Searches for violation of Lorentz invariance in $t\bar{t}$ production using dilepton events in proton-proton collisions at $\sqrt{s} = 13$ TeV

The CMS Collaboration^{*}

Abstract

A search for violation of Lorentz invariance in the production of top quark pairs ($t\bar{t}$) is presented. The measured normalized differential $t\bar{t}$ production cross section, as function of the sidereal time, is examined for potential modulations induced by Lorentz-invariance breaking operators in an effective field theory extension of the standard model (SM). The cross section is measured from collision events collected by the CMS detector at a center-of-mass-energy of 13 TeV, corresponding to an integrated luminosity of 77.8 fb^{-1} , and containing one electron and one muon. The results are found to be compatible with zero, in agreement with the SM, and are used to bound the Lorentz-violating couplings to be in ranges of $1\text{--}8 \times 10^{-3}$ at 68% confidence level. This is the first precision test of the isotropy in special relativity with top quarks at the LHC, restricting further the bounds on such couplings by up two orders of magnitude with respect to previous searches conducted at the Tevatron.

Submitted to Physics Letters B

1 Introduction

Lorentz invariance is a key ingredient of the relativistic description of our world, on the scale of elementary particles as well as on large scales in the Universe. The standard model (SM) of particle physics is a relativistic quantum field theory, and as such it must contain a Lorentz-invariant action. General relativity preserves Lorentz invariance locally. The Lorentz group contains rotations and boosts in Minkowski spacetime. Models of quantum gravity, e.g., string theory [1] and quantum loop gravity [2], can, however, predict breaking of Lorentz invariance at a high mass scale. A quantum theory including gravity may be governed by an energy scale lower than the Planck mass, possibly at the TeV scale. Thus, induced deviations from Lorentz invariance may be measurable at the LHC.

The standard model extension (SME) [3, 4] is an effective field theory in which all operators violating Lorentz invariance are added to the SM Lagrangian. Its Wilson coefficients, controlling the size of Lorentz invariance breaking, are different for each particle. While coefficients related to photons, neutrons, protons, and neutrinos have been measured precisely [5], the quark sector remains constrained at a relatively lower precision. The ZEUS Collaboration at the DESY HERA recently searched for violation of Lorentz invariance arising from light quarks in deep inelastic scattering data [6]. Searches for Lorentz invariance violation were performed in neutral meson mixing at KLOE [7], KTeV [8], FOCUS [9], BaBar [10], D0 [11], and LHCb [12]. Violation of Lorentz invariance was searched for with top quark pairs ($t\bar{t}$) by the D0 experiment [13] at the Fermilab Tevatron, showing compatibility with Lorentz invariance with an absolute uncertainty of about 10% on the tested SME coefficients. The proton-proton (pp) collisions at the CERN LHC at $\sqrt{s} = 13$ TeV produce $t\bar{t}$ events with a cross section approximately 100 times higher than that of the Tevatron. Studies showed that the measurements at the LHC have a large potential to improve existing bounds on the SME coefficients [14].

In this Letter, the first search for Lorentz invariance violation with top quarks at the LHC is presented, within the context of the SME. Signatures for violation of Lorentz invariance involving top quarks are parameterized with the SME Lagrangian [15]:

$$\mathcal{L}_{\text{SME}} = \frac{1}{2} i\bar{\psi} (\gamma^\nu + c^{\mu\nu} \gamma_\mu + d^{\mu\nu} \gamma_5 \gamma_\mu) \overleftrightarrow{\partial}_\nu \psi - m_t \bar{\psi} \psi, \quad (1)$$

where ψ and $\bar{\psi}$ are the Dirac fields for top quarks and antiquarks, m_t is the top quark mass, and $c^{\mu\nu}$ and $d^{\mu\nu}$ (μ or $\nu = T, X, Y, Z$, the space-time indices in the sun-centered frame (SCF) [5] defined below, to be distinguished from the space-time indices of the CMS frame) are the unitless SME Wilson coefficients. Unlike the SM fields, $c^{\mu\nu}$ and $d^{\mu\nu}$ are not modified under Lorentz transformations: they are constant 4×4 matrices, thereby breaking Lorentz invariance of the Lagrangian. They indicate a preferential direction in spacetime as seen by top quarks, violating the isotropy of special relativity. Boosts associated with the Earth's rotation and with the revolution around the sun are negligible relative to top quark boosts. Lorentz invariance is preserved when $c^{\mu\nu}$ and $d^{\mu\nu}$ are zero.

Choosing a reference frame is needed to report measurements of Lorentz-violating coefficients, in analogy, for instance, with the measurement of particle energies, which are not invariant under Lorentz transformation. By convention, results are reported in the SCF, with its origin at the center of the sun; the Z axis pointing north, parallel to the Earth's rotation axis; the X axis pointing to the intersection of the ecliptic and celestial equator on January 1st, 2000 (J2000); and the Y axis completing the direct basis. The SCF can be considered as inertial in the lifetime of a physics experiment. The relevant measure of time in this reference frame is called sidereal time. While one rotation period of the Earth is equal to approximately 23 h 56 min UTC (i.e., Universal Time Coordinated, where UTC seconds are defined from Cesium atomic

hyperfine transitions), one rotation period is defined as being equal to 24 sidereal hours. The CMS detector moves around the Earth’s rotation axis during a sidereal day, and so does the beam line direction at the interaction point, or the average direction of top quarks produced in the collisions. As a consequence, top quark couplings $c^{\mu\nu}$ and $d^{\mu\nu}$ depend on time, resulting in cross sections for top quark production modulating with sidereal time. Searching for such signatures is the goal of this Letter.

We report a search for violation of Lorentz invariance in $\text{pp} \rightarrow t\bar{t}$ production with the CMS experiment at $\sqrt{s} = 13$ TeV, using events with one muon and one electron of opposite charge in the final state, stemming from the decay $t\bar{t} \rightarrow b\bar{b}e\nu_e\mu\nu_\mu$ (where the particle or antiparticle nature of the leptons is implied). The $e\mu$ channel provides a high purity sample of $t\bar{t}$ events owing to the negligible contribution from $Z+\text{jets}$ processes. A data sample recorded in 2016–2017 with the CMS experiment and corresponding to an integrated luminosity of 77.8 fb^{-1} is analyzed. Events are categorized based on the number of jets identified as originating from b quarks (b jets) to improve the separation between the $t\bar{t}$ signal and the background processes. The normalized $t\bar{t}$ cross section is measured differentially as a function of the sidereal time, in bins of hours within the sidereal day, by performing a profile maximum likelihood fit to the event yields in the b jet multiplicity. The measurement is used to constrain, for the first time at the LHC, the Lorentz-violating coefficients $c^{\mu\nu}$ and $d^{\mu\nu}$ impacting top quarks. Tabulated results are provided in the HEPData record for this analysis [16].

2 Event reconstruction with the CMS detector

The CMS apparatus [17–19] is a multipurpose, nearly hermetic detector, designed to trigger on [20, 21] and identify electrons, muons, photons, and hadrons [22–24]. A global “particle-flow” (PF) algorithm [25] aims to reconstruct all individual particles in an event, combining information provided by the all-silicon inner tracker and by the crystal electromagnetic (ECAL) and brass-scintillator hadron (HCAL) calorimeters, operating inside a 3.8 T superconducting solenoid, with data from the gas-ionization muon detectors embedded in the flux-return yoke outside the solenoid. The reconstructed particles are used to build τ leptons, jets, and missing transverse momentum [26–28]. A more detailed description of the CMS detector, together with a definition of the coordinate system used and the relevant kinematic variables, can be found in Refs. [17–19].

Events of interest are selected using a two-tiered trigger system. The first level (L1), composed of custom hardware processors, uses information from the calorimeters and muon detectors to select events at a rate of around 100 kHz within a fixed latency of about $4 \mu\text{s}$ [20]. During the 2016–2017 data taking, a gradual shift in the timing of the inputs of the ECAL L1 trigger in the region at $|\eta| > 2.0$, where η is the pseudorapidity, caused a specific trigger inefficiency. Correction factors, which are small, were computed from data and applied to the simulation. The second level, known as the high-level trigger (HLT), consists of a farm of processors running a version of the full event reconstruction software optimized for fast processing, and reduces the event rate to around 1 kHz before data storage [21]. Events are selected at the HLT by requiring the presence of one or two leptons, with transverse momentum (p_T) thresholds as follows: one electron with $p_T > 12 \text{ GeV}$ and one muon with $p_T > 23 \text{ GeV}$; one electron with $p_T > 23 \text{ GeV}$ and one muon with $p_T > 8 \text{ GeV}$; one electron with $p_T > 27$ (35) GeV in 2016 (2017); or one muon with $p_T > 24$ (27) GeV in 2016 (2017).

