Search for Neutral Higgs Bosons of the Minimal Supersymmetric Standard Model in e^+e^- Interactions at $\sqrt{s} = 130 - 183$ GeV

L3 Collaboration

Abstract

A search for the lightest neutral scalar and neutral pseudoscalar Higgs bosons in the Minimal Supersymmetric Standard Model is performed on data collected at LEP by the L3 detector at center-of-mass energies 130 GeV $\leq \sqrt{s} \leq 183$ GeV. No significant excess of events is observed. Limits on the masses of the lightest neutral and pseudoscalar Higgs bosons are given as a function of tan β . Lower mass limits at the 95% confidence level are set at $m_{\rm h} > 70.7$ GeV and $m_{\rm A} > 71.0$ GeV.

Submitted to Phys. Lett. B

Introduction

In the Standard Model [1] (SM), one Higgs doublet [2] gives rise to one neutral, scalar particle, the Higgs boson. A lower limit on its mass has been set by L3 at 87.6 GeV, mainly from a search for the process $e^+e^- \rightarrow Z^* \rightarrow HZ$ [3]. In contrast to the SM, the Minimal Supersymmetric Standard Model [4] (MSSM) requires two Higgs doublets, which give rise to a charged scalar pair, two neutral scalars, the lightest of which is called h, and a neutral pseudoscalar, A. We consider the two production mechanisms most important at these LEP center-of-mass energies:

$$e^+e^- \rightarrow Z^* \rightarrow hZ$$
 (1)

$$e^+e^- \rightarrow Z^* \rightarrow hA.$$
 (2)

The rate for the Higgs-strahlung process (1) is, in general, reduced compared to the similar Standard Model reaction, but this is compensated by the additional pair-production process (2).

Previous searches for the h and A bosons have been reported by L3 [5] and other experiments [6]. In this letter, we present the results of the search for the production of h and A using a data sample with an integrated luminosity of 88.3 pb⁻¹ collected at center-of-mass energies 130 GeV $\leq \sqrt{s} \leq$ 183 GeV.

Data and Monte Carlo Samples

The data were collected using the L3 detector [7] at LEP from 1995 to 1997. The integrated luminosities are 6.1, 5.9, 10.8, 10.2 and 55.3 pb^{-1} at the average center-of-mass energies of 130.3, 136.3, 161.3, 172.3 and 182.7 GeV, respectively.

The signal cross sections and branching ratios are calculated using the HZHA generator [8]. For the efficiency studies, Monte Carlo samples of Higgs events are generated using PYTHIA [9]. For the background studies, the following Monte Carlo programs are used: PYTHIA ($e^+e^- \rightarrow q\bar{q}$), KO-RALW [10] ($e^+e^- \rightarrow W^+W^-$), KORALZ [11] ($e^+e^- \rightarrow \tau^+\tau^-$), PYTHIA and PHOJET [12] ($e^+e^- \rightarrow e^+e^-q\bar{q}$), and EXCALIBUR [13] ($e^+e^- \rightarrow f\bar{f}'f\bar{f}'$). The number of simulated background events for the most important background channels is typically 100 times the number of collected data events. The Monte Carlo signals are 300 times the number of events expected to be observed with these luminosities.

The L3 detector response is simulated using the GEANT 3.15 program [14], which takes into account the effects of energy loss, multiple scattering and showering in the detector. The GHEISHA program [15] is used to simulate hadronic interactions in the detector.

