DEAR Reader, it is our pleasure to present to you Proceedings of the 2018 Federated Conference on Computer Science and Information Systems (FedCSIS), which took place in Poznań, Poland, on September 9-12, 2018.

FedCSIS 2018 was Chaired by prof. Krzysztof Jassem, while dr. Paweł Skórzewski acted as the Chair of the Organizing Committee. This year, FedCSIS was organized by the Polish Information Processing Society (Mazovia Chapter), IEEE Poland Section Computer Society Chapter, Systems Research Institute Polish Academy of Sciences, Warsaw University of Technology, Wrocław University of Economics, and Adam Mickiewicz University.

FedCSIS 2018 was technically co-sponsored by: IEEE Region 8, IEEE Poland Section, IEEE Computer Society Technical Committee on Intelligent Informatics, IEEE Czechoslovakia Section Computer Society Chapter, IEEE Poland Section Gdańsk Computer Society Chapter, SMC Technical Committee on Computational Collective Intelligence, IEEE Poland Section Systems, Man, and Cybernetics Society Chapter, IEEE Poland Section Control System Society Chapter, IEEE Poland Section Computational Intelligence Society Chapter, ACM Special Interest Group on Applied Computing, International Federation for Information Processing, Committee of Computer Science of the Polish Academy of Sciences, Polish Operational and Systems Research Society, Mazovia Cluster ICT Poland and Eastern Cluster ICT Poland. FedCSIS 2018 was sponsored by Intel, Gambit, Samsung, Silver Bullet Labs, eSensei and Data Center PPNT.

During FedCSIS 2018, keynote lectures have been delivered by:

- Aksit, Mehmet, University of Twente, "*The Role of Computer Science and Software Technology in Organizing Universities for Industry 4.0 and Beyond*"
- Bosch, Jan, Chalmers University Technology, "*Towards a Digital Business Operating System*"
- Duch, Włodzisław, Nicolaus Copernicus University, "*Neurocognitive informatics for understanding brain functions*"
- O'Connor, Rory, V., Dublin City University, "*Demystifying the World of ICT Standardisation: An Insiders Viewpoint*"

FedCSIS 2018 consisted of the following events (conferences, symposia, workshops, special sessions). These events were grouped into FedCSIS conference areas**,** of various degree of integration. Specifically, those listed without indication of the year 2018 signify "abstract areas" with no direct paper submissions to them (but with submissions to their enclosed events).

- **AAIA'18 – 13th International Symposium Advances in Artificial Intelligence and Applications**
  - AIMaViG'18 – 3rd International Workshop on Artificial Intelligence in Machine Vision and Graphics
  - AIMA'18 – 8th International Workshop on Artificial Intelligence in Medical Applications
  - AIRIM'18 – 3rd International Workshop on AI aspects of Reasoning, Information, and Memory
  - ASIR'18 – 8th International Workshop on Advances in Semantic Information Retrieval
  - DMGATE'18 – 1st International Workshop on AI Methods in Data Mining Challenges
  - SEN-MAS'18 – 6th International Workshop on Smart Energy Networks & Multi-Agent Systems
  - WCO'18 – 11th International Workshop on Computational Optimization
- *CSS – Computer Science & Systems*
  - BEDA'18 – 1st International Workshop on Biomedical & Health Engineering and Data Analysis
  - CANA'18 – 11th Workshop on Computer Aspects of Numerical Algorithms
  - C&SS'18 – 5th International Conference on Cryptography and Security Systems
  - CPORA'18 – 3rd Workshop on Constraint Programming and Operation Research Applications
  - LTA'18 – 3rd International Workshop on Language Technologies and Applications
  - MMAP'18 – 11th International Symposium on Multimedia Applications and Processing
- *iNetSApp – International Conference on Innovative Network Systems and Applications*
  - INSERT'18 – 2nd International Conference on Security, Privacy, and Trust
  - IoT-ECAW'18 – 2nd Workshop on Internet of Things - Enablers, Challenges and Applications
- *IT4MBS – Information Technology for Management, Business & Society*
  - AITM'18 – 15th Conference on Advanced Information Technologies for Management
  - ISM'18 – 13th Conference on Information Systems Management
  - KAM'18 – 24th onference on Knowledge Acquisition and Management
- *SSD&A – Software Systems Development & Applications*
  - MDASD'18 – 5th Workshop on Model Driven Approaches in System Development
  - MIDI'18– 6th Conference on Multimedia, Interaction, Design and Innovation
  - LASD'18 – 2nd International Conference on Lean and Agile Software Development
  - SEW-38 & IWCPS-5 – Joint 38th IEEE Software Engineering Workshop (SEW-38) and 5th International Workshop on Cyber-Physical Systems (IWCPS-5)
- **DS-RAIT'18 – 5th Doctoral Symposium on Recent Advances in Information Technology**

The 2018 edition of an AAIA'18 Data Mining Challenge is a continuation of the topic from the previous year – data analytics related to video games. In particular, it was focused on a popular collectible card video game *Hearthstone: Heroes of Warcraft*. Awards for the winners of the contest were sponsored by: Silver Bullet Solutions, eSensei and the Mazovia Chapter of the Polish Information Processing Society. Papers resulting from the competition constitute a separate section of these Proceedings.

Each paper, found in this volume, was refereed by at least two referees and the acceptance rate of regular full papers was ~21,2% (74 papers out of 349 general submissions).

The program of FedCSIS required a dedicated effort of many people. Each event constituting FedCSIS had its own Organizing and Program Committee. We would like to express our warmest gratitude to all Committee members for

their hard work in attracting and later refereeing 349 submissions (regular and data mining).

We thank the authors of papers for their great contribution to research and practice in computing and information systems. We thank the invited speakers for sharing their knowledge and wisdom with the participants. Finally, we thank all those responsible for staging the conference in Poznań. Organizing a conference of this scope and level could only be achieved by the collaborative effort of a highly capable team taking charge of such matters as conference registration system, finances, the venue, social events, catering, handling all sorts of individual requests from the authors, preparing the conference rooms, etc.

We hope you had an inspiring conference and an unforgettable stay in the beautiful city of Poznań. We also hope to meet you again for FedCSIS 2019 in Leipzig, Germany.

Adopting a Digital Business Operating System

Jan Bosch

***Abstract*—The role of software in society and in industry in particular continues to grow exponentially. Most companies either have or are in the process of adoption continuous deployment of their software at products in the field and collect data concerning the performance of their systems. The continuous, fast feedback loops that companies now have available allow for a fundamentally different way of organizing. In fact, based on our work with dozens of companies, we have come to the conclusion that companies are moving towards a new, digital operating system. In this paper, we first present the key elements of the digital operating system and then discuss some of the challenges companies experience during the transformation.**

I. Introduction

AS A POPULAR QUOTE says, in the future, all companies will be software companies. It is safe to say that this is no longer the future, but reality today. Ranging from telecommunications to automotive and from banks to retail companies, the key differentiator for virtually any company these days is it's ability to create, deploy and evolve software better than its competitors. In fact, every company these days is a software-intensive business (SIB).

One of the main focus areas for SIBs is the adoption of continuous deployment, meaning that new software is deployed in systems on a frequent basis (at least every agile sprint). As part of continuous deployment, the company often also deploys instrumentation to ensure that the systems continue to function as desired. This instrumentation generates data that not only provides information about any quality issues, but also about the value that the software is generating for customers and for the company itself. This causes the adoption of data-driven practices.

Generalizing from these observations, and based on research that we have conducted with dozens of companies over the last decade, we have concluded that industry is moving towards an new, digital business operating system. This operating system consists of four dimensions:

- **Speed**: The history of SIBs is defined by constantly increasing speed. From yearly to quarterly to continuous releases, software is deployed more frequently. The primary driver for this speed is the shortening of feedback loops. The goal is to shorten the time from making a decision to observing or measuring the effect of the decision to the shortest possible.
- **Data**: When a company has a mechanism to deploy new software to its servers or products in the field, this implies that it also is possible to get data back. Although the notion of "Big Data" is prevalent and especially online companies can be very advanced in their use of data, such as through the application of A/B/n experimentation, our research shows that many companies still make quite limited use of the available data as a resource.
- **Ecosystems**: The third dimension is concerned with the ecosystems surrounding a SIB. Although traditional companies tend to aim at performing as much of the required activities internally, modern companies focus their own resources on the activities where the company is uniquely differentiating and partner with others for everything else.
- **Empowerment**: Finally, when a SIB has a solid understanding of what it seeks to do in-house and the data to track the creation and delivery of value, the need for the traditional hierarchical organization disappears or at least is diminished radically. Instead, individuals and teams can be empowered to deliver on defined output metrics without having to be managed in conventional ways. Teams that deliver continue to thrive and teams that fail to deliver on expectations receive help and support to improve or, failing that, are disbanded.

This work was supported by Software Center (www.software-center.se).

The remainder of this paper is organized as follows. In the next section, we present each of the dimensions of the digital business operating system framework in more detail. Subsequently, we highlight some of the challenges that companies experience when adopting aspects of the framework. Finally, we conclude the paper in section IV.

II. Digital Business Operating System

As we discussed in the introduction, software intensive businesses tend to adopt aspects of a new digital business operating system framework. This framework consists of four dimensions, i.e. speed, data, ecosystems and empowerment. In the subsequent sections, we present each dimension in a more detail.

A. Speed

Companies evolve through a number of typical steps when increasing the speed of their operations. As shown in figure 1, in our research, we have identified five key steps. These steps are traditional development, agile development, continuous integration, continuous deployment and, finally, R&D as an

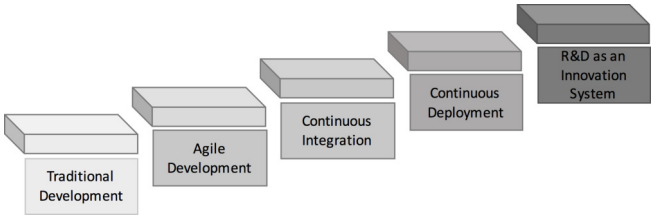

Fig. 1. The *speed* dimension

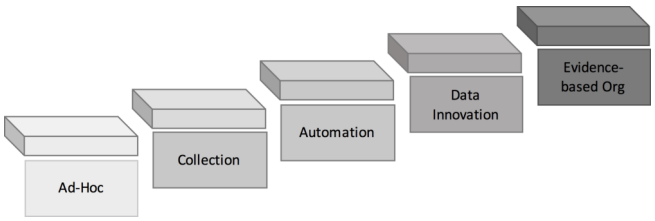

Fig. 2. The *data* dimension

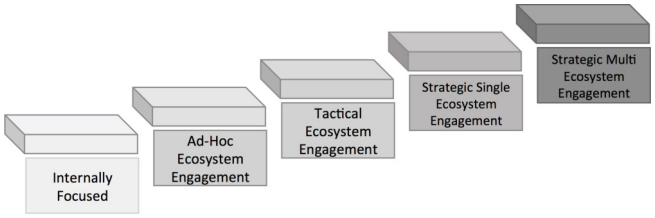

Fig. 3. The *ecosystems* dimension

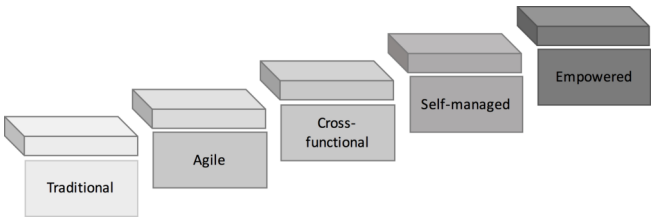

Fig. 4. The *empowerment* dimension

experiment system. All except the last term are well known. The final step is where the company starts to use its installed base and data capability to experiment with alternative ways of realizing functions and features.

For more information on the speed dimension, we refer to [5] and [4].

B. Data

The data dimension also presents the typical steps that a company evolves through when adopting data-driven practices. As shown in figure 2, companies move from working with data in an ad-hoc fashion to automating the collection to data. The next step is where the company introduces dashboards and other techniques to automatically collect, analyze and present data. The data innovation step is where the company continuously looks for novel insights in the available data in order to continuously update and improve dashboards and other outputs. The final stage is where all processes in the company are driven by data, including hiring, performance reviews and management.

For more information on the data dimension, we refer to [6], [7] and [8].

C. Ecosystems

The third dimension is concerned with the way the company works with the ecosystems surrounding it. No company is an island and by necessity interacts with suppliers, customers, complementers, competitors, regulators, governments and other stakeholders. However, many companies have a tendency to focus their energy internally and try to conduct as much as possible inside the walls of the company. Companies that have adopted the digital business operating system are much more concerned about focusing their own resources where they have the most differentiation and, consequently, can add the most value. For everything else, these companies engage their ecosystem partners.

In figure 3, the typical evolution path for a company is shown. Starting from an internal focus, the company initially engages with ecosystem partners in an ad-hoc fashion, then proceeds to a more tactical approach and over time becomes increasingly strategic about its engagements with the ecosystem.

For more information on the ecosystems dimension, we refer to [3], [10] and [2].

D. Empowerment

The final dimension of the digital business operating system addresses the organizational question. Traditionally, companies have been organized hierarchically, largely mirroring the military organizations that were one of the few examples of organizing large groups of individuals that existed at the beginning of the industrial revolution. Hierarchical organizations are effective for organizing repetitive and often manual work in low-complexity contexts, but fail in high complexity situations where creativity and non-standard solutions are required. As virtually all repetitive work these days is automated, the only work left for individuals is that which can not easily be standardized. Consequently, we need alternative ways of organizing and the common denominator is empowerment.

In figure 4, the typical evolution path for a company moving from traditional hierarchies to empowerment is shown. Starting from a hierarchical approach to organizing, agile software development provides a first step on the transition to empowerment as agile teams have significantly more freedom to operate than their counterparts working in a hierarchical waterfall approach. From there, we see companies adopt increasing cross-functional empowerment, fully self management and finally the fully empowered state.

For more information on the empowerment dimension, we refer to [9] and [1].

III. Challenges

Adopting the digital business operating system for a company that has worked traditionally is quite challenging as it affects all functions in the company. In addition, everything from business models to system architecture, from process to organization and from formal structures to company culture is affected. Consequently, the challenges that companies experience are significant and it is sometimes difficult to separate root causes from symptoms that are the consequence of root causes.

In order to provide a high-level overview of the key challenges that companies experience, we use the BAPO model [1]. The BAPO model considers business, architecture, process and organization. In the sections below, we briefly discuss the key challenges that companies experience when adopting the digital business operating system.

A. Business

Most product companies have traditionally maintained a transactional business model, meaning that customers engage with the company every couple of years or even decades. For instance, most people will buy a new car every five years and have little connection with the car company in the meantime. One of the consequences of digitalization is that it typically assumes a continuous deployment model for software. This has several consequences for the business.

The first consequence is that the business model changes from a product-centric to a service-centric model. In many industries, customers subscribe to a service in order to get access to the product, rather than buying it outright. That changes the customer relationship from a transactional to a continuous one. A second consequence is that it requires a different financial model because the company needs to finance the product for the customer and then earn back the cost through service.

B. Architecture

There are two primary changes required to the architecture when adopting a digital business operating system. First, because we're looking to support continuous deployment, it is typically required to deploy individual components independently in order to avoid significant downtime on systems in the field. This requires a significantly improved level of modularization.

Second, as we're looking to use the data from systems in the field for managing quality and for determining whether we're delivering value for customers, the architecture needs to be prepared for easy instrumentation of arbitrary parts of the system. Our research shows that companies often seek to add points of data collection and instrumentation continuously.

C. Process

Continuous deployment, as we saw in the speed dimension of the digital business operating system, requires continuous integration and test. Although many companies pride themselves on the high quality of their systems, experience shows that many companies require significant investment in build and test infrastructure before the quality of software reaches a point where it can be deployed continuously.

Second, although agile practices are widely adopted at the team level, true business agility where all functions in the company operate in short cycles and can rapidly respond to changes in the market is an elusive concept for many organizations. Product management, marketing, sales, systems engineering and general management often have a tendency to operate in yearly and quarterly cycles and convincing these functions to adopt a continuous, agile approach is a significant challenge.

D. Organization

As indicated in the discussion around the empowerment dimension, to successfully operate in this new approach, the traditional hierarchical and functionally structured company needs to be reorganized into smaller cross-functional teams. The amount of coordination overhead and delay in traditional organizations is simply too costly and slow.

An interesting observation from our research is that company culture often has significant number of implicit assumptions that are based on a waterfall style of doing business, meaning that the change towards digitalization requires a fundamental change of the company culture itself. As culture eats strategy for breakfast, as the saying goes, it requires significant effort and role modeling from leaders to instill the cultural changes required to successfully operate in this new model.

IV. Conclusion

Virtually all companies these days are software-intensive businesses. Across domains, such as telecommunications, automotive, finance, defense and retail, the ability to create, deploy and evolve better software faster than competitors is the key differentiator.

Our research that we have conducted with dozens of companies over the last decade has led us to the conclusion that industry is moving towards an new, digital business operating system. This operating system consists of four dimensions:

- **Speed**: The history of SIBs is defined by constantly increasing speed. From yearly to quarterly to continuous releases, software is deployed more frequently. The primary driver for this speed is the shortening of feedback loops. The goal is to shorten the time from making a decision to observing or measuring the effect of the decision to the shortest possible.
- **Data**: When a company has a mechanism to deploy new software to its servers or products in the field, this implies that it also is possible to get data back. Although the notion of "Big Data" is prevalent and especially online companies can be very advanced in their use of data, such as through the application of A/B/n experimentation, our research shows that many companies still make quite limited use of the available data as a resource.

- **Ecosystems**: The third dimension is concerned with the ecosystems surrounding a SIB. Although traditional companies tend to aim to performing as much of the required activities internally, modern companies focus their own resources on the activities where the company is uniquely differentiating and partner with others for everything else.
- **Empowerment**: Finally, when a SIB has a solid understanding of what it seeks to do in-house and the data to track the creation and delivery of value, the need for the traditional hierarchical organization disappears or at least is diminished radically. Instead individuals and teams can be empowered to deliver on defined output metrics without having to managed in a conventional way. Teams that deliver continue to thrive and teams that fail to deliver on expectations receive help and support to improve or, failing that, are disbanded.

The transition from a traditional mode of operating to this new operating system is far from trivial and in section III we discussed some of the key isseus that SIBs experience. These challenges range from business and business model to architecture, process, organization as well as the norms, beliefs and culture of the company.

In the context of Software Center, we continue to study the challenge of Digitalization with the partner companies and help accelerate the adoption of the digital business operating system at these and other companies.

ACKNOWLEDGMENT

I would like to thank the companies involved in the Software Center as well as other companies that I have interacted with during the last years.

The Role of Computer Science and Software Technology in Organizing Universities for Industry 4.0 and Beyond

Mehmet Akşit

***Abstract*—Based on intensive cooperation with four large companies, a comparative analysis of the recent developments in industry, university organizations, computer science and software technology is presented. Within this context, also the Industry 4.0 phenomena is discussed. This paper further identifies the necessary organizational structures of universities to assist companies in their transition processes, defines the relevant sub-disciplines in computer science and finally describes the software engineering and technology challenges in designing and implementing economical and robust industrial systems.**

I. Introduction

INDUSTRY 4.0 aims at increasing the efficiency and effectiveness of manufacturing processes with the help of large-scale computerization. It is stated that Industry 4.0 is the 4th industrial revolution in the history of manufacturing. Publications on Industry 4.0 generally try to set-up a conceptual framework to explain what the Industrial 4.0 phenomena is. There are also some ongoing efforts on structuring universities and knowledge institutes so that their research and education activities can seamlessly support this upcoming transition towards Industry 4.0. We consider Industry 4.0 as a natural development in continuous transition from traditional to modern manufacturing processes. Since transitions occur with the help of technology, organizational structure of universities are crucial in accomplishing the Industry 4.0 objectives. The role of computer science and software technology is undisputable, since the success of Industry 4.0 largely depends on effectiveness and efficiency of computing systems. Based on our experience with four large high-technology companies, this paper introduces the attributes of the phenomena Industry 4.0 and beyond, depicts the required organizational structures of universities to assist companies in their transition processes, identifies the relevant sub-disciplines in computer science and finally describes the software engineering and technology challenges in designing and implementing economical and robust high-quality Industry 4.0 systems.