The electron momentum is estimated by combining the energy measurement in the ECAL with the momentum measurement in the tracker. Electron candidates are required to satisfy $p_T > 25$

and 20 GeV for the highest p_T (leading) and second-highest p_T (subleading) lepton. Furthermore, electrons must have $|\eta| < 2.4$, and their energy deposit in the ECAL must lie outside of the transition region between the barrel and endcap sections ($1.44 < |\eta| < 1.56$). Electron candidates must satisfy tight identification criteria and are required to be isolated in the detector to reject jets misidentified as electrons. Identification criteria comprise selections on a shower shape variable in the ECAL, on the matching of the track with the ECAL energy deposit, on the ratio of HCAL over ECAL energy deposits around the candidate, the hits in the inner tracker, and on criteria to reject electrons arising from photon conversions [22]. An isolation variable is computed with the PF algorithm as the scalar p_T sum of photons, charged and neutral hadrons in a cone around the electron direction. The cone is defined by $\Delta R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} < 0.3$, where $\Delta\eta$ and $\Delta\phi$ are the η and azimuthal angle differences between the PF particles and the electron, respectively. Contributions to the isolation sum from other inelastic pp interactions in the same or nearby bunch crossing (pileup) are corrected using the FASTJET estimator [29]. The relative isolation, calculated as the isolation sum divided by the electron p_T , is used. Differences in reconstruction and identification efficiencies between data and simulation are corrected using $Z \rightarrow e^+e^-$ events with a “tag-and-probe” method [30].

Muons are measured in the range $|\eta| < 2.4$, with detection planes made using three technologies: drift tubes, cathode strip chambers, and resistive-plate chambers. Muon candidates are reconstructed with the PF algorithm. They are required to satisfy $p_T > 25$ (20) GeV for the leading (subleading) lepton. Muon candidates are required to satisfy tight identification and isolation criteria, to suppress contributions from jets misidentified as muons. Identification criteria include selections on the number of matched muon detector planes, hits in the pixel and tracker, the χ^2 of the trajectory fit including tracking layers and muon detector planes, and the transverse impact parameter of the track [23]. A relative isolation variable is calculated with the PF algorithm similar to electrons but with a cone size $\Delta R < 0.4$. Differences in identification and isolation efficiencies between data and simulation are corrected using $Z \rightarrow \mu^+\mu^-$ events with the tag-and-probe method.

Jets are reconstructed from PF candidates, using the anti- k_T algorithm with a distance parameter of 0.4 [29, 31]. Jet momentum is determined as the vectorial sum of all particle momenta in the jet, and is found from simulation to be, on average, within 5–10% of the true momentum over the entire p_T spectrum and detector acceptance. To mitigate pileup contributions, tracks identified to be originating from pileup vertices are discarded, and an offset correction is applied to correct for the remaining contributions. Jet energy corrections are derived from simulation studies so that the average measured energy of jets becomes identical to that of particle level jets. In situ measurements of the momentum balance in dijet, photon+jet, Z+jet, and multijet events are used to determine any residual differences between the jet energy scale in data and simulation, and appropriate corrections are made [27]. Additional selection criteria are applied to each jet to remove jets potentially dominated by instrumental effects or reconstruction failures. Jets are selected if they satisfy $p_T > 30$ GeV and $|\eta| < 2.4$. Jets are not considered if their distance ΔR from selected leptons is less than 0.4.

For the identification of b jets, a loose selection on the score of the DEEPCSV algorithm, a deep-learning discriminant using secondary vertex and lifetime information [32, 33], is used. The identification efficiency of b quark jets is about 84% with a probability of misidentifying light-quark and gluon jets of 10%, estimated for b jet candidates with $p_T > 20$ GeV in simulated $t\bar{t}$ events. Corrections for the difference in identification efficiency of b jets and light jets between data and simulation are computed as a function of the jet p_T and η and applied to all jets in the event.

3 Simulation samples

Monte Carlo (MC) samples for $t\bar{t}$ production are generated at next-to-leading order (NLO) in perturbative quantum chromodynamics (pQCD) with the POWHEG v2 [34] generator, interfaced with PYTHIA 8 [35] for simulating parton shower, hadronization, and the underlying event. Revision 3453 is used for all the MC samples generated with POWHEG, while all of the simulation samples use PYTHIA 8.226 (8.230) in 2016 (2017). The $t\bar{t}$ cross section is computed with the TOP++ v2.0 program [36] at next-to-NLO (NNLO) and next-to-next-to-leading logarithmic accuracy. It has been observed that the top quark p_T spectrum in data is softer than the spectrum predicted in simulation [37–39]. Simulated events for $t\bar{t}$ production are therefore corrected for the ratio of unfolded $t\bar{t}$ data over POWHEG predictions as a function of the top quark and antiquark p_T at parton level.

Since this analysis targets the $t\bar{t}$ final state with two charged leptons of different flavors and at least one b jet, single top quark production in association with a W boson (tW) constitutes the main background, with one lepton each arising from the top quark and associated W boson decay. Simulated samples of tW and t -channel single top quark production are generated at NLO in pQCD with POWHEG v2. The cross section for the tW channel is computed at approximate NNLO [40]. Other backgrounds involving top quarks include s -channel single top quark production and $t\bar{t}$ production in association with a vector boson ($t\bar{t}W$ and $t\bar{t}Z$, grouped together and denoted as $t\bar{t}V$). Simulated samples for these processes are generated at NLO with MADGRAPH5_aMC@NLO [41] (version 2.4.2 in 2016 and 2.6.0 in 2017 in all samples using MADGRAPH5_aMC@NLO) with additional jets using FxFx merging [42]. The cross sections for single top t - and s -channel production are computed with the HATHOR v2.1 program [43] at NLO accuracy. The cross sections for $t\bar{t}W$ and $t\bar{t}Z$ processes are computed at NLO with MADGRAPH5_aMC@NLO generation [41]. In the simulated samples, a fixed value of $m_t = 172.5$ GeV is used. Diboson production samples (WW, WZ, ZZ) are generated with PYTHIA 8. The cross section for the WW process is computed at NNLO [44], while the WZ and ZZ cross sections are computed at NLO with MCFM [45] version 6.6. The W+jets and Z+jets processes (grouped together and denoted as V+jets) are generated using MADGRAPH5_aMC@NLO, at leading order (LO) matched with additional jets using the MLM algorithm [46] or at NLO with additional jets using FxFx merging. Cross sections for Z+jets and W+jets processes are computed with FEWZ [47] version 3.1 at NNLO.

The underlying event is modeled with the CP5 tune [48] for all of the simulated samples with 2017 detector conditions, and for the simulation of $t\bar{t}$ and tW processes with 2016 detector conditions. The samples simulated with 2016 detector conditions are using the CUETP8M1 tune [49] for all other background processes. The parton distribution functions (PDFs) used are the NNPDF3.1 NNLO set [50] for samples using the CP5 tune, and NNPDF3.0 NNLO for samples using the CUETP8M1 tune.

The CMS detector response is simulated with the GEANT4 toolkit [51]. Data and simulation events are passed through the same CMS software reconstruction chain. Pileup interactions generated with PYTHIA 8 are added to the simulations, and the distribution in the number of pileup interactions is corrected for each MC sample to reproduce the numbers observed in data.

4 Event selection

Events with exactly one electron and one muon are selected. Events are rejected if there are additional electrons or muons with $p_T > 10$ GeV and identified with looser criteria. In addition, the invariant mass of the dilepton pair is required to satisfy $m_{e\mu} > 20$ GeV, to reduce contribu-

tions from low-mass resonances and Drell–Yan τ pair production. Events with at least two jets are selected, among which at least one must be identified as a b jet.

The distribution in the number of b jets is compared between data and simulation in Fig. 1. The MC simulation of signal and backgrounds provides a description of the data distribution in the number of b jets agreeing within uncertainties. Inclusively, the event yields are 7.1% (2016) and 2.7% (2017) lower in data than in simulation, as shown in Table 1.

