Characterizing and Automatically Finding Primary Effects in Planning

Eugene Fink [*] and **Qiang Yang** [†]

Abstract

The use of primary effects of operators in planning is an effective approach to reduce search costs. However, the characterization of "good" primary effects has remained at an informal level. In this paper we present a formal criterion for selecting useful primary effects, which guarantees planning efficiency, completeness, and optimality. We also describe an inductive learning algorithm based on this criterion that automatically selects primary effects of operators. Both the sample complexity and the time complexity of our learning algorithm are polynomial in the size of the domain.

1 Introduction

1.1 Planning with Primary Effects

Planning with primary effects is an effective approach to reduce search costs. The idea of this approach is to select *primary* effects among the effects of each operator and to use an operator only when we need to achieve one of its primary effects. A *primary-effect restricted* planner never inserts an operator in a plan in order to achieve any of the side effects of the operator. For example, the primary effect of lighting a fireplace is to heat the house. If we have lamps in the house, we could consider illuminating the room as a side effect of lighting a fireplace. We would not use a fireplace just to illuminate the room.

The advantages of using primary effects in planning are well-known. If a planner considers only operators whose primary effects match a current goal, the branching factor of search can be reduced. This may result in an exponential reduction of running time. For this reason, primary effects are used by many implemented planning systems, such as SIPE [Wilkins, 1988], PRODIGY [Carbonell *et al.*, 1990], and ABTWEAK [Yang and Tenenberg, 1990]. Besides, primary effects play an important role in systems that automatically generate abstraction hierarchies. Recent work [Knoblock, 1991], [Fink and Yang, 1992b] has shown that the use of primary effects allows us to increase the number of levels in abstraction hierarchies, resulting in hierarchies that in many cases increase the efficiency of abstract planning.

Despite the importance of primary effects, the characterization of a "good" selection of primary effects has remained at an informal level. Most systems rely on a human user to select primary effects. If the user has not chosen primary effects, then by default all effects are assumed to be primary.

A lack of a formal guideline for selecting primary effects could cause two serious problems in planning. First, an improper selection of primary effects may result in the loss of completeness in planning. Incompleteness happens when a primary-effect restricted planner cannot find a plan for a solvable planning problem. For example, if a fireplace is the only source of light, but lighting is not chosen as a primary effect of using fireplace, a primary-effect restricted planner will not find a plan to illuminate the room. Second, primary-effect restricted planning may produce non-optimal plans. This happens because primary effects place a bias in directing the search for a solution. If not set properly, the bias can favor a search path toward a more costly solution.

Recently we have developed an algorithm, MARGIE, for automatically selecting primary effects [Fink and Yang, 1992b]. Although in many cases this algorithm leads to a dramatic improvement in running time, our experiments revealed that the above two problems sometimes cause a planner to perform worse than without the use of primary effects.

1.2 Overview of the Results

The purpose of the paper is twofold. First, we pinpoint the exact reason for a primary-effect restricted planner to be incomplete and non-optimal. This result is presented in the form of a theorem, which states a *necessary and sufficient* condition for a primary-effect restricted planner to be admissible. The theorem formalizes the intuitions behind "good" choices of primary effects. Using the theorem, it is now possible to determine whether a given selection of primary effects enables a planner to be complete and admissible.

Second, for incomplete or inadmissible choices of primary effects we present an *inductive learning* algorithm to automatically find additional primary effects. The learned set of primary effects guarantees a planner's completeness and ensures its ability to find a near-optimal solution. To use the learning algorithm, an initial set of primary effects can be chosen by the user or by an initialization algorithm. The learner then analyzes either a collection of previous plans or new plans generated by the planner to augment the set of primary effects of operators.

The utility of our inductive learning algorithm is demonstrated by its time complexity and sample complexity. The former characterizes the running time of processing a set of sample plans, while the latter specifies the number of sample plans required by the learner to reduce the probability of planning errors to a small user-defined number. We show that the time complexity of our algorithm is *polynomial* in the size of the domain, and the sample complexity is linear in the total number of effects in operator definitions.
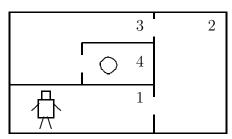

2 A Motivating Example

2.1 Planning Domain

We describe a planning domain with a robot, which may move within four rooms (see the picture), and a ball in Room 4. The robot may go between two rooms connected by a door, and it may carry the ball. Also, the robot may throw the ball through a door into another room. If two rooms are separated by a wall, the robot may break through the wall to create a new door.

