentified as electrons are largely rejected. Two categories of electrons with different identification quality are defined [64]: the first category implements *Tight* identification criteria and features a high rejection of non-prompt or fake electrons, while the second category with *Loose* identification criteria has higher efficiency at the price of lower purity in prompt electrons. Electrons from decays of weak gauge bosons with $p_T(e) > 15$ GeV satisfy the *Tight* (*Loose*) criteria with an average efficiency of 80% (93%).

Muon candidates are reconstructed by combining tracks in the MS with tracks in the ID [65]. The tracks must be in the range of $|\eta| < 2.5$ and have $p_T > 10$ GeV. Similarly to electrons, two levels of identification criteria are applied, defining *Medium* and *Loose* quality categories of muon candidates [65]. Muons originating from W bosons in $t\bar{t}$ events with $p_T(\mu) > 10$ GeV satisfy the *Medium* (*Loose*) quality criteria with an efficiency of 97% (99%).

The tracks matched to electron and muon candidates must point to the primary vertex, which is ensured by requirements imposed on the transverse impact-parameter significance, $|d_0/\sigma(d_0)| < 5$ for electrons and $|d_0/\sigma(d_0)| < 3$ for muons, and on the longitudinal impact parameter, Δz_0 , for which $|\Delta z_0 \sin(\theta)| < 0.5$ mm must be satisfied for both of the lepton flavours. Non-prompt and fake leptons are efficiently rejected using multivariate discriminants [65] computed with boosted decision trees that combine electromagnetic shower shapes, track information from the ID, and a discriminant used to identify b -jets. Prompt muons with a p_T between 20 and 100 GeV satisfy the imposed isolation requirement with an efficiency of 87%, while the efficiency for muons from semileptonic decays of bottom or charm hadrons is 0.5%. Scale factors are

used to correct the efficiencies in simulation to match the efficiencies measured for the electron [20] and muon [21] triggers, and the reconstruction, identification and isolation criteria [64, 65].

Jets are reconstructed from particle-flow objects [66] with the anti- k_t clustering algorithm [67, 68] using a radius parameter of 0.4. This algorithm matches topological clusters [69] in the calorimeters to selected tracks in the ID. The energy of tracks is subtracted from the matched topological clusters and both the tracks and the energy-subtracted topological clusters are used as input to the clustering. The jet energy is calibrated by applying several simulation-based corrections and techniques correcting for differences between simulation and data [5]. The jets must fulfil $p_T > 30$ GeV and $|\eta| < 4.5$.

To suppress jets originating from pile-up collisions, several track-based variables are combined with a multivariate technique in the jet-vertex-tagger (JVT) discriminant [70]. Jets with $p_T < 60$ GeV and $|\eta| < 2.4$ are required to have a JVT-discriminant above 0.5, which corresponds to an efficiency of 92% for non-pile-up jets, while 98% of jets from pile-up events are rejected. For jets with $p_T < 60$ GeV and $|\eta| > 2.5$, the forward-jet-vertex-tagger (fJVT) [71] is used and an fJVT value below 0.4 is required. In addition, the jet must satisfy a timing condition. Differences in the efficiencies of the JVT and fJVT requirements between collision data and simulation are corrected by corresponding scale factors.

Jets containing b -hadrons are identified (b -tagged) with the DL1r algorithm, which uses a deep feed-forward neural network with several b -tagging algorithms as inputs [6]. These input algorithms exploit the impact parameters of charged-particle tracks, the properties of reconstructed secondary vertices and the topology of b - and c -hadron decays inside the jets. The requirement on the DL1r discriminant is chosen such that the efficiency of tagging b -jets with $p_T > 20$ GeV produced in simulated dileptonic $t\bar{t}$ events is 60%. Differences in the b -tagging efficiency between collision data and simulation are corrected with simulation-to-data scale factors derived from $t\bar{t}$ events. The scale factors are determined as a function of jet p_T and are found to be consistent with unity within uncertainties. The obtained scale factors depend on the parton-shower generator used to produce the $t\bar{t}$ samples. When using samples produced with a different parton-shower generator, for example SHERPA, to model W +jets events, or when evaluating systematic uncertainties with a setup based on HERWIG, additional correction factors called MC-to-MC scale factors are applied. Since the DL1r algorithm uses measurements from the ID, the identification of b -jets is limited to the region with $|\eta| < 2.5$.

To avoid double-counting objects satisfying more than one selection criterion, a procedure called *overlap removal* is applied. Reconstructed objects defined with *Loose* quality criteria are removed in the following order: electrons sharing an ID track with a muon; jets within $\Delta R = 0.2$ of an electron, thereby avoiding double-counting electron energy deposits as jets; electrons within $\Delta R = 0.4$ of a remaining jet, for reducing the impact of non-prompt electrons; jets within $\Delta R = 0.2$ of a muon if they have two or fewer associated tracks with $p_T > 0.5$ GeV; and muons within $\Delta R = 0.4$ of a remaining jet, reducing the rate of non-prompt muons.

The missing transverse momentum \vec{p}_T^{miss} is reconstructed as the negative vector sum of the p_T of the reconstructed leptons and jets, as well as ID tracks that point to the primary vertex but are not associated with a reconstructed object [72]. The latter contribution to \vec{p}_T^{miss} is named soft-track component. The magnitude of \vec{p}_T^{miss} is denoted by E_T^{miss} .

4.2 Modelling of non-prompt and fake leptons

Events of the multijet background with an identified electron candidate are modelled using the *jet-electron* method [73]. Simulated events from dijet production are selected if they contain a jet depositing a large fraction ($>80\%$) of its energy in the electromagnetic calorimeter. This jet is classified as an electron, labelled as the jet-electron, and is treated in the subsequent steps of the analysis in the same way as a properly identified prompt electron as defined in the previous section. The jet-electrons must satisfy the nominal p_T and $|\eta|$ requirements, but electron identification requirements are not applied.

Multijet events with non-prompt muons are modelled with collision events highly enriched in non-prompt muons [73]. Starting from the same sample of collision events as the nominal selection, a subset of events enriched in non-prompt muons is obtained by inverting or modifying some of the muon isolation requirements, such that the resulting sample does not overlap with the nominal sample. The kinematic requirements on p_T and $|\eta|$ are the same as for the nominal muon selection.

4.3 Event selection and definition of signal regions

Candidate events are required to have exactly one charged lepton (ℓ) with $p_T(\ell) > 28$ GeV, either an electron of *Tight* quality or a muon of *Medium* quality. The charged lepton is required to match the object that caused the event to pass a single-lepton trigger. To reduce contributions from $t\bar{t}$ events in the dilepton decay channel, any event with an additional lepton satisfying the *Loose* quality conditions with $p_T > 10$ GeV is rejected.

Multijet events containing fake or non-prompt leptons tend to have low E_T^{miss} and low W transverse mass, in contrast to events with prompt leptons from W and Z decays. The W transverse mass is defined as

$$m_T(W) = \sqrt{2p_T(\ell)E_T^{\text{miss}}(1 - \cos \Delta\phi(\vec{p}_T^{\text{miss}}, \ell))},$$

using the difference between the azimuthal angles of \vec{p}_T^{miss} and the charged lepton, $\Delta\phi(\vec{p}_T^{\text{miss}}, \ell)$. To reduce the multijet background, $E_T^{\text{miss}} > 30$ GeV and $m_T(W) > 50$ GeV are applied as selection requirements.

Exactly two jets with $p_T > 30$ GeV and $|\eta| < 4.5$ are required. Exactly one of these jets must be b -tagged, while the second jet must fail to meet the b -tagging requirement. The latter jet is therefore called the *untagged* jet. The b -tagged jet is explicitly required to have $|\eta| < 2.5$. Events with forward jets with $2.3 < |\eta| < 4.5$ are removed if at least one of the jets has $30 \text{ GeV} < p_T < 35 \text{ GeV}$, leading to an improved modelling of the $|\eta|$ distribution of untagged jets in the given regime.

To further suppress the multijet background and to remove poorly reconstructed leptons with low p_T , an additional requirement is applied based on the azimuthal angle between the charged lepton and the leading jet (j_1), i.e. the jet with the largest p_T . This quantity is denoted by $\Delta\phi(j_1, \ell)$. The imposed requirement is

$$p_T(\ell) > 40 \text{ GeV} \cdot \frac{|\Delta\phi(j_1, \ell)|}{\pi}, \quad (1)$$

which leads to a tighter p_T requirement on the charged lepton than the baseline definition if the leading jet and the charged lepton have a back-to-back topology, namely if $|\Delta\phi(j_1, \ell)| > 0.7\pi$. For the maximum separation $|\Delta\phi(j_1, \ell)| = \pi$ between the two objects, $p_T(\ell) > 40$ GeV must be satisfied.

Furthermore, an additional selection criterion is imposed on the invariant mass of the charged lepton and the b -tagged jet, $m(\ell b)$. Since the off-shell region for top-quark decays is not included in the calculation

CR name	Requirement
B-e-plus	$q_e/e = +1, \eta(e) < 1.37, E_T^{\text{miss}} < 30 \text{ GeV}$
B-e-minus	$q_e/e = -1, \eta(e) < 1.37, E_T^{\text{miss}} < 30 \text{ GeV}$
EC-e-plus	$q_e/e = +1, \eta(e) > 1.52, E_T^{\text{miss}} < 30 \text{ GeV}$
EC-e-minus	$q_e/e = -1, \eta(e) > 1.52, E_T^{\text{miss}} < 30 \text{ GeV}$
CR μ -plus	$q_\mu/e = +1, 28 \text{ GeV} < p_T(\mu) < 40 \text{ GeV} \cdot \frac{ \Delta\phi(j_1, \ell) }{\pi}$
CR μ -minus	$q_\mu/e = -1, 28 \text{ GeV} < p_T(\mu) < 40 \text{ GeV} \cdot \frac{ \Delta\phi(j_1, \ell) }{\pi}$

Table 1: Summary of the definition of the CRs.

of the matrix element of the event generator, it is not modelled well. Therefore, the tail of the $m(\ell b)$ distribution is removed by requiring $m(\ell b) < 160 \text{ GeV}$; this imposes a threshold that is slightly above the kinematic limit at LO, $m(\ell b)_{\text{limit}}^2 = m_t^2 - m_W^2$.