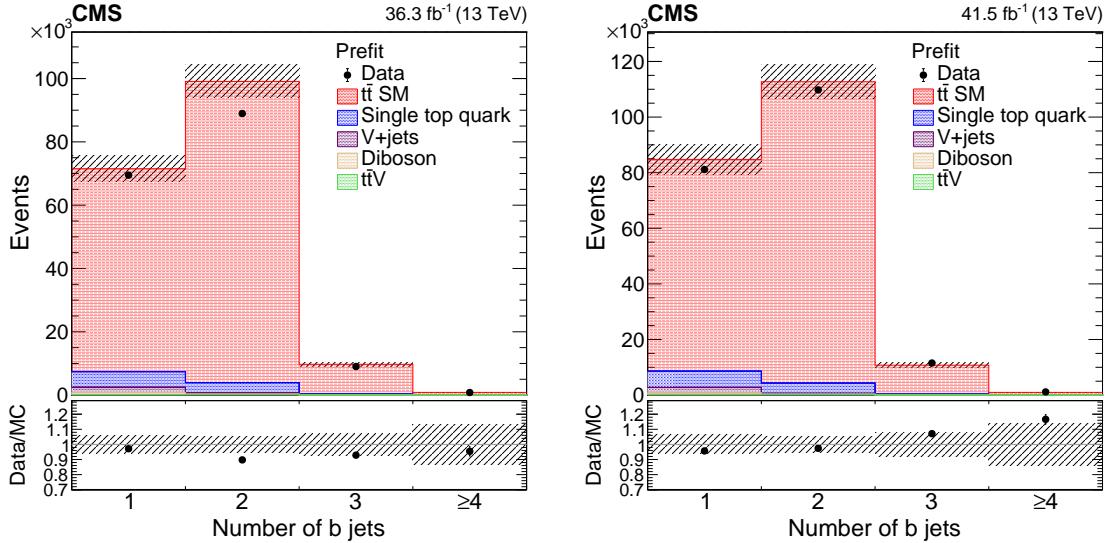

Figure 1: Distribution of the number of b jets in data and simulation, after the event selection, (left) in 2016 and (right) in 2017 samples. The hatched band includes statistical and systematic uncertainties in the predictions. The vertical bars associated with the data points represent their statistical uncertainty. The lower panels show the ratio of the observed data event yields to those expected from simulation.

Table 1: Event yields in data and MC simulation in 2016–2017, after selection. The uncertainties include statistical and systematic sources, with correlations.

| Process | 2016 | 2017 |
|------------------|---------------------|---------------------|
| $t\bar{t}$ SM | $169\,500 \pm 6100$ | $196\,000 \pm 7300$ |
| $t\bar{t}V$ | 460 ± 60 | 540 ± 70 |
| Single top quark | $8\,500 \pm 1600$ | $9\,900 \pm 2000$ |
| Diboson | 700 ± 150 | 650 ± 130 |
| V+jets | $2\,100 \pm 500$ | $2\,300 \pm 600$ |
| Total background | $11\,700 \pm 1700$ | $13\,404 \pm 2000$ |
| Total MC | $181\,000 \pm 6700$ | $209\,000 \pm 8100$ |
| Data | 168 282 | 203 584 |

The distribution in the number of b jets is used as discriminant for the signal extraction in Sections 6 and 7, since it provides clear separation between the $t\bar{t}$ signal and the single top quark background, with the latter having only one top quark decaying to bW , compared to two for the signal process.

5 Treatment of the sidereal time dependence in corrections and systematic uncertainties

The CMS data is recorded in UNIX time, whose seconds having the same duration as UTC seconds. The UNIX timestamp of the events is translated to sidereal time with the following formula:

$$\Omega_{\text{sidereal}} t_{\text{sidereal}} = \Omega_{\text{UTC}} t_{\text{UNIX}} + \phi_{\text{UNIX}} + \phi_{\text{longitude}}, \quad (2)$$

where $\Omega_{\text{sidereal}} = 2\pi/86\,400 \text{ s}^{-1}$ (sidereal) is the angular velocity of Earth's rotation around its axis in sidereal time, $\Omega_{\text{UTC}} = 2\pi/86\,164 \text{ s}^{-1}$ (UTC) is the angular velocity of Earth's rotation around its axis in UTC time, and t_{UNIX} represents the event timestamp recorded at CMS in UNIX time since January 1st, 1970 (UNIX epoch). The azimuthal angle ϕ_{UNIX} encodes the phase between the UNIX epoch and J2000, which is the origin of the sidereal time count, and $\phi_{\text{longitude}}$ is the effective longitude, defined as the angle between the LHC beam at the CMS interaction point and the Greenwich meridian in rad.

Data events are classified in 24 bins, corresponding to the 24 sidereal hours within a sidereal day. In the MC simulation, event timestamps are not included; instead, a time-integrated distribution is built and scaled by 1/24 to define the expected prediction in each sidereal hour bin. This prediction and its associated systematic uncertainties need to be corrected for effects that would potentially depend on sidereal time. According to the definition of sidereal time, events recorded every day within a year at the same UTC time would populate the bins uniformly.

The instantaneous luminosity delivered by the LHC, and thus the distribution of the number of pileup interactions per bunch crossing evolves over the year. To allow for differences in the instantaneous luminosity profile between sidereal time bins, the distribution in the number of pileup interactions in simulation is corrected to agree with data, as a function of the sidereal hour within a day. The associated uncertainty arises from our imprecise knowledge of the total inelastic cross section, and is computed by varying this cross section by its uncertainty (4.6%) simultaneously in each sidereal time bin.

The recorded integrated luminosity per sidereal time bin varies by up to 25% within a sidereal day, reflecting the time structure of the LHC operations. The simulated events are corrected to match the integrated luminosity in each sidereal time bin. The uncertainty in the integrated luminosity measurement originates from various sources in the normalization (related to the van der Meer calibration procedure [52–54]) and the integration of the luminosity measurement performed with several independent subdetectors (referred to as luminometers). The normalization, as well as detector-specific normalization uncertainties are not expected to depend on sidereal time and are treated as uniform. The uncertainties in the time stability and the linearity with respect to pileup, however, are estimated from cross-detector comparisons, i.e., by comparing the agreement between different luminometers, and their dependence on sidereal time can be evaluated explicitly. In 2016, the three main luminometers and methods used for the luminosity measurement [54] are the cluster counting in the pixel tracker, an occupancy-based algorithm using the HCAL measurement, and an LHC radiation monitoring system. In 2017, the three main luminometers and methods [55] are a method based on the sum of transverse energy in HCAL towers, pixel detector cluster counting, and the pixel luminosity telescope [56]. The main luminometers used for the luminosity measurement are not the same at all times, since the individual luminosity detectors can be affected by various operational issues. A small dependence of the stability and linearity estimates on the sidereal time is found:

- The cross-detector stability is evaluated separately in each sidereal time bin by taking the maximum difference among the integrated luminosities estimated with

the three main luminometers. The relative uncertainty is found to be 0.1–0.3 (0.2–0.4)% in 2016 (2017), consistent with the time-integrated uncertainties evaluated in Refs. [54, 55].

- The time dependence of the linearity of the luminometer response is evaluated in each sidereal time bin by computing the average single-bunch instantaneous luminosity (SBIL), as measured with the different luminometers, and weighting the largest difference with the corresponding cross-detector linearity slopes from Refs. [54, 55]. The slopes are obtained from a fit of the ratios of SBIL estimates for pairs of luminometers, as a function of SBIL. The relative uncertainty is found to be at most 0.3 (0.5)% in 2016 (2017), depending on the sidereal time bin. The 2016 result is in agreement with the time-integrated uncertainty evaluated in Ref. [54], but the 2017 result is smaller than the uncertainty from Ref. [55] due to the usage of the less-conservative approach from Ref. [54] for the evaluation of the 2017 luminosity.

Cross-detector stability and linearity uncertainties are included in the analysis with explicit dependence on sidereal time. The LHC-related uncertainties (normalization uncertainties related to the van der Meer scan procedure) are evaluated to be 0.6 (0.9)% in 2016 (2017), and other luminosity uncertainties related to the detector are evaluated to be 0.9 (1.4)% in 2016 (2017).