To describe a current *state* of the domain, we have to specify the location of the robot and the ball, and pairs of rooms connected by doors. This may be done with three predicates, *robot-in*(x), *ball-in*(x), and *door*(x,y). Literals describing a current state of the domain may be obtained from these predicates by substituting specific room numbers for x and y. For example, the literal *robot-in*(1) means that the robot is in Room 1, *ball-in*(4) means that the ball is in Room 4, and *door*$(1,2)$ means that Room 1 and Room 2 are connected by a doorway.

The operations performed by the robot, such as moving between rooms or throwing the ball, are called *operators*. Each operator α is described by a *set of precon-*

operator	preconditions	effects	cost
go(x,y)	robot-in(x) door(x,y)	robot-in(y) ¬robot-in(x)	2
carry-ball(x,y)	robot-in(x) ball-in(x) door(x,y)	robot-in(y) ¬robot-in(x) ball-in(y) ¬ball-in(x)	3
throw(x,y)	robot-in(x) ball-in(x) door(x,y)	ball-in(y) ¬ball-in(x)	2
break(x,y)	robot-in(x)	robot-in(y) ¬robot-in(x) door(x,y)	4

ditions Pre(α), a *set of effects Eff*(α), and a real-valued cost (see the table). The *preconditions* of α are the conditions that must hold before the execution of the operator, and the *effects* are the results of the execution. If l is a member of *Eff*(α), then we say that α *achieves l*.

A *plan* is a sequence of operators that achieves some desired goal[1]. For example, assume that the initial state is as shown in the picture, and we wish to bring both the robot and the ball into Room 3. This goal may be achieved by the plan (*break*$(1,4)$, *carry-ball*$(4,3)$). A plan is *correct* if (1) all goal literals are achieved, and (2) the preconditions of every operator α of the plan are satisfied before the application of α. We define the cost of a plan as the sum of the costs of its operators. The cost of our plan is $4 + 3 = 7$. An *optimal plan* is one that achieves the goals with the minimal cost.

2.2 The Completeness Problem

If an operator has several effects, we may choose certain "important" effects among them and insert the operator into a plan only for the sake of these effects. Intuitively, an effect is not important if it may be achieved by some other, less expensive operator. The chosen important effects are called *primary*. Using primary effects in planning restricts the branching factor of search, which may improve efficiency.

For example, consider the following selection of primary effects:

go(x,y) {robot-in(y)}
carry-ball(x,y) {robot-in(y), ball-in(y)}
throw(x,y) {ball-in(y)}
break(x,y) {door(x,y)}

Assume that the initial state is as shown on the picture

---

[1]In this paper we consider total-order plans. However, our results can be easily generalized to partial-order plans.

and the robot must go into Room 3. The robot may achieve this goal by breaking through the wall between Rooms 1 and 3. However, since changing the location of the robot is *not* a primary effect of breaking through a wall, a planner will not consider this possibility. Instead, it will find the plan $(go(1,2), go(2,3))$.

The planner is not as fortunate when we consider another goal: to remove the robot from Room 1. The formal description of this goal is $\{\neg robot\text{-}in(1)\}$. This may be achieved by the operator $go(1,2)$ or, less efficiently, by $break(1,3)$. However the planner will not find either of these plans, because $\neg robot\text{-}in$ is *not* a primary effect of any operator. Therefore, the planner will report that the goal cannot be achieved. This shows that planning with primary effects *may not be complete*, that is, it may fail to find a plan for an achievable goal.

To preserve completeness, we have to add some additional primary effects to our selection:

$go(x,y)$	$\{robot\text{-}in(y), \neg robot\text{-}in(x)\}$
carry-ball(x,y)	$\{robot\text{-}in(y), ball\text{-}in(y)\}$
throw(x,y)	$\{ball\text{-}in(y), \neg ball\text{-}in(x)\}$
break(x,y)	$\{door(x,y)\}$

With this modification the planner is complete. However planning with these primary effects may still prevent us from finding an *optimal* plan. Suppose that we want the robot to go from Room 1 to Room 4. The goal may be achieved by the operator $break(1,4)$, the cost of which is 4. However, entering Room 4 is *not* a primary effect of this operator, and a planner will not apply the operator. The best plan that the planner may find using primary effects is $(go(1,2), go(2,3), go(3,4))$, with the cost 6. This example demonstrates that planning with primary effects *may not be admissible*, that is, it may fail to find an optimal plan.