II. Industry 4.0 and Beyond

The term Industry 4.0 refers to computerization of manufacturing processes. There are four principle scenarios in Industry 4.0 [1]:

- **Interoperability** meaning that sensors, devices, machines, and people can connect and exchange information with each other.
- **Information transparency** meaning that a rich set of data can be gathered from various sources.
- **Technical assistance** meaning that machines, systems, processes, human beings, etc. can be intelligently and effectively assisted to monitor, control and optimize the overall manufacturing process.
- **Decentralized decisions** meaning that subsystems can autonomously take decisions where possible.

It is claimed that Industry 4.0 is the 4th industrial revolution in the history of manufacturing [2]. With Industry 4.0, it is expected that machines and systems will become more self-aware and self-learning so that their effectiveness and maintenance can be improved. In addition, due to networked data gathering and intelligent and autonomous process control, the manufacturing processes will be much more efficient and effective than traditional manufacturing processes.

One criticism to these claims is that industrial innovation is continuous and as such one cannot talk about a revolution [3]. Moreover, although there are some attempts to define the technical implications of Industry 4.0, it seems that Industry 4.0 touches to a large set of disciplines from sensors, industrial manufacturing to computer science and software technology (CS-ST). In particular, almost all disciplines of CS-ST are relevant for Industry 4.0.

We think that the concepts relevant to Industry 4.0 must be defined and understood in the process of on-going transition from traditional to modern manufacturing processes. It is important to stress that such transitions are not abrupt in nature but gradual, depending on the characteristics of manufacturing, technological and societal progresses. In the following we will make an attempt to compare traditional and modern manufacturing processes with each other.

Traditionally, the term industrial manufacturing referred to labor-intensive factories with specialized product portfolio. Production processes and products to be manufactured had to be predefined precisely. Process and product control and optimization activities were carried out in each phase of production separately. Due to advent of new technologies and changes in social structures, however, there have been

continuous changes to the ways how industrial manufacturing is realized. For example, during the last two to three decades, the following transitions have been observed in highly industrialized countries:

1. Knowledge intensive manufacturing **instead of** labor/ resource-intensive manufacturing. There is a greater dependence on intellectual capabilities than on physical inputs or natural resources [4].
2. Focus on owning and managing knowledge and skills and intellectual property rights **instead of** focusing on labor/resource intensive manufacturing processes [5]. When planned carefully and in certain circumstances, it may be much more profitable to outsource some activities and manufacturing processes [6].
3. Dynamically managed and optimized, multi-asset portfolio **instead of** fixed/ad-hoc, single-asset portfolio. The advantages are risks reduction, controlled risk taking, capital preservation and enhanced returns [7][8].
4. Mass customization **instead of** mass production. Mass customization is the automated manufacturing of tailored products. It has the combined advantages of the low unit costs of mass production with the flexibility of building products for more customer satisfaction [9].
5. Proactive self-organizing companies **instead of** inflexible hierarchically-organized companies. Such new organizational structures aim at effectively responding to changing markets and business contexts [10].
6. End-to-end alignment and optimization of (manufacturing) processes **instead of** focusing only on the improvement of individual phases. This improves companies due to enhancement of the whole supply-chain [11].
7. Multi-disciplinary usage of teamed personnel **instead of** working with solely operating individuals. Teaming helps organizations in continuous improvement, understanding complex systems, and in successful innovation [12].
8. Organizing businesses/enterprises globally through networks **instead of** isolated and/or localized organizations. This is an increasing necessity for any entrepreneurship and value creation [13]-[15].
9. Improved time-to-market **instead of** long sequences of research, design, manufacturing and marketing phases [16].
10. Intensive use of state-of-art CS-ST as the "main enabler" of modern businesses **instead of** considering CS-ST just like any other technical skill. CS-ST is essential in fulfilling the requirements of modern businesses, such as described in [9][11][13]-[16].
11. Strong cooperation with universities for the purpose of innovation **instead of** considering universities mainly as theoretical institutions that educate people [17]-[19].

From a rather narrow perspective, the term Industry 4.0 refers to autonomous cyber physical systems. Transitions that we observe in industry and formulated in 11 items in this section give a more comprehensive picture of this phenomena. They also refer to changes in business, manufacturing, marketing, organizational and industry-university cooperation processes. The related technical challenges will be discussed in the following sections of this paper. It is clear from these items that Industry 4.0 refers to (or a new name of) a part of a natural transition in manufacturing processes which has been taking place since several decades. We therefore term this list as "a list of attributes of manufacturing processes for Industry 4.0 and beyond".

III. Organizing Universities for Industry 4.0 and Beyond

Traditional universities have contributed to industries by educating engineers, applied mathematicians, administrative personnel, managers, etc. Within this context, two main categories of activities have been considered essential:

- **Research**, where academic personnel of the university are expected to be expert in certain fields. The selection of the topic of a field is not necessarily derived from industrial and societal needs; it can be ad hoc. The expertise is quite specific and theoretical. The excellence is measured according to number of publications in certain pre-classified journals.
- **Education**, where academic personnel of the university are expected to give lectures in their fields of expertise and examine the students by appropriate tests. In addition, students are expected to be supervised in writing their theses.

We believe that traditional universities with these characteristics cannot fulfil the requirements as demanded by modern industrial manufacturing processes and businesses as formulated in the previous section. Moreover, classical education methods, like long lectures followed by classical examinations cannot give the necessary education baggage to the students as desired. As such, we think that the following strategical and tactical changes are required:

1. Excellence in knowledge and in-depth specialization for academic personnel are still required. However, **the specializations must be derived from the needs of the targeted society and industry** instead of ad-hoc selection of topics; along this line, the topics must be synthesized through the scope of industrial and societal mid-term and long-term objectives. Otherwise, universities cannot be equipped with the necessary expertise in supporting companies in their innovative processes.

2. **The academic personnel must learn to work together in multi-disciplinary teams**. For example, theory-oriented persons must be able to work with practically-oriented-persons, and vice versa, different experts in the same discipline or among different disciplines, must cooperate together in university-industry joint projects. Otherwise, the complex problems of industry and society cannot be addressed effectively.
3. **The academic personnel must be proactive in forming networks** to cooperate with national and international institutions and colleagues not only from his/her own discipline but also from other disciplines. This is necessary to share expertise, to jointly define the desired research agenda, and to find solutions to complex industrial and societal problems.
4. **The academic personnel must be flexible enough to adapt themselves** in changing demands from industry and society. Otherwise, in due time, the expertise of academic personnel can be outdated or become less relevant.
5. The **education process must be tailored** to answer the mid-term and long-term needs of industry and society:

    - It must focus on the core concepts **instead of** hypes.
    - It must focus on gaining analytical skills, critical thinking and reasoning **instead of** memorizing what are in the books.
    - It must aim at teaching problem solving/synthesis **instead of** gaining knowledge which cannot be utilized for solving actual problems.
    - It must emphasize working in multi-disciplinary projects **instead of** only focusing on mono-disciplinary exercises.
    - It must enhance communication skills, such as oral and written presentation and argumentation skills **instead of** educating students with non-communicative and introvert attitude.
    - It must aim at increasing consciousness of students in ethical concerns **instead of** educating students with irresponsible and/or indifferent attitude.

6. The university must create **suitable organizational structures** to enable the academic personnel efficiently and effectively fulfil the objectives listed above. These include:

    - **Proactive and self-adaptive organization** to support the objectives of the university in dynamically changing contexts.
    - Organization to set-up and carry-out **multi-disciplinary projects** for industry and society.
    - Organization with an **award system to motivate** the academic personnel and students along the objectives of the university.
    - Organization which **emphasizes CS-ST** since it is the “main enabler” of all disciplines at the university.

To derive the required specializations within universities the following activities can be carried out:

1. **Understanding the context** of the university.
2. **Defining the strategic needs** of companies and society.
3. **Analyzing the current structure** of the university.
4. **Identifying the strong and weak points** of the university.
5. Based on the observations of the future trends as stated in the paper, **formulate a transition plan**.

These steps look quite obvious but due to involvement of many stakeholders, they are harder to implement than one may expect. While realizing the transition, the following quality attributes can be considered:

- **Relevancy**: The university must be highly relevant in addressing technical and social needs. To this aim, research, education and organization activities must be defined in close cooperation with the relevant companies and societal organizations.
- **Alignment with the current state-of-the-art research**: The research and education activities to be carried out must advance the state-of-the-art so that the companies and businesses can be matured to be the leaders in their context.
- **Cross-fertilization**: Different university research and education activities can benefit from each other. To maximize the benefit, it is important to strongly coordinate the related activities with each other.
- **Industry-as-laboratory**: To identify the relevant problems and to test the proposed solutions, it is important that the principle investigators and the affiliated (Ph.D. and/or M.Sc., etc.) students visit the companies regularly and carry out experiments within industrial and societal context. To this aim, companies must provide personal assistance and industrial case studies.
- **Academic research steering committee**: To coordinate the activities effectively and efficiently, it is important to mentor the students and monitor the progress of research and education activities and evaluate them with respect to the desired objectives. To this aim, academic research steering committees can be established where all the relevant stakeholders participate.

There have been also some attempts to classify universities according to their contributions to industry and society. To this aim, the concept of University 4.0 has been introduced. In [20], University 4.0 is defined as "an university which is outward looking, deeply connected to industry and the communities around it, and committed to serving the needs of its students". The definition of University 4.0 is largely consistent with our observations about the necessary changes of university organizations as presented in this paper. However, we consider evolution of industries and as well as universities as continuous processes which influence each other. Although correlated, it looks like that the developments around Industry 4.0 and University 4.0 currently are not structurally related. That is, both developments can actually be viewed and realized independent of each other. Our focus in this paper is more from technological perspective, which needs to be supported by dedicated methods. We consider discussions around University 4.0 is useful, but the conceptualization of this terminology is still in a premature state.

IV. The Developments in Computer Science and Software Technology

CS-ST is the main force in almost all industries; it creates added value for products and businesses. There is almost no product in the market which does not contain software or is not produced by a process controlled by software. To accomplish the objectives of Industry 4.0 and beyond, advanced CS-ST is needed.

There are all kinds of hypes over CS-ST in the popular media. Nevertheless, the recent developments in CS-ST are more or less shaped around the following topics:

1. Large infrastructures, service-oriented architectures, cloud computing, systems-of-systems, ecosystems [21]-[23].
2. Sensors, Internet of Things (IOT), and pervasive computing [24]-[26].
3. Big data and big data analytics [27]-[29].
4. Security and cybersecurity [30][31].
5. Cyber-physical systems [32].
6. Artificial intelligence and related topics including computational intelligence, machine learning and multi-agent systems [33]-[36].
7. Graphical processing, visualization and human-machine interaction including virtual reality [37][38].
8. High performance, and/or multi-core/parallel architectures including parallel programming [39].
9. Theoretical and practical work on algorithms and/or constraint-based "solvers" [40][41] to address a large category of mathematical problems. In general algorithms/solvers are applied to every category of computer science specializations listed in this section.
10. Software (engineering) methods and techniques [42] to fulfil the functional and qualitative requirements of software systems. The concepts of software engineering can be applied to every computer science specialization listed in this section.

V. The Role of Software Engineering Methods and Techniques

Economical, sustainable and robust software systems which fulfil functional and qualitative requirements are essential for all software systems. To accomplish the requirements of Industry 4.0 and beyond, software engineering methods and techniques are crucial. **No matter how intelligent a software solution is, if it cannot be realized with the desired quality attributes, one cannot expect an economical value out of it**. As such software engineering methods and techniques can be defined as crosscutting (meta-level) concerns that relate to all developments within CS-ST. In addition, many recent developments in computer science are more and more utilized within software engineering methods and techniques. The trends in software engineering methods and techniques therefore cannot be considered separately from the recent developments in computer science. For example, big data analytics and machine learning techniques are increasingly used to tune and optimize software engineering models and methods, cloud architectures and ecosystems are becoming part of software development environments, visualization techniques are used to detect anomalies in software architecture, etc.

After 4 years of intensive cooperation with high-tech industry, for example, we have identified the following trends [19]:

1. Product-line **instead of** product design. Most products are developed and manufactured by specialized companies, which market families of products. It is not economical to develop each product from scratch [43][44].
2. Systems of systems **instead of** systems perspective. Software systems for Industry 4.0 are generally adopted in large distributed settings. Scale-ability and interoperability of systems are essential. Systems of systems architectures, are therefore the natural candidates of the platforms of Industry 4.0 architectures [23].
3. Ecosystem design **instead of** platform design. Software ecosystems are an effective and economical way to construct large software systems for Industry 4.0 on top of a software platform by adding up software modules developed by different actors. In ecosystem design software engineering is spread outside the traditional borders of software companies to a group of companies and private persons [45].
4. Auto-adaptive control architectures **instead of** architectures without any control mechanisms. To realize the monitoring and controlling activities in Industry 4.0 and to cope with the changing requirements and context, software systems are expected to be more re-

active and self-adaptive. This generally requires built-in feedback control mechanisms in software. Self-adaptation can be realized at system level, subsystem level and/or at component-level. In addition, different styles can be adopted, such as single, master-slave, hierarchical and/or peer-to-peer control architectures [46][47].

5. Distributed problem solving including distributed algorithms, coordinating systems and multi-agent architectures **instead of** centralized problem solving with monolithic and/or localized architectures. Since computer systems for Industry 4.0 are distributed, to reduce complexity and enhance reliability, algorithms and intelligence in systems must be distributed as well. Accordingly, programming languages and techniques must adequately support distributed programming efforts by offering expressive and flexible abstractions [48]-[52].
6. Model-based development **instead of** straight-forward programming. Since more and more companies are specialized in certain product categories and in manufacturing processes, deriving software architecture from relevant domain models can help in reducing complexity, enhancing reuse and testability/verifiability of software systems. Model-based development has been adopted in various approaches such as product-line engineering (SPLE), model-driven engineering (MDE), domain specific architectures (DSA) and domain-specific programming languages (DSL), model-based verification (MBV), etc. [53]-[56].
7. Multi-objective optimization **instead of** ad-hoc handcrafted and/or single objective optimization. Along the line of model-based development, various algorithmic techniques and search-based methods have been introduced to compute the "optimal" architectural decomposition with respect to certain quality attributes. In addition, various run-time optimization techniques can be adopted in computing optimal control strategies and scheduling processes [57]-[59].
8. Modularization of semantic concerns **instead of** traditional abstraction mechanisms based on implementation concerns such as data or function. As a consequence of model-based development, software abstractions more and more correspond to the concerns of models. The concerns of a model are naturally based on the semantics of the model, and these cannot always be effectively represented as a data or function. Moreover, concerns in Industry 4.0 systems can be emerging meaning that they may appear or disappear dynamically. As such, programming languages and techniques must adequately support programming efforts by offering expressive and flexible abstractions for emergent semantic concerns [60] [61].
9. A rich set of composition mechanisms **instead of** a fixed set of language constructs for hierarchical organization of programs (such as class-inheritance). To support flexibility in control strategies and to cope with various evolution schemes, languages must offer generic and/or domain specific composition mechanisms to express, for example, object, aspect and event compositions and transformational techniques in a uniform manner. The languages must maintain their closure property in compositions so that scaleability of systems can be provided [62]-[67].
10. Uniform integration of verification techniques **instead of** independent tool- and technique-specific verification approaches. There are various model-based verification and testing approaches available. Examples are model-checking, static and dynamic analysis, run-time verification, model-based testing, adopting model-specific verification (simultaneously) based on continuous and/or discrete models, etc. Most of these techniques are complementary and as such combined usage of these may help in finding faults with less false-positive and false-negative cases [62][67]-[69].

VI. Conclusions

Industrial manufacturing today differs considerably from the past and there is a strong evidence that this trend will also continue in the future. The Industry 4.0 phenomena should be considered in this context. The main force behind this chance is the continuous evolution in CS-ST. Naturally, universities are indispensable elements of this progress. It is therefore important to carefully monitor and comparatively understand the recent developments in industry, and accordingly understand the impact of the trends in university organizations, computer science and software technologies.

13th International Symposium Advances in Artificial Intelligence and Applications

AAIA'18 brings together scientists and practitioners to discuss their latest results and ideas in all areas of Artificial Intelligence. We hope that successful applications presented at AAIA'18 will be of interest to researchers who want to know about both theoretical advances and latest applied developments in AI.

Topics

Papers related to theories, methodologies, and applications in science and technology in the field of AI are especially solicited. Topics covering industrial applications and academic research are included, but not limited to:

- Decision Support
- Machine Learning
- Fuzzy Sets and Soft Computing
- Rough Sets and Approximate Reasoning
- Data Mining and Knowledge Discovery
- Data Modeling and Feature Engineering
- Data Integration and Information Fusion
- Hybrid and Hierarchical Intelligent Systems
- Neural Networks and Deep Learning
- Bayesian Networks and Bayesian Reasoning
- Case-based Reasoning and Similarity
- Web Mining and Social Networks
- Business Intelligence and Online Analytics
- Robotics and Cyber-Physical Systems
- AI-centered Systems and Large-Scale Applications

We also encourage researchers interested in the following topics to submit papers directly to the corresponding workshops, which are integral parts of AAIA'18:

- AI in Medical Applications (AIMA'18 workshop)
- AI in Machine Vision and Graphics (AIMaVIG'18 workshop)
- AI in Reasoning Foundations (AIRIM'18 workshop)
- AI in Information Retrieval (ASIR'18 workshop)
- AI in Data Mining Challenges (DMGATE'18 workshop)
- AI in Smart Energy Networks (SEN-MAS'18 workshop)
- AI in Computational Optimization (WCO'18 workshop)

All submissions accepted to the main track of AAIA'18 and to the above workshops are treated equally in the conference programme and are equally considered for the paper awards.

Professor Zdzisław Pawlak Best Paper Awards

We are proud to continue the tradition started at the AAIA'06 and grant two "Professor Zdzisław Pawlak Best Paper Awards" for contributions which are outstanding in their scientific quality. The two award categories are:

- Best Student Paper. Papers qualifying for this award must be marked as "Student full paper" to be eligible.
- Best Paper Award.

Each award carries a prize of 300 EUR funded by the Mazowsze Chapter of the Polish Information Processing Society.