The trigger efficiency, potentially changing slightly over the course of the year with the instantaneous luminosity profile, might also depend on sidereal time. Simulated events are therefore corrected for the difference in the trigger efficiency between data and simulation as a function of sidereal time. The trigger efficiencies are measured with the same method as in Ref. [57], using events triggered with requirements on the missing transverse momentum p_T^{miss} , which is the magnitude of the \vec{p}_T^{miss} vector, defined as the projection onto the plane perpendicular to the beam axis of the negative vector sum of the momenta of all PF objects in the event, corrected for pileup effects. Events triggered with p_T^{miss} requirements are correlated at less than 1% with those passing single-lepton and dilepton triggers. Events must satisfy a requirement on reconstructed $p_T^{\text{miss}} > 100 \text{ GeV}$. At least one jet identified as b jet is required. For each sidereal time bin, a statistical uncertainty is computed, and two systematic uncertainties are evaluated by repeating the measurement in subpartitions of the data: an uncertainty for the dependence of the trigger efficiency on the number of jets and on the period of data taking. The ratio of trigger efficiencies in data and simulation is found to be in a range 97–99%, with uncertainties at the level of 1%, depending on the sidereal time bin.

For other experimental corrections and uncertainties, the dependence on sidereal time is unknown. As a consequence, an individual nuisance parameter per sidereal time bin is conservatively attributed to most of the other experimental uncertainties, whose size is evaluated from an estimate not depending on time, allowing the fit to accommodate possible time dependence. These experimental uncertainties include the following sources: ratios of efficiencies between data and simulation for electron and muon reconstruction, identification, and isolation that arise from tag-and-probe measurements with $Z \rightarrow \ell^+\ell^-$ events [22, 23] (where $\ell = e$ or μ); uncertainties associated with the jet energy corrections (including jet energy resolution) [27]; uncertainties arising from the identification of b jets [32]; and uncertainties associated with the gradual shift in the timing of the inputs of the ECAL L1 trigger. All of these uncertainties are treated as impacting the shape of the number of b jets distribution, as well as its normalization, and are treated as uncorrelated across sidereal time. Where relevant, each uncertainty source is split into systematic uncertainties correlated year-to-year, and a year-to-year uncorrelated component essentially of statistical nature. Two additional sources of theoretical origin impact experimental quantities and are treated as correlated as functions of sidereal time and years: the uncertainty in the jet energy scale arising from the parton flavors, obtained by comparing

HERWIG and PYTHIA simulation; and the uncertainty in lepton isolation arising from the phase space extrapolation of efficiencies, from $Z \rightarrow \ell^+ \ell^-$ to $t\bar{t}$ events. The uncertainties inducing the largest impact on the distribution of the number of b jets for the $t\bar{t}$ process are the electron identification (1.2% in 2016 and 2.1% in 2017) and b jet identification uncertainty (2% at low number of jets to 5% at high number of jets).

Contributions from background processes are estimated from simulation. After the selection, the event yield for background processes is about 8% of the total number of expected events (Table 1), dominated by single top quark processes. The normalization of single top quark processes, whose contribution is dominated by the tW process, is assigned an uncertainty of 30%, accounting for the interference with the $t\bar{t}$ process in the selected phase space. Diboson and V+jets processes are attributed an uncertainty of 30% as well estimated for the predictions in the selected phase-space. All these uncertainties are estimated following the prescription from Ref. [58]. An uncertainty of 20% is associated with $t\bar{t}V$ processes [59]. A normalization uncertainty of 4% is assigned to the SM $t\bar{t}$ process [58] in the SME fit (Section 7).

The uncertainty corresponding to the correction of the top quark p_T in the $t\bar{t}$ process is estimated by the difference with respect to not applying the correction (signatures for violation of Lorentz invariance searched for in this Letter cannot induce a modification of the top quark and antiquark p_T , once integrated over time). Other theoretical uncertainties are arising from the top quark mass (obtained by varying m_t by 1 GeV up and down around its nominal value); from the parameter h_{damp} controlling the matching between matrix element and parton shower in the POWHEG generator (varied around its nominal value as $1.379^{+0.926}_{-0.505}$ times m_t); uncertainties associated with the CP5 underlying event tune (estimated during the tuning process [48]); and color reconnection uncertainties in the parton shower. Uncertainties in the parton shower modeling, related to initial- and final-state radiation, are included for $t\bar{t}$ and single top quark processes by varying the renormalization scale for initial- and final-state QCD emission in the parton shower by a factor 2 up and down. Uncertainties arising from our missing knowledge of higher-order corrections in pQCD are included separately for $t\bar{t}$, single top quark, $t\bar{t}V$, and V+jets processes by constructing an envelope of maximum variation computed from renormalization and factorization scale varied by a factor 1/2 to 2, excluding anticorrelated variations. Uncertainties in the PDFs and the strong coupling constant α_S are evaluated with the Hessian set of NNPDF3.1 (102 replicas) and added in quadrature, with a single nuisance parameter for $t\bar{t}$, single top quark, $t\bar{t}V$, and V+jets processes. The h_{damp} , CP5 tune, and color reconnection sources modify the normalization of the distribution in the number of b jets, while all the other theoretical uncertainties modify the shape of the distribution. Theoretical uncertainties related to SM predictions are uniform across sidereal time.

A theoretical uncertainty corresponding to single top quark time modulation in the SME is included in the SME fit (described in Section 7), and treated as correlated across sidereal time.

The same MC samples are used to predict the event yields in each sidereal time bin, separately for 2016 and 2017. Statistical uncertainties in the MC samples are included as log-normal uncertainties independently for each bin of the b jet multiplicity distribution, treated as correlated across sidereal time bins.

The assumed correlations of the uncertainties between years of data taking and sidereal time bins are detailed in Table 2.

Table 2: Summary of the systematic uncertainties and their correlation scheme between 2016 and 2017 data sets, and between sidereal time bins. Sources marked with an asterisk are only included in the SME fits. Sources marked with a dagger are uniform and correlated in sidereal time.

| Systematic uncertainty source | Correlation 2016–2017 | Correlation time bins | Magnitude |
|---|--------------------------|--------------------------|-----------|
| Flat luminosity, year-to-year correlated part | 100% | 100% | 0.6–0.9% |
| Flat luminosity, year-to-year uncorrelated part | 0% | 100% | 0.9–1.4% |

6 Measurement of the normalized $t\bar{t}$ differential cross section with sidereal time

The normalized differential cross section for $t\bar{t}$ production is measured simultaneously in all sidereal time bins. A profiled likelihood template fit of simulation events to the data is employed, based on the LHC test statistic [60–62]. Since the SM predictions for the $t\bar{t}$ cross section are identical in each particle-level bin i , and because unfolding for detector effects is not needed (particle- and reconstructed-level sidereal time are identical), the normalized differential cross section $\sigma_i/\sigma_{\text{avg}}$ in bin i (where σ_{avg} is the averaged cross section over all sidereal time bins) reduces to μ_i/μ_{avg} , where μ_i is the ratio of the observed $t\bar{t}$ yield to the $t\bar{t}$ yield predicted in the SM, and $\mu_{\text{avg}} = \sum_k \mu_k/24$. The fractions $f_i = \mu_i/\mu_{\text{avg}}$ for 23 sidereal time bins are directly fitted as parameters of interest together with μ_{avg} ; the remaining fraction and its uncertainty is computed via error propagation using the covariance matrix of the fit.

In performing the measurement of the $t\bar{t}$ normalized differential cross section as a function of sidereal time, the discriminant observable between $t\bar{t}$ and background processes is built with the distribution in the number of b jets in each sidereal time bin. Uncertainties described in Section 5 are considered either as nuisance parameters with log-normal distribution attributed to the normalization of the distribution in the number of b jets, or as nuisance parameters distorting the shape of the distribution in the number of b jets. Uncertainties follow the correlation scheme highlighted in Table 2: when the dependency with sidereal time is known, the uncertainties are treated as correlated across sidereal time bin (including uniform theory and background normalization uncertainties); and when the dependency is not known, the uncertainties are treated as uncorrelated across sidereal time bin. Prefit and postfit distributions are illustrated in Fig. 2. The predicted distributions of the number of b jets are not the same in each time bin, because corrections for integrated luminosity, pileup, and trigger efficiencies are applied as a function of sidereal time.

The normalized differential cross section is shown in Fig. 3. A goodness-of-fit test including constraints from the nuisance parameters [63] results in a p -value [64] of 0.92 for the adequacy of the MC model to describe data.

Figure 4 shows a breakdown of the uncertainties associated with the measurement of $t\bar{t}$ normalized differential cross section, according to the treatment of their dependences on sidereal time. The measurement is dominated by systematic uncertainties. The experimental uncertainties that are treated as uncorrelated in sidereal time have the largest impact on the normalized differential cross section, and they arise mainly from sources related to electrons, jet energy scale, and b tagging. The uncertainties featuring explicit dependence on sidereal time have an impact that is smaller than the statistical uncertainty, and are dominated by trigger uncertainties. Uncertainties that are uniform in sidereal time (flat luminosity component, background normalization, theory uncertainties) contribute to a lesser extent.