In the following sections, we formalize the notion of planning with primary effects and present a technique for ensuring the completeness and admissibility of planning.

3 Formalizing Primary Effects

3.1 Primary-Effect Restricted Planning

A planner is called *primary-effect restricted* if, when it inserts a new operator to achieve a goal or a precondition of another operator, it always uses an operator with a matching primary effect. To describe the completeness of a primary-effect restricted planner, we need to define a number of key concepts.

We first define the notion of *justification*. Informally, an effect l of some operator α in a plan Π is justified if achieving l by α is required for the correctness of Π.

Definition 1 *An effect l of an operator α in a correct plan is* justified *if either*

- *l is a goal, and no operator after α achieves l, or*

- *l is a precondition of some operator α_1, such that one of the effects of α_1 is justified and no operator between α and α_1 achieves l*

Observe that the operators that do not have justified effects may be removed from the plan without violating the correctness of the plan [Fink and Yang, 1992a]. In this paper we assume that all operators of every plan have justified effects.

Definition 2 *A correct plan Π is* primary-effect justified *if every operator of Π has a justified primary effect.*

One may verify that if a planning problem has a primary-effect justified solution, then the primary-effect restricted versions of many planning systems, such as STRIPS [Fikes and Nilsson, 1971], TWEAK [Chapman, 1987], and PRODIGY [Carbonell *et al.*, 1990], will find a solution to the problem.

Definition 3 *Primary-effect restricted planning is* complete *if, for any initial state S_0 and goal state S_g, the existence of some plan that achieves S_g from S_0 always implies the existence of a primary-effect justified plan that achieves S_g from S_0.*

Our next concern is the optimality of primary-effect justified plans. To describe the possible loss of efficiency when using primary effects, we introduce the notion of the *greatest cost increase*. A positive real number C is called the greatest cost increase for a given selection of primary effects, if for any goal achieved by any plan Π, there exists a primary-effect justified plan for achieving this goal, with the cost no greater than $C \cdot cost(\Pi)$.

For example, consider the plan in the last example of Subsection 2.2. The optimal way for the robot to travel from Room 1 to Room 4 is to break through the wall, with the cost 4. However, the best primary-effect justified plan is to go through Rooms 2 and 3, which costs 6. Thus the cost increase for this problem is $6/4 = 1.5$.

The greatest cost increase is the factor we will use for judging the degree of optimality for a given selection of primary effects. Its value is always greater than or equal to 1. The smaller its value, the better the selection of primary effects.

3.2 Necessary and Sufficient Condition of Completeness

To address the problem of selecting primary effects, we present a theorem that allows us to test whether a given choice of primary effects guarantees the completeness of planning and to estimate the greatest cost increase.

Let S be a state and α be an operator whose preconditions are satisfied in S. A plan Π_1 with the initial state S is called a *replacing plan* for α in S if Π_1 is a primary-effect justified plan such that

1. Π_1 achieves all side effects of α, and

2. Π_1 leaves unchanged all literals of S that are not changed by α

For example, consider the state $S = \{robot\text{-}in(1), ball\text{-}in(4)\}$ and the operator $break(1,4)$. The side effects of

this operator are *robot-in*(4) and ¬*robot-in*(1). A replacing plan for *break*(1,4) is $\Pi_1 = (go(1,2), go(2,3), go(3,4))$, since Π_1 achieves both side effects of *break* operator and does not change any other literals of S.

The *replacing cost increase* is the ratio of the cost of an optimal replacing plan Π_1 to the cost of α, $\frac{\text{cost}(\Pi_1)}{\text{cost}(\alpha)}$. In our example the cost of *break* is 4, and the cost of Π_1 is 6, and thus the replacing cost increase is $\frac{6}{4} = 1.5$.

Theorem 1
[**Completeness**] *Primary-effect restricted planning is complete if and only if for every state S and for every operator α whose preconditions are satisfied in S, there exists a replacing plan.*
[**Optimality**] *For a given complete selection of primary effects, the greatest cost increase equals*

$$\max\{1, \max_{\alpha}\{\text{replacing cost increase of } \alpha\}\}.$$

The second part of the theorem states that the greatest cost increase is equal to the maximum of replacing cost increases when the latter is greater than 1. Otherwise, it equals 1.