Event Chairs

- **Kwaśnicka, Halina,** Wrocław University of Science and Technology, Poland
- **Markowska-Kaczmar, Urszula,** Wrocław University of Science and Technology, Poland

Advisory Board

- **Kacprzyk, Janusz,** Polish Academy of Sciences, Poland
- **Marek, Victor,** University of Kentucky, United States
- **Matwin, Stan,** Dalhousie University, Canada
- **Michalewicz, Zbigniew,** University of Adelaide, Australia
- **Skowron, Andrzej,** University of Warsaw, Poland
- **Ślęzak, Dominik,** University of Warsaw, Poland

Area Supervisory Committee

- **Derksen, Christian,** SEN-MAS'18
- **Janusz, Andrzej,** DMGATE'18
- **Lasek, Piotr,** AIMA'18
- **Loukanova, Roussanka,** AIRIM'18
- **Markowska-Kaczmar, Urszula,** AAIA'18
- **Mozgovoy, Maxim,** ASIR'18
- **Śluzek, Andrzej,** AIMaViG'18
- **Zaharie, Daniela,** WCO'18

Program Committee

- **Baron, Grzegorz**
- **Bartkowiak, Anna,** Wrocław University, Poland
- **Bazan, Jan,** University of Rzeszów, Poland
- **Bembenik, Robert**
- **Betliński, Paweł,** Security On Demand, Poland

***Abstract*—Although deep learning methods have been applied to the selection of features in the classification problem, current methods of learning parameters to be used in the classification approach can vary in terms of accuracy at each time interval, resulting in potentially inaccurate classification. To address this challenge, this study proposes an approach to learning these parameters by using two different aspects of Kestrel bird behavior to adjust the learning rate until the optimal value of the parameter is found: random encircling from a hovering position and learning through imitation from the well-adapted behaviour of other Kestrels. Additionally, deep learning method (that is, recurrent neural network with long short term memory network) was applied to select features and the accuracy of classification. A benchmark dataset (with continuous data attributes) was chosen to test the proposed search algorithm. The results showed that KSA is comparable to BAT, ACO and PSO as the test statistics (that is, Wilcoxon signed rank test) show no statistically significant differences between the mean of classification accuracy at level of significance of 0.05. However, KSA, when compared with WSA-MP, shows a statistically significant difference between the mean of classification accuracy.**

***Index Terms*—kestrel-based search algorithm, deep learning, random encircling, long short term memory network.**

I. Desire Models

THE CONCEPT of big data may be characterized by volume, velocity, value, veracity and variety. The volume relates to the amount of data that has to be processed within a given time; velocity relates to how fast incoming data need to be processed and how quickly the receiver of information needs the results from the processing system [1]; and the value is what a user will gain in terms of insight from the data analysis; the variety is the different structures that data may take such as text and images while the veracity is authenticity of the data source. In order to manage effectively these aspects of big data, an important step is to reduce the volume of dataset by selecting relevant features for classification. However, this may not be achieved without tuning different parameters that fit the data to select relevant features and ensure accurate classification. This paper proposes a search strategy for classification that is based on the behaviour of kestrel bird (to discover the optimal weight parameter) and deep learning network (for classification of features).

The related work is presented in Section II. Section III describes the behaviour of the Kestrel bird with its mathematical modeling and algorithm. Section IV outlines the experimental setup; and provides experimental results with comparative meta-heuristic algorithms. Conclusions and future work are given in Section V.

II. Related Work

Feature selection is the process of selecting relevant features from large number of features in a dataset, while ignoring the rest of features that have little value on the output feature set. The feature selection methods are categorized into the filter method (that is classifier-independent) [2], wrapper method (that is classifier-dependent) [2] and embedded method [3]. However, when big data is involved, it results in high computational cost in training and selection of features [4]. This challenge led to the concept of deep learning which historically originated from artificial neural network [5].

A. Deep learning network

Deep learning is a sub-field of machine learning that is based on learning several levels of representations, corresponding to a hierarchy of features where higher-level features are defined from lower-level ones, and the same lower level features can help to define many higher-level features [5, 6]. It has been indicated in [7] that deep learning is a statistical technique that help in classifying patterns based on sampled data using neural networks with multiple layers. In principle, deep learning uses multiple hidden layers of non-linear processing that is hierarchical; and uses different parameters to learn from hidden layers using algorithms (such as back-propagation algorithms) with large amounts of available training data [8]. Deep learning methods for classification are deep discriminative models/supervised-learning (e.g., deep neural networks (DNN), recurrent neural networks (RNN), etc.) and generative/unsupervised models (e.g., deep belief networks (DBN), etc.). Deep neural network (DNN) sometimes referred at as DBN is a multilayer network with many hidden layers, whose weights are fully connected and initialized (pre-trained) using stacked RBMs or DBN [9]. Recurrent neural networks (RNN) is a discriminative model but also has been used as generative model where output results from a model represents the predicted input data. When RNN is used as a discriminative model, the output results from the model is a label sequence associated with input data sequence [9]. The learning of parame-

ters in RNN are improved by information flow in bi-directional RNN and by a cell with LSTM (long short-term memory where cells are responsible for remembering parameters within a time interval) [6] which are the building units for layers of RNN. The RNN composed of LSTM units is often referred to as LSTM network. However, the challenge with the RNN is that when training neural network for deep learning classification problems, the back-propagated gradients approach that is often used either grows or shrinks at each time step, so over many time steps it typically explodes or vanishes [10]. Building a classification model from deep learning techniques integrated with metaheuristic search methods (also referred to as random search strategy as earlier mentioned) enhances accuracy/quality to select useful and relevant features [11] in a dataset. The advantage of meta-heuristic search method is the use of random search strategy to avoid being trapped in local optima when the search space grows exponentially.

B. *Meta-heuristic algorithms*

Among the random search/meta-heuristic algorithms for feature selection in classification problems are Genetic algorithm (GA) [12], Ant Colony Optimization (ACO) [13], Particle Swarm Optimization (PSO) [14], BAT [15] and Wolf Search Algorithm (WSA) [16].

Genetic algorithms is an evolutionary approach that is based on survival of the fittest. Genetic algorithm has the biological principle that species live in a competitive environment and their continuous survival depends on the mechanics of "natural selection" (Darwin, 1868 as cited by [12]) in which an element or chromosomes in the genetic structure is represented by a binary string. A genetic algorithm is an adaptive search procedure which involves the use of operators such as crossover, mutation and selection methods to find a global optimal results/solution by optimizing an objective function/fitness function.

The Ant Colony Optimization (ACO) [13] is a meta-heuristics search method that is inspired by the foraging behavior of real ants in their search for the shortest paths to food sources. When a source of food is found, ants deposit pheromone to mark their path for other ants to traverse. Pheromone is an odorous substance that is used as a medium for indirect communication among ants. The quantity of pheromone depends on the distance, quantity and quality of food source. However, pheromone substance tends to decay or evaporate with time. While a lost ant that moves at random detects a laid pheromone, it is likely that it will follow the path to reinforce the pheromone trails by further depositing some amount of the trail substances while this path leads to a desired outcome. If the path does not lead to a desired outcome, it is no longer followed and the pheromone evaporates in time until it is no longer detectable. Thus, ants make probabilistic decisions on updating their pheromone trail and local heuristic information in order to explore larger search areas. The ACO has been applied to solve many optimization related problems, including data mining, where it was shown to be efficient in finding best possible solutions. ACO, when applied to feature selection, improves on performance of feature selection by finding the best possible path.

The Wolf Search Algorithm (WSA) [16], is bio-inspired heuristic optimization algorithm which is based on wolf preying behavior. The behaviour of wolves includes the ability to hunt independently by remembering their own trait (meaning wolves have memory); ability to only merge with its peer when the peer is in a better position (meaning there is trust among wolves to never prey on each other); ability to escape randomly upon appearance of a hunter; and the use of scent marks as a way of demarcating its territory and communicating with other wolves of the pack [17].

The Bat algorithm [15] is a bio-inspired method based on the behaviour of micro-bats in their natural environment. The unique behaviour that characterize bats is their echolocation mechanism. This mechanism helps bats orient and find prey within their environment. The search strategy of bat is controlled by the pulse rate and loudness of their echolocation mechanism. Whilst the pulse rate changes to improve on better position that was previously found, the loudness indicates to each other bat that best position is accepted/found. The bat behaviour has been applied in several optimization problems to find the best optimal solution. The bat algorithm search process starts with random initialization of the population, evaluation of the new population using a fitness function and finding the best population. Unlike wolf algorithm that uses attractiveness of prey to govern its search, bat algorithm uses the pulse rate and loudness to control the search for the optimal solution.

The Particle swarm [14] is a bio-inspired method based on the swarm behaviour such as fish and bird schooling in nature. The swarm behaviour is expressed in terms of how particles adapt, exchange information and make decision on change of velocity and position within a space based on position of other neighboring particles. The advantage of swarm behaviour is that as individual particle makes a decision, it leads to an emergent behaviour. This emergent behaviour is as a result of local interaction among individual particles in a population of particles.

The novelty of this paper is the integration of RNN with LSTM, with the proposed bio-inspired/meta-heuristic search method for feature selection. The section III discusses the proposed bio-inspired search method that tune parameters unto an RNN with LSTM so as to select features.

III. Proposed Kestrel-Based Search Algorithm

The bio-inspired algorithm is based on the behaviour of Kestrel bird when hunting for a prey. The Kestrel is a kind of bird that hunts by hovering (that is flight-hunt) or from a perch. These birds are strongly territorial and hunt individually. Author of [18] has shown that during a hunt, Kestrels are imitative rather than cooperative. This suggests that Kestrels prefer not to communicate with each other but rather they imitate the behaviour of other Kestrels with better hunting technique. Authors of [19] have shown that hunting behaviour can change based on type of prey, prevailing weather conditions and energy requirements (for gliding or dive). Aside these behaviour, during hunt, Kestrels use their eyesight to watch small and agile prey within its circling radius or coverage area referred to as the visual circling radius. The minute air disturbance from flying preys, and trail

of urine and faeces from ground preys give an indication of the availability of prey. Once available prey is detected, the Kestrel positions itself to hunt. Kestrels are able to hover in changing airstream, maintain fixed forward looking position with its eye on a prey, and uses random bobbing of head to find the least distance between its position and the position of a prey. Also, the Kestrel possess an excellent ultraviolet sensitive eyesight characteristic to visually locate trails because these trails of urine and faeces of prey reflect ultra-violet light.

In hovering, Kestrel perform a wider search (global exploration) across territories within their visual circling radius, maintain a motionless position with its forward looking eye fixed on prey, detect minute air disturbance from flying prey (particularly flying insects) to best position themselves to hunt prey, and mostly move with precision through changing airstream. Kestrels are able to flap their wings and adjust their long tails to stay in a place that is referred to as a still position in changing airstream. While in perch, mostly from high fixed structures, Kestrel changes its perch every few minutes, performs a thorough search (a local exploitation using its individual hunt behaviour) of its local territory with less energy requirements than a hovering hunt, and uses its ultraviolet sensitive capabilities to detect mammals such as voles closer to a perched area. The characteristics of Kestrels are summarized as follows:

1) Soaring: gives a larger search space (global exploration) within visual coverage area.

a. Still (motionless) position with forward looking eyesight fixed on prey.

b. Encircles prey beneath with keen eyesight.

2) Perching: Each Kestrel does thorough search (local exploitation) within visual coverage area.

a. Frequent bobbing of head.

b. Attracted to prey using detected visible trail then glides to capture.

3) Imitates the behaviour of a well-adapted Kestrel.

The following assumptions are made on the characteristics of the Kestrel: the still position gives a near perfect circle, thus frequent change in a circle direction depends on position of a prey in shifting the center of its circling direction; Frequent bobbing of head gives a degree of magnified or binocular vision that helps in measuring the distance to a prey that then enables the Kestrel to move with a speed to strike; Attractiveness is proportional to light reflection; thus, the higher or longer a distance from Kestrel to the trail, the less bright a trail. This distance rule applies to both hovering height and distance away from the perch; New trails are more attractive and worth pursuing than an old trail. Thus, the trail decay or trail evaporation depends on the half-life of trail; and a Kestrel, which is not well adapted to an environment, imitates the behaviour of well-adapted kestrels.

A. Mathematical formulation on Kestrel behaviour

The proposed computational model for Kestrel's is based on the description of Kestrel's behaviour and characteristics. The following mathematical expressions depict characteristics of the Kestrel:

1) Random Encircling

Encircling is when Kestrel randomly shifts (or changes) the center of circling direction in order to recognize the current position of prey. As the prey changes its current position, Kestrel uses the encircling behaviour to randomly encircle its prey. This movement of prey determines the best possible position assumed by Kestrel. The encircling $\vec{D}$ [20] is expressed as:

$$\vec{D}=|\vec{C}*\vec{x_p}(t)-\vec{x}(t)| \tag{1}$$

Thus:
$$\vec{C}=2*\vec{r1} \tag{2}$$

Where $\vec{C}$ is the coefficient vector, $\vec{x_p}(t)$ is the position vector of the prey, and $\vec{x}(t)$ indicates the position vector of a Kestrel, *r1* and *r2* are random numbers generated between 0 and 1.

2) Current position

The current best position of Kestrel is expressed as:

$$\vec{x}(t+1)=\vec{x_p}(t)-\vec{A}*\vec{D} \tag{3}$$

Thus:
$$\vec{A}=2*\vec{z}*\vec{r2}-\vec{z} \tag{4}$$

Where $\vec{A}$ is coefficient vector, $\vec{D}$ is the encircling value obtained, $\vec{x_p}(t)$ is the position vector of the prey, $\vec{x}(t+1)$ represents the current best position of Kestrels. $\vec{z}$ represents a parameter to control the active mode with $\vec{z}_{hi}$ as the parameter for flight mode and $\vec{z}_{low}$ as the parameter for perched mode, which linearly decreases from 2 (high active mode value) to 0 (low active mode value) respectively during the iteration process. This is expressed as:

$$\vec{z}=\vec{z}_{hi}-(\vec{z}_{hi}-\vec{z}_{low})\frac{itr}{Max_{itr}} \tag{5}$$

Where *itr* is the current iteration, *Max_itr* is the total number of iterations which are performed during the search. Other Kestrels that are involved in the search update their position according to the best position of the leading Kestrel. Also, the change in position of a Kestrel in airstream depends on frequency of bobbing, attractiveness and trail evaporation. This is expressed as the following:

a) Frequency of bobbing

The frequency of bobbing *f* is used for sight distance measurement in the search space. This frequency is expressed as:

$$f^{k}_{t+1}=f_{min}+(f_{max}-f_{min})*\alpha \tag{6}$$

Where, $\alpha \in [0,1]$ is a random number to control the frequency of bobbing within a visual range. f_{max} represents the maximum frequency and f_{min} is the minimum frequency both between 1 and 0 respectively.

b) Attractiveness

Attractiveness β indicates the light reflected from a trail, which is defined by:

$$\beta(r)=\beta_o e^{-\gamma r^2} \tag{7}$$

Where $\beta_o$represents the attractiveness, γ represents variation of light intensity between [0, 1]. *r* represents the sight distance $s(x_i, x_c)$ measurement which is expressed using Minkowski distance formulation as:

$$s(x_i, x_c) = \left(\sum_{k=1}^{n} |x_{i,k} - x_{c,k}|^{\lambda}\right)^{\frac{1}{\lambda}} \quad (8)$$

Thus, $$V \leq s(x_i, x_c) \quad (9)$$

Where x_i is the current sight measurement, x_c are all potential neighboring sight measurement near x_i, n is the total number of neighboring sights, λ is the order of position being considered (that is, 2), and V is the visual range.

c) Trail evaporation

A definition of a trail is the formation and maintenance of a line [13]. In natural environment, ants use trail both to trace the path to a food source and to prevent themselves from getting stuck in a single food source. Thus, ants, using these trails, can search many food sources in a search space. As ants continue to search, trails are drawn and pheromones are deposited on a trail. This pheromone help ants to communicate with each other about the location of food sources. Therefore, other ants continuously follow this path and also deposit substances for the trail to remain fresh. Similar to ants, Kestrels use trails in search of food sources. However, these trails are rather deposited by preys which provides an indication to Kestrels on availability of food sources. The assumption is that the substances deposited by a prey is similar to pheromone deposited on ants' pheromone trail. Additionally, when the source of food depletes, Kestrels no longer follow this path that leads to the location of a prey. Consequently, the trail pheromone begins to diminish with time at an exponential rate causing trails to become old and not worth pursuing. This diminishment denotes the unstable nature of the trail substances which can be theoretically stated as: if there are *N* unstable substances in a trail with an exponential decay rate γ, then an equation can be formulated to describe how *N* substance decreases in time *t* [21]. This equation is expressed as follows:

$$\frac{dN}{dt} = -\gamma N \quad (10)$$

Since the substances are unstable, it introduces a degree of randomness in the decay process. Thus, decay rate (γ) with time (t) is re-expressed as:

$$\gamma_t = \gamma_o e^{-\varphi t} \quad (11)$$

Where γ_o is a random initial value of substance that is decreased at each iteration and where *t* is the number of iterations or time steps. $t \in [0, Max\_itr]$ where *Max_itr* is the maximum number of iterations. The decay rate $\gamma_t$at time *t* to indicate a new trail or old trail is expressed as:

$$if\ \gamma_t \rightarrow \begin{cases} \gamma_t > 1, & trail\ is\ \text{new} \\ 0, & otherwise \end{cases} \quad (12)$$

Thus, a γ_t value greater than 1 indicates that a trail is new and trail is not decayed therefore KSA explores the search area, while a $\gamma_t$value of 0 indicates that trail is old, unattractive and trail has decayed therefore KSA would not explore the search area. Again, the decay constant φ is expressed by:

$$\varphi = \frac{\phi_{max} - \phi_{min}}{t_{1/2}} \quad (13)$$

Where φ is the decay constant, $\phi_{max}$is the maximum number substances in trail, ϕ_{min} is the minimum number of substances in trail and $t_{\frac{1}{2}}$ is the half-life period of a trail. Finally, position of Kestrel is expressed by:

$$x_{i+1}^k = x_i^k + \beta_o e^{-\gamma r^2}\left(x_j - x_i^k\right) + f_i^k \quad (14)$$

Where x_{i+1}^k is the current best position of the Kestrel that represents candidate solution and $x_i^k$is the previous position of Kestrel. Where $\beta_o e^{-\gamma r^2}$represents the attractiveness as expressed in equation (7) where γ is equal to γ_t. x_j represents a Kestrel with a better position whilst f_i^k is the frequency of bobbing as expressed in equation (6).

d) Velocity

The velocity of Kestrel is updated using the expression:

$$v_{t+1}^k = v_t^k + x_t^k \quad (15)$$

Where v_{t+1}^k is the current best velocity, v_t^k represents the initial velocity, whilst x_t^k represents the current best position of Kestrel.

3) Imitative behaviour

Kestrel birds are territorial and hunt individually rather than hunt collectively. As a consequence, a model by [22] that depicts the collective behaviour of birds for feature similarity selection could not be applied. Since Kestrels are imitative, it implies that a well-adapted Kestrel would perform action appropriate to its environment, while other Kestrels that are not well-adapted imitate and remember the successful actions. The imitation behaviour reduces learning and improves upon the skills of less adapted Kestrels. The imitation behaviour is mathematically expressed and applied to select similar features into a subset. A similarity value $Sim_{value(O,T)}$ that helps with the selection of similar features is expressed by:

$$Sim_{value(O,T)} = e^{\left(\frac{-\sum |O_i - E_i|^2}{n}\right)} \quad (16)$$

Where *n* is the total number of features, $\|(O_i - E_i)\|$represents the deviation between two features where O is the observed, E_i is estimate that is the velocity of kestrel in (15). Since the deviation is calculated for each feature dimension and the possibility of large volume of features in dataset, each time a deviation is calculated only the minimum is selected (the rest of the dimension is discarded), thus, to allow the handling of different problem to different scale of dimension of data [23]. Moreover, in cases where features that were imitated are not similar (that is dissimilarity), this is calculated by:

$$dis\_sim_{value(O,T)} = 1 - Sim_{value(O,T)} \quad (17)$$

The fitness function, which is similar to fitness function formulation used by [24], to evaluate each solution is expressed in terms of classification error of the RNN and the similar value obtained from each solution. The fitness function is formulated as:

$$fitness = \rho * Sim_{value(O,T)} + dis\_sim_{value(O,T)} * \rho \quad (18)$$

Where $\rho \in (0,1)$ is a parameter that controls the chances of imitating features that are dissimilar, C_{error} is the classification error of a RNN classifier and $Sim_{value(O,T)}$ refers to the feature similarity value obtained in feature imitation.