7 Testing Lorentz invariance with the SME

Corrections to the matrix element of $t\bar{t}$ production and decay arising from Lorentz-violating terms in the SME are known at LO in pQCD [15], and are linear in the Wilson coefficients, stemming from the interference between SME and SM predictions. Within the CMS reference frame, the variation of the $t\bar{t}$ cross section with sidereal time t is quantified with the func-

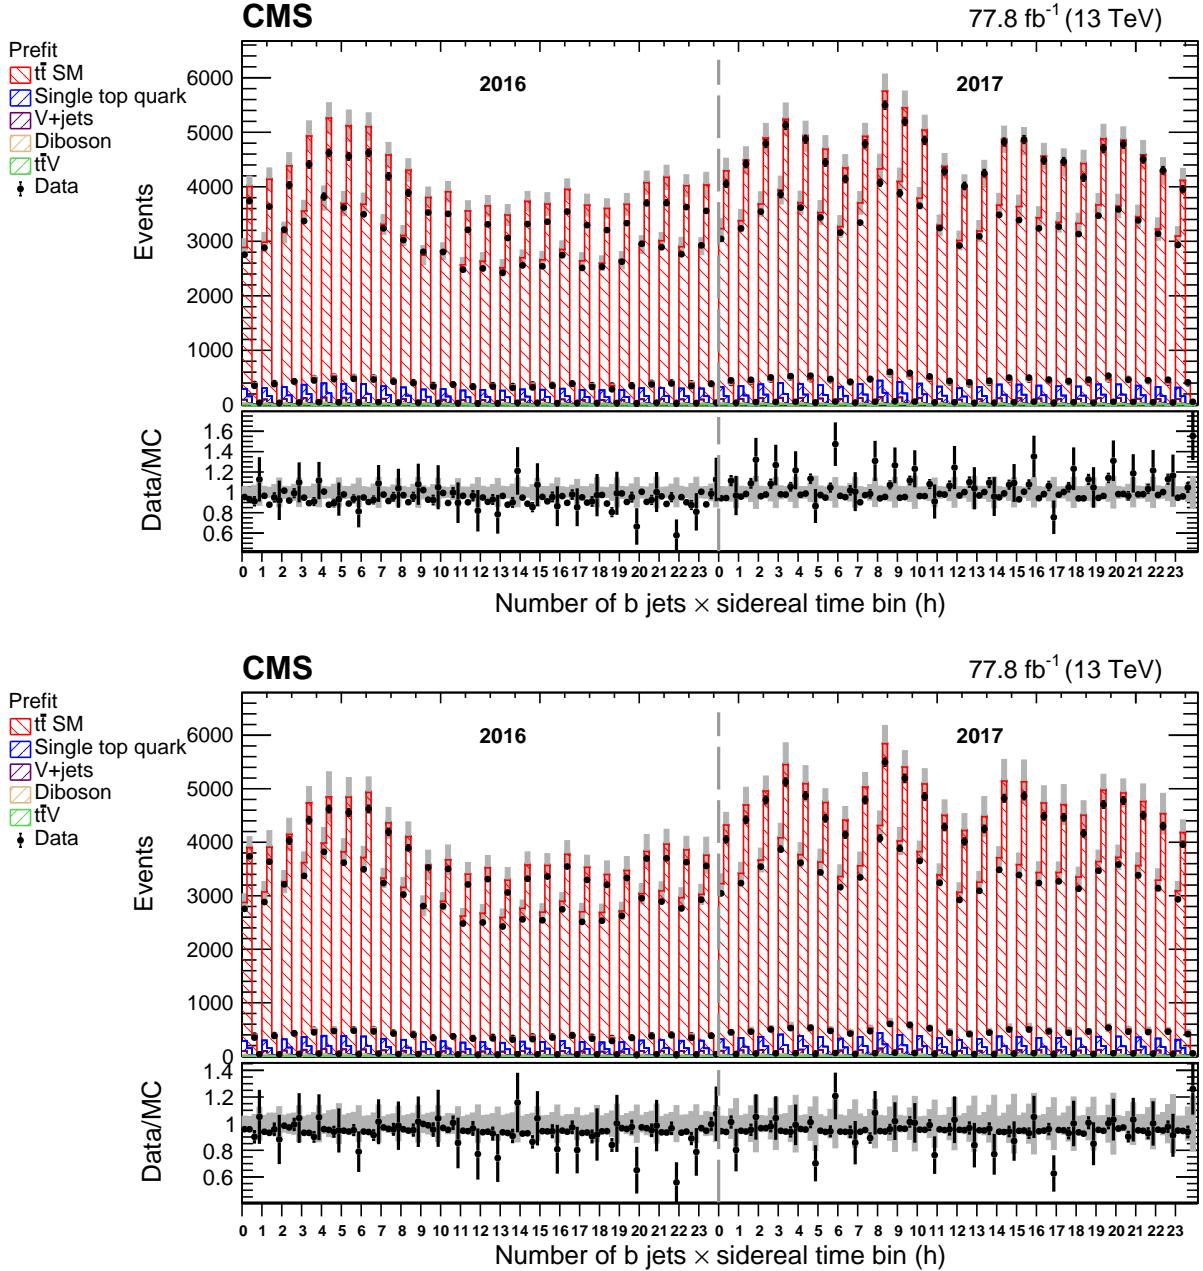

Figure 2: Prefit (upper) and postfit (lower) distributions of the number of b jets in sidereal hour bins, in 2016 and 2017 data. The gray band reflects the statistical and systematic uncertainty predicted in each bin, including correlations across bins. The vertical bars associated with the data points represent their statistical uncertainty. The lower panels show the ratio of the observed data event yields to those expected from simulation.

tion [13] $f(t) = \sigma_{\text{SME}}(t)/\sigma_{\text{SM}} - 1$, where σ_{SME} (σ_{SM}) are the values predicted in the SME (SM):

$$f(t) = (c_{L,\mu\nu} + c_{R,\mu\nu}) R_\alpha^\mu(t) R_\beta^\nu(t) \left(\frac{\delta P}{P} \right)^{\alpha\beta} + c_{L,\mu\nu} R_\alpha^\mu(t) R_\beta^\nu(t) \left(\frac{\delta F}{F} + \frac{\delta \bar{F}}{\bar{F}} \right)^{\alpha\beta}, \quad (3)$$

with $c_{L,\mu\nu} = c^{\mu\nu} + d^{\mu\nu}$ and $c_{R,\mu\nu} = c^{\mu\nu} - d^{\mu\nu}$; where α and β represent summation over space-time indices in the CMS detector frame; P , F , and \bar{F} are the squared LO matrix elements of

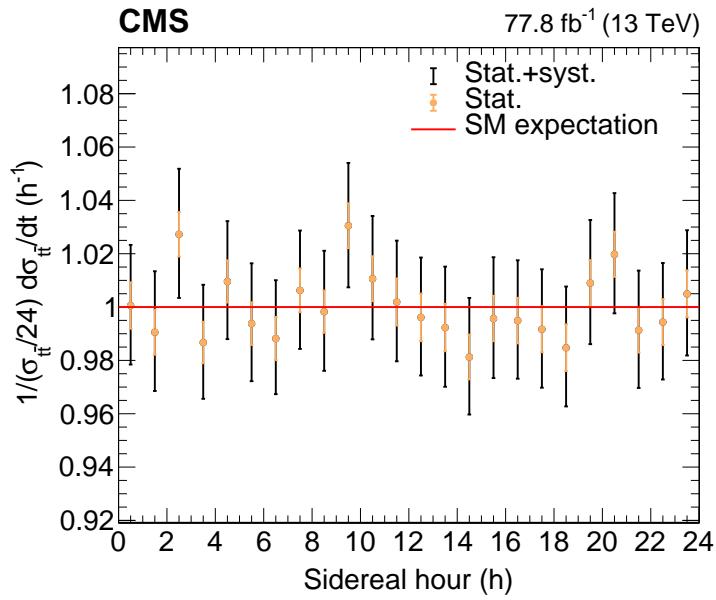

Figure 3: The normalized differential cross section for $t\bar{t}$ as a function of sidereal time, using combined 2016–2017 data. The error bars show statistical, as well as statistical and systematic uncertainties, including correlations across bins.