Two separate signal regions (SRs) are defined for events with a positively or a negatively charged lepton. These regions are denoted SR plus and SR minus, respectively.

4.4 Control regions for the multijet background

Since the misidentification of jets as electrons or muons are not well modelled by the detector simulation, the rate of the multijet background is determined in a data-driven way by including dedicated CRs in the fits of the statistical analysis. The rate of fake and non-prompt electrons is constrained in four CRs that are defined by the same selection criteria as the two SRs but inverting the E_T^{miss} requirement. Since the relative numbers of electrons detected in the barrel ($|\eta| < 1.37$) and endcap ($|\eta| > 1.52$) sections of the electromagnetic calorimeter are not modelled well enough by the sample of simulated dijet events, separate CRs are defined for the barrel and endcap regions and are denoted CR B-e-plus, CR B-e-minus, CR EC-e-plus and CR EC-e-minus. Only the event yields in these regions are included in the maximum-likelihood fit. The rate of non-prompt muons is constrained in two CRs defined by the same selection criteria as used for the two SRs but inverting the requirement on the p_T in Eq. 1. The two CRs are named CR μ -plus and CR μ -minus. The distributions of the difference in the azimuthal angles of \vec{p}_T^{miss} and the muon, $\Delta\phi(\vec{p}_T^{\text{miss}}, \mu)$, are included in the maximum-likelihood fits. Table 1 provides a summary of the definition of the CRs.

5 Separation of signal from background events

An artificial neural network is used to separate signal and background events in the two SRs by combining several kinematic variables into an optimised NN discriminant named D_{nn} . In addition to variables derived from the reconstructed objects, the NN builds on a reconstruction of the W boson and the top quark. The reconstruction of the leptonically decaying W boson requires the determination of the neutrino momentum.

Figure 2: Probability densities of the two most discriminating input variables to the NN in SR plus. (a) The invariant mass $m(jb)$ of the untagged jet and the b -tagged jet and (b) the absolute value of the pseudorapidity of the untagged jet $|\eta(j)|$. The distributions are shown for the tq signal process, and the $t\bar{t}$ and the $W+b\bar{b}$ backgrounds. Events beyond the x -axis range are included in the last bin.

While the x - and y -components of the neutrino momentum, $p_x(\nu)$ and $p_y(\nu)$, are approximated by the components of \vec{p}_T^{miss} , the z -component, $p_z(\nu)$, is determined by constraining the mass of the reconstructed W boson to match the measured world average [74]. If the resulting quadratic equation has two real solutions, the one with the smallest $|p_z(\nu)|$ is chosen. In the case of complex solutions, which occur due to the limited E_T^{miss} resolution, a kinematic fit is performed that rescales the $p_x(\nu)$ and $p_y(\nu)$ such that the imaginary part vanishes and at the same time the distance between the transverse components of the neutrino momentum and \vec{p}_T^{miss} is minimised [75]. The W boson is formed by adding the four-vectors of the reconstructed neutrino and the charged lepton. The top quark is reconstructed by adding the four-vector of the W boson and the b -jet.

The NN is implemented using the NeuroBayes package [76, 77], which combines a three-layer feed-forward NN with a complex and robust preprocessing of the input variables before they are presented to the NN. The preprocessing produces a ranking of the input variables based on an algorithm employing the total correlation of a set of variables to the target function, which assumes the value 1 for signal and 0 for background events [78]. Utilising this ranking, NNs with different numbers of variables are trained, the full analysis is performed and the expected uncertainty of the measurement is determined. Networks using more input variables tend to result in measurements with lower uncertainties in $\sigma(tq)$, $\sigma(\bar{t}q)$, $\sigma(tq + \bar{t}q)$, and R_t . However, when employing 15–30 variables, only marginal further improvements are found if more variables are added. As a result, the 17 highest-ranking input variables are chosen for training the final NN. These input variables are listed and described in Table 2. The probability densities of the two most discriminating variables, $m(jb)$ and $|\eta(j)|$, are shown for the tq signal process, and the $t\bar{t}$ and the $W+b\bar{b}$ backgrounds in Figure 2 for SR plus. The symbol j represents the untagged jet.

A single NN is trained using a sample of simulated events comprising both the positively and negatively charged leptons, since the event kinematics of tq and $\bar{t}q$ production is very similar. This simple approach gives similar sensitivity as a scenario in which separate NNs are trained in the SR plus and SR minus. The NN is trained against all considered backgrounds with a fraction of 50% signal events and 50% background events. The different background processes are weighted relative to each other according to their expected numbers of events. NeuroBayes uses Bayesian regularisation techniques for the training process to improve

No.	Symbol	Description
1.	$m(jb)$	Invariant mass of the untagged jet (j) and the b -tagged jet (b)
2.	$ \eta(j) $	Absolute value of the pseudorapidity of the untagged jet
3.	$ \Delta p_{\text{T}}(W, jb) $	Absolute value of the difference in transverse momentum between the reconstructed W boson and the jet pair
4.	$ \Delta\phi(W, jb) $	Absolute value of the difference in azimuthal angle between the reconstructed W boson and the jet pair
5.	$m(t)$	Invariant mass of the reconstructed top quark
6.	$ \Delta\eta(\ell, j) $	Absolute value of the difference in pseudorapidity between the charged lepton (ℓ) and the untagged jet
7.	$\Delta R(\ell, j)$	Angular distance of the charged lepton and the untagged jet
8.	$ \Delta\eta(b, \ell) $	Absolute value of the difference in pseudorapidity between the b -tagged jet and the charged lepton
9.	$m_{\text{T}}(W)$	Transverse mass of the W boson
10.	$m(\ell b)$	Invariant mass of the charged lepton and the b -tagged jet
11.	$H_{\text{T}}(\ell, \text{jets}, E_{\text{T}}^{\text{miss}})$	Scalar sum of the transverse momenta of the charged lepton and the jets and $E_{\text{T}}^{\text{miss}}$
12.	$ \Delta\eta(b, j) $	Absolute value of the difference in the pseudorapidity of the two jets
13.	$ \Delta\phi(j, t) $	Absolute value of the difference in the azimuthal angle between the untagged jet and the reconstructed top quark
14.	$\cos\theta^*(\ell, j)$	Cosine of the angle θ^* between the charged lepton and the untagged jet in the rest frame of the reconstructed top quark
15.	$ \eta(\ell) $	Absolute value of the pseudorapidity of the charged lepton
16.	S	Sphericity defined as the sum of the 2nd and 3rd largest eigenvalues of the sphericity tensor multiplied by $3/2$
17.	$ \Delta p_{\text{T}}(\ell, j) $	Absolute value of the difference in transverse momentum of the charged lepton and the untagged jet

Table 2: The 17 variables used for the training of the NN ordered by their discriminating power. The sphericity tensor $S^{\alpha\beta}$ used to define the sphericity S is formed with the three-momenta \vec{p}_i of the reconstructed objects, namely the jets, the charged lepton and the reconstructed neutrino. The tensor is given by $S^{\alpha\beta} = \frac{\sum_i p_i^\alpha p_i^\beta}{\sum_i |\vec{p}_i|^2}$ where α and β correspond to the spatial components x , y and z .

the generalisation performance and to avoid overtraining. The network infrastructure consists of one input node for each input variable plus one bias node, followed by 22 nodes arranged in a single hidden layer, and one output node that gives a continuous output in the interval $(-1, +1)$. As a non-linear activation

Figure 3: Probability densities of the NN discriminants for the tq and $\bar{t}q$ signal processes, and the $t\bar{t}$ and $W+b\bar{b}$ backgrounds in (a) SR plus and (b) SR minus.

function NeuroBayes uses the symmetric sigmoid function

$$S(x) = \frac{2}{1 + e^{-x}} - 1,$$

which maps the interval $(-\infty, +\infty)$ to the interval $(-1, +1)$. In the region close to zero, the sigmoid function has a linear response. The final discriminant D_{nn} is obtained by linearly scaling the output of the NN to the interval $(0, 1)$.

The probability densities of D_{nn} for the two SRs are shown in Figure 3 for the tq signal process and the main backgrounds, namely the $t\bar{t}$ and $W+b\bar{b}$ processes. Prior to the application of the NN to the observed collision data in the SRs, the modelling of the input variables is checked. For this purpose, a preliminary estimate of the rate of the multijet background is obtained by fitting the full E_T^{miss} distribution for electron events and fitting the $\Delta\phi(E_T^{\text{miss}}, \ell)$ distributions in CR μ -plus and CR μ -minus. Since the resulting estimate of the multijet background is only a preliminary step towards the final results, this fit is performed without using uncertainties other than the statistical data uncertainty and the MC statistical uncertainties. In the validation plots, the rates of all other processes including the signal process are set to their predicted values. The distributions of the eight most discriminating variables before performing the final maximum-likelihood fit (pre-fit) are shown in Figures 4 and 5 for SR plus. In all cases, the model describes the observed distributions within the estimated uncertainties. The pre-fit D_{nn} distributions are shown in Figure 6 for SR plus and SR minus.