Our method to select features uses the RNN with LSTM network (as discussed in section II) and to also make decision on classification accuracy. Authors of [24] has shown that, the less the number of features in a subset and the higher the classification accuracy, the better the solution. The proposed algorithm to implement feature selection is expressed in Table 1 as follows:

TABLE 1: PROPOSED ALGORITHMIC STRUCTURE

Set parameters Initialize population of n Kestrels using equation. Start iteration (loop until termination criterion is met) Generate new population using random encircling Compute the velocity of each kestrel using equation (15) Evaluate fitness of each solution (18) Update encircling position for each Kestrel for all i=1 to n Find the optimal features using RNN with LSTM End loop Output results

In Kestrel Search Algorithm, each kestrel referred as search agent checks the brightness of trail substances using the half-life period; random encircling of each position of a prey before moving with a velocity; imitates the velocity of another Kestrel so that each Kestrel will swarm to the best skilled search agent.

IV. EXPERIMENTAL RESULTS

A. Experimental setup

The proposed algorithmic structure was implemented in MATLAB 2018A. In each run, we performed 100 iterations to select the best/optimal parameter. The best parameter was fed into the LSTM network in which 100 epochs were performed as suggested by [25] that it guarantees optimum results on classification accuracy. To avoid the network instability, all neurons in the input to output layers on a network learned at the same rate (that is with smaller learning rate) [25]. The initial parameters for each meta-heuristic algorithm is defined as follows: KSA (Frequency of bobbing (fb=0.97); perched parameter (zmin=0.2); flight parameter (zmax=0.8); half-life parameter (half-life=0.5); dissimilarity = 0.2; similarity =0.8); PSO [14] (w=1;c1=2.5;c2=2.0); ACO [13] (α=1;ρ=0.05); BAT [15] (β=1; A=1; r=1); WSA-MP [16] v=1;pa = 0.25; α = 0.2, which were suggested by authors of the algorithms as the best parameter that guarantee an optimal solution. To test the robustness of our proposed algorithm, six benchmark datasets shown in Table 2 (from Arizona State University) were used as it represent a standard benchmark dataset with continuous data.

TABLE 2: DATASET FOR EXPERIMENT

Dataset	#of Instances	#of classes	#of features in original dataset

CLL_SUB_111	111	3	11340

B. Experimental results

In order to select the best optimal solution, the study applied the concept that the higher the classification accuracy, the better the solution and hence, the less the number of features in a subset [24]. With this concept in mind, the study first applied KSA and comparative algorithms to find the best learning parameter presented in Table 3. There are ten separate runs performed on each algorithm and the best was recorded as shown in Table 3

It is observed from Table 3 that out of the six datasets, KSA has the best learning parameter (highlighted in bold) in three datasets. The learning parameter of each meta-heuristic algorithm are fed into LSTM and the classification accuracy are recorded in Table 4:

It is observed from Table 4 that the algorithm with the best parameter is not the best choice on some datasets. For instance, BAT produced the best parameter of **0.0002043** on Tox_171 dataset but produced a classification accuracy of 0.6925. It could be observed that KSA provided the highest classification accuracy on four out of six datasets. This shows that our proposed approach can explore and exploit search space efficiently and find the best results that guarantees higher classification accuracy. The results from this experiment also indicate that no single algorithm can perform better than any other. Moreover, the average classification accuracy for each algorithm when computed shows that KSA has the higher average classification accuracy of **0.7267** while PSO has least of **0.4793**. In order to select features, [24] indicated that the higher the classification accuracy, the better the solution and hence, the less the number of features in a subset. Table 5 shows the number of feature selected by each algorithm.

It is observed from Table 5 that KSA selected less number of features in **four** datasets namely **Carcinom, SMK_CAN_187, Tox_171** and **CLL_SUB_111**; PSO selected less feature in **two** datasets namely **Glioma** and **Lung**. Additionally, on average KSA selected 2422 (see table 5) features, with average accuracy of 0.7267 (see table

CLL_SUB_111	**2482**	6177	2649	6510	9072
Average	**2422**	**3156**	**2855**	**3544**	**5618**

4) and average parameter of 1.67E-01 (see table 3); while on average PSO selected 5618 (see table 5) features, with average accuracy of 0.4793 (see table 4) and average parameter of 2.62E+00 (see table 3).

The study conducted statistical test on classification accuracy to identity the best algorithm. In order not to prejudice which algorithm outperformed each other, the mean of all the algorithms were considered as equal for the statistical analysis. The Wilcoxon signed rank test which is a non-parametric statistical procedure was used because it does not make underlying assumption about the distribution of parameters and underlining dataset for the evolutionary algorithm. The advantage of Wilcoxon test is that it helps to perform pairwise comparison while not making any assumptions about the population used since Wilcoxon test can guarantee to about 95% (that is, 0.05 level of significance) of efficiency if the population is normally distributed. The results on the test statistic is shown in Table 6

TABLE 6: ALGORITHM AND P-VALUE

Algorithm	Asymp. Sig. (2-tailed) (that is, p-value)
BAT – KSA	0.225
WSAMP - KSA	0.043
ACO – KSA	0.080
PSO – KSA	0.173

Based on the results on test statistics ($p<0.05$), the following analysis can be drawn. In respect of KSA comparison with BAT, ACO and PSO, there is no statistically significant differences between the mean of classification accuracy at level of significance of 0.05. Thus, KSA is comparable to BAT, ACO and PSO algorithms. In contrast, the comparison between KSA and WSA-MP shows a statistically significant difference between the mean of classification accuracy, where $p< 0.05$ (that is, $0.043<0.05$). Thus, comparing algorithms (KSA and WSA-MP) using the Wilcoxon text show the classification accuracy of these algorithms are different.

V. CONCLUSION AND FUTURE WORK

Compared with meta-heuristic algorithms, the classification accuracy results on KSA is different from WSA-MP while the classification accuracy of KSA is comparable to ACO, BAT and PSO. The advantage of KSA is the ability to adapt to different datasets and guarantees good solutions that is comparable to other meta-heuristic search methods for feature selection.

***Abstract*—Digital media have enormous impact on the public opinion. In the ideal world the news in public media should be presented in a fair and impartial way. In practice the information presented in digital media is often biased and may distort the opinion on a given entity/event or concept. It is important to work on tools that could support the detection and analysis of the information bias. One of the first steps is to study the methods of automatic detection of the articles reporting on the same topic, event or entity to further use them in comparative analysis or building a test or training set.**

In this paper we report on the experimental results concerning the problem of automatic detection of articles reporting on the same events or entities. We also report some experiments on detecting the source of information based on the content.

I. Introduction

In the ideal world the news in the public media should be presented in a fair and impartial way so that the reader is provided with honest and high-quality unbiased information and can make his own opinion about the political, economical, social or historical events, entities or concepts, etc.

Impartiality of the media that present news to the citizens is a crucial property of democratic system and is what one would expect.

For several reasons the information presented in the media is usually far from being impartial. One of the reasons for this is that various people may see the world events differently what may influence the way they present them. More importantly, in some cases the authors of news articles can intentionally introduce some bias into their publications, e.g. for political reasons, etc.

The problem is even more important in cases when some media (web portals, magazines, etc.) *systematically* introduce consequent intentional bias into the published content in order to intentionally misinform the reader about the state of the world.

This problem is important especially for the digital media, since they have significant influence on public opinion. The way they work changes over the time but they still remain one of the main source of information about daily events. The problem of text bias is common. It happens in newspapers, blogs, social networks etc. Each source of media may represent different point of view. Even such media as news portals, that should present impartial information, can describe events or people framing it differently.

It would be very valuable to work on tools that could support the detection and analysis of such systematic or intentional information bias in digital media in order to contribute to improve the quality and fairness of the information provided to the citizens.

Such tools are very complex and involve interdisciplinary approach including the elements of artificial intelligence, text mining, statistical data analysis, psychology, sociology, etc. One of a basic modules in any bias-analysis tool is a module that makes it possible to automatically or semi-automatically detect *pairs* of news articles (or, more generally: text documents), that report on the same event, topic or entity. Such pairs of articles, where each article comes from a different *source* (e.g. web portal, particular author, etc.) can be further used to make comparison-based analysis towards detecting information bias. The pairs are also necessary to build a training, test or reference set in the case of machine-learning approach to the described research problem.

In this paper we present a method and experimental results of detecting pairs of news articles on the same (similar) topic or reporting the same (similar) event, etc. We focus here on the news articles in news portals.

II. Related work

There exist multiple approaches to identifying text bias. For most of them the first inevitable phase of bias identification is to find the pairs (or clusters) of similar articles, paragraphs or sentences.

A. News articles similarity

The approach of finding similar texts by using Siamese networks is described in [8]. Siamese networks describe how similar a pair of text documents are. This networks use the same architecture of network and feed two text documents as an input. Then, given such an input pair, an output in the form of the value representing the distance, for example Manhattan distance, between the two text documents from the output is calculated as a measure of (dis)similarity.

In the paper [3] the author describes document text representations and variety of similarity measures for text clustering. They include the measures like: cosine similarty, Euclidean distance, Jaccard coefficient, Pearson Correlation Coefficient and Averaged Kullback-Leibler Divergence. Then, based on

the results of a clustering algorithm, there is made a comparison of the results on datasets including variety of news articles, academic papers and web pages.

Authors of the article [12] describe a similarity measure for news recommender systems. In this work there is made a comparison-based analysis of human judgement of similarity and some other measures such as: Lin and WASP measures.

Another work [7] presents research concerning articles on events. In particular it concerns tracking similar articles and clustering them to summarise the events under interest.

B. Media bias

In work [11] the authors identify the news framing which is the way of presentation of news. They compare it to google trends and demonstrate how news framing influences the public attention. They used the concept of mean similarity of a corpus. The mean similarity is calculated on pairs of n articles by average cosine distance of DocVec representation of articles. They discovered that the public opinion change with the mean similarity.

In paper [10] the authors describe some linguistic features that reveal the bias in a text. They refer to the form of verbs, part of speech tags and subjective words. Instead of news articles they used data from Wikipedia, however their results may be used also for other types of texts.

A related work concerning the usability of linguistic features in the task of detecting special form of bias related to the phenomenon of Web Spam is presented in [9].

An interesting approach is presented in the very recent paper [2], where the authors identify three roles of entities framing people in news articles. These roles are hero, villain and victim. The results are presented in a visual form to compare how entities are described in different articles.

Article [4] presents an approach of identifying bias through analysis of mentions and quotations of politicians among different parties and in different periods of time.

Bias and its propagation is also investigated in social networks [6]. This work used twitter data to identify bias in short texts and to analyse its propagation among the users.

III. Problem Specification

In this paper we consider two research problems:

- news similarity detection problem
- information source recognition problem

A. News similarity detection

We proposed two approaches to news similarity detection: find all similar articles to the given one and given two articles decide if they are similar or not. The first approach to the problem is as follows. In a given collection of news articles from a given time window (e.g. particular day, etc.) detect the groups of articles that report on the same topic/event, etc. A manually labelled training set that is a collection of manually grouped news articles is prepared. We apply text mining techniques to identify the similar events. The models are evaluated using the metrics presented in the next section: averaged precision, averaged recall and averaged F-measure.

The second approach is to identify if 2 articles are similar. We apply the machine-learning approach to this problem. For each article there are computed several attributes based on the textual contents, keywords, etc. Then, the set is used to train some ML models. Finally, the models are used to automatically detect similar articles. The models are evaluated using the prepared group labels and some standard measures such as precision, recall or f-measure.

B. Towards news bias detection

The second research problem studied in this paper is the following. Given an article and the set of information sources (e.g. web news portals) is it possible to automatically recognise which source does this article comes from based only on the contents? This kind of experiment can be viewed as a one of simple tests of imparity of information sources. I.e. if it is possible to correctly predict the source of the news article based on its content then it is more likely that this information source has some information bias.

Of course some other reasons may make it possible to predict the source of the news article including the writing style, etc. However this simple test may serve as one of the multiple tools that could in ensemble help to detect information bias. More advanced bias-detection tools are envisaged in our ongoing research.

IV. Experimental Setup

A. Data Collection

We collect the data from two Polish news portals: 'dorzeczy.pl' and 'gazeta.pl'. These two are chosen from among the most popular Polish news portals. In addition, they are considered by many readers as examples of media having completely different views on the reality in Poland especially in the domain of social issues or politics and hence making it possible to build an interesting dataset with a potential of containing pairs (or clusters) of articles on the same/similar topic/event/entity but with potentially various forms of information bias. Articles are categorised by a predefined set of topic categories on each of the portals. The decision was made to focus on events connected to the politics in Poland or world. In this case we were looking for articles from category 'Information' ('Wiadomosci') in 'gazeta.pl' and in portal 'dorzeczy.pl' for categories 'Country' and 'World' ('Kraj' and 'Swiat').

In this work we decided to focus only on Polish media but it is possible to extend our research to other languages.

We have collected the articles from 01.01.2018 to 07.04.2018. Table I presents the number of articles.

1) Database: We store the data in MongoDB - a document database. We create article collection of news articles and their comments. The comments made by the users to the articles are not used in the experiments reported in this article but are kept for future, extended analyses. Each item in the collection

Table I
DATASET

news portal	number of articles
gazeta.pl	2623
dorzeczy.pl	4197

Table II
DISTRIBUTION OF ARTICLES AMONG GROUPS

group quantity	number of groups
1	145
2	36
3	17
4 or more	16

represents an article and contains the following fields: _id', 'article_id', title', 'date', 'lead_text', 'text', 'keywords', 'source', 'url' and 'comments'. Field comments contains 'author', date', 'comment_id', 'text'.

B. Data Annotation

For news similarity detection we needed to manually create an annotated data set. The common approach for text similarity recognition is to create a set of article pairs and annotate if they are similar or not. We realised that for news articles this approach may not be the best one. We want to find all articles that are similar and sometimes one news portal describes an event in one article and other news portal writes about this in a series of four articles, for example. Thus we define the task of annotating similar articles as follows.

For a given time window (e.g. a particular date) we collect all articles from the specified web news portals. Each article is assigned to a group with articles about similar event using some particular method. If there is no group with articles describing the event create there is created a new one. The group contains all articles about the same event.

We have annotated 385 articles from 6 randomly chosen days. Articles formed 213 groups. There are groups of consisting of one article or groups containing many articles. The distribution of articles among groups quantity is presented in table II Each record of annotated data contains (among others) the following attributes: 'date', 'article_id', 'group_id'.

C. Data Preprocessing

In the preprocessing phase we apply several operations including: removing stop-words, normalising- convert words to the base form using `Morfeusz` library [1].

D. Evaluation Measures

In order to evaluate experimental results we calculate the average precision, recall and f measure in each experiment.

The average precision is the average of precision of each group. That is given by the following expression:

$$ap = \frac{1}{N}\sum_{n=1}^{N} p_n = \frac{1}{N}\sum_{n=1}^{N} \frac{tp_n}{tp_n + fp_n} \tag{1}$$

Where N is the number of evaluated groups. Accordingly average of recall is given as:

Table III
EVALUATION OF ARTICLE'S SIMILARITY DETECTION

Algorithm	ap	ar	af1
Keywords similar.	0.60	0.57	0.42
Doc2Vec + cos sim	0.72	0.57	0.50
Doc2Vec+bigram+cos simililar.	**0.93**	0.60	0.64
Doc2Vec+trigram+cos similar.	0.92	0.63	0.66
TF-IDF +cos similar.	0.50	**0.69**	**0.53**

$$ar = \frac{1}{N}\sum_{n=1}^{N} r_n = \frac{1}{N}\sum_{n=1}^{N} \frac{tp_n}{tp_n + fn_n} \tag{2}$$

Finally, average F-measure is defined as follows:

$$af1 = \frac{1}{N}\sum_{n=1}^{N} \frac{2 * p_n * r_n}{p_n + r_n} \tag{3}$$

V. EXPERIMENTAL RESULTS ON ARTICLES SIMILARITY DETECTION

A. Group approach

In a group approach of finding similar articles we experimented with three methods for the news similarity detection problem:

- keyword set similarity - this is our simple baseline solution. We compared the number of similar keywords and find the most similar articles using predefined threshold based on the number of keywords.
- tf-idf with cosine similarity- after preprocessing of a textual data, we calculated tf-idf and cosine similarity between articles from a given data frame. Again we choose the most similar articles based on the predefined threshold.
- doc2vec[5] with cosine similarity in three variants: unigrams, bigram phrases, trigram phrases. For Each of these we choose doc2vec based on bag of words model. Similar preprocessing was done as for tf-idf.

The results of evaluation are presented in a table III. The best averaged results for a given measures were highlighted in bold. The best average precision is observed for two doc2vec models. That means for these models there are the least false positives. However the best f-measure and recall is observed for tf-idf algorithm. This algorithm is better choice if we want to find as many similar articles as possible without caring about dissimilar articles among them.

B. Pair approach

In this task we wished to identify if a pair of articles is similar or not. The data was split into test and train datasets as presented in IV. Similar articles was labelled as '1' and not similar articles as '0'. We have created the following features: cosine similarity on tf-idf vectors, number of similar keywords, normalized number of similar entities that is number of similar entities/sum of entities in both articles. In table V we present an evaluation of proposed algorithms.

Table IV
NUMBER OF ARTICLE PAIRS FOR SIMILARITY DETECTION

news portal	training set	test set
similar (1)	320	151
not similar (0)	7837	2624

Table V
EVALUATION OF ONE TO ONE ARTICLES PAIRS

Algorithm	Class	Precision	Recall	F1-score	Support
Siamese	0.0	0.95	0.86	0.90	2624
LSTM	1.0	0.07	0.19	0.10	151
	avg / total	0.90	0.82	0.86	2775
SVM	0.0	0.98	0.91	0.94	2624
polynomial	1.0	0.29	0.63	0.40	151
kernel	avg / total	0.94	0.90	0.91	2775
SVM	0.0	0.98	0.85	0.91	2624
linear	1.0	0.20	0.68	0.31	151
kernel	avg / total	0.94	0.84	0.88	2775
Logistic	0.0	0.98	0.89	0.93	2624
regression	1.0	0.24	0.63	0.35	151
	avg / total	0.94	0.87	0.90	2775
Gradient	0.0	0.96	0.95	0.96	2624
boosting	1.0	0.27	0.28	0.27	151
classifier	avg / total	0.92	0.92	0.92	2775

Except of Siamese LSTM all algorithms have quite good results. Support vector machines occur to be the best one. Siamese neural networks has high results in total but very low scores for similar pairs where the reason may be that it was not able to detect dependencies in long text.

VI. EXPERIMENTAL RESULTS ON NEWS ARTICLE SOURCE DETECTION

We experimented with three machine learning algorithms in the problem stated as prediction of the news article source based on its content. In all the experiments concerning this problem, the articles' attributes explicitly mentioning the actual source (e.g. the "source" attribute) were ignored in the prediction phase. Dataset for this task is presented in table VI. We have used the following algorithms: naive bayes, logistic regression, support vector machines.

The evaluation of proposed methods is presented in table VII. Support vector machines has the best score slightly outperforming logistic regression. These results show that based on simple approach, analysing the basics of used language we are able recognise the source.

VII. SUMMARY AND FUTURE WORK

Our ongoing research concerns the helper problem of recognizing news articles on (nearly) the same topic/event in order to find media bias.We have proposed 2 approaches and presented their advantages and disadvantages.