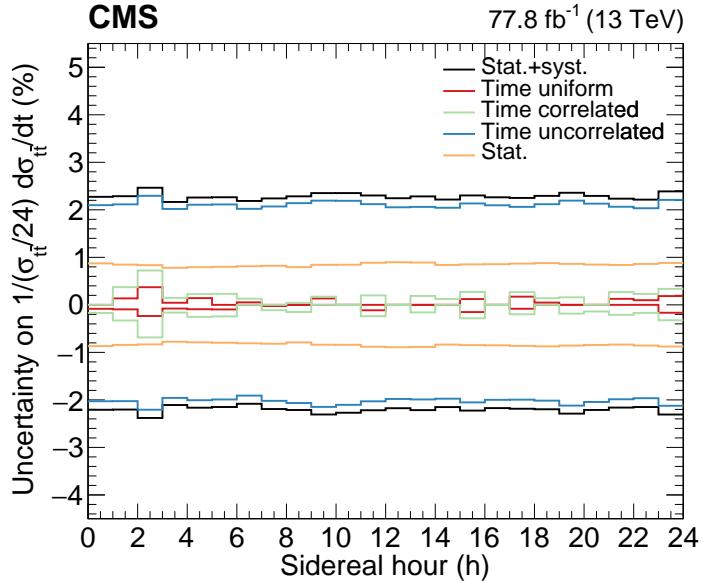

Figure 4: Comparison of systematic and statistical uncertainties, where the former are grouped according to the treatment of time dependence: uniform (flat luminosity component, background normalization, theory), correlated (trigger, luminosity stability and linearity, pileup, and MC statistical uncertainty), or uncorrelated (other experimental uncertainties) across sidereal time bins.

the SM $t\bar{t}$ production (either quark-antiquark annihilation or gluon fusion), and top quark and antiquark decays; and δP , δF , $\delta \bar{F}$ are their corrections predicted in the SME. Rotation matrices $R(t)$ represent transformations of observer coordinates from the SCF to the CMS reference frame, depending on the Earth’s rotation around its axis with angular velocity Ω_{sidereal} . The coordinates of the CMS interaction point are specified [65] by the azimuth on the LHC ring

$(\phi = 101.28^\circ)$, the latitude ($\lambda = 46.31^\circ$ N), and the longitude ($\ell = 6.08^\circ$ E). Furthermore, the LHC plane, and thus the CMS cavern, has an angle of $\gamma = 0.705^\circ$ relative to the surface.

A $t\bar{t}$ production sample, generated with MADGRAPH5_aMC@NLO at LO in pQCD with parton shower, underlying event, and hadronization simulated with PYTHIA 8, followed by full detector simulation, is used to evaluate the signal $f(t)$ functions. The $f(t)$ functions are computed for each number of reconstructed b jets separately for each year and sidereal time bin. Events containing exactly 1, 2, 3, or ≥ 4 b jets at the reconstructed level are used to evaluate the matrix elements P , F , \bar{F} and their SME corrections, using exact LO kinematics before showering.

The SME coefficients are extracted separately in four scenarios, corresponding to $c_{L,\mu\nu}$ (assuming $c_{R,\mu\nu} = 0$), $c_{R,\mu\nu}$ (assuming $c_{L,\mu\nu} = 0$), $c^{\mu\nu}$ (assuming $d^{\mu\nu} = 0$), and $d^{\mu\nu}$ (assuming $c^{\mu\nu} = 0$). Within the chosen basis of Wilson coefficients adopted in the SME, these matrices are defined as symmetric and traceless. Coefficients with indices $\mu\nu = TT$ induce a shift in the $t\bar{t}$ cross section and are not considered. Since the Z-axis is defined as the Earth's rotation axis, and because modulation of the $t\bar{t}$ cross section with sidereal time is induced by rotation around this axis, there is by definition no sensitivity in the coefficients with indices $\mu\nu = ZZ$. For similar reasons, coefficients with indices $\mu\nu = ZT$ are not considered. Coefficients with $\mu\nu = XT$ or YT are found to induce very small SME corrections and are also not considered. Remaining coefficients correspond to the combinations $c_{XX} = -c_{YY}$, $c_{XZ} = c_{ZX}$, $c_{YZ} = c_{ZY}$, and $c_{XY} = c_{YX}$ (and similar expressions for the three other scenarios). A total of 16 sets of coefficients is determined. An illustration of their impact on the $t\bar{t}$ cross section is shown in Fig. 5.

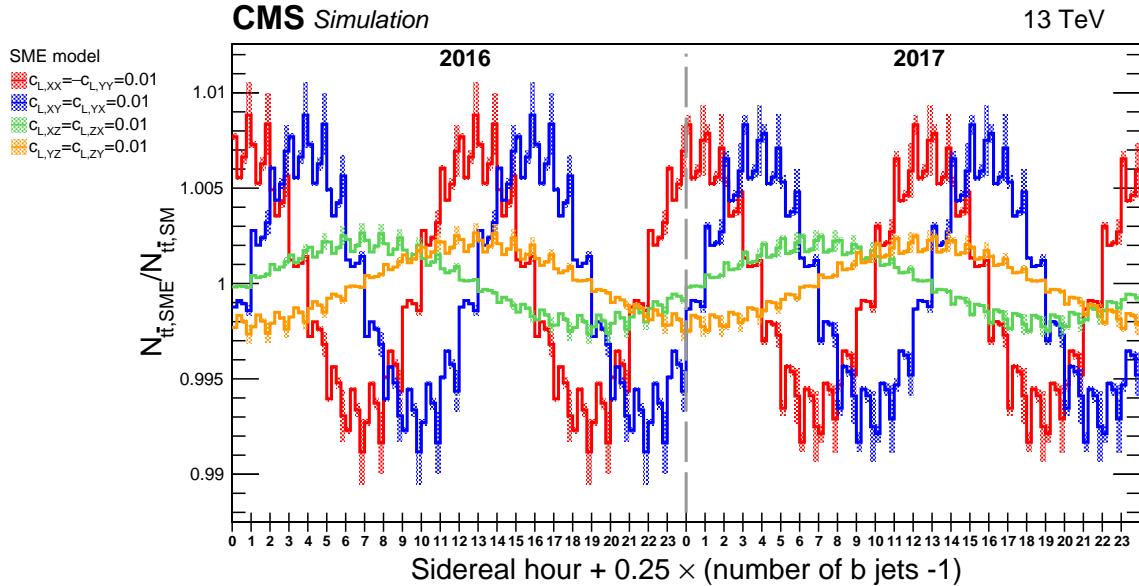

Figure 5: Number of $t\bar{t}$ events reconstructed in the SME hypothesis divided by the number of events in the SM hypothesis, as a function of the number of b jets and sidereal time, for the four directions of the c_L coefficients. The uncertainty band represents the MC statistical uncertainty in the sample used to compute the SME hypothesis. The sinusoidal variation is arising from the $f(t)$ dependence on sidereal time, while smaller structures reflect the number of b jets in each sidereal time bin.

The Lagrangian defined in Eq. (1) impacts all processes involving top quarks, including single top quark and $t\bar{t}V$ processes. The latter processes have a small yield and their variation with sidereal time can be neglected, contrary to the former processes. Expressions for the matrix elements of single top quark production in the SME are not available, to our knowledge.

Among the single top quark processes, tW production has the largest contribution in the selected dileptonic event sample. Therefore, uncertainties corresponding to single top quark time modulation in the SME are attributed to single top quark processes, and computed from matrix elements predicted in the SME for top quark and antiquark decay only, in an MC sample of tW processes generated at LO. These uncertainties correspond to a value of the SME coefficients of $\pm 3 \times 10^{-3}$ in XX and XY directions, and $\pm 10 \times 10^{-3}$ in XZ and YZ directions, at the same order of magnitude as the expected sensitivity in the worst case among c_L , c_R , c , and d sets of coefficients. In the case of $c_{R,\mu\nu}$ coefficients, which do not affect the top quark or antiquark in the decay (as highlighted in Eq. (3)), the uncertainty model for $c_{L,\mu\nu}$ is used. In measuring individually the SME coefficients, the SME uncertainty for single top quark processes in a given direction has been verified to impact only the coefficients related to the same direction, with an uncertainty corresponding to approximately 15% of the total uncertainty on the coefficient.