Analysis Procedures

The search for hA and hZ production is carried out using three different sets of MSSM parameters, as suggested in Reference [16]. This choice of parameters makes use of the Grand Unification assumption [17]. This assumption has little impact on the masses of the Higgs bosons, but it reduces the number of free parameters in the MSSM. The free parameters are chosen to be the ratio of the two Higgs vacuum expectation values, $\tan \beta$; the pseudoscalar Higgs mass, m_A ; the gaugino mass parameter, M_2 ; the scalar fermion mass, m_0 ; the scalar quark mixing mass, A; and the Higgs mass parameter, μ . The three sets of MSSM parameters used in this letter are called "minimal mixing", where A is zero and $\mu = -0.1$ TeV; "typical mixing", A = 1 TeV and $\mu = -1$ TeV; and "maximal mixing", $A = \sqrt{6}$ TeV and $\mu = -0.1$ TeV. For all three mixing scenarios $M_2 = m_0 = 1$ TeV and the mass of the top quark, m_t , is taken to be $m_t = 175$ GeV [18]. Finally, a scan over the two remaining independent parameters, tan β and m_A , is performed in each mixing scheme for the ranges

$$1 \le \tan \beta \le 50$$

30 GeV $\le m_A \le 1000$ GeV

Values of tan β and m_A outside of these ranges are not considered since the sensitivity to the signal drops for tan $\beta < 1$ and for values of $m_A < 30$ GeV the analysis is complicated by the possibility of $h \rightarrow AA$ decays. In addition, these low masses have been previously excluded [5,6] for these choices of MSSM parameters.

Because the relative production rate of the two complementary processes, $e^+e^- \rightarrow Z^* \rightarrow hA$ and $e^+e^- \rightarrow Z^* \rightarrow hZ$, varies over the range of MSSM parameters considered, it is important to devise an analysis scheme that has good sensitivity to both channels for a broad range of these parameters. In the case of hZ decay, four event topologies representing approximately 98% of the decay modes are considered: $q\bar{q}q\bar{q}$, $q\bar{q}\nu\bar{\nu}$, $q\bar{q}\ell^+\ell^-$ ($\ell = e, \mu, \tau$) and $\tau^+\tau^-q\bar{q}$. The analyses of the $q\bar{q}\nu\bar{\nu}$ and $q\bar{q}\ell^+\ell^-$ ($\ell = e, \mu$) channels were taken from the Standard Model Higgs search [3]. The hZ analyses are optimized for $h \rightarrow b\bar{b}$, but the efficiencies for the small contributions from the decay modes $h \rightarrow c\bar{c}$, gg are also considered. The hZ $\rightarrow b\bar{b}q\bar{q}$ and $hZ \rightarrow b\bar{b}\tau^+\tau^-$ ($\tau^+\tau^-q\bar{q}$) analyses used in this letter achieve similar performances to the corresponding analyses used in the Standard Model Higgs search, which are described in detail in Reference [19].

There are two event topologies considered for the hA channel, which generally make up approximately 97% of the available decay modes for these ranges of MSSM parameters: $hA \rightarrow b\bar{b}b\bar{b}$ and $hA \rightarrow b\bar{b}\tau^{+}\tau^{-}$ ($\tau^{+}\tau^{-}b\bar{b}$). These topologies are very similar to their hZ counterparts, but the Z-mass constraint cannot be used and, on average, the hA events are more likely to contain b hadrons.

The analyses of the hA and hZ channels are performed in three stages. First, a high-multiplicity hadronic event selection is applied. This greatly reduces background events with large missing energy and low multiplicity while maintaining a high signal efficiency over a broad range of possible Higgs masses. Second, a set of cuts tailored to the specific Higgs decay in question is chosen using an automated optimization procedure [19, 20]. These cuts are optimized for each center-of-mass energy. Third, a discriminating variable is built for each analysis, which depends on the mass hypothesis and relative production rates of hA and hZ. The spectrum of this discriminant is recomputed for each point in the (tan β , m_A) scan and it is used in the likelihood calculation which tests for the presence of a signal.

The b-tagging variable plays a large role in the calculation of this discriminant. The neural network b-tag [21] for each hadronic jet is calculated from inputs including the measured decay lengths of particles in three dimensions, information about prompt leptons and jet shape variables. The event btag variable, B_{tag}^{event} , is then defined to be the negative-logarithm of the probability that all the hadronic jets in the event are consistent with jets containing no b hadrons.