Table VI
NUMBER OF ARTICLES FOR MEDIA OUTLET DETECTION

news portal	training set	test set
gazeta.pl	2436	395
dorzeczy.pl	3591	606

Table VII
EVALUATION OF ARTICLE'S MEDIA OUTLETS DETECTION

algorithm	news portal	precision	recall	f1-score	support
Naive	dorzeczy.pl	0.69	0.98	0.81	606
Bayes	gazeta.pl	0.89	0.32	0.47	395
	avg / total	0.77	0.72	0.67	1001
Logistic	dorzeczy.pl	0.90	0.83	0.86	606
Regression	gazeta.pl	0.76	0.86	0.81	395
	avg / total	0.85	0.84	0.84	1001
SVM	dorzeczy.pl	0.88	0.86	0.87	606
	gazeta.pl	0.79	0.83	0.81	395
	avg / total	**0.85**	**0.85**	**0.85**	1001

We also presented preliminary results on predicting the source of news article based on the contents that seems to illustrate that bias might be present as one of the aspects making such prediction possible, however this needs deeper analysis.

Since some news articles often report multiple events, to improve our results, we plan to increase the granularity of recognition i.e. add recognising fragments of articles instead of the whole documents about similar events. That means that it is planned to detect fragments of text concerning similar events and detect bias in them. Also, we aim to extend research to other languages (e.g. Polish, English).

***Abstract*—An important issue in predictive modeling is model selection. This process is time consuming and can be simplified with meta-learning. However, meta-learning systems need appropriate data descriptors for proper functioning. One of them are data compression measures which can be extracted out of the instance selection methods. When we only need to estimate the classification accuracy of the model, the compression obtained from instance selection is a good approximator, but when we need to estimate other performance measures such as the precision and sensitivity then the quality of the estimated performance drops. To overcome this issue we propose a new type of compression measure: the *balanced compression* which is sensitive to the class label distribution and shows high correlation with precision and sensitivity of the final classifiers. We also show that the application of the *balanced compression* as a meta-learning descriptor allows for precise assessment of the model performance, as proved by the presented experimental evaluation.**

I. Introduction

NOWADAYS, meta-learning [1], [2] is gaining more and more popularity. It is aimed at speeding up the prediction model construction which consists of model selection and model parameters optimization. The model selection process can be done without actually training the given model, by using other meta-model which assesses the quality of the data and estimates the performance of the desired classier or returns a ranking.

As shown in [3], [4], a good indicator that characterizes the dataset quality is the compression of the dataset obtained with instance selection algorithms [7]. It is defined as: $Cmp = 1 - \frac{\|\mathbf{P}\|}{\|\mathbf{T}\|}$ where $\mathbf{T} = [\{\mathbf{x}_1, y_1\}, \{\mathbf{x}_2, y_2\}, \ldots \{\mathbf{x}_n, y_n\}]$ is a training dataset that consists of n training instances $\{\mathbf{x}, y\}$, where $\mathbf{x} \in \Re^m$ and y is a label which takes one of l symbols, and the dataset $\mathbf{P}$ is a subset of the instances from $\mathbf{T}$ selected by the instance selection algorithm, so that $\mathbf{P} \subset \mathbf{T}$.

The main idea of using compression as a meta-learning descriptor (also called meta-attribute) is based on the observation that a dataset in which there is a lot of regularity can be compressed well, and thus high prediction accuracy should be achievable, while a dataset containing a lot of irregularities and a lot of noise will have a low compression ratio. Moreover, the instance selection methods are often used at the stage of data preprocessing, which means that the value of compression is obtained without additional computational cost. Some algorithms, including *CNN* and *ENN*, have been identified as the most useful for predicting the final model performance [4]. For example, the correlation between the compression ratio and the accuracy of the *k*NN, Gaussian SVM and Random Forest, obtained for *CNN* and *ENN* instance selection methods is above 0.9. However, the research carried out so far has focused only on the classical definition of the measure of prediction accuracy expressed as the ratio of the correctly classified examples to all evaluated examples.

It turns out that although correlation between compression and classification accuracy is very high, the correlation between compression and other measures of classifier performance is much weaker. We refer to such measures as the average precision (also known as the balanced accuracy), or the average sensitivity also called recall, which are especially important in the context of unbalanced classification problems.

This work addresses this problem by introducing a new type of compression, so-called balanced compression, which takes into account the number of rejected instances which belong to particular classes. The balanced compression linearizes the relationship between compression and precision and between compression and sensitivity. Implementing these measures allows to enhance the meta-learning system performance.

II. Instance Selection Algorithms

As it was mentioned, the compression achieved by instance selection can be used as a measure of the dataset quality. We presented also an intuitive dependence, which indicates that stronger compression is connected with greater regularity of the decision boundaries in the dataset, and at the same time it is easier for the classifier to reconstruct the desired decision boundary. In practice, however, this depends on the particular instance selection algorithm. These algorithms can be divided into three basic groups: condensing methods, noise filters and hybrid methods. Condensing methods are a set of algorithms used to reduce the dataset size, where the only criterion is maximization of compression while maintaining comparable prediction accuracy. A typical example is the *CNN* algorithm [8]. *CNN* was developed for use with the *k*NN classifier to reduce the computational complexity. The acceleration is accomplished by eliminating (compressing)

unnecessary instances in the dataset. However, this does not help increasing the prediction quality of this classifier. There are algorithms that allow for stronger compression at the same accuracy level, e.g. evolutionary based instance selection [6]. However, as the evolutionary approach belongs to the hybrid group, the correlation we observed although is still significant, is weaker then that obtained with *CNN*.

Noise filters, on the other hand, are a set of algorithms created with the purpose of finding and removing training instances that constitute noise in a dataset. An example and historically the first noise filter is the *ENN* algorithm designed to improve prediction accuracy of 1-NN [9]. *ENN* was also developed to work with the *k*NN algorithm. Its operation is based on the analysis of the closest neighborhood of a given instance and checking if the nearest neighbors will vote for the examined instance in accordance with its label. If not, then the instance is removed.

Also generalizations of these algorithms were proposed, where different classifiers, not only *k*NN can be embedded into the instance selection process [10]. However, in the experiments presented in this paper only instance selection based on 1-NN will be considered.

The third group of instance selection algorithms are hybrid methods. They combine the properties of the first two groups. They start by filtering out the noisy samples from the data and then condense the remaining dataset.

As it was shown in [4], each group of instance selection methods behaves differently with regard to the prediction accuracy. For the condensing methods, an increase in compression corresponds to an increase in prediction accuracy. In the case of noise filter methods, this relation is reversed, because the noise filters regularize and clean the datasets from noise. Thus more removed instances indicate here more noisy dataset, which means that with the increase of compression of the noise filters, the reduction of prediction accuracy is observed. The last group - hybrid methods combine both elements. This causes that the relationship between compression and prediction accuracy gets much weaker or totally disappear, because the properties of condensation methods are canceled out by the properties of noise filters. This causes that only the instance selection methods, which obtain different compression depending on noise in data find application in estimating the prediction accuracy.

III. Balanced Compression measure

As mentioned in the introduction, for unbalanced classification problems usually classical accuracy measure is not used and rather other performance measures are evaluated like average precision or average sensitivity. The purpose of these measures is to reflect the quality of the prediction model in the context of the number of instances in individual classes. A similar situation occurs in the case of compression measures. The commonly used compression measure ignores the number of rejected instanced within individual classes. It simply represents the ratio of the number of rejected samples to the size of the training set $\mathbf{T}$, thus, this measure is similar to the classical accuracy used in prediction systems. The natural conclusion from this is that we should adapt the measure of compression to data with unbalanced class distribution, so that the measure not only indicates the number of rejected samples but also the number of rejected samples within individual classes. It can bring tangible benefits in the form of additional information about the nature of the classification problem, in particular in the context of meta-learning systems.

An important difference between accuracy and compression is the fact, that in contrast to the evaluation of the accuracy of the classifier, in the case of compression we do not have the confusion matrix and the values resulting from it like *False Positives* or *False Negatives*. It is because instance selection methods do not perform prediction, instead we only have information which instances were selected and which rejected, so we do not know what type of error occurred. Therefore, the only factor possible to determine is the level of class c_i compression defined as $\frac{\|y_{\mathbf{T}}==c_i\|-\|y_{\mathbf{P}}==c_i\|}{\|y_{\mathbf{T}}==c_i\|}$, where $\|y_{\mathbf{T}} == c_i\|$ denotes the number of samples in the training set $\mathbf{T}$ which belong to class c_i and $\|y_{\mathbf{P}} == c_i\|$ denotes the number of instances in the dataset $\mathbf{P}$ (after instance selection) which belong to class c_i.

Based on this class compressions we define balanced compression as an average over all classes

$$Cmp_{Bal} = \frac{1}{l}\sum_{i=1}^{l}\frac{\|y_{\mathbf{T}} == c_i\| - \|y_{\mathbf{P}} == c_i\|}{\|y_{\mathbf{T}} == c_i\|} \tag{1}$$

where l denotes the number of classes. This measure can be also generalized by introducing class weights denoted as w_i which describes importance of particular class, so the balanced compression takes the form:

$$Cmp_{Bal} = \frac{1}{\sum w_i}\sum_{i=1}^{l} w_i\frac{\|y_{\mathbf{T}} == c_i\| - \|y_{\mathbf{P}} == c_i\|}{\|y_{\mathbf{T}} == c_i\|} \tag{2}$$

In the conducted experiments we assumed equal values of the weights $\underset{i=1\ldots l}{\forall} w_i = 1$.

IV. Experiments and Results

In order to verify the usefulness of the proposed *balanced compression* in the context of meta-learning systems, we carried out an experimental evaluation on 45 datasets obtained from Keel Project [11] using three popular classifiers: *k*NN, linear SVM and Random Forest. The experiments were performed with RapidMiner and the Information Selection package developed by the authors of this paper, which is available from the RapidMiner Marketplace and on the website www.prules.org [12]. The experiments were divided into two parts. In the first part the correlation measure was evaluated between compression measures and performance measures of the evaluated classifiers. It indicates how the new compression measure reflects the obtained classification performances. In the second part a real meta-learning system was constructed which is designed to predict performance of the three classifiers. The meta-learning system utilizes meta-attributes which are based on compressions obtained by both *CNN* and *ENN*.

A. Relationships Between Compression and Various Performance Measures

The first part of the experiments consists of two stages. In stage I, the three performance measures (accuracy, average precision and average sensitivity) for each of the 45 datasets were estimated using the cross-validation procedure. This stage also included parameter optimization for all evaluated classifiers (k for *k*NN, C- for linear SVM and the number of trees for Random Forest). In stage II, each dataset was compressed using the two previously described algorithms *ENN* and *CNN*, each time measuring both compression and balanced compression. The obtained results were then used to calculate Pearson's correlation coefficient between given type of compression and the type of classification performance measure independently for each classifier. Obtained correlations were collected in Tab. I for *CNN* instance selection, and in Tab. II for *ENN* instance selection algorithm.

Table I: Correlation between two types of compression obtained for *CNN* and the three performance measures for *k*NN, Linear-SVM and Random Forest

Compression type	Performance measure	*k*NN	SVM	Random Forest
Compression	Accuracy	0.937	0.902	0.900
Compression	Precision	0.783	0.662	0.767
Compression	Recall	0.738	0.640	0.767
Balanced compression	Precision	0.920	0.794	0.880
Balanced compression	Recall	0.932	0.808	0.880

Table II: Correlation between two types of compression obtained for *ENN* and the three performance measures for *k*NN, Linear-SVM and Random Forest

Compression type	Performance measure	*k*NN	SVM	Random Forest
Compression	Accuracy	-0.965	-0.924	-0.917
Compression	Precision	-0.774	-0.672	-0.745
Compression	Recall	-0.758	-0.661	-0.765
Balanced compression	Precision	-0.935	-0.844	-0.883
Balanced compression	Recall	-0.981	-0.863	-0.895

The results in the tables indicate that the correlation between classical compression and prediction accuracy is very high and ranges from 0.917 to 0.965 for the *ENN* algorithm and from 0.900 to 0.937 for the *CNN* (here for simplicity we evaluate absolute values of the correlation as the sign does not matter). However, changing the measure of the prediction quality to average precision or average sensitivity causes the correlation coefficient to drop rapidly to a level between 0.64 and 0.77 depending on the method of instance selection and on the classifier. Changing compression to the balanced compression results in a significant increase in the correlation coefficient, which for the *k*NN classifier again exceeds 0.9, and for the other classifiers varies between 0.8 and 0.88. This is a significant improvement over the correlation coefficients obtained with standard compression.

B. Meta-system - compression-based estimation of prediction quality

Meta-learning systems are used for the estimation of quality of predictive models [13], [1], [14], [15]. In these systems, for a known dataset repository, which consists of n_r datasets, the prediction performance of the selected classifier is estimated and the meta-attributes describing the properties of each of these datasets are extracted [16]. Next, a meta-set is created. The meta-set consists of the extracted meta-attributes (an input vector of the meta-learning system) and labels that express the accuracy of the given model, for which we would like to estimate the accuracy. Therefore, the meta-set consists of n_r samples, where a single instance describes one dataset from the repository. So we obtain a typical regression problem, because labels in the meta-set represent numerical values (accuracies). In the next step, the meta-set is used to build a meta-model, a model capable of estimating prediction accuracy for a given, previously unknown data set. When applying a meta-model to a new data set, it is necessary in the first step to determine the meta-attributes, create a record from them, and then pass them to the meta-model input. The meta-model then returns the estimated accuracy. Another commonly used solution is learning the meta-ranking model, where the meta-model returns the ranking of the best models or just the best prediction model [17].

It was shown in [4] that the use of compressions as meta-attributes lead to an improvement in the quality of the estimated accuracy in comparison to the classic meta-attributes used in the MLWizzard system [15]. Therefore, in the experiments a meta-system based only on the data set compression measures is constructed.

As a meta-model, Generalized Linear Model was used. In total we had 9 meta-models (for each of the three performance measures and for each of the tree classifiers). The meta-model was tested using the 5x10 cross-validatin procedure. The quality of the whole system was evaluated using *RMSE* calculated between predicted and real prediction performance. The obtained results are presented in Tab. III.

The results are placed in two columns. The first column contains the results obtained using classical compression of both *CNN* and *ENN* as meta-attributes, and the second column contains the results obtained with a balanced compression. For each of the tested classifiers, the three measures of accuracy (accuracy, average sensitivity and average precision) were estimated, and Welch's t-test [18] was used to determine if the results are statistically significantly different at $\alpha = 0.05$. The symbol (+) indicates results which are significantly better.

The obtained results clearly indicate that for meta-learning systems where the task is to estimate classical accuracy, the standard compression measure gives better results. However, when the aim of the process is to estimate average precision or average sensitivity, a much better solution is to use the balanced compression; each time the results obtained using balanced compression were statistically significantly better than those obtained with standard compression.

Table III: Results of the meta-learning system. The columns represent RMSE of the meta-model aimed at estimating classification performance of three classifiers: *k*NN, Linear SVM, and Random Forest using two meta-sets which consisted of: clasical compression based meta-attributes (column 1) and balanced compression - based meta-attributes (column 2)

		Compression RMSE±std	Balanced Compression RMSE±std
*k*NN	Accuracy	0.0328±0.0207(+)	0.0799±0.0400
	Recall	0.1336±0.0529	0.0703±0.0575(+)
	Precision	0.1265±0.0607	0.0884±0.0628(+)
SVM	Accuracy	0.0640±0.0296(+)	0.0910±0.0416
	Recall	0.1523±0.0610	0.1130±0.0600(+)
	Precision	0.1453±0.0711	0.1171±0.0622(+)
Random Forest	Accuracy	0.0437±0.0281(+)	0.0739±0.0408
	Recall	0.1276±0.0632	0.0954±0.0711(+)
	Precision	0.1284±0.0644	0.0979±0.0711(+)

The prediction quality of the *k*NN model can be estimated more precisely than those of SVM or Random Forest, which is natural, as the instance selection methods internally use the nearest neighbor mechanism to evaluate each of the instances. Random Forest ranked lower than *k*NN in terms of performance estimation but ranked higher than SVM. SVM's high performance estimation error was caused by the fact that the SVM considered in this study utilized a linear kernel, and thus it was a linear classifier, while Random Forest is a nonlinear classifier. By their very nature, methods of instance selection are nonlinear, and thus they can overestimate the results obtained by the linear model.

V. Conclusions

In this study we have shown that compression forms a strong linear relationship with the standard prediction accuracy. We have also shown that other measures of prediction quality do not correlate strongly with the standard compression obtained by instance selection.

To address this problem, we proposed a modified measure of compression called balanced compression. The purpose of balanced compression is to express the characteristics of the dataset preserving distribution of the class labels. This allowed to obtain almost linear relationship between the balanced compression and the accuracy measures such as average precision and average sensitivity. The importance of this linear relationship can be efficiently used in meta-learning systems, where the balanced compression allowed for a significant improvement in the estimation of average precision and average sensitivity compared to estimation performed using standard compression.

***Abstract*—A deep evolving stacking convex neo-fuzzy network is proposed. It is a feedforward cascade hybrid system, the layers-stacks of which are formed by generalized neo-fuzzy neurons that implement Wang–Mendel fuzzy reasoning. The optimal in the sense of speed algorithms are proposed for its learning. Due to independent layer adjustment, parallelization of calculations in non-linear synapses and optimization of learning processes, the proposed network has high speed that allows to process information in online mode.**

I. Introduction

DEEP neural networks (DNNs) are currently the most intensively developing direction of Computational Intelligence due to their universal capabilities in solving a variety of information processing tasks. At the same time, DNNs are not without significant drawbacks, the main of which is the low speed of training due to the need to use error backpropagation across multiple layers. In this regard, increasing of the training speed of DNNs is a topical task.

It should be noted here that historically the first deep networks [2] were information processing systems based on the group method of data handling (GMDH) [5], [6], where training was conducted sequentially from input to output, all nodes of the system being independently tuned. Another advantage of the GMDH-networks is the possibility of increasing the number of layers to achieve the required accuracy of the resulting solution. Thus, this network evolves over time [7], [8], increasing the number of layers. It is important that the previously formed layers are not tuned anymore in the process of evolution, that significantly reduces the total training time. Deep neural networks based on GMDH were proposed in [9], [10] that exceeded the known DNNs in learning speed. However, in situations when data under processing are received online in the form of an information stream [11], [12], this learning speed may not be sufficient.

In such situations, it is more preferable to use the idea of cascaded neural networks [13], where each cascade is formed by a pool of neurons, and the input signal of each cascade is formed from the inputs of the network and the outputs of the previous cascades.

The usage of the traditional elementary perceptrons by F. Rosenblatt in the cascades leads to a significant increase in the number of these cascades, that again increases the learning time, although in principle the cascade network can operate in online mode. In connection with this, it was suggested in [14], [15] to optimize the output signal in each cascade, and instead of the usual neurons to use neo-fuzzy neurons (NFNs) [16]-[18], that have high approximating properties.

At the intersection of cascade neural networks and deep stacking neural networks [2] deep stacking hybrid networks have emerged [19], [20], where hybrid generalized additive wavelet-neuro-neo-fuzzy systems (HGAWNNFS) were used as stacks-cascades [21]-[25], synthesized on the basis of hybrid systems of computational intelligence and generalized additive models [26]. These systems showed high quality of information processing and high enough speed, although the computational bulkiness of stacks-HGAWNNFS reduces the speed of the network learning.

In this regard, it is interesting to introduce a deep evolving stacking cascade system, that has high learning speed, good approximating properties and that is simple in numerical implementation.

II. The Deep Evolving Stacking Cascade Network Architecture

In Fig. 1 the architecture of deep stacking cascade network is presented. It contains g layers-cascades-stacks [2], [27], [28], each of them is a hybrid system of computational intelligence with high approximating properties.

It can be seen that adding new stacks to the architecture does not require retraining of the already formed layers. Thus, this architecture evolves over time [7], [8], [15] by adding new stacks to achieve the required accuracy.