The discriminant observable used to extract the SME coefficients is the same as in the differential measurement (Section 6), with event corrections and systematic uncertainties described in Section 5. The likelihood fit is performed in two scenarios: 1) independently for each set of coefficients as a single parameter of interest, with all other parameters being set to zero; 2) independently for each set of coefficients as a single parameter of interest, with the parameters corresponding to the three other directions (among XX, XY, XZ, YZ directions) floating in the fit, for the four families of coefficients c_L , c_R , c , and d separately. The measured values of the SME sets of coefficients in the latter scenario is shown in Fig. 6, while Table 3 compares the values for the two scenarios. Scenarios 1 and 2 yield expected uncertainties identical up to the second digit, because the correlation between the four sets of coefficients in a family is found to be 0–4%. A p -value of 0.98 is obtained for the measurements of the coefficients in a given direction while the coefficients corresponding to the three other directions are floating in the

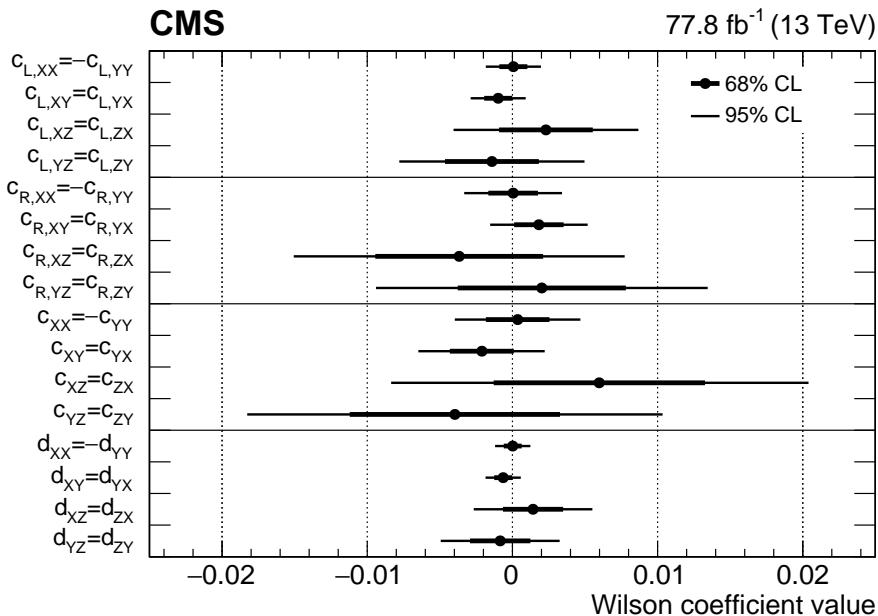

Figure 6: Fitted SME coefficients and their 68 and 95% CL, measured in fits of single coefficients while the coefficients corresponding to the three other directions are left floating, within the c_L , c_R , c , and d families. The error bar includes statistical and systematic uncertainties. Fitting a single coefficient, with the others fixed to the SM value, leads to negligible changes in the results.

Table 3: Expected and observed 68% confidence level interval measured for the SME fits of single coefficients while the others are fixed to their SM value, and while coefficients for the three other directions are floating.

fit. All of the measured values for the SME coefficients are compatible with zero, in agreement with the SM within one standard deviation or less, indicating no sign of deviation from Lorentz invariance. The precision achieved on the values of the coefficients of the c_L and c_R families on the one hand, and on the values of the coefficients of the d family on the other hand, is improved respectively by a factor 20–50 and up to 100 over the previous constraints [13]. The coefficients of the c family are measured for the first time.

The impact of the uncertainties in the SME coefficients is shown in Fig. 7 in the case of the fit of individual sets of coefficients, while the coefficients corresponding to the three other directions are left floating. Systematic uncertainties uncorrelated between sidereal time bins are dominating the precision, at a level of approximately three times higher than the statistical uncertainties. The systematic uncertainties that are nonuniform and correlated across sidereal time impact the precision at about half the impact of the statistical uncertainties. The uncertainties that are uniform in sidereal time have a smaller impact.

8 Summary

A search for violation of Lorentz invariance has been performed using top quark pairs ($t\bar{t}$), requiring the presence of one muon and one electron in the events. Data collected in 2016–2017 with the CMS detector corresponding to an integrated luminosity of 77.8 fb^{-1} are used. A measurement of the $t\bar{t}$ normalized differential cross section as a function of sidereal time is performed. The Lorentz invariance assumption is tested by measuring 16 sets of Wilson coefficients within the standard model extension, an effective field theory predicting a modulation of the $t\bar{t}$ cross section with sidereal time. Measurements of the Lorentz-violating couplings

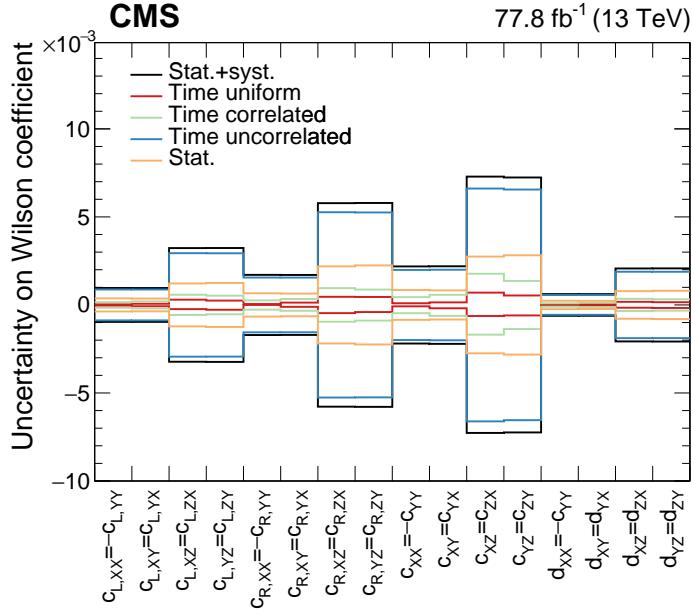

Figure 7: Uncertainty breakdown for SME fits of single coefficients while the coefficients corresponding to the three other directions are left floating, by splitting according to the treatment of time dependence: flat across sidereal time (flat luminosity component, background normalization, theory), correlated in sidereal time bins (trigger, luminosity stability and linearity, pileup, MC statistical uncertainty, single top quark decay in the SME), systematics uncorrelated in sidereal time bins (other experimental uncertainties), and statistical uncertainty.

are found to be compatible with the standard model hypothesis. The precision of the results ranges from less than 1×10^{-3} to 8×10^{-3} for the measured coefficients. This constitutes the most precise test of the isotropy in special relativity using top quarks at a hadron collider.

Acknowledgments

We congratulate our colleagues in the CERN accelerator departments for the excellent performance of the LHC and thank the technical and administrative staffs at CERN and at other CMS institutes for their contributions to the success of the CMS effort. In addition, we gratefully acknowledge the computing centers and personnel of the Worldwide LHC Computing Grid and other centers for delivering so effectively the computing infrastructure essential to our analyses. Finally, we acknowledge the enduring support for the construction and operation of the LHC, the CMS detector, and the supporting computing infrastructure provided by the following funding agencies: SC (Armenia), BMBWF and FWF (Austria); FNRS and FWO (Belgium); CNPq, CAPES, FAPERJ, FAPERGS, and FAPESP (Brazil); MES and BNSF (Bulgaria); CERN; CAS, MoST, and NSFC (China); MINCIENCIAS (Colombia); MSES and CSF (Croatia); RIF (Cyprus); SENESCYT (Ecuador); ERC PRG, RVTT3 and MoER TK202 (Estonia); Academy of Finland, MEC, and HIP (Finland); CEA and CNRS/IN2P3 (France); SRNSF (Georgia); BMBF, DFG, and HGF (Germany); GSRI (Greece); NKFIH (Hungary); DAE and DST (India); IPM (Iran); SFI (Ireland); INFN (Italy); MSIP and NRF (Republic of Korea); MES (Latvia); LMTLT (Lithuania); MOE and UM (Malaysia); BUAP, CINVESTAV, CONACYT, LNS, SEP, and UASLP-FAI (Mexico); MOS (Montenegro); MBIE (New Zealand); PAEC (Pakistan); MES and NSC (Poland); FCT (Portugal); MESTD (Serbia); MCIN/AEI and PCTI (Spain); MOSTR (Sri Lanka); Swiss Funding Agencies (Switzerland); MST (Taipei); MHESI and NSTDA (Thailand); TUBITAK and TENMAK (Turkey); NASU (Ukraine); STFC (United Kingdom); DOE and NSF