6 Systematic uncertainties

Several sources of systematic uncertainty affect the expected event yield from signal and background processes, and the shape of the NN discriminants used in the maximum-likelihood fits. The systematic uncertainties are divided into two major categories. Experimental uncertainties are associated with the reconstruction of the four-momenta of final-state objects: electrons, muons, untagged jets, b -tagged jets, and E_T^{miss} . The second category of uncertainties is related to the modelling of scattering processes. All uncertainties are propagated through the analysis and their effects on the expected event yields and

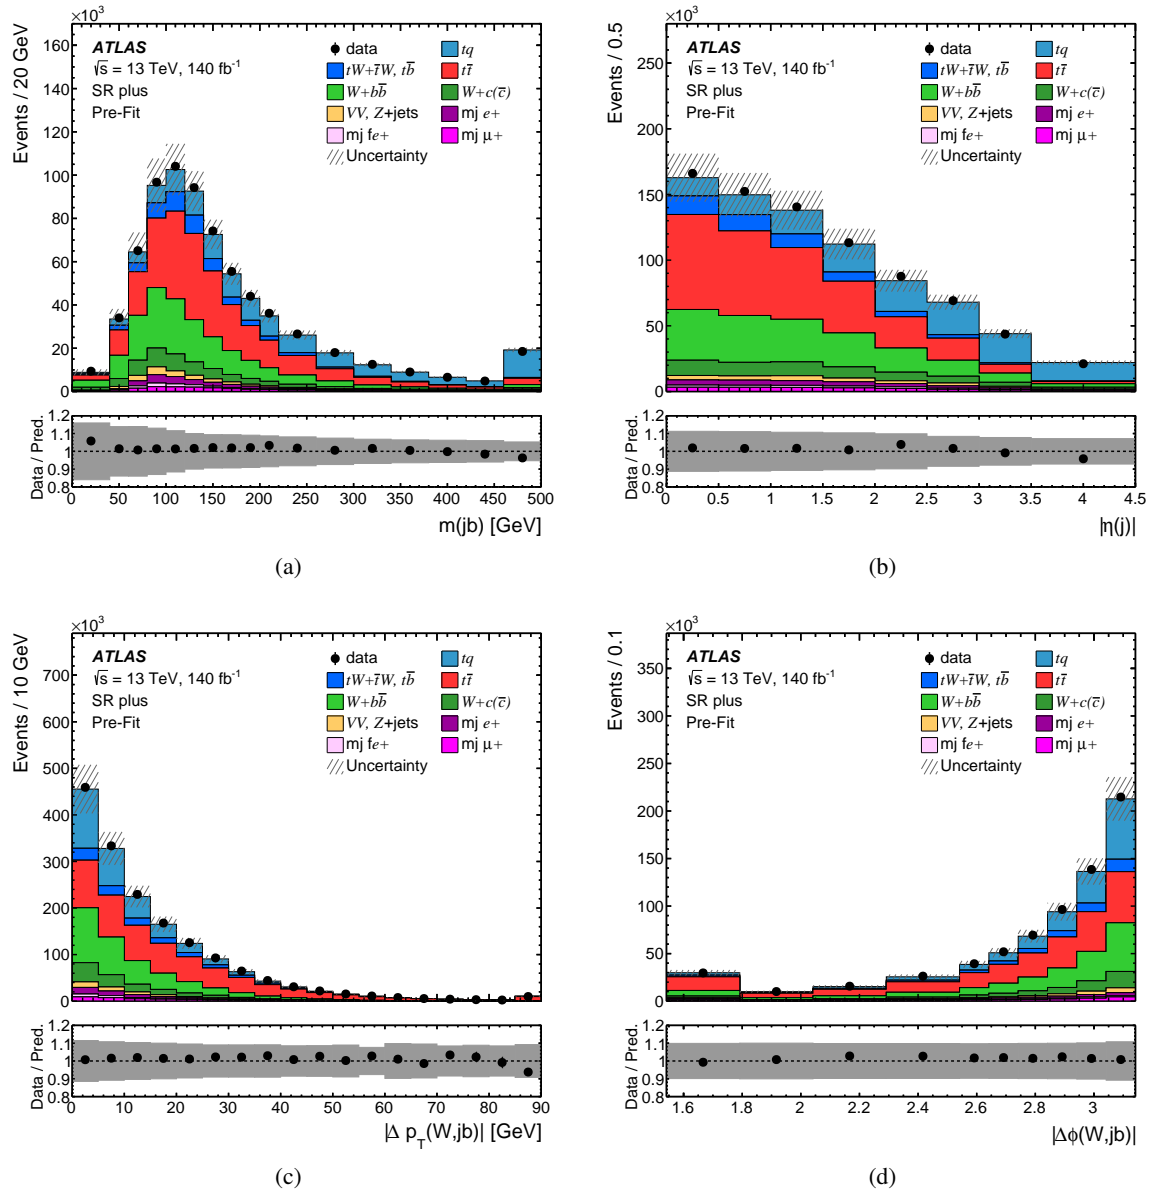

Figure 4: Pre-fit distributions of the four most discriminating input variables to the NN in SR plus: (a) the invariant mass $m(jb)$ of the untagged jet and the b -tagged jet, (b) the absolute value of the pseudorapidity of the untagged jet $|\eta(j)|$, (c) the absolute value of the difference in p_T between the reconstructed W boson and the jet pair, and (d) the difference in azimuth angle between the reconstructed W boson and the jet pair $|\Delta\phi(W, jb)|$. The observed distributions (dots) are compared with the expected distributions (histograms) from simulated events. In these distributions, the signal contribution is shown stacked on top of contributions from all considered background processes. All uncertainties considered in the analysis are included in the hatched uncertainty band. Events beyond the x -axis range are included in the last bin; the same applies to the first bin of the $|\Delta\phi(W, jb)|$ distribution in (d). The lower panel shows the ratio of data and the prediction; in this panel, the uncertainty is displayed as a grey band.

discriminant distributions are accounted for by including corresponding nuisance parameters in the fit. In the following, the estimation of experimental and modelling uncertainties is explained in more detail.

Figure 5: Pre-fit distributions of the four next most discriminating input variables to the NN in SR plus: (a) the invariant mass of the reconstructed top quark $m(t)$, (b) the absolute value of the difference in pseudorapidity between the charged lepton and the untagged jet $|\Delta\eta(\ell, j)|$, (c) the angular distance of the charged lepton and the untagged jet $\Delta R(\ell, j)$, and (d) the absolute value of the difference in pseudorapidity between the b -tagged jet and the charged lepton $|\Delta\eta(b, \ell)|$. The observed distributions (dots) are compared with the expected distributions (histograms) from simulated events. In these distributions, the signal contribution is shown stacked on top of contributions from all considered background processes. All uncertainties considered in the analysis are included in the hatched uncertainty band. Events beyond the x -axis range are included in the last bin. The lower panel shows the ratio of data and the prediction; in this panel, the uncertainty is displayed as a grey band.

In these distributions, the signal contribution is shown stacked on top of contributions from all considered background processes. All uncertainties considered in the analysis are included in the hatched uncertainty band. The lower panel shows the ratio of data and the prediction; in this panel, the uncertainty is displayed as a grey band.

6.1 Experimental uncertainties

The uncertainty in the integrated luminosity of the combined 2015–2018 data set is 0.83% and is based on a calibration of the luminosity scale using x – y beam-separation scans [18]. The luminosity uncertainty is applied to the expected signal and background event yields except for the multijet background, which is estimated in a data-driven way.

Scale factors are applied to simulated events to correct for reconstruction, identification, isolation and trigger performance differences between data and detector simulation for electrons and muons. These scale factors and their systematic uncertainties, as well as the lepton momentum scale and resolution, were assessed using $Z \rightarrow e^+e^-$ and $Z \rightarrow \mu^+\mu^-$ events in simulation and data [64, 65, 79, 80]. The probability of charge misidentification of reconstructed electrons is estimated from simulated events to be 1.9×10^{-3} . The net effect is a migration of events at the level of 6×10^{-4} from the SR plus to the SR minus (see Table 6). An uncertainty of 100% on this rate is applied in the maximum-likelihood fits and is taken to be anticorrelated between the tq and the $\bar{t}q$ processes.

The jet energy scale (JES) was calibrated using a combination of test-beam data, simulation and in situ techniques [5]. The JES is parameterised in bins of jet p_T and η . Its uncertainty is decomposed into a set of 30 uncorrelated components, of which 29 are non-zero in a given event depending on the type of simulation used. Sources of uncertainty contributing to the JES uncertainties computed using the detector position η_{det} include the η intercalibration of forward jets within $0.8 < |\eta_{\text{det}}| < 4.5$ with those in the central barrel region ($|\eta_{\text{det}}| < 0.8$), pile-up modelling, jet flavour composition and response, differences between jets induced by b -quarks and those from gluons or light-quarks, single-particle response, detector modelling, non-closure, and effects of jets not fully contained within the calorimeter.

The uncertainty of the jet energy resolution (JER) is evaluated by smearing jet energies according to a Gaussian function with width σ_{smear} [5]. Thirteen orthogonal components account for jet p_T - and η -dependent differences between simulation and data that were determined using dijet events and noise measurements based on random cones. The smearing is applied to simulated events, used to build the fit model, if the resolution in data is larger than in MC simulation, and to pseudo-data, obtained from simulated events, when the resolution is larger in simulation than in collision data. The JER uncertainties are defined by combining both variations and thereby taking the anticorrelation between different components into account. The nominal data remain unchanged. The uncertainty in the efficiency to satisfy the JVT requirement for pile-up suppression was derived in $Z(\rightarrow \mu^+ \mu^-)$ +jets events and is also considered [70]. The uncertainty in E_T^{miss} due to a possible miscalibration of its soft-track component was derived from data–simulation comparisons of the p_T balance between the hard and soft E_T^{miss} components [72].