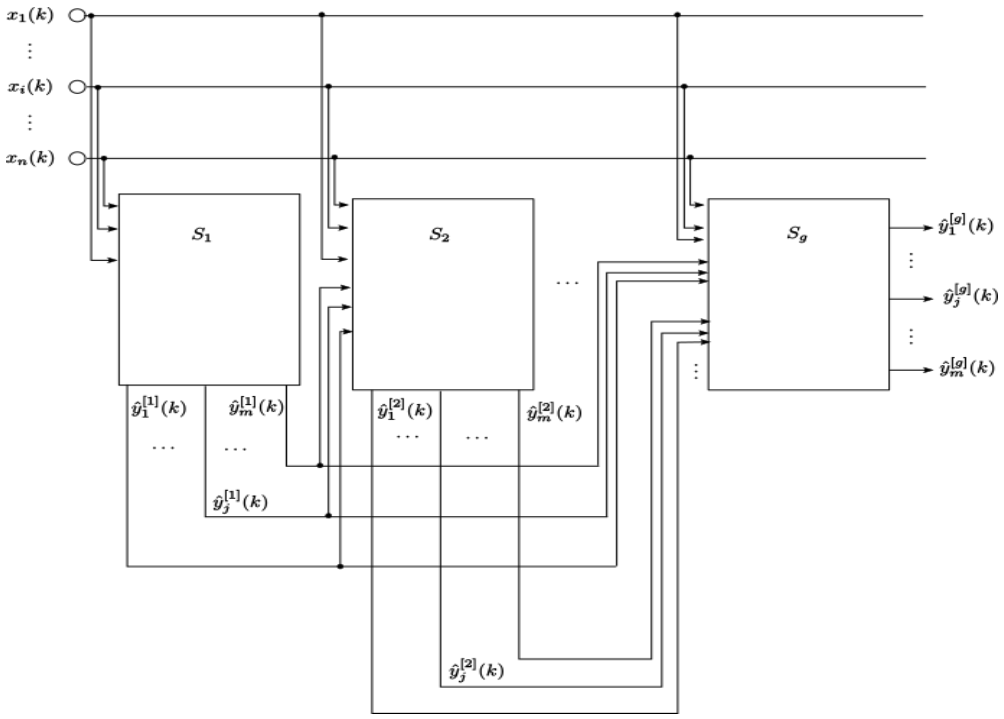

Fig. 1 Deep evolving stacking cascade network

To the input of the network's first layer S_1 an input vector $x(k)=(x_1(k),...,x_i(k),...,x_n(k))^{\mathrm{T}}\in R^n$ is fed (here $k=1,2,...$ is either the number of the observation in the training set, or the current discrete time index). On the output of this layer an output signal $\hat{y}^{[1]}(k)=(\hat{y}_1^{[1]}(k),...,\hat{y}_j^{[1]}(k),...,\hat{y}_m^{[1]}(k))^{\mathrm{T}}\in R^m$ is formed. In the situation when the signal $\hat{y}^{[1]}(k)$ at the output of the trained S_1 satisfies in accuracy all the requirements, i. e. the process of the network forming ends. Otherwise, the second layer S_2 is formed, the input of which is an extended vector $\left(x^{\mathrm{T}}(k),\hat{y}^{[1]\mathrm{T}}(k)\right)^{\mathrm{T}}\in R^{n+m}$ and the output of which is $\hat{y}^{[2]}(k)\in R^m$. To the third stack S_3 a signal $\left(x^{\mathrm{T}}(k),\hat{y}^{[1]\mathrm{T}}(k),\hat{y}^{[2]\mathrm{T}}(k)\right)^{\mathrm{T}}\in R^{n+2m}$ is fed.

And, finally, the input of the S_g is a vector $\left(x^{\mathrm{T}}(k),\hat{y}^{[1]\mathrm{T}}(k),...,\hat{y}^{[g-1]\mathrm{T}}(k)\right)^{\mathrm{T}}\in R^{n+(g-1)m}$, and the output of the whole network is $\hat{y}^{[g]}(k)\in R^m$.

Thus, the network provides a non-linear mapping $R^n\to R^m$, and the number of layers is limited only by the maximal permissible dimension of the input signal of the g th stack. At the same time, when the learning process is paralleled, this restriction is not essential.

It is important that the training of layers-stacks is realized practically independently of each other, and error backpropagation is not required in principle.

III. Generalized Neo-Fuzzy-Neuron as Stack of Proposed Network

As a "building block"-stack of the system under consideration, we propose to use the generalized neo-fuzzy-neuron (GNFN) [29], that is a generalization of the neo-fuzzy neuron (NFN) [16-18] for the multidimensional case. In Fig. 2 the architecture of the first S_1 GNFN-layer is presented. It contains n inputs and m outputs. All other GNFN-layers $S_2,...,S_g$ coincide in architecture with S_1 and differ only in the number of inputs. It should be also noted that GNFN has high approximating properties, simplicity of numerical implementation and parallelization of information processing.

A sequence of input signals $x(k)=(x_1(k),...,x_i(k),...,x_n(k))^{\mathrm{T}}\in R^n$ is fed to the input of a GNFN that is formed by the first layer-stack S_1. This stack consists of n multidimensional parallel non-linear synapses $MNS_i^{[1]}$, $i=1,2,...,n$, each of which has only one input, m outputs, h membership functions $\mu_{li}^{[1]}(x_i(k))$, $l=1,2,...,h$ and mh adjustable synaptic weights $w_{jli}^{[1]}$, $j=1,2,...,m$.

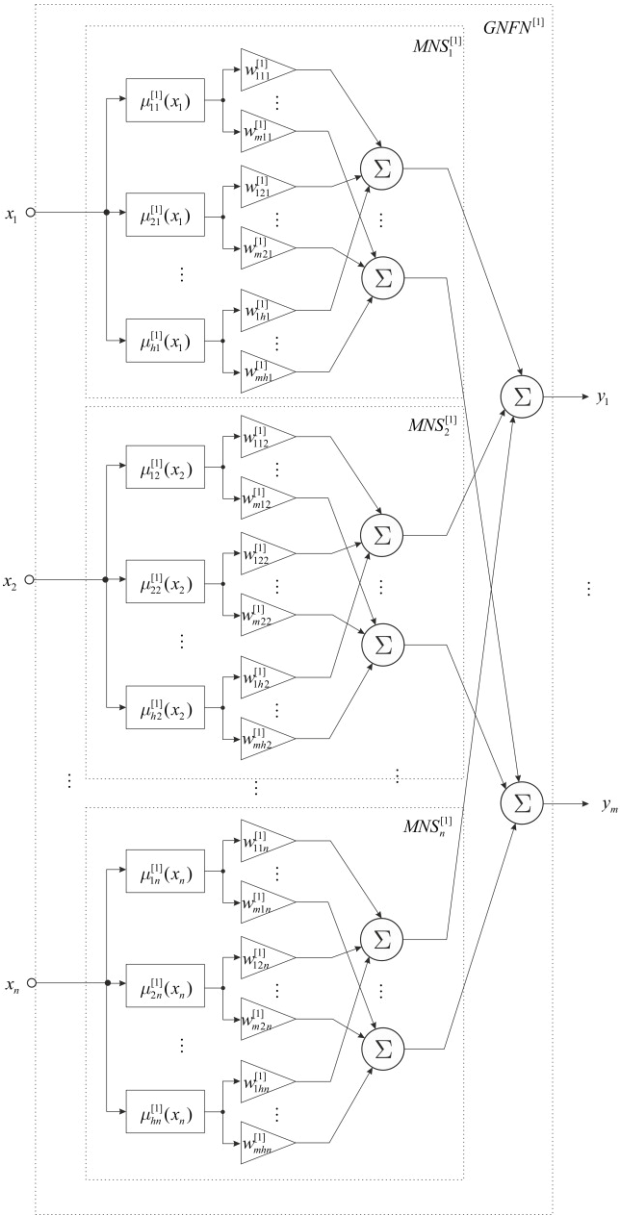

Fig. 2 Generalized neo-fuzzy neuron (GNFN)

The output of the first layer is a vector $\hat{y}^{[1]}(k)=\left(\hat{y}_1^{[1]}(k),...,\hat{y}_j^{[1]}(k),...,\hat{y}_m^{[1]}(k)\right)^{\mathrm{T}}$, that further together with the vector $x(k)$ is fed to the inputs of the layer S_2 in the form of $\left(x^{\mathrm{T}}(k),\hat{y}^{[1]\mathrm{T}}(k)\right)^{\mathrm{T}}$. Thus, S_1 contains nh membership functions and nhm synaptic weights.

Non-linear mapping, realized by this GNFN, in general case can be written in the form

$$\hat{y}_j^{[1]}(k)=\sum_{i=1}^{n}\sum_{l=1}^{h}w_{jli}^{[1]}\mu_{li}^{[1]}\left(x_i(k)\right)\ \ \forall j=1,2,...,m \qquad (1)$$

and it significantly depends both on the type of membership functions used and the algorithm for synaptic weights learning.

It should be also noted that multidimensional non-linear synapses $MNS_i^{[1]}$ in general case are zero-order Takagi–Sugeno–Kang (i.e. Wang–Mendel) neuro-fuzzy systems, that provide high approximating properties.

As the membership functions in the simplest case we can use triangular ones:

$$\mu_{li}^{[1]}(x_i)=\begin{cases}\dfrac{x_i-\bar{x}_{l-1,i}^{[1]}}{\bar{x}_{li}^{[1]}-\bar{x}_{l-1,i}^{[1]}}\ if\ x_i\in\left[\bar{x}_{l-1,i}^{[1]},\bar{x}_{li}^{[1]}\right],\\ \dfrac{\bar{x}_{l+1,i}^{[1]}-x_i}{\bar{x}_{l+1,i}^{[1]}-\bar{x}_{li}^{[1]}}\ if\ x_i\in\left[\bar{x}_{li}^{[1]},\bar{x}_{l+1,i}^{[1]}\right],\\ 0\ otherwise.\end{cases}$$

They satisfy the conditions of unity partition

$$\begin{cases}\mu_{l-1,i}^{[1]}(x_i)+\mu_{li}^{[1]}(x_i)=1\ if\ x_i\in\left[\bar{x}_{l-1,i}^{[1]},\bar{x}_{li}^{[1]}\right],\\ \mu_{li}^{[1]}(x_i)+\mu_{l+1,i}^{[1]}(x_i)=1\ if\ x_i\in\left[\bar{x}_{li}^{[1]},\bar{x}_{l+1,i}^{[1]}\right]\end{cases}$$

where $\bar{x}_{li}^{[1]}$, $l=1,2,...,h$ are membership functions' centers, that are in the simplest case evenly distributed on the x_i-axis.

The usage of triangular membership functions leads to the fact that at each instant of time k only two neighboring functions fire. This allows to adjust not all nhm synaptic weights on each iteration, but only $2nm$ of them. It is clear that the learning speed can be increased in this case.

IV. Deep Stacking Convex Neo-Fuzzy Network Learning

The learning process of the system under consideration is its synaptic weights' adjustment. Due to the cascade architecture of the system, each stack can be trained independently of the others. It is clear that in online mode the learning algorithms used must provide the maximum possible speed, i.e. they have to be based on the Gauss-Newton algorithms of second-order optimization for convex functions. In this case, the network itself is a convex one [30].

The learning process will be considered using the example of the first layer of the system S_1. For this, let's introduce a $(hn\times 1)$-vector of membership functions $\mu^{[1]}(x(k))=\left(\mu_{11}^{[1]}(x_1(k)),\mu_{21}^{[1]}(x_1(k)),...,\mu_{h1}^{[1]}(x_1(k)),\right.$ $\left.\mu_{12}^{[1]}(x_2(k)),...,\mu_{li}^{[1]}(x_i(k)),...,\mu_{hn}^{[1]}(x_n(k))\right)^{\mathrm{T}}$ and $(m\times hn)$-matrix of synaptic weights

$$W^{[1]}=\begin{pmatrix}w_{111}^{[1]} & w_{121}^{[1]} & \cdots & w_{1hn}^{[1]}\\ w_{211}^{[1]} & w_{221}^{[1]} & \cdots & w_{2hn}^{[1]}\\ \vdots & \vdots & \ddots & \vdots\\ w_{m11}^{[1]} & w_{m21}^{[1]} & \cdots & w_{mhn}^{[1]}\end{pmatrix}.$$

Thus, the mapping, realized in the first layer, can be written as

$$\hat{y}^{[1]}(k) = W^{[1]}\mu^{[1]}(x(k)).$$

Next, let's introduce the learning error of the j th component of $\hat{y}_j^{[1]}(k)$ of the output signal $\hat{y}^{[1]}(k)$:

$$e_j^{[1]}(k) = y_j(k) - \hat{y}_j^{[1]}(k) = y_j(k) - w_j^{[1]}\mu^{[1]}(x(k))$$

(here $w_j^{[1]}$ is the j th row of the weights matrix $W^{[1]}$, $y_j(k)$ is the j th component of the reference signal $y(k) = (y_1(k),...,y_j(k),...,y_m(k))^{\mathrm{T}}$ and the standard squared learning criterion of the j th output

$$E_j^{[1]}(k) = \sum_k \left(e_j^{[1]}(k)\right)^2 = \sum_k \left(y_j(k) - w_j^{[1]}\mu^{[1]}(x(k))\right)^2. \quad (2)$$

The gradient procedure for minimizing the criterion (2) has a general form

$$\begin{aligned} w_j^{[1]}(k) &= w_j^{[1]}(k-1) - \eta^{[1]}(k)\nabla_{w_j^{[1]}} E_j(k) = \\ &= w_j^{[1]}(k-1) - \eta^{[1]}(k)\nabla_{w_j^{[1]}}\left(e_j^{[1]}(k)\right)^2 = \\ &= w_j^{[1]}(k-1) + \eta^{[1]}(k)e_j^{[1]}(k)\mu^{[1]\mathrm{T}}(x(k)) = \\ &= w_j^{[1]}(k-1) + \eta^{[1]}(k)\times \\ &\times\left(y_j(k) - w_j^{[1]}(k-1)\mu^{[1]}(x(k))\right)\mu^{[1]\mathrm{T}}(x(k)) \end{aligned} \quad (3)$$

where $\eta^{[1]}(k)$ is learning rate parameter for S_1.

It is possible to increase the speed of the learning procedure (3) using either the standard recursive least-squares method (RLSM), that is a second-order optimization procedure:

$$\begin{cases} w_j^{[1]}(k) = w_j^{[1]}(k-1) + \dfrac{e_j^{[1]}(k)\mu^{[1]\mathrm{T}}(x(k))P^{[1]}(k-1)}{1+\mu^{[1]\mathrm{T}}(x(k))P^{[1]}(k-1)\mu^{[1]}(k)}, \\ P^{[1]}(k) = P^{[1]}(k-1) - \dfrac{P^{[1]}(k-1)\mu^{[1]}(x(k))\mu^{[1]\mathrm{T}}(x(k))}{1+\mu^{[1]\mathrm{T}}(x(k))P^{[1]}(k-1)\mu^{[1]}(k)}\times \\ \quad \times P^{[1]}(k-1), \end{cases} \quad (4)$$

or the optimized algorithm with tracking and filtering properties [31,32]:

$$\begin{cases} w_j^{[1]}(k) = w_j^{[1]}(k-1) + \left(r^{[1]}(k)\right)^{-1} e_j^{[1]}(k)\mu^{[1]\mathrm{T}}(x(k)), \\ r^{[1]}(k) = \alpha r^{[1]}(k-1) + \mu^{[1]\mathrm{T}}(x(k))\mu^{[1]}(x(k)) \end{cases} \quad (5)$$

where $0 \le \alpha \le 1$ is smoothing parameter.

The algorithm (5) can be rewritten in the matrix form

$$\begin{cases} W^{[1]}(k) = W^{[1]}(k-1) + \left(r^{[1]}(k)\right)^{-1} e^{[1]}(k)\mu^{[1]\mathrm{T}}(x(k)), \\ r^{[1]}(k) = \alpha r^{[1]}(k-1) + \left\|\mu^{[1]}(x(k))\right\|^2, \end{cases} \quad (6)$$

that with $\alpha = 1$ coincides with the multidimensional version [33] of the Kaczmarz – Widrow – Hoff learning algorithm:

$$\begin{aligned} W^{[1]}(k) &= W^{[1]}(k-1) + \frac{e^{[1]}(k)\mu^{[1]\mathrm{T}}(x(k))}{\left\|\mu^{[1]}(x(k))\right\|^2} = \\ &= W^{[1]}(k-1) + e^{[1]}(k)\mu^{[1]+}(x(k)), \end{aligned} \quad (7)$$

where $(\bullet)^+$ is pseudo-inversion symbol.

It should also be noted that the Kaczmarz algorithm is optimal by speed in the class of gradient adaptive learning procedures.

All other layers $S_2,...,S_g$ are adjusted in the same way, however with the increase in the dimensionality of the vector $\mu^{[g]}(x(k))$ defined as $(h(n+(g-1)m)\times 1)$, the advantage should be given to the procedures (6), (7), since RLSM (4) can be numerically unstable at high dimensions of the input space.

V. Experiments

To demonstrate the efficiency of the proposed system, we solved the classification task for the wine data set [34]. This data set has 13 attributes, 178 instances and 3 classes of wine. We used 80% of the data set to train the system and 20% for testing. For training the Kaczmarz – Widrow – Hoff algorithm (7) was used. The results of the experiment are shown in Table I. Classes predicted by the trained system on the test set are shown in Fig. 3 as a scatter plot of the first two principal components calculated using PCA.

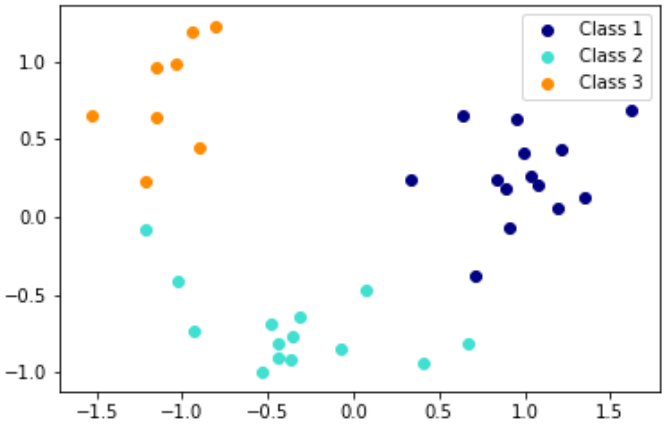

Fig. 3 Classes of wine predicted by the proposed system

VI. Conclusion

In the paper a deep evolving stacking convex neo-fuzzy network is proposed. It is a multi-layered hybrid system of computational intelligence. This network has a feedforward cascade architecture, the layers-stacks of which are formed

by generalized neo-fuzzy neurons that implement Wang–Mendel fuzzy reasoning. Since the output signals of the stacks depend linearly on the adjustable synaptic weights, the optimal in the sense of speed algorithms are used for their learning. Due to independent layer adjustment, parallelization of calculations in non-linear synapses and optimization of learning processes, the proposed network has high speed that allows to process information in online mode.

***Abstract*—Applying the cardinality of finite sets, interval numbers can be assigned to rough sets represented by nested sets. Borrowing two different comparison methods from Multiple Attribute Decision Making analysis, rough sets are compared and ranked on the model of interval numbers. Some special cases are investigated. Illustrative examples are presented relying on both methods. The calculated results are compared and interpreted.**

***Index Terms*—Rough sets, interval arithmetic, Possibility Degree Method, Midpoints Comparison Method.**

I. Introduction

ROUGH set theory (RST) was proposed by Pawlak in the early 1980's [1]. Information system in the Pawlak's sense can be viewed to some extent as a Multiple Attribute Decision Making (MADM) scheme (see, e.g., [2]).