[†]: Deceased

¹Also at Yerevan State University, Yerevan, Armenia

²Also at TU Wien, Vienna, Austria

³Also at Institute of Basic and Applied Sciences, Faculty of Engineering, Arab Academy for Science, Technology and Maritime Transport, Alexandria, Egypt

- ⁴Also at Ghent University, Ghent, Belgium
- ⁵Also at Universidade Estadual de Campinas, Campinas, Brazil
- ⁶Also at Federal University of Rio Grande do Sul, Porto Alegre, Brazil
- ⁷Also at UFMS, Nova Andradina, Brazil
- ⁸Also at Nanjing Normal University, Nanjing, China
- ⁹Now at The University of Iowa, Iowa City, Iowa, USA
- ¹⁰Also at University of Chinese Academy of Sciences, Beijing, China
- ¹¹Also at China Center of Advanced Science and Technology, Beijing, China
- ¹²Also at University of Chinese Academy of Sciences, Beijing, China
- ¹³Also at China Spallation Neutron Source, Guangdong, China
- ¹⁴Now at Henan Normal University, Xinxiang, China
- ¹⁵Also at Université Libre de Bruxelles, Bruxelles, Belgium
- ¹⁶Also at an institute or an international laboratory covered by a cooperation agreement with CERN
- ¹⁷Also at Cairo University, Cairo, Egypt
- ¹⁸Also at Suez University, Suez, Egypt
- ¹⁹Now at British University in Egypt, Cairo, Egypt
- ²⁰Also at Purdue University, West Lafayette, Indiana, USA
- ²¹Also at Université de Haute Alsace, Mulhouse, France
- ²²Also at İstinye University, Istanbul, Turkey
- ²³Also at Tbilisi State University, Tbilisi, Georgia
- ²⁴Also at The University of the State of Amazonas, Manaus, Brazil
- ²⁵Also at Erzincan Binali Yıldırım University, Erzincan, Turkey
- ²⁶Also at University of Hamburg, Hamburg, Germany
- ²⁷Also at RWTH Aachen University, III. Physikalisches Institut A, Aachen, Germany
- ²⁸Also at Isfahan University of Technology, Isfahan, Iran
- ²⁹Also at Bergische University Wuppertal (BUW), Wuppertal, Germany
- ³⁰Also at Brandenburg University of Technology, Cottbus, Germany
- ³¹Also at Forschungszentrum Jülich, Juelich, Germany
- ³²Also at CERN, European Organization for Nuclear Research, Geneva, Switzerland
- ³³Also at Institute of Physics, University of Debrecen, Debrecen, Hungary
- ³⁴Also at Institute of Nuclear Research ATOMKI, Debrecen, Hungary
- ³⁵Now at Universitatea Babes-Bolyai - Facultatea de Fizica, Cluj-Napoca, Romania
- ³⁶Also at Physics Department, Faculty of Science, Assiut University, Assiut, Egypt
- ³⁷Also at HUN-REN Wigner Research Centre for Physics, Budapest, Hungary
- ³⁸Also at Punjab Agricultural University, Ludhiana, India
- ³⁹Also at University of Visva-Bharati, Santiniketan, India
- ⁴⁰Also at Indian Institute of Science (IISc), Bangalore, India
- ⁴¹Also at Birla Institute of Technology, Mesra, Mesra, India
- ⁴²Also at IIT Bhubaneswar, Bhubaneswar, India
- ⁴³Also at Institute of Physics, Bhubaneswar, India
- ⁴⁴Also at University of Hyderabad, Hyderabad, India
- ⁴⁵Also at Deutsches Elektronen-Synchrotron, Hamburg, Germany
- ⁴⁶Also at Department of Physics, Isfahan University of Technology, Isfahan, Iran
- ⁴⁷Also at Sharif University of Technology, Tehran, Iran
- ⁴⁸Also at Department of Physics, University of Science and Technology of Mazandaran, Behshahr, Iran
- ⁴⁹Also at Helwan University, Cairo, Egypt
- ⁵⁰Also at Italian National Agency for New Technologies, Energy and Sustainable Economic

Development, Bologna, Italy

⁵¹Also at Centro Siciliano di Fisica Nucleare e di Struttura Della Materia, Catania, Italy

⁵²Also at Università degli Studi Guglielmo Marconi, Roma, Italy

⁵³Also at Scuola Superiore Meridionale, Università di Napoli 'Federico II', Napoli, Italy

⁵⁴Also at Fermi National Accelerator Laboratory, Batavia, Illinois, USA

⁵⁵Also at Laboratori Nazionali di Legnaro dell'INFN, Legnaro, Italy

⁵⁶Also at Ain Shams University, Cairo, Egypt

⁵⁷Also at Consiglio Nazionale delle Ricerche - Istituto Officina dei Materiali, Perugia, Italy

⁵⁸Also at Riga Technical University, Riga, Latvia

⁵⁹Also at Department of Applied Physics, Faculty of Science and Technology, Universiti Kebangsaan Malaysia, Bangi, Malaysia

⁶⁰Also at Consejo Nacional de Ciencia y Tecnología, Mexico City, Mexico

⁶¹Also at Trincomalee Campus, Eastern University, Sri Lanka, Nilaveli, Sri Lanka

⁶²Also at Saegis Campus, Nugegoda, Sri Lanka

⁶³Also at National and Kapodistrian University of Athens, Athens, Greece

⁶⁴Also at Ecole Polytechnique Fédérale Lausanne, Lausanne, Switzerland

⁶⁵Also at Universität Zürich, Zurich, Switzerland

⁶⁶Also at Stefan Meyer Institute for Subatomic Physics, Vienna, Austria

⁶⁷Also at Laboratoire d'Annecy-le-Vieux de Physique des Particules, IN2P3-CNRS, Annecy-le-Vieux, France

⁶⁸Also at Near East University, Research Center of Experimental Health Science, Mersin, Turkey

⁶⁹Also at Konya Technical University, Konya, Turkey

⁷⁰Also at Izmir Bakircay University, Izmir, Turkey

⁷¹Also at Adiyaman University, Adiyaman, Turkey

⁷²Also at Bozok Universitetesi Rektörlüğü, Yozgat, Turkey

⁷³Also at Marmara University, Istanbul, Turkey

⁷⁴Also at Milli Savunma University, Istanbul, Turkey

⁷⁵Also at Kafkas University, Kars, Turkey

⁷⁶Now at Istanbul Okan University, Istanbul, Turkey

⁷⁷Also at Hacettepe University, Ankara, Turkey

⁷⁸Also at Istanbul University - Cerrahpasa, Faculty of Engineering, Istanbul, Turkey

⁷⁹Also at Yildiz Technical University, Istanbul, Turkey

⁸⁰Also at Vrije Universiteit Brussel, Brussel, Belgium

⁸¹Also at School of Physics and Astronomy, University of Southampton, Southampton, United Kingdom

⁸²Also at University of Bristol, Bristol, United Kingdom

⁸³Also at IPPP Durham University, Durham, United Kingdom

⁸⁴Also at Monash University, Faculty of Science, Clayton, Australia

⁸⁵Also at Università di Torino, Torino, Italy

⁸⁶Also at Bethel University, St. Paul, Minnesota, USA

⁸⁷Also at Karamanoğlu Mehmetbey University, Karaman, Turkey

⁸⁸Also at California Institute of Technology, Pasadena, California, USA

⁸⁹Also at United States Naval Academy, Annapolis, Maryland, USA

⁹⁰Also at Bingol University, Bingol, Turkey

⁹¹Also at Georgian Technical University, Tbilisi, Georgia

⁹²Also at Sinop University, Sinop, Turkey

⁹³Also at Erciyes University, Kayseri, Turkey

⁹⁴Also at Horia Hulubei National Institute of Physics and Nuclear Engineering (IFIN-HH),

Bucharest, Romania

⁹⁵Now at an institute or an international laboratory covered by a cooperation agreement with CERN

⁹⁶Also at Texas A&M University at Qatar, Doha, Qatar

⁹⁷Also at Kyungpook National University, Daegu, Korea

⁹⁸Also at another institute or international laboratory covered by a cooperation agreement with CERN

⁹⁹Also at Universiteit Antwerpen, Antwerpen, Belgium

¹⁰⁰Also at Northeastern University, Boston, Massachusetts, USA

¹⁰¹Also at Imperial College, London, United Kingdom

¹⁰²Now at Yerevan Physics Institute, Yerevan, Armenia

¹⁰³Also at Institute of Nuclear Physics of the Uzbekistan Academy of Sciences, Tashkent, Uzbekistan