The b -tagging requirement made in the measurement requires the consideration of uncertainties in the b -tagging efficiency of true b -jets and in the mistagging rates of light-quark jets and c -jets. The b -tagging efficiency is measured in dileptonic $t\bar{t}$ events. Differences between data and detector simulation are corrected by p_T -dependent scale factors applied to simulated events. The uncertainty in the scale factors is decomposed into 45 orthogonal components [81]. The uncertainties depend on the p_T of the b -jets and are propagated through the analysis as weights. The rate of mistagging c -jets as b -jets was measured in semileptonic $t\bar{t}$ events, where one of the W bosons decays into an electron or a muon and a neutrino and the other decays into a quark–antiquark pair [82]. This event sample allows the measurement to utilise the relatively large and known $W \rightarrow cs$ branching ratio. The mistagging rate of c -jets depends on the jet p_T and has a total uncertainty in the range of 3%-17%. The uncertainties are decomposed into 20 orthogonal components. The misidentification rate of light-quark jets was evaluated based on the techniques described in Ref. [83]. The resulting calibration factors are in the range of about 1.5 to 3 with uncertainties up to 50%. The uncertainties are decomposed into 20 independent eigenvectors.

6.2 Modelling uncertainties

Uncertainties in the theoretical cross-sections are evaluated for the top-quark background processes ($t\bar{t}$, tW and $t\bar{b}$) as quoted in Section 3.1. Due to the tight b -tagging requirement the largest contribution to the W +jets background comes from $W+b\bar{b}$ production in which the b -quarks are produced via gluon splitting ($g \rightarrow b\bar{b}$). An uncertainty of $\pm 40\%$ is assigned to the expected rate of this process, covering differences seen in previous measurements [84] between the SHERPA prediction and ATLAS collision data. The contribution of the associated production of a W boson and light-quark jets to the expected event yield is much smaller and therefore this contribution is merged with the $W+b\bar{b}$ process in the statistical analysis. The same uncertainty of $\pm 40\%$ is assigned to it. Events in which a W boson is produced in association with c -jets are mainly due to the $sg \rightarrow W^- c$ and $\bar{s}g \rightarrow W^+ \bar{c}$ scattering processes. An uncertainty of $\pm 20\%$ is assigned to the rate of $W+c$ -jets production. The same uncertainty is applied to the rate of the combined process of Z +jets and diboson production. The fit result and its uncertainty depend only marginally on the specific assignment of the uncertainties ($\pm 40\%$ and $\pm 20\%$, respectively) in the $W+b\bar{b}$, Z +jets, and diboson cross-sections. In the maximum-likelihood fit, separate nuisance parameters are used for the cross-section uncertainties of $W+b\bar{b}$ production and $W+c$ -jets production in the regions with positive and negative charge.

Uncertainties in modelling parton showers and hadronisation are assigned to the tq signal and the top-quark background processes ($t\bar{t}$, tW and $t\bar{b}$ production) by comparing the nominal samples with alternative samples for which POWHEG Box v2 was interfaced to HERWIG 7.2.1 [85, 86] (for $t\bar{t}$ production) or HERWIG 7.1.6 (for

tq , tW and $t\bar{b}$ production) instead of PYTHIA 8.230. The uncertainties are considered to be uncorrelated for the different scattering processes, namely the tq signal process and the three top-quark background processes. In the statistical analysis, normalisation and shape effects are decorrelated as well.

Uncertainties related to the choice of μ_r and μ_f for the matrix-element calculations are evaluated by varying the scales independently by factors of 2 and 0.5, separately for each of the top-quark production processes and for W +jets production. The scale variations are implemented as generator weights in the nominal sample. These weights are propagated through the entire analysis.

The uncertainty in matching the NLO matrix elements to the parton shower when generating $t\bar{t}$ and tq events is evaluated by comparing the nominal samples of simulated events to samples with an alternative setting of the p_T^{hard} parameter in the matching code, using 1 instead of the default setting of 0. This parameter regulates the definition of the vetoed region of the parton shower, important to avoid overlap in the phase space filled by POWHEG and PYTHIA. This estimate of the uncertainty follows the description in Ref. [87]. The uncertainty in the choice of the h_{damp} parameter for the $t\bar{t}$ event generation is estimated by using an additional $t\bar{t}$ sample produced with the h_{damp} parameter set to $3 \times m_t$, while keeping all other generator settings the same as for the nominal sample of events.

Uncertainties in the amount of initial-state and final-state radiation are assessed for the top-quark production processes by varying the parameter Var3c of the A14 parton-shower tune within the uncertainties of the tune and, for final-state radiation, by varying the renormalisation scale μ_r , at which the strong coupling constant α_s is evaluated, by factors of 0.5 and 2.0. The two variations are handled independently. The uncertainty due to the scheme for removing the overlap of the tW process with $t\bar{t}$ production is evaluated by comparing the nominal sample, using the diagram-removal scheme, with a sample produced with an alternative scheme (diagram subtraction) [39].

In all uncertainty evaluations mentioned above the alternative samples or reweighted samples are normalised to the total cross-section of the nominal samples.

Uncertainties in the PDFs are evaluated for the top-quark production processes using the PDF4LHC15 prescription with 30 eigenvectors [88]. Simulated events are reweighted to the central value and the eigenvectors of the combined PDF set. Systematically varied templates are constructed by taking the differences between the samples reweighted to the central value and those reweighted to the eigenvectors. In the likelihood fit, the PDF uncertainties are treated as correlated across the top-quark production processes.

The uncertainty in the multijet background is evaluated by modifying the selection criteria for jet-electron and non-prompt-muon candidates. Two alternative selections of jet-electron candidates are defined by varying the requirement on the energy fraction measured in the electromagnetic calorimeter, leading to two alternative shapes of the D_{nn} distributions for the multijet background in the SRs. In the statistical analysis, these shapes are used as “up” and “down” variations of a single nuisance parameter. For non-prompt-muon candidates a single variation is defined by varying the isolation criteria.

To account for differences in the pile-up distribution between simulation and data, the pile-up profile in the simulation is corrected to match the one in data. The uncertainty associated with the correction factor is applied in the measurement as a variation of the event weight.

The uncertainties due to the finite number of simulated events, also called the MC statistical uncertainty, is accounted for by adding a nuisance parameter for each bin of the D_{nn} distributions and the distributions in the CRs, implementing the Barlow–Beeston approach [89].

7 Measurement results

The cross-sections $\sigma(tq)$ and $\sigma(\bar{t}q)$ are determined in a simultaneous binned profile maximum-likelihood fit. To properly account for the correlations of systematic uncertainties when forming the sum and the ratio of $\sigma(tq)$ and $\sigma(\bar{t}q)$, $\sigma(tq + \bar{t}q)$ and R_t are measured in a second fit in which the parameterisation of the signal strength parameters is modified accordingly, while all other parameters of the fit setup are kept the same. The fitted distributions are the D_{nn} distributions in SR plus and SR minus, the $\Delta\phi(E_T^{\text{miss}}, \ell)$ distributions in the CR μ -plus and the CR μ -minus, and the event yields in the CR B-e-plus, the CR B-e-minus, the CR EC-e-plus and the CR EC-e-minus. In both fits, the event yields of the multijet background are left floating, while the yields of all other backgrounds are constrained to their predictions within the associated uncertainties.

The likelihood function is constructed as a product of Poisson probability terms over all considered bins. The fitted event yields in the bins depend on nuisance parameters that include the effects of systematic uncertainties. Each nuisance parameter, except those representing the MC statistical uncertainties, is constrained by a Gaussian term in the likelihood function. Some systematically varied discriminant distributions are smoothed and nuisance parameters of systematic uncertainties with negligible impact are entirely removed to reduce spurious effects in the minimisation, improve the convergence of the fit, and reduce the computing time. Normalisation and shape effects of a source of systematic uncertainty are treated separately in this removal process. Single-sided systematic variations are turned into symmetric variations by taking the full difference in event yield and shape between the nominal model and the alternative model and mirroring this difference in the opposite direction. For most sources with two variations, their effects are made symmetric by using the average deviation from the nominal prediction. Exceptions are the uncertainties in the JER and in the jet-electron model, for which the asymmetric variations are kept because the underlying effects are known to be asymmetric. No significant pulls of nuisance parameters are observed.

The total cross-sections for tq and $\bar{t}q$ production are measured to be

$$\sigma(tq) = 137^{+8}_{-8} \text{ pb} \quad \text{and} \quad \sigma(\bar{t}q) = 84^{+6}_{-5} \text{ pb}.$$

The NNLO predictions for these cross-sections (see Section 3.1) agree very well with the measurements. The relative precision reached is +5.9% and -5.5% for $\sigma(tq)$ and +6.6% and -6.2% for $\sigma(\bar{t}q)$. The fits to the observed data for the combined tq and $\bar{t}q$ cross-section and R_t give the following results:

$$\sigma(tq + \bar{t}q) = 221^{+13}_{-13} \text{ pb} \quad \text{and} \quad R_t = 1.636^{+0.036}_{-0.034}$$

with a relative precision of +6.1% and -5.7% for the combined cross-section and +2.2% and -2.1% for R_t . The global goodness of fit is evaluated with the saturated model [74] yielding a p -value of 76%. Table 3 provides a breakdown of the uncertainties categorised in groups according to different sources. The impact of a particular group of uncertainties is evaluated by performing an alternative likelihood fit in which the nuisance parameters related to the sources of uncertainty under investigation are fixed to their best-fit values as obtained from the nominal fit. The squared impact of the considered group of uncertainties is determined as the difference between the square of the nominal total uncertainty and the square of the uncertainty obtained from the alternative fit. For the measured cross-sections, the uncertainties in the signal modelling are the dominating ones, while they largely cancel out for the measurement of R_t . The data statistical uncertainty is very small compared with the systematic uncertainties. Since many uncertainties largely cancel out when forming the ratio, the uncertainty in R_t is much reduced compared with the uncertainties in the cross-sections.