Sketch of the proof We prove the second part of the theorem, that the greatest cost increase is equal to the maximum of replacing cost increases. The proof of the first part is similar.

Let C_r be the maximal replacing cost increase. We have to show that (1) the cost increase for every planning problem is at most C_r, and (2) there is a planning problem for which the cost increase is exactly C_r.

(1) Consider an arbitrary planning problem with an initial state S_0 and a goal S_g, and an optimal plan $\Pi = (\alpha_1, .., \alpha_n)$ that achieves the goal. We have to show that there exists a primary-effect justified plan achieving the same goal, with the cost no larger than $C_r \cdot \text{cost}(\Pi)$. We may convert Π into a primary-effect justified plan by replacing some of its operators. We begin by considering the last operator, α_n. If it is not primary-effect justified, we replace it with the corresponding replacing plan. Since C_r is the largest replacing cost increase, the cost of the replacement is no larger than $C_r \cdot \text{cost}(\alpha_n)$. We repeat this process for the rest of the operators, α_{n-1}, α_{n-2}, and so on, until all operators without justified primary effects are replaced by primary-effect justified plans. It may be shown that when we replace some operator α_i, all operators *after* it remain primary-effect justified. So, after we replace all n operators, we obtain a primary-effect justified plan the cost of which is no greater than $C_r \cdot \text{cost}(\alpha_1) + .. + C_r \cdot \text{cost}(\alpha_n) = C_r \cdot \text{cost}(\Pi)$. We conclude that the cost of an optimal primary-effect justified plan that achieves S_g from S_0 is at most $C_r \cdot \text{cost}(\Pi)$, and therefore the cost increase is no greater than C_r.

(2) Consider an operator α and a state S such that the replacing cost increase of α in S is C_r, the largest of the replacing cost increases. Consider a planning problem with the initial state S and the goal to achieve all

side effects of α and to preserve the values of all literals not changed by α. The goal may be achieved by a single operator α, and thus the cost of an optimal plan is no greater than $\text{cost}(\alpha)$. On the other hand, an optimal primary-effect justified plan that solves the problem is a replacing plan for α in S, and therefore its cost is $C_r \cdot \text{cost}(\alpha)$. Thus, the cost increase is at least C_r. □

The theorem can be applied to check whether a given choice of primary effects ensures the completeness and near-optimality of a primary-effect restricted planner, by examining each operator in the domain and finding a replacing plan for the operator's side effects. The theorem can also be used to design a learning algorithm that automatically finds primary effects. We present our learning algorithm in the next section.

4 Automatically Finding Primary Effects

We would like to minimize the number of primary effects in order to limit the branching factor of search, but the selected set of primary effects must be large enough for ensuring the planner's completeness and optimality. Our algorithm is designed to ensure both of these criteria. The initial phase of the algorithm attempts to minimize the number of the primary effects. Then a learning component augments the selected set to ensure completeness and optimality.

4.1 Initial Selection of Primary Effects

First, all user-defined primary effects are taken as a part of the initial selection. Then the algorithm ensures that every literal is a primary effect of at least one operator. Thus, the algorithm makes each literal l be a primary effect of some operator. Since we wish to minimize the cost increase of planning with primary effects, the algorithm chooses the operator with the minimal cost among all operators achieving l. The corresponding procedure, *Initial_Choice*, is presented in Table 1. Here the function *User-Defined_Eff* adds primary effects chosen by the user. The function *Cheapest_Operator*(l) finds the minimal-cost operator α among the operators achieving l. If no operator achieves l, *Cheapest_Operator* returns "not-found".

Example Suppose that *Initial_Choice* is applied to our robot domain, and the user has chosen *robot-in*(x) and ¬*robot-in*(y) as primary effects of *carry-ball*(x, y). The procedure finds the cheapest operators for the remaining literals, *ball-in*, ¬*ball-in*, and *door*. The cheapest operator that achieves the literals *ball-in* and ¬*ball-in* is *throw*, and the cheapest operator for *door* is *break*. Thus, *Initial_Choice* selects the following primary effects:

go(x, y)	*none*
break(x, y)	{door(x, y)}
throw(x, y)	{ball-in(y), ¬ball-in(x)}
carry-ball(x, y)	{robot-in(y), ¬robot-in(x)}

4.2 Learning Additional Primary Effects

The learning algorithm augments the set of primary effects chosen by the procedure *Initial_Choice*. It asks the user to provide the greatest cost increase C. The value of C is the cost increase that the user is willing to accept. Then the algorithm randomly generates example plans and tests whether every example plan Π may be replaced with a primary-effect justified plan Π_1 that achieves the same goal, with the cost no greater than $C \cdot \text{cost}(\Pi)$. If such a plan Π_1 cannot be found, the algorithm selects additional primary effects for the operators.