The hA \rightarrow bbbb and hZ \rightarrow bbqq Channels

The signature of both the hA \rightarrow bbbb and hZ \rightarrow bbqq decay modes is four high-multiplicity hadronic jets and the presence of b hadron decay products. The dominant backgrounds come from qq production and hadronic decays of W-pairs. In the case of hA \rightarrow bbbb, the identification of b hadrons plays an especially important role. Both analyses proceed in three stages.

First, a high-multiplicity hadronic event preselection common to both channels is made at all center-of-mass energies. At least 15 tracks and 45 calorimetric clusters are required, the visible energy, E_{vis} , must exceed $0.6\sqrt{s}$ and radiative returns to the Z-resonance are rejected. Events passing

the preselection are then forced to have four jets using the DURHAM [22] clustering algorithm and a kinematic fit requiring 4-momentum conservation (4C) is performed.

The second stage of the analyses optimizes the signal sensitivity by automatically adjusting a set of cuts to maximize the average confidence level using the technique described in Reference [19]. The values of the optimized cuts for all the center-of-mass energies are discussed in detail in Reference [23]. As an example, we describe the cuts for $\sqrt{s} = 183$ GeV since these data contribute the most to the sensitivity of the search due to the high center-of-mass energy and large integrated luminosity. The optimized cuts at the lower center-of-mass energies are similar to those of the $\sqrt{s} = 183$ GeV, but take into account the different background conditions and signal cross sections.

For the hZ \rightarrow bbqq and hA \rightarrow bbbb analyses, the following mass variables are defined:

$$\chi_{hZ} = \log \left(\operatorname{Prob} \left(\min \left((\Sigma_i - (m_Z + m_h))^2 w_{\Sigma} + (\Delta_i - |m_Z - m_h|)^2 w_{\Delta} \right) \right) \right)$$
(3)
$$\chi_{hA} = \log \left(\operatorname{Prob} \left(\min \left((\Sigma_i - (m_A + m_h))^2 w_{\Sigma} + (\Delta_i - |m_A - m_h|)^2 w_{\Delta} \right) \right) \right) ,$$

where Σ_i and Δ_i are the sum and difference, respectively, of the *i*th dijet masses of one the three jet pairings. The weights w_{Σ} and w_{Δ} are respectively $1/(4 \text{ GeV})^2$ and $1/(6 \text{ GeV})^2$ reflecting the typical mass resolutions, and Prob is the probability of a χ^2 with two degrees of freedom. In the hZ \rightarrow bbqq selection, the mass variable, χ_{hZ} , must be $\chi_{hZ} > -13.3$ and in the hA \rightarrow bbbb selection, $\chi_{hA} > -6.1$. This rejects events with dijet mass combinations far away from the Higgs mass hypothesis. The Y_{cut} parameter in the DURHAM scheme, Y_{34}^{D} , ensures the four-jet nature of the selected events and must be $Y_{34}^{\rm D} > 0.0044$ in the hZ \rightarrow bbqq analysis and $Y_{34}^{\rm D} > 0.0030$ in the hA \rightarrow bbbb analysis. A cut on the maximum energy difference between any two jets rejects events with gluonic jets and is chosen to be $max(\Delta E_{iet}) < 0.22\sqrt{s}$ for hZ \rightarrow bbqq and $max(\Delta E_{iet}) < 0.32\sqrt{s}$ for hA \rightarrow bbbb. To further reject $q\bar{q}$ background, the minimum dijet mass is required to be inside a window of $0.14\sqrt{s} < \min(M_i) < 10^{-1}$ $0.66\sqrt{s}$ for the hZ \rightarrow bbqq selection and $0.09\sqrt{s} < \min(M_i) < 0.78\sqrt{s}$ for the hA \rightarrow bbbb selection. The final and most important optimized cut is on $B_{\text{tag}}^{\text{event}}$, which mainly rejects W-pair decays. In the $hZ \rightarrow b\bar{b}q\bar{q}$ analysis, $B_{\text{tag}}^{\text{event}}$ needs to be $B_{\text{tag}}^{\text{event}} > 0.06$ and in the $hA \rightarrow b\bar{b}b\bar{b}$ analysis $B_{\text{tag}}^{\text{event}} > 0.67$. The most discriminating of these variables are shown in Figure 1 for the data and Monte Carlo at \sqrt{s} = 183 GeV after the preselection but before the optimized cuts have been applied. The signal efficiencies and the number of accepted events after the preselection and after passing either set of the optimized cuts (except the cut on the mass variable) for $hZ \rightarrow b\bar{b}q\bar{q}$ or $hA \rightarrow b\bar{b}b\bar{b}$ are shown in Table 1 for the data and Monte Carlo background.