Table 5: The impact of the eight most important systematic uncertainties on R_t in %.

scale of the tq process. The eight most important systematic uncertainties in the R_t measurement are listed in Table 5. As a cross-check, the selected sample of events was split according to the lepton flavour into an electron and a muon sample and the measurements were repeated, leading to results compatible with the nominal analysis.

The D_{nn} distributions after performing the fit are shown for both of the SRs in Figure 7. The correlations induced by the maximum-likelihood fit are taken into account and lead to a large reduction in the size of the uncertainty band. The post-fit event yields of the different processes are provided in Table 6.

Dependence on m_t The cross-sections and the ratio R_t are determined at a fixed value of $m_t = 172.5$ GeV. The mass dependence of the measurements is determined by repeating the measurement with samples of simulated events produced with different values of m_t , namely $m_t = 171$ GeV and $m_t = 174$ GeV. The dependence of the resulting cross-sections on m_t is fitted with a first-order polynomial, for which the constant term is given by the central value at $m_t = 172.5$ GeV, namely

$$\sigma(m_t) = \sigma(172.5 \text{ GeV}) + a \cdot \Delta m_t [\text{GeV}],$$

where $\Delta m_t = m_t - 172.5$ GeV. The slopes are fitted to be $a = (-1.50 \pm 0.26)$ pb GeV⁻¹ for $\sigma(tq)$, $a = (-0.85 \pm 0.31)$ pb GeV⁻¹ for $\sigma(\bar{t}q)$, and $a = (-2.35 \pm 0.69)$ pb GeV⁻¹ for $\sigma(tq + \bar{t}q)$. For R_t the effect is found to be negligible.

(a)

(b)

Figure 7: The observed D_{nn} distributions (dots) for (a) SR plus and (b) SR minus are compared with the expected distributions (histograms) from simulated events after the fit (post-fit). In these distributions, the signal contribution is shown stacked on top of contributions from all contributing background processes. All uncertainties considered in the analysis are included in the hatched uncertainty band. The correlations induced by the fit are taken into account. The lower panel shows the ratio of data and the prediction; in this panel, the uncertainty is displayed as a grey band.

Process	SR plus	SR minus
tq	$169\,000 \pm 6\,000$	150 ± 150
$\bar{t}q$	90 ± 90	$109\,000 \pm 4\,000$
$tW + \bar{t}W, t\bar{b} + \bar{t}b$	$51\,000 \pm 4\,000$	$49\,000 \pm 4\,000$

Z+jets, diboson	$21\,000 \pm 4\,000$	$19\,000 \pm 4\,000$
Multijet	$50\,000 \pm 10\,000$	$50\,000 \pm 10\,000$
Total	$814\,000 \pm 2\,100$	$698\,800 \pm 2\,000$
Observed	814 185	698 845

Table 6: The post-fit event yields in the two SRs. All uncertainties applied in the analysis are included. Correlations, including anticorrelations, among the nuisance parameters related to the uncertainties are taken into account as determined in the maximum-likelihood fit, leading to a reduction in the size of the uncertainties, in particular for the total prediction. The event yields of the different processes as quoted in the table do not add up to the total sum given because of rounding effects.

8 Interpretation of the measurements

The measurements of the tq production cross-sections presented in Section 7 are interpreted in different ways. Predictions based on different PDF sets are compared with the measured R_t value in Section 8.1. A search for a contribution of a four-quark EFT operator to tq production using the D_{nn} distributions in the SRs is presented in Section 8.2. The result of this search yields a confidence interval for the EFT coefficient $C_{Qq}^{3,1}/\Lambda^2$. In addition, the measurement of $\sigma(tq + \bar{t}q)$ is used to derive limits on the EFT coefficient $C_{\phi Q}^3/\Lambda^2$. The corresponding operator $O_{\phi Q}^3$ has the same Lorentz structure as the Wtb vertex in the SM, and thus simply scales the cross-section of tq production, while kinematic distributions are not altered by its presence. The CKM matrix element V_{tb} is extracted from the measurement of $\sigma(tq + \bar{t}q)$ (see Section 8.3). In a more general approach, confidence contours are determined in the $f_{LV}|V_{td}|$ -versus- $f_{LV}|V_{tb}|$, the $f_{LV}|V_{ts}|$ -versus- $f_{LV}|V_{tb}|$, and the $f_{LV}|V_{ts}|$ -versus- $f_{LV}|V_{td}|$ planes; the results are presented in Section 8.4.

8.1 Sensitivity of R_t to PDF sets

With an uncertainty of $+2.2\% / -2.1\%$, the measurement of R_t can potentially distinguish between different PDF sets. Predictions of R_t made with different PDF sets at NNLO, namely ABMP [90], ATLAS [91], CTEQ [92], MSHT [93], NNPDF [36, 94], and PDF4LHC [45], are compared with the measured value in Figure 8. The calculations were performed with the MCFM 10.1 program [44]. The differences between the R_t predictions are driven by differences between the u - and d -quark PDFs. The PDFs provided by the different groups differ in the data used, the value of α_s assumed, the values of quark masses used, and the treatment of heavy quarks. The scale uncertainties for the theoretical predictions are included in Figure 8. The scale uncertainties are determined by varying μ_r and μ_f independently up and down by a factor of two, whilst never allowing them to differ by a factor greater than two from each other. The scale uncertainty is defined as the envelope of the six resulting variations. The uncertainties in the predictions also include the uncertainties provided by the PDF set under investigation and, where possible, uncertainties in α_s .²

The prediction of ABMP is incompatible with the measurement of R_t at the level of approximately three standard deviations. All other predictions are in agreement with the measured value within the experimental and theoretical uncertainties. The predictions of ATLASpdf21 and NNPDF3.0 are the closest to the central value of the measurement; all other predictions are approximately one standard deviation above. The slightly higher uncertainty of the ATLASpdf21 prediction compared with those predictions based on other ATLAS PDF sets is attributed to the usage of a wider range of input data samples and, associated to that, a modified uncertainty definition.

8.2 EFT interpretation

The Standard Model Effective Field Theory (SMEFT) provides a model-independent framework for indirect searches for new physics. Within this framework, the SM is regarded as a low-energy approximation of a more fundamental theory involving interactions at an energy scale Λ . The impact of new physics is

² There is no functionality implemented to vary α_s for ATLAS (epWZ16). For MSHT the strong coupling constant is varied simultaneously with the PDF eigenvectors rather than independently.

Figure 8: The measured value of R_t (dot). The yellow band represents the statistical uncertainty and the green band represents the total uncertainty of the measurement. For comparison, the NNLO predictions of MCFM based on different PDF sets are included: ABMP [90], ATLAS [91], CTEQ [92], MSHT [93], NNPDF [36, 94], and PDF4LHC [45]. The uncertainties in the theoretical predictions include PDF, scale and α_s uncertainties.

parameterised by higher-dimensional operators maintaining SM symmetries. The effective Lagrangian is given by

$$\mathcal{L}_{\text{eff}} = \mathcal{L}_{\text{SM}} + \sum_i \frac{C_i}{\Lambda^2} O_i + \text{Hermitian conjugate},$$

where \mathcal{L}_{SM} is the SM Lagrangian. The O_i are effective dimension-6 operators and the C_i are the associated Wilson coefficients. In this EFT interpretation, two operators are considered, the four-quark operator $O_{qq}^{3,1}$ and the operator $O_{\phi Q}^3$ coupling the third quark generation to the Higgs boson doublet Φ .

The relevant operators, expressed in the Warsaw basis, are

$$\begin{aligned} O_{qq}^{1(ijkl)} &= (\bar{q}_i \gamma^\mu q_j)(\bar{q}_k \gamma_\mu q_l), \\ O_{qq}^{3(ijkl)} &= (\bar{q}_i \gamma^\mu \tau^I q_j)(\bar{q}_k \gamma_\mu \tau^I q_l) \quad \text{and} \\ O_{\phi Q}^3 &= i(\Phi^\dagger \tau^I D_\mu \Phi)(\bar{Q} \gamma^\mu \tau^I Q). \end{aligned}$$

The q denote weak-isospin doublets with $ijkl \in 1, 2, 3$ as quark generation indices, while Q represents the doublet of the third quark generation. All contributing four-quark processes depend solely on a linear

Figure 9: Representative LO Feynman diagram of a four-quark contact interaction leading to the production of a single top quark.

combination of Wilson coefficients

$$C_{Qq}^{3,1} = \sum_{i=1,2} C_{qq}^{3(ii33)} + \frac{1}{6} C_{qq}^{1(i33i)} - \frac{1}{6} C_{qq}^{3(i33i)},$$

therefore the four-quark interaction is fully characterised by $O_{Qq}^{3,1}$ [95].