In RST, rough sets represented by nested sets can be considered as an *interval set structure* to represent nonnumeric uncertainty on the model of interval numbers [3]. In our approach, however, by the cardinality of finite sets, *interval numbers* are assigned to rough sets represented by nested sets. Then, borrowing Possibility Degree Method and Midpoints Comparison Methods from MADM, rough sets can be compared and ranked numerically based on these interval numbers.

Section II presents some elementary notations for reasons of clarity. Section III and IV state fundamental knowledge about rough sets and interval arithmetic, respectively. Section V shows two comparison methods of interval numbers, namely, Possibility Degree Method and Midpoints Comparison Method. Then, it deals with the comparison and ranking of rough sets applying these two methods. It also contains simplified illustrative examples.

II. Basic Notations

Let U be a nonempty set, and $\mathcal{P}(U)$ denote the power set of U. Set operations union, intersection, difference, and complementation are denoted by $\cup$, $\cap$, $\setminus$, and ^{c}, respectively. Let $S \in P(U)$, and $\mathcal{S} \subseteq \mathcal{P}(U)$ be a nonempty family of sets. $|S|$ denotes the cardinality of S. $\cup\mathcal{S}$ and $\cap\mathcal{S}$ are defined by:

$$\cup\mathcal{S} = \{u \mid \exists S \in \mathcal{S}(u \in S)\},\ \cap\mathcal{S} = \{u \mid \forall S \in \mathcal{S}(u \in S)\}.$$

If $\mathcal{S}$ is empty, the conventions $\cup\emptyset = \emptyset$ and $\cap\emptyset = X$ are used.

The shorthand expression "iff" is used for "if and only if".

From now on, throughout the paper let U be a finite nonempty set of objects called the *universe*.

III. Rough Sets

Notions of rough set theory can be represented in many forms. For our purposes, their constructive granule based definitions [4] are formulated as follows.

Let E be an equivalence relation on U. The partition of U generated by E is denoted by U/E. The subset $[u]_E \in \mathcal{P}(U)$ is an equivalence class from U/E containing $u \in U$. The members of U/E are called *elementary sets* or simply *base sets*. Any union of base sets is referred to as *definable set*. By definition, $\emptyset$ is definable for any equivalence relation on U. Their collection is denoted by $\mathcal{D}_{U/E}(\subseteq \mathcal{P}(U))$.

The principal notions of RST are defined by:

$$\mathsf{l} : \mathcal{P}(U) \to \mathcal{D}_{U/E},\ S \mapsto \cup\{[u]_E \in U/E \mid [u]_E \subseteq S\},$$
$$\mathsf{u} : \mathcal{P}(U) \to \mathcal{D}_{U/E},\ S \mapsto \cup\{[u]_E \in U/E \mid [u]_E \cap S \neq \emptyset\}.$$

Values $\mathsf{l}(S)$ and $\mathsf{u}(S)$ are commonly called the *lower* and *upper approximations* of S. With the above notations, the ordered quintuple $PAS = \langle U, U/E, \mathcal{D}_{U/E}, \mathsf{l}, \mathsf{u}\rangle$ is called a finite Pawlak approximation space.

Having given an approximation pair, to identify and characterize the features of set approximations in RST, the following fundamental notions are defined:

- *boundary* of S is $\mathsf{bnd}(S) = \mathsf{u}(S) \setminus \mathsf{l}(S)$;
- S is *exact* (*crisp*), if $\mathsf{l}(S) = \mathsf{u}(S)$, i.e., $\mathsf{bnd}(S) = \emptyset$;
- S is *rough* (*inexact*), if it is not exact, i.e., $\mathsf{bnd}(S) \neq \emptyset$.

In RST the notions of exactness and definability coincide.

For any set S, an approximation pair divides the universe U into three mutual disjoint regions:

- $POS(S) = \mathsf{l}(S)$ — *positive region* of S;
- $NEG(S) = U \setminus \mathsf{u}(S) = \mathsf{u}^c(S)$ — *negative region* of S;
- $BN(S) = \mathsf{bnd}(S)$ — *borderline region* of S.

There are (at least) four equivalent definitions of rough sets, see, e.g., [5], [6]. In the following, the nested pair of sets $\langle \mathsf{l}(S), \mathsf{u}(S)\rangle$ will be used to represent rough sets. It is a family of inexact sets in such a way that for any $T \in \langle \mathsf{l}(S), \mathsf{u}(S)\rangle$, $\mathsf{l}(S) = \mathsf{l}(T)$, $\mathsf{u}(S) = \mathsf{u}(T)$ and $\mathsf{l}(S) \subseteq T \subseteq \mathsf{u}(S)$ hold.

Proposition III.1 ([7], Proposition 3.2) *Let $S_1 \subseteq S_2$. The pair $\langle S_1, S_2\rangle$ is a rough set of the form $\langle \mathsf{l}(S), \mathsf{u}(S)\rangle$ for a set S ($S_1 \subseteq S \subseteq S_2$) if and only if S_1 and S_2 are definable and $S_2 \setminus S_1$ does not contain any singleton base set.*

IV. Basics of Interval Arithmetic

An *interval number* or *interval* [2], [8] is a closed real interval of the form $a = [a^l, a^u] = \{x \in \mathbb{R} \mid a^l \leq x \leq a^u\}$. If $a^l = a^u$, $[a^l, a^u]$ contains a single real number $a = a^l = a^u$.

Two intervals $a = [a^l, a^u]$ and $b = [b^l, b^u]$ are said to be equal, in notation $a = b$, if $a^l = b^l$ and $a^u = b^u$.

The most common special terms for an interval a are:

- $m(a) = \frac{1}{2}(a^l + a^u)$ is the *midpoint* or *center* of a;
- $w(a) = a^u - a^l$ is the *width* or *diameter* of a.

Binary operations $+, -, \cdot, /$, addition, subtraction, multiplication, and division, respectively, can be defined on the set of intervals. Their endpoint formulae are the following [8]:

$$\begin{aligned} a + b &= [a^l + b^l, a^u + b^u];\\ a - b &= a + (-b) = [a^l - b^u, a^u - b^l], -b = [-b^u, -b^l];\\ a \cdot b &= [\min\{a^l b^l, a^l b^u, a^u b^l, a^u b^u\},\\ &\qquad \max\{a^l b^l, a^l b^u, a^u b^l, a^u b^u\}];\\ a/b &= a \cdot (1/b), \text{ where } 1/b = [1/b^u, 1/b^l] \ (0 \notin b). \end{aligned}$$

For nonnegative intervals a, b ($0 \leq a^l, b^l$), multiplication and division formulae are simplified to:

- $a \cdot b = [a^l b^l, a^u b^u]$;
- $a/b = [a^l/b^u, a^u/b^l]$, provided in addition that $0 < b^l$.

V. Comparing and Ranking Rough Sets

A. Possibility Degree Method

Many different equivalent methods have been proposed to compare two interval numbers [2], [9].

Definition V.1 ([2], Definition 4.5) *Let $a=[a^l,a^u]$, $b=[b^l,b^u]$ be two nonnegative intervals with $w(a) > 0$ or $w(b) > 0$. The* possibility degree *of $a \geq b$ is defined by*

$$p(a \geq b) = \max\left\{1 - \max\left\{\frac{b^u - a^l}{w(a) + w(b)}, 0\right\}, 0\right\}.$$

It is also said that $p(a \geq b)$ is the possibility degree of a over b.

Theorem V.2 ([2], Theorem 4.1) *Let $a = [a^l, a^u], b = [b^l, b^u]$ and $c = [c^l, c^u]$ be three nonnegative intervals. For their possibility degrees, the following properties hold:*

1) $0 \leq p(a \geq b) \leq 1$.
2) $p(a \geq b) + p(b \geq a) = 1$. *Especially,* $p(a \geq a) = \frac{1}{2}$.
3) $p(a \geq b) = 1$ *iff* $b^u \leq a^l$.
4) $p(a \geq b) = 0$ *iff* $a^u \leq b^l$.
5) $p(a \geq b) \geq \frac{1}{2}$ *iff* $a^u + a^l \geq b^u + b^l$.
   Especially, $p(a \geq b) = \frac{1}{2}$ *iff* $a^u + a^l = b^u + b^l$.
6) *If* $p(a \geq b) \geq \frac{1}{2}$ *and* $p(b \geq c) \geq \frac{1}{2}$, *then* $p(a \geq c) \geq \frac{1}{2}$.

It is said that

- a *superior to* b in the degree $p(a \geq b)$, in notation $a \succ b$, if $p(a \geq b) > p(b \geq a)$;
- a is *indifferent to* b, in notation $a \sim b$, if $p(a \geq b) = p(b \geq a) = \frac{1}{2}$;
- a is *inferior to* b in the degree $p(b \geq a)$, in notation $a \prec b$, if $p(b \geq a) > p(a \geq b)$.

Let $\{S_1, \ldots, S_n\} \subseteq \mathcal{P}(U)$ be a family of sets. Let us form the rough sets relating to them by their nested pair representations: $RS_i = \langle \mathsf{l}(S_i), \mathsf{u}(S_i)\rangle$ $(i = 1, 2, \ldots, n)$.

The cardinality of finite sets, as some sort of "size" of them, plays a key role in the rough set theory. Applying it, interval numbers can be assigned to the above rough sets:

$$RS_i \mapsto [RS_i] = [|\mathsf{l}(S_i)|, |\mathsf{u}(S_i)|] \ (i = 1, 2, \ldots, n).$$

To avoid heavy notations, the following simplified notations are introduced: $|\mathsf{l}(S_i)|$, $|\mathsf{u}(S_i)|$, $|\mathsf{bnd}(S_i)|$ are denoted by S_i^l, S_i^u, S_i^{bnd}, respectively.

By applying the method described by Xu in [2], ranking of rough sets can be carried out in the following steps:

Step 1. Provided that $w([RS_i]) > 0$ $(i = 1, \ldots, n)$, comparing each rough set with all rough sets as $(i, j = 1, 2, \ldots, n)$:

$$\begin{aligned} p_{ij} &= p([RS_i] \geq [RS_j])\\ &= \max\left\{1 - \max\left\{\frac{\mathsf{S}_j^u - \mathsf{S}_i^l}{w([RS_i]) + w([RS_j])}, 0\right\}, 0\right\}; \end{aligned}$$

arranging the numbers p_{ij}'s in a possibility degree matrix:

$$P = \begin{pmatrix} p_{11} & p_{12} & \cdots & p_{1n}\\ p_{21} & p_{22} & \cdots & p_{2n}\\ & & \vdots & \\ p_{n1} & p_{n2} & \cdots & p_{nn} \end{pmatrix}.$$

Of course, $p_{ij} \geq 0$, $p_{ij} + p_{ji} = 1$, $p_{ii} = \frac{1}{2}$ for $i, j = 1, \ldots, n$.

Step 2. Summing the numbers line by line:

$$p_i = \sum_{j=1}^{n} p_{ij} \ (i = 1, 2, \ldots, n).$$

Step 3. Ranking rough sets RS_i in descending (increasing) order in accordance with the values p_i's $(i = 1, 2, \ldots, n)$. The ith rough set is ranked higher (lower) than the jth rough set, if $p_i > p_j$ $(p_i < p_j)$.

B. Possibility Degree Method — A Special Case

The sets $S_1, S_2 \in \mathcal{P}(U)$ form an orthopair, if $S_1 \cap S_2 = \emptyset$. An orthopair is a reasonable means to represent bipolar information. Bipolarity arises in a natural way in RST as positive and negative regions. According to the Dubois and Prade typology [10], [11], orthopair models usually belong under the "Type II: Symmetric bivariate unipolarity". This bipolarity type well fits the nature of bipolarity representation in RST [12].

Let $\langle S_1, S_2\rangle$ be an orthopair. S_1 and S_2 are called the *positive* and *negative* reference set, respectively. Here, the positive and negative adjectives claim nothing else, only the sets S_1 and S_2 are well separated.

Let us form the rough sets relating to S_1, S_2 by their nested pair rough set representations:

$$RS_1 = \langle \mathsf{l}(S_1), \mathsf{u}(S_1)\rangle \text{ and } RS_2 = \langle \mathsf{l}(S_2), \mathsf{u}(S_2)\rangle.$$

By the above Steps 1–3, the following entities can be obtained with which the constituents of an orthopair can be ranked:

$$\begin{aligned} p_1 &= p_{11} + p_{12} = p([RS_1] \geq [RS_1]) + p([RS_1] \geq [RS_2]),\\ p_2 &= p_{21} + p_{22} = p([RS_2] \geq [RS_1]) + p([RS_2] \geq [RS_2]). \end{aligned}$$

Several interpretations of the obtained results can be stated:

- $p_1 > p_2$ ($p_1 < p_2$) means that the positive (negative) reference set is ranked higher than the negative (positive) reference set.
- $p([RS_1] \geq [RS_2]) = 1$ iff $\mathsf{S}_2^u \leq \mathsf{S}_1^l$.
  It means that the positive reference set is certainly superior to the negative reference iff the number of elements of U which can *possibly be classified as belonging to the negative reference set* is less than or equal to the number of elements of U which can *certainly be classified as belonging to the positive reference set*.
- $p([RS_1] \geq [RS_2]) = 0$ iff $p([RS_2] \geq [RS_1]) = 1$ iff $\mathsf{S}_1^u \leq \mathsf{S}_2^l$.
  It means that the negative reference set is certainly superior to the positive reference set iff the number of elements of U which can *possibly be classified as belonging to the positive reference set* is less than or equal to the number of elements of U which can *certainly be classified as belonging to the negative reference set*.
- $p([RS_1] \geq [RS_2]) = \frac{1}{2}$ iff $\mathsf{S}_1^u + \mathsf{S}_1^l = S_2^u + \mathsf{S}_2^l$ iff $\mathsf{S}_1^u - \mathsf{S}_2^u = \mathsf{S}_2^l - \mathsf{S}_1^l$. Let $\mathsf{S}_1^u - \mathsf{S}_2^u = \mathsf{S}_2^l - \mathsf{S}_1^l = K$.
  $K = 0$ means that the possibility degree of the positive reference set over the negative reference set is equal to $\frac{1}{2}$, iff the number of elements of U which can *possibly* be classified as belonging to the positive and negative reference sets, respectively, are equal, and, at the same time, the number of elements of U which can *certainly* be classified as belonging to the positive and negative reference sets, respectively, are also equal.
  Similar interpretations can be made for $K > 0$ and $K < 0$.

C. Possibility Degree Method — Illustrative Examples

These examples deal with studying the symptoms of thyroid dysfunctions. Although the problem emerged in Csajbók et al. [13], a substantially different solution is presented here.

Thyroid dysfunction diagnosis via clinical symptoms is an important problem [14]. We deal with only hypothyroidism and hyperthyroidism thyroid disorders [15]. The thyroid gland produces thyroid hormone. Hyperthyroidism occurs when the thyroid gland is "overactive", i.e., releases too much hormone, whereas hypothyroidism takes place when the thyroid gland is "underactive", i.e., does not produce enough hormone.

Let us consider a data table given in Table I, taken from [13]. It contains clinical symptoms which may indicate that someone, a patient, develops hypothyroidism or hyperthyroidism, perhaps neither of them. There are, of course, more symptoms of hypothyroidism and hyperthyroidism, but the example has been simplified here for illustrative purposes.

Clinical symptoms which are taken into account are the following: Weight change, Edema, Tachycardia, Increased sweating, Mood. Hypothyroidism and hyperthyroidism can accurately be diagnosed with laboratory tests. The last two columns in Table I are based on these results.

In the example, the universe U is a set of clinically observed patients: $U = \{P_1, P_2, P_3, P_4, P_5\}$. Let $S_1 = \{P_2, P_3\}$ and $S_2 = \{P_4, P_5\}$ be the sets of patients who demonstrably suffer from hypothyroidism and hyperthyroidism, respectively.

Example V.3 *If the column "Weight change" is chosen, the universe U can be partitioned into $\{P_1, P_5\}$, $\{P_2, P_3\}$, and $\{P_4\}$, reflecting the weight change being "no change", "gain", "loss", respectively. Then, based on this partition,*

$$\mathsf{l}(S_1) = \{P_2, P_3\},\ \mathsf{u}(S_1) = \{P_2, P_3\},\ \textit{i.e.,}\ [RS_1] = [2, 2];$$
$$\mathsf{l}(S_2) = \{P_4\},\ \mathsf{u}(S_2) = \{P_1, P_4, P_5\},\ \textit{i.e.,}\ [RS_2] = [1, 3].$$

Since $2+2 = 1+3$, $p([RS_1] \geq [RS_1]) = \frac{1}{2}$, by Theorem V.2, (5)*. That is $[RS_1]$ is indifferent to $[RS_2]$. It can be interpreted as follows: with respect to our knowledge represented in Table I and partitioning U by "Weight change", weight change does not contribute specifically to developing any of hypothyroidism and hyperthyroidism.*

Example V.4 *If the columns "Edema" and "Mood" are chosen, the universe U can be partitioned into $\{P_5\}$ and $\{P_1, P_2, P_3, P_4\}$, reflecting the edema and mood being "Edema = yes", "Mood = nervousness" and "Edema = no", "Mood = no", respectively. Then, based on this new partition,*

$$\mathsf{l}(S_1) = \emptyset,\ \mathsf{u}(S_1) = \{P_1, P_2, P_3, P_4\},\ \textit{i.e.,}\ [RS_1] = [0, 4];$$
$$\mathsf{l}(S_2) = \{P_5\},\ \mathsf{u}(S_2) = \{P_1, P_2, P_3, P_4, P_5\},\ \textit{i.e.,}\ [RS_2] = [1, 5].$$

With a simple calculation, we have

$$p([RS_1] \geq [RS_2]) =$$
$$= \max\left\{1 - \max\left\{\frac{\mathsf{S}_2^u - \mathsf{S}_1^l}{w([RS_1]) + w([RS_2])}, 0\right\}, 0\right\} = \frac{3}{8},$$
$$\textit{and } p([RS_2] \geq [RS_1]) = 1 - p([RS_1] \geq [RS_2]) = \frac{5}{8}.$$

These results can be interpreted as follows: with respect to our knowledge represented in Table I and partitioning U by "Edema" and "Mood", the overall contribution of the clinical symptoms edema and mood to the presence of

- *hypothyroidism has the possibility degree $\frac{3}{8}$,*
- *hyperthyroidism has the possibility degree $\frac{5}{8}$.*

D. Midpoints Comparison Method

In **Theorem V.2**, properties (3) and (4) mean that the possibility degree of a over b is equal to 0 or 1 iff they do not have a common area *regardless of the distance between a and b.*

To overcome this problem, Dymova et al. [16] proposed a method to measure the distance between intervals which, in addition, also indicates which interval is greater/lesser.

Let $a = [a^l, a^u]$, $b = [b^l, b^u]$ be two intervals and form their subtraction: $c = a - b = [c^l, c^u] = [a^l - b^u, a^u - b^l]$. Clearly, $c^l \leq 0$ and $c^u \geq 0$, if a and b overlap each other.

Then, the proposed distance measure between a and b is:

$$\Delta(a, b) = \frac{1}{2}\left(\left(a^l - b^u\right) + \left(a^u - b^l\right)\right) = m(a) - m(b).$$

That is, $\Delta(a, b)$ is simply the difference of the midpoints of a and b. This immediately implies that for intervals a and b with common midpoints, $\Delta(a, b) = 0$ holds.