Events passing the optimized cuts are then categorized: 1) those that pass only the hZ cuts; 2) those that pass only the hA cuts; and 3) those that pass both sets of cuts. Category (1) is called the hZ_{bbqq} analysis and category (2) the hA_{bbbb} analysis. Events in category (3) are split into two separate samples by choosing the most likely production hypothesis based on the probability of the χ^2 of the mass hypothesis and the relative production rates. If $\sigma_{hA \rightarrow b\bar{b}b\bar{b}}$ Prob($\chi^2(m_A, m_h)$) > $\sigma_{hZ \rightarrow b\bar{b}q\bar{q}}$ Prob($\chi^2(m_Z, m_h)$), then the event is classified as hA $\rightarrow b\bar{b}b\bar{b}$ and this analysis is called hA'_{b\bar{b}b\bar{b}}, otherwise it is classified as hZ $\rightarrow b\bar{b}q\bar{q}$ and called hZ'_{b\bar{b}q\bar{q}}.

In the last stage of the $hZ_{b\bar{b}q\bar{q}}$, $hA_{b\bar{b}b\bar{b}}$, $hZ'_{b\bar{b}q\bar{q}}$ and $hA'_{b\bar{b}b\bar{b}}$ analyses, the discriminating variables, $F(m_Z, m_h)$ and $F(m_A, m_h)$, are computed. These variables are the weighted combination of the B_{tag}^{event} and χ probabilities:

$$F(m_x, m_h) = -\log\left(\frac{\omega P_B^{1/\omega} P_{\chi} - P_B P_{\chi}^{\omega}}{\omega - 1}\right),\tag{4}$$

where m_x is either m_Z or m_A , P_B and P_{χ} are the probabilities of $B_{\text{tag}}^{\text{event}}$ and χ each being consistent with their respective background distributions, and ω is a weighting parameter that is optimized for

each analysis. For the $hZ_{b\bar{b}q\bar{q}}$ and $hZ'_{b\bar{b}q\bar{q}}$ analyses, the mass variable $\chi = \chi_{hZ}$ is used and F is a function of the m_h hypothesis, $F(m_Z, m_h)$. Conversely, for $hA_{b\bar{b}b\bar{b}}$ and $hA'_{b\bar{b}b\bar{b}}$, $\chi = \chi_{hA}$ is used and F depends on the m_A and m_h mass hypothesis, $F(m_A, m_h)$. Spectra of $F(m_A, m_h)$ for the $\sqrt{s} = 183$ GeV data can be seen in Figures 2a and 2b, for the $hA_{b\bar{b}b\bar{b}}$ and $hA'_{b\bar{b}b\bar{b}}$ analyses with a mass hypothesis of $m_A = m_h = 70$ GeV for typical mixing. In Figures 2c and 2d, we show the spectra for $F(m_Z, m_h)$ in the $hZ_{b\bar{b}q\bar{q}}$ analyses for the $m_h = 85$ GeV mass hypothesis in the typical mixing scheme.

The discriminant variable, *F*, is recomputed at each $(\tan \beta, m_A)$ point in the scan for the mixing scenario under consideration. Because of the cut on the χ variables, the number of accepted data, Monte Carlo background and signal events is different at each scanned point.