The operator $O_{Qq}^{3,1}$ leads to non-SM single top-quark production, as illustrated in Figure 9, for example via the process $b + u \rightarrow t + d$. Top quarks produced in this way feature different angular distributions and kinematics than those produced via SM processes. A non-zero contribution from the operator $O_{\phi Q}^3$ does not alter the Lorentz structure of the Wtb vertex, it merely leads to a rescaling of the vertex strength, and thus changes the total cross-section, but it does not alter the shape of any kinematic distributions.

Events with single top quarks produced via SM vertices (tq and $t\bar{b}$ production) and via $O_{Qq}^{3,1}$ vertices were generated with MADGRAPH, as detailed in Section 3.4. These samples are subjected to the regular analysis chain, including the event selection and the processing of the NN analysis. Using the five different EFT samples, the single top-quark event yield ν_j in each bin j of the D_{nn} distributions in SR plus and SR minus is parameterised by a polynomial of second degree in the EFT coefficient $C_{Qq}^{3,1}$.

$$\nu_j = \nu_{0j} + a_{1j} \frac{C_{Qq}^{3,1}}{\Lambda^2} + a_{2j} \frac{(C_{Qq}^{3,1})^2}{\Lambda^4}.$$

The constant term ν_{0j} represents tq and $t\bar{b}$ production in the SM and is normalised to the SM cross-section predictions of both the processes, as reported in Section 3.1. The term linear in $C_{Qq}^{3,1}$ represents the effect of the interference of SM and non-SM amplitudes and the term proportional to $(C_{Qq}^{3,1})^2$ is entirely due to the four-quark operator. Based on a maximum-likelihood scan of the parameter $C_{Qq}^{3,1}/\Lambda^2$ the 95% CL interval is determined to be

$$-0.37 < C_{Qq}^{3,1}/\Lambda^2 < 0.06.$$

All SM processes are modelled in the same way as in the cross-section measurements presented in Section 7. The same systematic uncertainties are applied. The constraints presented improve the limits set by the ATLAS measurement of the charge asymmetry in $t\bar{t}$ production [96], which obtained a confidence interval of $[-0.70, 0.75]$. The interpretation of cross-section measurements of $t\bar{t}Z$ production by ATLAS [97] reaches the constraints $[-0.34, 0.23]$, similar to the ones presented above. Limits on the parameter $C_{Qq}^{3,1}/\Lambda^2$ were also set by global EFT fits that include inputs from measurements by the ATLAS and CMS

Collaborations. The results in Ref. [7] are based on various measurements of Higgs boson, diboson and top-quark production processes and lead to a confidence interval for $C_{Qq}^{3,1}/\Lambda^2$ of $[-0.088, 0.166]$ at the 95% CL when including terms of order Λ^{-4} . A similar approach by a different group of analysers [8] leads to a confidence interval of $[-0.043, 0.16]$. Using only top-quark measurements for the analysis, the authors of Ref. [9] obtain $C_{Qq}^{3,1}/\Lambda^2 \in [-0.39, 0.11]$. The comparison to these results of global EFT analyses demonstrates that the limits on $C_{Qq}^{3,1}/\Lambda^2$ obtained from the tq cross-section measurements presented in this document are quite competitive. An important difference to appreciate is that the results of Refs. [7–9] do not account for reconstruction effects on EFT signal events, while the results presented here are based on simulated samples that include detector effects.

Since the EFT operator $O_{\phi Q}^3$ has the same Lorentz structure as the Wtb vertex in the SM, and kinematic distributions of tq and $\bar{t}q$ events are thus not altered by contributions from $O_{\phi Q}^3$, limits on the corresponding Wilson coefficient $C_{\phi Q}^3/\Lambda^2$ are derived from the measured cross-section $\sigma(tq + \bar{t}q)$. The cross-section $\sigma(tq + \bar{t}q)$ is calculated for different values of $C_{\phi Q}^3/\Lambda^2$ with MADGRAPH5_AMC@NLO 2.7.3 using the SMEFTatNLO-NLO model [62] with the five-flavour scheme and the NNPDF3.0_{NLO} PDF set, and is obtained as the sum of $\sigma(tq)$ and $\sigma(\bar{t}q)$. The contribution of the quadratic term in $C_{\phi Q}^3/\Lambda^2$ is negligible in the relevant parameter range, and thus a linear function is fitted to the relative change in $\sigma(tq + \bar{t}q)$ as a function of $C_{\phi Q}^3/\Lambda^2$ relative to its value at $C_{\phi Q}^3/\Lambda^2 = 0$, resulting in a slope of 0.12 ± 0.02 . Based on this parameterisation, the 95% CL interval of $C_{\phi Q}^3/\Lambda^2$ is determined to be

$$-0.87 < C_{\phi Q}^3/\Lambda^2 < 1.42.$$

These constraints improve limits obtained by the interpretation of cross-section measurements of $t\bar{t}Z$ production that yielded the confidence interval $[-0.95, 2.0]$ [97]. However, the combined interpretation of Higgs boson, diboson, and top-quark measurements yielded a stronger limit of $[-0.375, 0.344]$ [7].

8.3 Determination of $|V_{tb}|$

Single top-quark production in the t -channel proceeds primarily via a Wtb vertex and the cross-section is proportional to $f_{LV}^2 \cdot |V_{tb}|^2$. In the SM, the left-handed form factor f_{LV} is exactly one and the CKM matrix is unitary. Assuming the unitarity relations, the measured values of other CKM matrix elements suggest that $|V_{tb}|$ is very close to one. However, new-physics contributions could alter the value of f_{LV} significantly. The determination of $f_{LV} \cdot |V_{tb}|$ based on single-top-quark cross-section measurements is independent of assumptions about the number of quark generations and the unitarity of the CKM matrix. The only assumptions made are that $|V_{tb}| \gg |V_{td}|, |V_{ts}|$ and that the Wtb interaction is a left-handed weak coupling, as in the SM.

The value of $f_{LV}^2 \cdot |V_{tb}|^2$ is extracted by dividing the measured value of $\sigma(tq + \bar{t}q)$ by the SM expectation of $214.2 \pm 3.4(\text{scale} + \text{PDF}) \pm 1.8(\Delta m_t)$ pb [44]. When calculating $f_{LV}^2 \cdot |V_{tb}|^2$, the experimental and theoretical uncertainties are added in quadrature. The uncertainty in m_t is also considered, assuming $\Delta m_t = \pm 1$ GeV. The result obtained is

$$f_{LV} \cdot |V_{tb}| = 1.015 \pm 0.031,$$

improving the precision by 30% compared with the combination of Run 1 measurements by ATLAS and CMS [98]. The Particle Data Group combined all available measurements performed at the Tevatron and the LHC to 1.014 ± 0.029 [74].

Restricting the range of $|V_{tb}|$ to the interval $[0, 1]$ and setting $f_{LV} = 1$, as required by the SM, a lower limit on $|V_{tb}|$ is extracted: $|V_{tb}| > 0.95$ at the 95% CL. In the Bayesian-style limit computation, it is assumed that the likelihood curve of $|V_{tb}|^2$ is a Gaussian function, centered at the measured value. A flat prior in $|V_{tb}|^2$ is applied, being one in the interval $[0, 1]$ and zero otherwise.

8.4 Generalised CKM interpretation

The interpretation of the tq cross-section measurements presented in Section 8.3 neglects the contributions due to Wts and Wtd vertices. In a more general approach, this caveat is avoided. Nine contributions to tq production are considered, differing in the combination of Wtq vertices for top-quark production and decay with $q \in \{d, s, b\}$. In $t\bar{t}$ production, Wtq vertices occur for the top-quark and top-antiquark decays. Again, nine different combinations of vertices are considered, thus treating the most important background process at the same level of modelling as the tq signal process. Including the effect of Wts and Wtd vertices for $t\bar{t}$ production improves the sensitivity of the measurement to $|V_{ts}|$ and $|V_{td}|$ by approximately 20%. The effects of Wts and Wtd vertices on the event yields of tW and $t\bar{b}$ production are neglected, since the corresponding event yields for these processes are much smaller than the yields for tq and $t\bar{t}$ production. Three different fit scenarios are investigated. In each scenario, two V_{tq} matrix elements are considered to be free parameters, while the third parameter is fixed to be either 0 or 1:

$$\text{Scenario 1} \quad |V_{tb}| \neq 0, |V_{td}| \neq 0 \text{ and } |V_{ts}| = 0,$$

$$\text{Scenario 2} \quad |V_{tb}| \neq 0, |V_{ts}| \neq 0 \text{ and } |V_{td}| = 0,$$

$$\text{Scenario 3} \quad |V_{td}| \neq 0, |V_{ts}| \neq 0 \text{ and } |V_{tb}| = 1.$$

The form factor f_{LV} is non-zero in all scenarios. For each scenario, a maximum-likelihood scan of the two non-zero CKM matrix elements is performed. As a result, confidence contours are determined at the 95% CL in the $f_{LV}|V_{td}|$ -versus- $f_{LV}|V_{tb}|$, the $f_{LV}|V_{ts}|$ -versus- $f_{LV}|V_{tb}|$, and the $f_{LV}|V_{ts}|$ -versus- $f_{LV}|V_{td}|$ planes. These contours are shown in Figure 10. The parameter $f_{LV}|V_{tb}|$ is constrained at the 95% CL to a range between 0.95 and 1.05, and $f_{LV}|V_{td}|$ and $f_{LV}|V_{ts}|$ are constrained to be < 0.23 and < 0.58 , respectively. The constraint on $|V_{td}|$ is stronger compared with the one on $|V_{ts}|$ because the d -quark is a valence quark of the proton, while s -quarks appear as sea-quarks only. The interpretation uses the nominal simulation-to-data corrections for the efficiency of tagging b -quark jets, which was determined with $t\bar{t}$ events in the dilepton channel assuming $|V_{tb}| = 1$ and thus $\mathcal{B}(t \rightarrow Wb) = 100\%$. This assumption is increasingly violated when moving to large values of $|V_{td}|$ and $|V_{ts}|$ and thus constitutes a caveat of the generalised CKM interpretation presented here.