Our method may be viewed as an inductive learning algorithm. At any moment of learning, the current selection of primary effects is the *hypothesis* of our learning method. Example plans are produced by a random-example generator. An example plan Π is a *positive example* if the planner finds a replacing primary-effect justified plan with the cost at most $C \cdot \text{cost}(\Pi)$ that achieves the same goal as Π. If a replacing plan cannot be found, the example is *negative*. Our inductive learner ignores positive examples. For each negative example, it improves the hypothesis by selecting new primary effects.

Processing One Example Plan The learning algorithm selects additional primary effects by analyzing correct plans. Given an initial state S_0, a goal S_g, and a plan Π that achieves the goal, the algorithm converts Π into a primary-effect justified plan that achieves S_g, with the cost no greater than $C \cdot \text{cost}(\Pi)$. (Recall that C is the greatest cost increase set by the user.) If the selected primary effects do not allow such a conversion, the learner selects additional primary effects.

To obtain a primary-effect justified plan, the algorithm considers each operator α of Π without justified primary effects and calls the procedure *Prim_Eff_Planner* to replace α by primary-effect justified plan Π_1, such that the cost of Π_1 is at most $C \cdot \text{cost}(\alpha)$. If the replacement found by *Prim_Eff_Planner* does not achieve all justified effects of α, then the learner chooses some justified effect l of α that is not achieved by the replacing plan and makes l a primary effect of α. After all operators are processed and new primary effects are selected as necessary, the learner obtains a primary-effect justified plan that achieves S_g. These operations are performed by the procedure *Process_Plan* shown in Table 1.

Example Let us apply the learning algorithm to our robot domain, with the initial selection of primary effects from the previous example. We choose $C = 1.5$ and consider the single-operator plan $(go(1,2))$ with the initial state as shown on the picture and the goal $\{robot\text{-}in(2)\}$. Since the operator *go* does not have primary effects, this plan is not primary-effect justified. So the learner calls the planner *Prim_Eff_Planner* (see line 3b of the algorithm) to find a primary-effect replacement for *go*. The planner fails to find a primary-effect justified plan to achieve the goal, and the learner chooses $robot\text{-}in(y)$ as a primary effect of $go(x,y)$. Thus, the selection of primary effects becomes as follows:

$go(x,y)$	$\{robot\text{-}in(x)\}$
$break(x,y)$	$\{door(x,y)\}$
$throw(x,y)$	$\{ball\text{-}in(y), \neg ball\text{-}in(x)\}$
$carry\text{-}ball(x,y)$	$\{robot\text{-}in(y), \neg robot\text{-}in(x)\}$

Now we consider another plan. Let the initial state again be as shown on the picture, and the goal is to bring the robot into Room 4, $\{robot\text{-}in(4)\}$. This may be achieved by the plan $(break(1,4))$, with the cost 4. This plan is not primary-effect justified, since the location of the robot is not the primary effect of *break*. So the learner will achieve the same goal by a primary-effect justified plan $(go(1,2), go(2,3), go(3,4))$. The cost of this plan is 6, and the cost increase is $6/4 = 1.5$, which is no greater than $C = 1.5$. Thus, the learner concludes that the effect $robot\text{-}in$ of *break* may be achieved by a replacing plan and does *not* choose it as a primary effect.

The Learner and the Example Generator The above algorithm for processing one plan is used as a subroutine by a top level loop that scans the set of operators. For each operator, it uses the condition of Theorem 1 to generate example plans for the learner. For every state S and every operator α whose preconditions are satisfied in S, the condition of the theorem makes it necessary to find a primary-effect justified replacing plan that achieves all side effects of α and leaves unchanged all literals of S that are not changed by α. Let us denote the state resulting from applying α to S by $\alpha(S)$. Then a replacing plan must achieve all literals of $\alpha(S)$ except the primary effects of α, i.e. its goal is $(\alpha(S) - Prim\text{-}Eff(\alpha))$. Thus, the example generated for a state S and an operator α is the single-operator plan (α) with the initial state S and the goal $(\alpha(S) - Prim\text{-}Eff(\alpha))$. This information is then passed to the subroutine *Process_Plan*.