$hA \rightarrow b\bar{b}\tau^{+}\tau^{-}(\tau^{+}\tau^{-}b\bar{b}), hZ \rightarrow b\bar{b}\tau^{+}\tau^{-} and hZ \rightarrow \tau^{+}\tau^{-}q\bar{q}$ Channels

The signatures of these events are a pair of high-energy taus accompanied by two hadronic jets. The main backgrounds are $q\bar{q}$ production and four-jet W-pair decays. The identification criteria of hadronically and leptonically decaying taus are given in Reference [24]. As in the hA \rightarrow bbbb and hZ \rightarrow bbdq selection, the analysis proceeds in three stages.

First, a preselection is made for high-multiplicity events with tau leptons. At least 5 tracks are required, the number of calorimetric clusters must be greater than 15 and at least two taus must be present. Then, in the same spirit as the $hA \rightarrow b\bar{b}b\bar{b}$ and $hZ \rightarrow b\bar{b}q\bar{q}$ analyses, an automated procedure [20] is used to optimize cuts on visible energy, visible mass, effective center-of-mass energy, and cuts devoted to tau isolation for each center-of-mass energy.

The isolation and energy requirements for the taus are optimized to reduce contributions from semileptonic and hadronic decays of W-pairs and $q\bar{q}$ backgrounds. Energy clusters not belonging to the taus are forced into two jets using the DURHAM scheme and a 4C kinematic fit is performed, which defines the dijet and ditau invariant masses, M_i and M_{τ} .

Finally, events passing the common set of optimized cuts are classified as either $hA \rightarrow b\bar{b}\tau^{+}\tau^{-}$ $(\tau^{+}\tau^{-}b\bar{b})$, $hZ \rightarrow b\bar{b}\tau^{+}\tau^{-}$ or $hZ \rightarrow \tau^{+}\tau^{-}q\bar{q}$ by choosing the most likely production hypothesis based on the mass χ^{2} variables and the relative production rates as in the $hA \rightarrow b\bar{b}b\bar{b}$ and $hZ \rightarrow b\bar{b}q\bar{q}$ analyses. The mass χ^{2} variables are defined as in Equation 3 but the weights, w_{Σ} and w_{Δ} , are $1/(5 \text{ GeV})^{2}$ and $1/(10 \text{ GeV})^{2}$, respectively, for the sum and difference of M_{i} and M_{τ} . The mass-dependent variable, $\mathcal{P} = 10^{-F}$, is defined using Equation 4 with a weight of unity, which reduces to $\mathcal{P} = P_{B}P_{\chi}(1-\ln(P_{B}P_{\chi}))$. Here, P_{B} and P_{χ} are the confidence levels that the b-tag from the two hadronic jets and mass χ^{2} are consistent with their signal distributions. In the case of the $hZ \rightarrow \tau^{+}\tau^{-}q\bar{q}$ analysis, the b-tagging information is not used and $\mathcal{P} = P_{\chi}$. The event is classified depending on the value of

$$\mathcal{P}' = \max\{\sigma_{hA \to b\bar{b}\tau^{+}\tau^{-}(\tau^{+}\tau^{-}b\bar{b})}\mathcal{P}(m_{A}, m_{h}), \sigma_{hZ \to b\bar{b}\tau^{+}\tau^{-}}\mathcal{P}(m_{Z}, m_{h}), \sigma_{hZ \to \tau^{+}\tau^{-}q\bar{q}}\mathcal{P}(m_{Z}, m_{h})\}/\sigma_{b\tau}$$

where $\sigma_{b\tau}$ is the sum of these cross sections.