The CKM matrix elements $|V_{td}|$ and $|V_{ts}|$ are determined very precisely using measurements of the mass differences Δm_d and Δm_s of the mass eigenstates of B_d^0 and B_s^0 mesons [74]. However, these determinations are based on $B-\bar{B}$ meson oscillations that are induced by box diagrams with top quarks, use lattice QCD results, and neglect corrections suppressed by $|V_{tb}| - 1$, and thus introduce a certain level of model dependence that is reduced in the studies presented here for tree-level processes, namely single top-quark production and decay. In addition, the top-quark processes give access to a much higher energy scale.

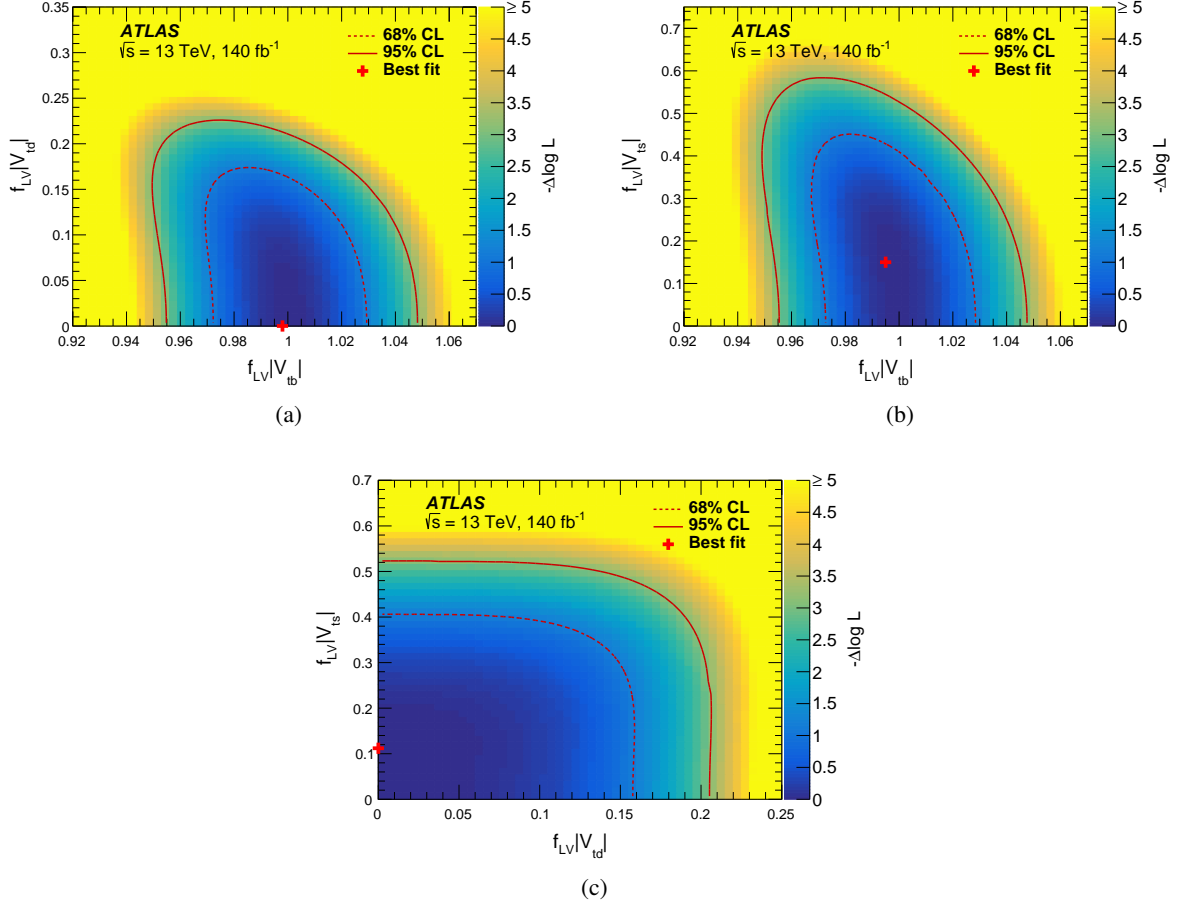

Figure 10: Confidence contours obtained from maximum-likelihood scans in (a) the $f_{LV}|V_{td}|$ -versus- $f_{LV}|V_{tb}|$ plane, (b) the $f_{LV}|V_{ts}|$ -versus- $f_{LV}|V_{tb}|$ plane, and (c) the $f_{LV}|V_{ts}|$ -versus- $f_{LV}|V_{td}|$ plane. Contours at the 68% and 95% confidence levels are shown. The two-dimensional histogram contains the values of the difference of the log-likelihood function at a certain point in the plane to the minimum of the log-likelihood function indicated by the red cross.

9 Conclusions

The production of single top quarks and top antiquarks via the t -channel exchange of a virtual W boson is measured in proton–proton collisions at the LHC at a centre-of-mass energy of 13 TeV, using the full Run 2 data sample of 140 fb^{-1} recorded with the ATLAS detector. Events are selected with either one isolated electron or muon, high E_T^{miss} , and exactly two hadronic jets with high p_T . Exactly one of these jets is required to be b -tagged. An artificial NN is used to construct a discriminant that separates signal and background events. The distributions of the discriminant are used in profile maximum-likelihood fits to determine the signal yields.

The total cross-sections are determined to be $\sigma(tq) = 137_{-8}^{+8} \text{ pb}$ and $\sigma(\bar{t}q) = 84_{-5}^{+6} \text{ pb}$ for top-quark and top-antiquark production, respectively. The combined cross-section is found to be $\sigma(tq + \bar{t}q) = 221_{-13}^{+13} \text{ pb}$ and the cross-section ratio is $R_t = \sigma(tq)/\sigma(\bar{t}q) = 1.636_{-0.034}^{+0.036}$. The predictions made at NNLO in perturbation theory are in good agreement with the measured cross-sections, which reach greater precision than previous measurements by the ATLAS and CMS Collaborations with partial Run 2 data samples at

$\sqrt{s} = 13$ TeV. The relative precision of the measurements presented also surpasses the precision reached in ATLAS Run 1 measurements at $\sqrt{s} = 7$ TeV and $\sqrt{s} = 8$ TeV. The new results are thus the most precise measurements of tq and $\bar{t}q$ production to date.

The predictions using various sets of PDFs are compared with the measured value of R_t , demonstrating the potential of further constraining the functions if the measurement is included into future fits. The measurements of $\sigma(tq)$, $\sigma(\bar{t}q)$, and $\sigma(tq + \bar{t}q)$ are interpreted in an EFT approach, setting limits at the 95% CL on the strength of the four-quark operator $O_{Qq}^{3,1}$ and the operator $C_{\phi Q}^3/\Lambda^2$: $-0.37 < C_{Qq}^{3,1}/\Lambda^2 < 0.06$ and $-0.87 < C_{\phi Q}^3/\Lambda^2 < 1.42$, respectively. The measured value of $\sigma(tq + \bar{t}q)$ is further used to derive the constraint $|V_{tb}| > 0.95$ at the 95% CL and determine $f_{LV} \cdot |V_{tb}| = 1.015 \pm 0.031$, improving by 30% the determination of this quantity based on a combination of Run 1 measurements by ATLAS and CMS. In a more general approach, confidence contours are determined in the $f_{LV}|V_{td}|$ -versus- $f_{LV}|V_{tb}|$, the $f_{LV}|V_{ts}|$ -versus- $f_{LV}|V_{tb}|$, and the $f_{LV}|V_{ts}|$ -versus- $f_{LV}|V_{td}|$ planes. The parameter $f_{LV}|V_{tb}|$ is constrained at the 95% CL to a range between 0.95 and 1.05, and $f_{LV}|V_{td}|$ and $f_{LV}|V_{ts}|$ are constrained to be < 0.23 and < 0.58 , respectively.

Acknowledgements

We thank CERN for the very successful operation of the LHC and its injectors, as well as the support staff at CERN and at our institutions worldwide without whom ATLAS could not be operated efficiently.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN, the ATLAS Tier-1 facilities at TRIUMF/SFU (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), RAL (UK) and BNL (USA), the Tier-2 facilities worldwide and large non-WLCG resource providers. Major contributors of computing resources are listed in Ref. [99].

We gratefully acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; ANID, Chile; CAS, MOST and NSFC, China; Minciencias, Colombia; MEYS CR, Czech Republic; DNRF and DNSRC, Denmark; IN2P3-CNRS and CEA-DRF/IRFU, France; SRNSFG, Georgia; BMBF, HGF and MPG, Germany; GSRI, Greece; RGC and Hong Kong SAR, China; ISF and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; NWO, Netherlands; RCN, Norway; MEiN, Poland; FCT, Portugal; MNE/IFA, Romania; MESTD, Serbia; MSSR, Slovakia; ARRS and MIZŠ, Slovenia; DSI/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SERI, SNSF and Cantons of Bern and Geneva, Switzerland; MOST, Taipei; TENMAK, Türkiye; STFC, United Kingdom; DOE and NSF, United States of America.