For every operator α, the procedure *Learn_Prim_Eff* (Table 1) randomly chooses several states in which the preconditions of α are satisfied and generates the corresponding single-operator example plans. It generates examples until it considers m consecutive examples without adding new primary effects, where m is an integer chosen by the user. In the next section we show a relationship between m and the probability of failure when planning with the selected primary effects.

Our experiments show that it is best to process the operators in the ascending order of the number of their side effects. Intuitively, the more side effects an operator has, the larger is the probability to make a non-optimal choice of primary effects among them. However, if we consider an operator α with a large number of effects at a later stage, we may use the already selected primary effects of other operators for constructing a replacing plan for α and thus reduce the opportunities for a non-optimal choice of a new primary effect of α.

Table 1: Learning algorithm

5   Sample and Time Complexities

The performance of our inductive learning algorithm is characterized by two factors. The first factor, known as sample complexity, is the number of example plans required by the learning algorithm to reduce the probability of completeness violation to a user-specified value. The second factor is the time complexity. In this section we show that both the sample and time complexities of the learner are polynomial in domain size.

The purpose of learning is to ensure that planning with primary effects is complete and the cost increase for any problem is no greater than C. We denote by ϵ the probability that for a randomly chosen initial state S_0 and a random goal S_g achievable from S_0 by an optimal plan Π, there is no primary-effect justified solution with the cost no greater than $C \cdot \text{cost}(\Pi)$. Informally, ϵ is

the probability that a primary-effect restricted planner behaves worse than expected.

Intuitively, the value of ϵ decreases with increasing the number of example plans analyzed by the learner. The number of plans produced by the example generator depends on the user-defined constant m (see the previous section and line 8c of the algorithm). The theorem below establishes a relationship between m and ϵ.

Theorem 2 *Consider a random problem with an optimal solution* $(\alpha_{\text{init}}, \alpha_1, \alpha_2, .., \alpha_n, \alpha_{\text{goal}})$. *The probability that the problem does not have a primary-effect justified solution within the cost increase C is no larger than*

$$\frac{|Eff(\alpha_1)| + |Eff(\alpha_2)| + ... + |Eff(\alpha_n)| + n}{m + 1}$$

The proof of the theorem may be found in [Fink and Yang, 1992c]. The theorem shows that ϵ decreases in reverse proportion to m.

The running time of the learning algorithm depends on the size of a domain, the maximum allowed cost increase C, and m. For every α, the algorithm generates examples until the value of *Count* reaches m (see line 8c). *Count* is used to count the number of the already generated examples. It is set back to 0 when the algorithm selects a new primary effect of α, and thus it may be set to 0 at most $|Eff(\alpha)|$ times, where $|Eff(\alpha)|$ is the number of effects of α. Therefore, the maximal number of examples generated for α is $m \cdot |Eff(\alpha)|$, and the number of examples for all operators is no greater than $m \cdot \sum_\alpha |Eff(\alpha)|$. Thus, the number of examples is proportional to m, and therefore *the value of ϵ decreases in the reverse proportion to the number of examples.*

The maximal allowed cost increase, C, determines the depth of the search for replacing plans, performed by the procedure *Process_Plan*. Thus the running time of analyzing each example exponentially depends on C. However, for small C search does not take long time. If we assume that C is a *constant*, the time complexity of *Prim_Eff_Planner* becomes polynomial in the size of a domain. The other parts of *Learn_Prim_Eff* and the procedure *Initial_Choice* run in polynomial time.

6   Conclusions

This paper presents a formalism for planning with primary effects. It describes a method of selecting primary effects for the purpose of improving the efficiency of planning without losing its completeness. The paper also demonstrates a tradeoff between the reduction of the branching factor of planning and the cost of resulting plans. This tradeoff shows a dependency between the running time of a primary-effect restricted planner and the quality of plans produced by the planner.

The algorithm presented in the paper is novel in that it *automatically* finds primary effects. The learner may be integrated with an algorithm presented in [Fink

and Yang, 1992b] to increase the number of levels of ordered abstraction hierarchies generated by ALPINE [Knoblock, 1990], while preserving the completeness of planning and ensuring a small cost increase.