Unlike the hA \rightarrow bbbb and hZ \rightarrow bbqq analyses, the events are not split into separate categories based on this decision, but are instead kept as one inclusive analysis. The discriminant, \mathcal{P}' , is recalculated at each (tan β , m_A) point in the scan for each mixing scenario. The spectrum for \mathcal{P}' at (tan $\beta = 50$, $m_A = 70$ GeV) is shown in Figure 3 for the $\sqrt{s} = 183$ GeV data, Monte Carlo background and an inclusive signal of hA \rightarrow bb $\tau^+\tau^-(\tau^+\tau^-bb)$ + hZ \rightarrow bb $\tau^+\tau^-$ + hZ $\rightarrow \tau^+\tau^-q\bar{q}$ in the minimal mixing scenario.

Results

No evidence of the production of the h and A bosons is observed in the data. The mass limits are evaluated by calculating the confidence level (CL) that the expected signal is absent in the observed data for the plane defined by $\tan \beta$ and m_h . The CL is calculated using the technique described in References [21, 25]. The results of the analyses for all the physics processes and decay channels are combined into bins of one distribution, ordered in the logarithm of signal-over-background. The CL is then calculated from this signal-over-background distribution.

Systematic and statistical errors on the signal and background are considered using the same procedure as in the Standard Model Higgs search [3] taking into account detector uncertainties in the energy scale of the individual sub-detectors, the global energy scale, the tracking and b-tagging efficiencies, and experimental uncertainties in the LEP center-of-mass energy [26] and the luminosity measurement. Theoretical errors on the Higgs boson production cross section due to the uncertainties in α_s [27], interference effects [28] and errors on Higgs decay branching fractions due to quark masses [29] introduce an uncertainty on the predicted number of signal events. The overall systematic error is estimated to be 4% on the number of signal and 10% on the number of background events. The statistical error is larger, but completely uncorrelated among the different bins of the individual channels and is taken into account bin-by-bin [3].

Bins of an analysis with a signal-over-background ratio of less than 0.10 are not considered in the calculation of CL. This cut is chosen to maximize the average CL in the presence of the systematic and statistical error, as calculated from a large set of Monte Carlo experiments. The inclusive signal efficiency for hZ + hA production and the number of selected data and expected background events are shown in Figures 4a and 4b for m_h at the average 95% CL limit as a function of tan β , before and after the signal-over-background cut. Two examples of the distribution used to calculate the CL are given in Figures 4c and 4d, for low and high tan β for the m_h point where the CL crosses 95%. No significant excess is observed at any point in the $(m_h, \tan \beta)$ plane for the three mixing scenarios.

Lower limits on the Higgs boson masses as a function of $\tan \beta$ are shown in Figure 5 for the different mixing hypotheses. The 95% CL lower mass limits on m_A and m_h , as well as the probability to obtain a limit on m_h larger than the one observed, are shown in Table 3 at the two extrema of the scan over $\tan \beta$. In Table 3 we also list the average and median mass limits at the 95% CL, calculated from Monte Carlo, as an indication of the sensitivity of this search. The lowest value of m_h excluded is at $\tan \beta = 20.3$ for typical mixing, and the lowest value of m_A excluded is at $\tan \beta = 22.4$ for minimal mixing. For the MSSM parameters considered, this results in lower mass limits at the 95% CL of

$$m_{\rm h} > 70.7 \text{ GeV}, m_{\rm A} > 71.0 \text{ GeV}.$$

Acknowledgments

We acknowledge the efforts of all the engineers and technicians who have participated in the construction and maintenance of L3 and express our gratitude to the CERN accelerator divisions for the superb performance of LEP.