Individual groups and members have received support from BCKDF, CANARIE, CRC and DRAC, Canada; PRIMUS 21/SCI/017 and UNCE SCI/013, Czech Republic; COST, ERC, ERDF, Horizon 2020, ICSC-NextGenerationEU and Marie Skłodowska-Curie Actions, European Union; Investissements d’Avenir Labex, Investissements d’Avenir Idex and ANR, France; DFG and AvH Foundation, Germany; Herakleitos, Thales and Aristeia programmes co-financed by EU-ESF and the Greek NSRF, Greece; BSF-NSF and MINERVA, Israel; Norwegian Financial Mechanism 2014-2021, Norway; NCN and NAWA, Poland; La Caixa Banking Foundation, CERCA Programme Generalitat de Catalunya and PROMETEO and GenT Programmes Generalitat Valenciana, Spain; Göran Gustafssons Stiftelse, Sweden; The Royal Society and Leverhulme Trust, United Kingdom.

Appendix

Figure 11 illustrates the fractions of selected events in the two SRs for the different scattering processes based on the post-fit event yields reported in Table 6.

Figure 11: Pie chart of the composition of (a) the SR plus and (b) the SR minus in terms of the different scattering processes. The fractions are based on the post-fit event yields.

The rate of the multijet background is determined by including CRs enriched in this background in the maximum-likelihood fit. Figure 12 shows the post-fit distributions of the variable $\Delta\phi(\vec{p}_T^{\text{miss}}, \mu)$ in the CR μ -plus and CR μ -minus.

Figure 13 compares NNLO predictions obtained with different PDF sets with the measured values of $\sigma(tq)$ and $\sigma(\bar{t}q)$. The PDF sets used are ABMP [90], ATLAS [91], CTEQ [92], MSHT [93], NNPDF [36, 94], and PDF4LHC [45]. All predictions agree with the measurements within the uncertainties.

A 95% CL interval is determined for the EFT coefficient $C_{Qq}^{3,1}/\Lambda^2$ by scanning the likelihood function relative to this parameter. Figure 14 shows the difference between the natural logarithm of the likelihood function relative to its minimum as a function of $C_{Qq}^{3,1}/\Lambda^2$.

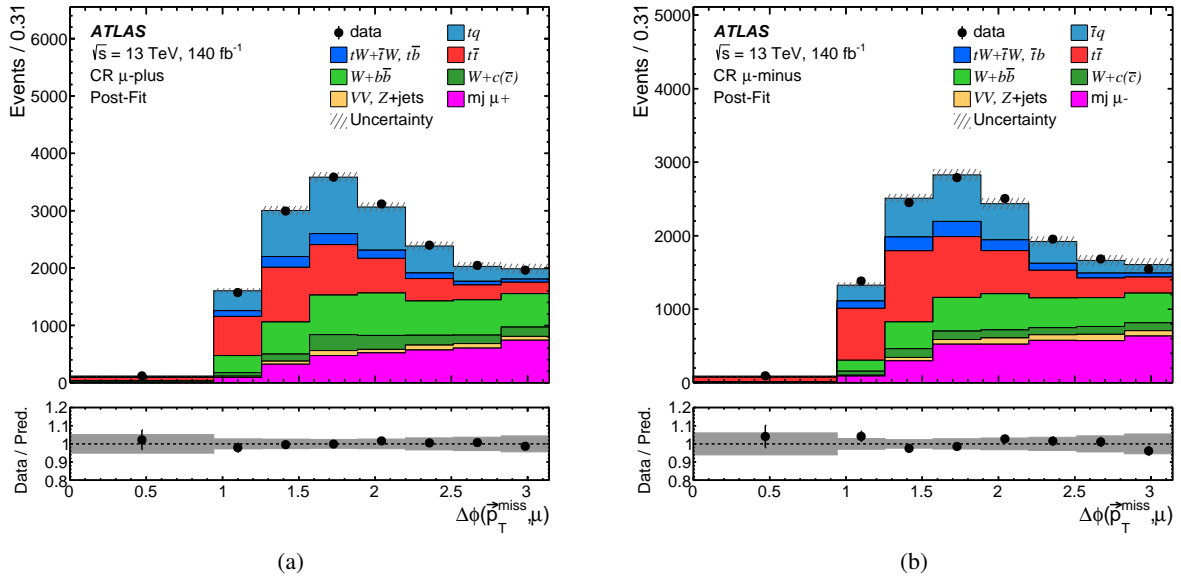

Figure 12: Distributions of the variable $\Delta\phi(\vec{p}_T^{\text{miss}}, \mu)$ in (a) the CR μ -plus and (b) the CR μ -minus after the maximum-likelihood fit is performed (post-fit). In these distributions, the signal contribution is shown stacked on top of contributions from all contributing background processes. All uncertainties considered in the analysis are included in the hatched uncertainty band. The correlations induced by the fit are taken into account. The lower panel shows the ratio of data and the prediction; in this panel, the uncertainty is displayed as a grey band.

Figure 13: Comparison of NNLO predictions based on several different PDF sets with the measured values (dots) of (a) $\sigma(tq)$ and (b) $\sigma(\bar{t}q)$. The yellow band represents the statistical uncertainty and the green band the total uncertainty. The uncertainties in the theoretical predictions include PDF, scale and α_s uncertainties.

Figure 14: Likelihood scan of the EFT coefficient $C_{Qq}^{3,1}/\Lambda^2$.

- ¹⁶⁴Department of Physics, University of British Columbia, Vancouver BC; Canada.
- ¹⁶⁵Department of Physics and Astronomy, University of Victoria, Victoria BC; Canada.
- ¹⁶⁶Fakultät für Physik und Astronomie, Julius-Maximilians-Universität Würzburg, Würzburg; Germany.
- ¹⁶⁷Department of Physics, University of Warwick, Coventry; United Kingdom.
- ¹⁶⁸Waseda University, Tokyo; Japan.
- ¹⁶⁹Department of Particle Physics and Astrophysics, Weizmann Institute of Science, Rehovot; Israel.
- ¹⁷⁰Department of Physics, University of Wisconsin, Madison WI; United States of America.
- ¹⁷¹Fakultät für Mathematik und Naturwissenschaften, Fachgruppe Physik, Bergische Universität Wuppertal, Wuppertal; Germany.
- ¹⁷²Department of Physics, Yale University, New Haven CT; United States of America.
- ^a Also Affiliated with an institute covered by a cooperation agreement with CERN.
- ^b Also at An-Najah National University, Nablus; Palestine.
- ^c Also at Borough of Manhattan Community College, City University of New York, New York NY; United States of America.
- ^d Also at Center for High Energy Physics, Peking University; China.
- ^e Also at Center for Interdisciplinary Research and Innovation (CIRI-AUTH), Thessaloniki; Greece.
- ^f Also at Centro Studi e Ricerche Enrico Fermi; Italy.
- ^g Also at CERN, Geneva; Switzerland.
- ^h Also at Département de Physique Nucléaire et Corpusculaire, Université de Genève, Genève; Switzerland.
- ⁱ Also at Departament de Física de la Universitat Autònoma de Barcelona, Barcelona; Spain.
- ^j Also at Department of Financial and Management Engineering, University of the Aegean, Chios; Greece.

- k* Also at Department of Physics and Astronomy, Michigan State University, East Lansing MI; United States of America.
- l* Also at Department of Physics, Ben Gurion University of the Negev, Beer Sheva; Israel.
- m* Also at Department of Physics, California State University, Sacramento; United States of America.
- n* Also at Department of Physics, King's College London, London; United Kingdom.
- o* Also at Department of Physics, Stanford University, Stanford CA; United States of America.
- p* Also at Department of Physics, University of Fribourg, Fribourg; Switzerland.
- q* Also at Department of Physics, University of Thessaly; Greece.
- r* Also at Department of Physics, Westmont College, Santa Barbara; United States of America.
- s* Also at Hellenic Open University, Patras; Greece.
- t* Also at Institutio Catalana de Recerca i Estudis Avancats, ICREA, Barcelona; Spain.
- u* Also at Institut für Experimentalphysik, Universität Hamburg, Hamburg; Germany.
- v* Also at Institute for Nuclear Research and Nuclear Energy (INRNE) of the Bulgarian Academy of Sciences, Sofia; Bulgaria.
- w* Also at Institute of Applied Physics, Mohammed VI Polytechnic University, Ben Guerir; Morocco.
- x* Also at Institute of Particle Physics (IPP); Canada.
- y* Also at Institute of Physics and Technology, Mongolian Academy of Sciences, Ulaanbaatar; Mongolia.
- z* Also at Institute of Physics, Azerbaijan Academy of Sciences, Baku; Azerbaijan.
- aa* Also at Institute of Theoretical Physics, Ilia State University, Tbilisi; Georgia.
- ab* Also at L2IT, Université de Toulouse, CNRS/IN2P3, UPS, Toulouse; France.
- ac* Also at Lawrence Livermore National Laboratory, Livermore; United States of America.
- ad* Also at National Institute of Physics, University of the Philippines Diliman (Philippines); Philippines.
- ae* Also at Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo; Japan.
- af* Also at Technical University of Munich, Munich; Germany.
- ag* Also at The Collaborative Innovation Center of Quantum Matter (CICQM), Beijing; China.
- ah* Also at TRIUMF, Vancouver BC; Canada.
- ai* Also at Università di Napoli Parthenope, Napoli; Italy.
- aj* Also at University of Colorado Boulder, Department of Physics, Colorado; United States of America.
- ak* Also at Washington College, Chestertown, MD; United States of America.
- al* Also at Yeditepe University, Physics Department, Istanbul; Türkiye.