161	0.94	0.95	134.5	128	0.85	0.75	25.2	14	
172	0.95	0.97	193.7	186	0.83	0.89	84.0	80	
183	0.89	0.91	655.6	652	0.78	0.84	380.5	376	

Table 1: The effects of the preselection and optimized cuts at the five center-of-mass energies. On the left hand side are the signal efficiencies, the number expected background events, N_{bg}, and the number of data events, N_{data}, passing the common hA and hZ preselection in the four-jet channel. On the right hand side, the same is shown for events passing either set of the optimized cuts. The signal efficiencies, $\varepsilon_{hA\rightarrow b\bar{b}b\bar{b}}$, are for the following center-of-mass energies and signal masses: $\sqrt{s} = 130 - 136$ GeV, $m_A = m_h = 50$ GeV; $\sqrt{s} = 161 - 172$ GeV, $m_A = m_h = 60$ GeV; and $\sqrt{s} = 183$ GeV, $m_A = m_h = 70$ GeV. The efficiencies, $\varepsilon_{hZ\rightarrow b\bar{b}q\bar{q}}$, are for: $\sqrt{s} = 161 - 172$ GeV, $m_h = 71$ GeV; and $\sqrt{s} = 183$ GeV, $m_h = 85$ GeV. At this stage of the analysis, the acceptances are independent of tan β .

$\sqrt{s}(\text{GeV})$	$\mathcal{E}_{hA \rightarrow b \bar{b} \tau^+ \tau^-}$	$\mathcal{E}_{hZ \rightarrow b \bar{b} \tau^+ \tau^-}$	$\mathcal{E}_{hZ \rightarrow \tau^+ \tau^- q \bar{q}}$	N _{bg}	N _{data}
133	0.27	_	_	2.7	4
161	0.32	0.30	0.28	1.8	2
172	0.33	0.27	0.28	4.2	3
183	0.32	0.27	0.30	14.0	17

Table 2: Events passing the optimized $b\bar{b}\tau^+\tau^-$ selection. The efficiencies, $\varepsilon_{hA\to b\bar{b}\tau^+\tau^-}$, are for the following center-of-mass energies and signal masses: $\sqrt{s} = 133$ GeV, $m_A = m_h = 50$ GeV; $\sqrt{s} = 161 - 172$ GeV, $m_A = m_h = 60$ GeV; and $\sqrt{s} = 183$ GeV, $m_A = m_h = 70$ GeV. The efficiencies, $\varepsilon_{hZ\to b\bar{b}\tau^+\tau^-}$ and $\varepsilon_{hZ\to \tau^+\tau^-q\bar{q}}$, are for signal masses: $\sqrt{s} = 161 - 172$ GeV; $m_h = 70$ GeV; and $\sqrt{s} = 183$ GeV, $m_h = 85$ GeV. The last two columns are the number of Monte Carlo background events, N_{bg}, and number of data events, N_{data}, surviving the cuts.

	Nevents at 95% CL			Lower mass limits in GeV at 95% CL						
Mixing, $\tan \beta$	N_{bg}	N _{data}	N _{sig}	$\overline{m_{\mathrm{h}}}$	$\overline{m_{\rm A}}$	$< m_{\rm h} >_{50}$	$< m_{\rm A} >_{50}$	CL_b	$m_{\rm h}$	m _A
minimal, 1	Excluded to theoretical limit

maximal, 1	10.3	13	6.1	85.6	183	87.2	208	54%	87.0	204
maximal, 50	7.9	7	4.7	68.9	68.9	70.4	70.5	43%	71.4	71.5

Table 3: Higgs mass limits in the MSSM from the data at 130 GeV $\leq \sqrt{s} \leq$ 183 GeV. At the observed 95% CL, N_{bg}, N_{data} and N_{sig} are respectively the number of events expected from background, the number of observed events and the number of expected signal events from hA + hZ at the tan β listed. The masses \overline{m} and $\langle m \rangle_{50}$ are respectively the average and median mass limits for the h and A bosons as calculated from a large set of Monte Carlo trials. CL_b is the probability to obtain a mass limit on m_h larger than the one observed. The masses in boldface are the lower mass limits set at the 95% CL from the data.

Figure 1: Distributions of the most important variables in the hA \rightarrow bbbb and hZ \rightarrow bbqq analyses. In the plots, the points are the $\sqrt{s} = 183$ GeV data, the solid histograms are the Monte Carlo backgrounds and the superimposed hatched histograms are the hA ($m_A = m_h = 70$ GeV) or hZ ($m_h = 85$ GeV) signals normalized to efficiency times 500. The distributions are shown after preselection, but before optimized cuts: **a**) Event b-tag, $B_{\text{tag}}^{\text{event}}$, for the hA \rightarrow bbbb analysis; **b**) Mass variable, χ_{hA} , for the hA \rightarrow bbbb analysis; **c**) Y_{34}^{D} for the hZ \rightarrow bbqq analysis; and **d**) Minimum normalized dijet mass, min(M_i/\sqrt{s}), for the hZ \rightarrow bbqq analysis.

Figure 2: The discriminant, $F(m_A, m_h)$ and $F(m_Z, m_h)$, after the optimized cuts have been applied. Data are the points, the open histograms are Monte Carlo background and the superimposed hatched histograms are signal efficiency times 50: **a**) hA_{bbbb} analysis at tan $\beta = 50$, $m_A = m_h = 70$ GeV, typical mixing; **b**) same as (a) but for the hA'_{bbbb} analysis; **c**) hZ_{bbqq} analysis at tan $\beta = 1$, $m_h = 85$ GeV, typical mixing; and **d**) same as (c) but for the hZ'_{bbqq} analysis.

Figure 3: Variables used in the calculation of the discriminant, \mathcal{P}' , for the hA \rightarrow bb $\tau^+\tau^-$ ($\tau^+\tau^-$ bb), hZ \rightarrow bb $\tau^+\tau^-$ and hZ \rightarrow $\tau^+\tau^-$ q \bar{q} analyses at $\sqrt{s} = 183$ GeV for (tan $\beta = 50$, $m_A = 70$ GeV) for minimal mixing. The dots are data, the solid histograms are Monte Carlo and the hatched histograms are the inclusive signal hA \rightarrow bb $\tau^+\tau^-$ ($\tau^+\tau^-$ bb) + hZ \rightarrow bb $\tau^+\tau^-$ + hZ \rightarrow $\tau^+\tau^-$ q \bar{q} . **a**) The joint probability of both hadronic jets to be from b-decays. **b**) The mass probability to be signal. **c**) The mass probability for the hZ mass hypothesis. **d**) The discriminant, \mathcal{P}' , for the inclusive bb $\tau^+\tau^-$ analysis.

Figure 4: Accepted events and signal efficiency near the average 95% CL limit as a function of tan β for maximal mixing. **a**) Inclusive efficiency for hA + hZ production before a signal-over-background cut (dotted line) and after a signal-over-background cut of 0.1 (solid line). **b**) Upper plot: Number of accepted data events (dots) and expected background (dotted line) before a signal-over-background cut. Lower plot: Number of data events (dots) and background (solid line) passing a signal-over-background cut of 0.1. **c**) Distribution for all analyses combined in bins of log(Signal/Background) for (tan $\beta = 1, m_A = 207$ GeV), where hZ is the dominant production mode (open histogram is expected background, dots are data, hatched histogram is combined signal). **d**) Same as (**c**), but for (tan $\beta = 50, m_A = 71.6$ GeV), where hA is dominant.

Figure 5: Exclusion plots of the Higgs mass versus $\tan \beta$ at the 95% CL from the data collected at $\sqrt{s} = 130-183$ GeV. In all the plots, the area shaded by horizontal lines is the 95% CL exclusion; the white area is the non-excluded region; the cross-hatched area is disallowed by theory and the area in the lower left hand corner of plots a,b and c between the 95% exclusion and the theoretically excluded regions represents the lower boundary of the scan over m_A which starts at 30 GeV. **a**) 95% CL exclusion of m_h versus $\tan \beta$ in the minimal mixing scenario. **b**) Same as (a) but for typical mixing. **c**) Same as (a,b) but for maximal mixing scenarios. The solid line is the maximal mixing exclusion, the dotted line is typical mixing, and the dashed lined is minimal mixing.