Remark V.5 *It may seem that the measure $\Delta(a, b)$ is too simple. For its discussion, see [16]. In addition, on the important role of midpoints in comparison of intervals, see [17].*

TABLE I
CLINICAL SYMPTOMS OF THYROID DYSFUNCTION AND DIAGNOSIS BASED ON TEST RESULTS

No.	Weight change	Edema	Tachy-cardia	Increased sweating	Mood	Hypothy-roidism	Hyperthy-roidism
P_1	no change	no	no	no	normal	no	no
P_2	gain	no	no	no	normal	yes	no
P_3	gain	no	yes	no	normal	yes	no
P_4	loss	no	yes	yes	normal	no	yes
P_5	no change	yes	no	yes	nervousness	no	yes

E. Comparing the Two Methods

In [16], *experimental observations* show that the sign of $\Delta(a,b)$ is positive (negative), if $a \succ b$ ($a \prec b$). In addition, $abs(\Delta(a,b))$ is close to the Hamilton distance d_H and Euclidean distance d_E of the intervals a and b, where

$$d_H = \frac{1}{2}\left(abs\left(a^l - b^l\right) + abs\left(a^u - b^u\right)\right),$$
$$d_E = \frac{1}{2}\sqrt{\left(a^l - b^l\right)^2 + \left(a^u - b^u\right)^2}.$$

In regard to these experimental observations, let us compare our numerical results which were calculated with the help of the possibility degree method and midpoints comparison method.

S_1, S_2 are the sets of patients who demonstrably suffer from hypothyroidism and hyperthyroidism, respectively.

According to **Example V.3**, $[RS_1] = [2,2]$; $[RS_2] = [1,3]$, where RS_1, RS_2 are the rough sets concerning S_1, S_2 and based on the partition of U formed by "Weight change".

By applying the possibility degree method, $p([RS_1] \geq [RS_2]) = \frac{1}{2}$, i.e., $[RS_1]$ is indifferent to $[RS_2]$.

By applying the midpoints comparison method, the intervals $[RS_1]$, $[RS_2]$ are equal, i.e, $\Delta([RS_1],[RS_2]) = 0$, since their midpoints are equal. Of course, the sign rule does not work here.

The one interpretation is in accordance with the other.

According to **Example V.4** $[RS_1] = [0,4]$; $RS_2] = [1,5]$, where RS_1, RS_2 are the rough sets concerning S_1, S_2 and relying on the partition of U formed by "Edema" and "Mood".

By applying the possibility degree method, $p([RS_2] \geq [RS_1]) = \frac{5}{8}$, i.e., $[RS_1]$ is inferior to $[RS_2]$, $[RS_1] \prec [RS_2]$, in the degree $\frac{5}{8}$.

By applying the midpoints comparison method,

$$\Delta([RS_1],[RS_2]) = m([RS_1]) - m([RS_2]) = 2 - 3 = -1.$$

According to the sign rule of the midpoint comparison method, since the sign of $\Delta([RS_1],[RS_2])$ is negative, $[RS_1]$ is lesser than $[RS_2]$. This result coincides with the result $[RS_1] \prec [RS_2]$ obtained by the possibility degree method.

If the midpoints of two intervals are the same, there is no sense in comparing $abs(\Delta([RS_1],[RS_2]))$ with the Hamilton and Euclidean distances. This is the case in **Example V.3**.

In **Example V.4**, $abs(\Delta([RS_1],[RS_2])) = 1$. In this case, Hamilton and Euclidean distances can be calculated. For $[RS_1] = [0,4]$, $[RS_2] = [1,5]$, $d_H = 1$ and $d_E = \frac{\sqrt{2}}{2} \approx 0,71$. The Hamilton distance is the same as $abs(\Delta([RS_1],[RS_2]))$, and Euclidean distance estimates it to some extent.

VI. CONCLUSION

The paper has presented two comparison and ranking methods for rough sets in Pawlak approximation spaces. Although the two methods are borrowed from Multiple Attribute Decision Making analysis, their application to rough sets is a new approach. Based on the presented calculations and interpretations, it seems that this approach deserves attention.

***Abstract*—The improvement of the efficiency in teaching requires knowing the understanding level of each student. However, it is difficult due to limited time in a class. We propose a Virtual Reality (VR) space imposing assignments on students, to know their understanding level from their behavior which comes from cognitive loads during their answering. The VR space presents a student an assignment and a working space to answer it. In general, students solve assignments, using elements on their short term memory. When students solve same kind of assignments many times, they build generalized solution methods in their long term memory. When they engage in such assignments, their cognitive load is low enough to make them watch only the working spaces, keeping their hands working. On the other hand, when students have no solution pattern, their short term memory works hard. Their high cognitive load often stop their hands, because of confusion. They also look assignments and the working space many times, to reconsider solutions. Since answering behavior of students exposes their cognitive load, a VR space is ideal to estimate cognitive load. We conducted an experiment to evaluate the ability of the method to estimate the cognitive load. We examined the movement of the hand and the edit distance of student's answer from the correct sentence during their answering. We confirmed a fair correlation of the hands' stagnation with the confidence in students of good scores. We also found a relationship of eye movement with the change of the edit distance. The experiment result implies the possibility to estimate the cognitive load. The estimation would enable teachers to know students' understanding faults, which leads to education according to the understanding level.**

I. Introduction

IN EDUCATION, adjusting the difficulty of tasks in the class maximizes the learning effect[1][2]. Students cannot learn anything from too difficult tasks, nor anything from too easy tasks. Therefore, teachers try to adjust the progress of classes. For the adjustment, they need to know the cognitive load on students. In the context, the cognitive load in learning refers to the total amount of mental activity imposed on students. In face to face class, teaches can estimate the load, looking their behaviors. Teachers can also ask questions to students, to receive feedbacks from students. Such direct communications is the best way to know the cognitive load on students, but it takes so long time to communicate with large number of students. To avoid it, teachers assign students paper tests or e-learning tests instead of direct communication. Although these tests can check understanding level of many students at one time, teachers cannot know behavior of students from these tests. These tests cause miss-understanding of the cognitive load. One example is a correct answer by luck. In addition, it is a hard work for students and teachers to perform tests many times. It is troublesome to adjust the difficulty level of the class for students. We must find the easy way to estimate student understanding level correctly.

There are two types of memories in human brain: a working memory and a long term memory. Each of the memories has its own functions. We focus on difference of these functions to estimate understanding level. The function of the working memory is information processing to understand situations and carry out tasks. Its capacity is limited[4] and the memory is lost within about 20 s[5]. On the other hand, the long term memory has large size, to store patterns which are often used in the processing in the working memory. Each of the patterns is treated as one chunk, when it is restored from the long term memory to the working memory. The patterns are referred to as schemata[6].

To solve tasks which are not mastered well, students need to process information without schema. It is hard for students, because the working memory should store a lot of information at the same time[7]. Since the capacity of the working memory is small, the tasks make the cognitive load high. By contrast, when students master the tasks through repeated practices, they restore the schemata corresponding to them from the long term memory to the working memory. Since schemata combine several pieces of information into one chunk, they help students reduce the number of pieces on the working memory. Consequently, schemata reduce the cognitive load[8][9][10].

When students make mistakes and show hesitation in learning tasks, they seem not to have established schemata on the knowledge to achieve the tasks. They seem to have high cognitive load caused by a lot of information on the working memory. Based on the idea, this study proposes a method to estimate student understanding level correctly from their behaviors to answer tasks in learning using a VR space. In this study, we utilize tests to sort English words in a VR space. In a VR space, we can record detailed behavior such as gaze shifts and hand movements. We analyze the behavior along with test results, to estimate their cognitive load. The estimation reveals student understanding level. In addition, this paper discusses a way to examine what part of the learning task imposes the

high cognitive load on the students, which enables us to find what knowledge they lack.

In this paper, section Ⅱ explains the relationship of operation in a VR space with cognitive load. Section Ⅲ clarifies the method to figure out the understanding level from behavior. Section Ⅳ presents an asessment system of understanding level using a VR tool. Section V evaluates the method by an experiment. Section Ⅵ discusses the result of the experiment. Section Ⅶ concludes our works.

II. Relationship of operation in VR space with cognitive load

A. Cognitive load

When people understand matters, their brains memorize the information on the matter. It imposes the loads on their brain. The load is referred to as cognitive load. People cannot understand the matter without memorizing it. Some people take things as they are. Other people connect the related things as single facts before they remember them. It is good to group the related facts as single ones, in order to reduce the load of the memories. People would memorize the pattern of related things which are often used on the memories. The patterns of related things and processing results are treated as chunks[11] .

There are two types of human memory: the working memory and the long term memory. Each memory is specialized for their role.

The working memory stores the information temporarily to process it. People must store all information on tasks in their working memory to achieve them[2][3]. Nevertheless, the capacity of the working memory is small[4]. It is reported the working memory only can store around four pieces of information even in the case of young adults[12].

By contrast, the long term memory has large capacity. The long term memory stores the pattern of thinking and relationship of information. It is referred to as a schema. A schema can combine several chunks as a bigger chunk. The combination makes the load of the working memory smaller[8][9][10]. For example, let us assume to remember a sequence of six letters of “MEMORY”. If a child who does not know English tries to remember this alphabet sequence, the child has to memorize each character like ’M’, ’E’, ’M’, ’O’, ’R’, ’Y’. On the other hand, if you know English word “MEMORY”, you can combine that information as one chunk, which reduces the burden on the working memory. The difficulty of a learning task depends on the cognitive load, while the cognitive load is determined by knowledge of students. Students who have appropriate knowledge to solve questions can decrease the number of chunks in the working memory. Therefore, the cognitive load is also reduced.

Students can learn no knowledge from too difficult assignments, because they cannot proceed the task. In the same way, too easy assignments give no knowledges to students, because there are no new things for them. Estimation of the cognitive load can change the teaching, because we can adjust the difficulty for each student to maximize the effect of learning.

B. Human sense in VR space

In VR space, the movement of users is measured to make the users feel they move in the space, as if they move in the real space. The movement is measured with 2 wearable devices: a head mount display, and handy mortion controllers.

The head mount display, which is used to display the VR space to users, measures the position and the rotation of the user, to display the virtual space naturally to the user. The space presented inside the head mound display changes according to the head movement, so that the users take their views just like in their ordinal life. They can see anything in a VR space from any position and any direction in the way they want. For this reasons, users can take three important factors to feel reality, 3D spatiality, real time responsibility and self-projecting[13].

Recent VR can detect hands movement using handy motion controllers. Due to the motion controllers, users can interact with VR objects. We can know quickly the detailed position and rotation of the motion controllers. We can also detect the grasping of users. Therefore, we can reproduce their hands in VR space, through the projection of the virtual hand models on the position where the users feel their real hands are placed. In addition, the device enables us not only to rotate the virtual hands as the actual hands rotate, but also to bend the virtual fingers as the real fingers. Since the movement of virtual hands is identical with real ones, the reality is provided wiht users.

Suppose students engage in learning tasks in in a VR classroom. Using wearable devices, we can detect the movement of the gaze and the hand of the students. Users can interact with virtual objects without operative difficulties, because they can grasp virtual objects as they do in the real life. The records expressing their behaviors contain few noises. The movement shows their hesitation, confidence and cognitive load in the learning tasks. It shows purely their understanding level.

C. Related works

Many studies try educational data mining[14]. For example, Ivancevic, Celikovic & Lukovic find the seats selection of students in classroom, which is related to their assessment[15].

There are some studies to reveal the understanding level of e-learning students. As one example, Nakamura[16] used a camera to analyze the facial movement. His team succeeded estimating 75% of the subjective difficulty of the students from their facial behavior. However, facial behavior depends on individuals. The method requires a specialized estimator for each student. It has also a problem to record the behavior of the students by a camera, from the viewpoint of privacy.

Eye gaze is used to know focus and attention of users[17]. In the case of VR, eye gaze is one of the pointing way to interact virtual objects without hand interaction. Some of head-mount displays can detect gaze of users(e.g. FOVE[18]). However, they are expensive. Since most of them cannot detect the gaze, they use head-based interactions as a proxy of gaze pointing[19][20]. This pointing is an operation, which is a conscious behavior. To estimate the students understanding, it

is also important to analyze the unconscious behavior such as taking a look at hints.

We need a method to estimate each student understanding level. To do this, we should find predictors which explain the understanding level of individual students.

III. Clarifying Understanding Level from Behavior

A. Recording behavior consisting of small tasks

We propose the method which estimates student understanding level from their behavior. A task of a specific student consists of small tasks. When the student finishes each of the small tasks, the main task is over too. We focus on these small tasks such as looking at a question and picking up a word card. We record the order of these small tasks as behavior, which is the target data to be analyzed.

After teachers estimate the understanding level from behavior, they can improve their classes with the records so that the classes suit for the student understanding.(Fig. 1)

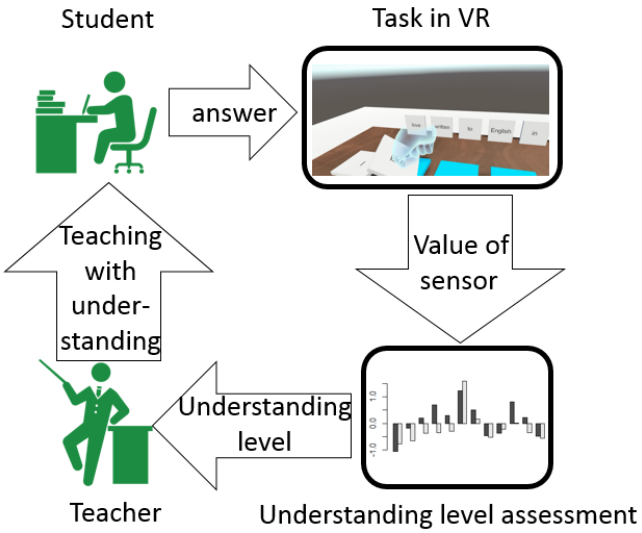

Fig. 1. Operation of proposal method

B. Estimating understanding level of each student

This paper takes an example which is a sort test of English words to explain the way to assess student understanding level. The tests are conducted in a VR space. Every student who tries the test wears a head mount display and hand gears specific to the VR space. The pair of the head mount display and the hand gears enables the student to experience the sort test provided in the VR space. At the same time, the pair is equipped functions to record the movement of the head and the both hands of the student.

We record movement of the hands and the head of the student in VR test (Fig. 2). When students have low cognitive load, the movement of their hands and head is smooth. On the other hand, when students have high cognitive load, the movement often stops. Our research estimates the cognitive load from the movement. Furthermore, we reveal what students do not understand through analysis of test results and the cognitive load, which is estimated from their behavior.

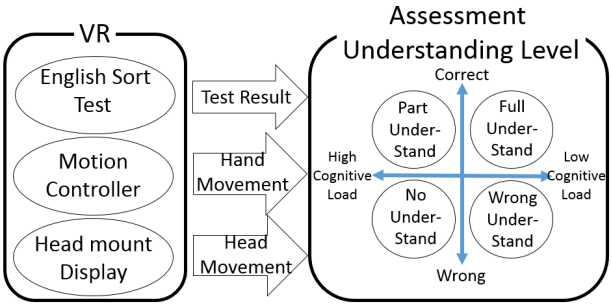

Fig. 2. Method overview

C. Assessment of cognitive load

We can estimate the student understanding level with the analysis of the cognitive load, deeper than that without behavior. We quantify the cognitive load based on machine learning. Since cognitive load is phenomenon in brain, it is not observable. It is difficult to quantify. However, students who solve questions with low cognitive load have high confidence, while high cognitive load makes confidence low. We can know the cognitive load from confidence of students appearing on their behavior. We examine the following two relationships to assess the cognitive load.

(1) Relationship between the hand movement and the confidence
As we mentioned, high confidence is assumed to make hands movement smooth. We tried to confirm this assumption.

(2) Relationship between the gaze movement and the edit distance
If students have high confidence, they do not look same place repeatedly. This gaze movement seems to be related to edit distance, which represents the number of how many correction is needed to finish the English sort test. In the test, we assume the more the edit distance is, the higher the cognitive load gets, because it is more difficult for the students to image correct sentences. To make the assumption confirmed, we examine the relationship between the gaze movement and the edit distance.

IV. Assessment of Understanding Level using VR

A. VR English sort test

We prepared a VR English sort test to know what behavior students show while they engage is the test. This test is constructed using Unity5.6.2 p2. Fig. 3 shows a snapshot of a participant sight when a student takes the test. The movie of experiment is located at www.de.is.ritsumei.ac.jp/publication/englishtest.mp4

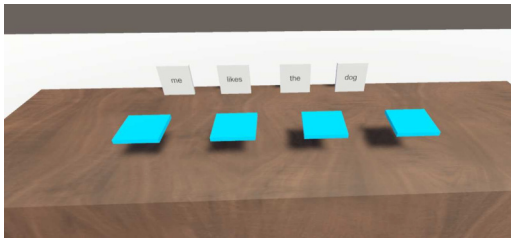

Fig. 3. Sight of students in VR test

In the experiment, participants move the words to correct order of sentence. The blue squares are columns for answer. Participants grab word cards by their hands to place them on those columns. As a hint, a Japanese sentence is presented above the word cards. The participants should look up the hint. When they look up and look around, the head mounted display they wear sense its position and direction. The data show the participant gaze movement which include the information of their understanding level.

B. Head movement and gaze movement

We used Oculus Rift, a head mount display. The participants engage in the test, wearing it on their heads. They usually look at a specific item in the VR space, to move the item from one place to another. For the participants, this behavior in the VR space is more natural than their behavior while they engage in conventional e-learning using a mouse to scroll pages. This head movement is related to the gaze movement. It implies the difficulty the participants have. Since students who have enough knowledge can imagine the correct English sentence consisting of the given words, they can solve the test without looking the hint many times. On the other hand, students fail to imagine the correct one try to make their answers, looking the hint many times and gazing many word cards repeatedly.

C. Hand movement

We used Oculus Touch, the motion controller. When users wear a pair of the motion controllers on their hands, virtual hands appear in VR space. The virtual hands move in the VR space according to that of the hands of users. Using the motion controllers, the users can grab and put things in the VR space by their hands. Since the movement of the virtual hands is coincident with that of the user hands, the VR test is better than conventional e-learning in terms of the ease of control. Because of the ease, the hand movement which students take while VR test contain information which achieves clear analysis of the student understanding level.

V. Experiment

A. Experiment contents and purposes

We experiment on the confidence of participants for a sort test of English words in the VR space.

There are two purposes in this experiment. One is to confirm the relationship between the movement of hands and the confidence. The other purpose is to examine the possibility to assess the confidence from their gaze movement.

In the experiments, 11 college students took assignments to sort English words in the VR space. We conducted 2 kinds of experiment. The first one provides 12 assignments taken by four students. The second one provides 15 assignments taken by 7 students. Some assignments are difficult, while others are easy. We recorded the movement of their heads and right hands every 20 milliseconds. Every time the students finish assignments, we asked their confidence for their answer. In the first experiment, they evaluate their confidence on a scale of 1 to 5. In the second one, they used 4 grade evaluation. No students took both assignments.

B. Relationship of hand movement with confidence

We calculated the ratio of the time in which the hand is stopped to the whole answering time, where the stop of the hand means the sum of the absolute values of the hand location change in x, y, and z directions in 20 milliseconds is less than 2 millimeters. We examined the correlation between the ratio and the confidence.

Unfortunately, we experienced data missing for 2 students. Excluding the two student data, we analyzed the correlation of 9 students. The results are shown in Table I.

In the results, the correlation coefficient goes below -0.7 for seven of the nine students. It means 78% students have low confidence when they hold their hand in assignments. We confirmed the correlation coefficient between their confidence and the hand movement, which means we can estimate the confidence of students from their hand movements.

The two students who were low in the correlation got poor scores in the assignments than others. These students may have answered in the assignments without deep considerations.

C. Relationship between gaze movement and edit distance

Students who have low confidence to solve the assignments would repeat to look at the hints and the word cards alternatively. They are likely to show many gaze shifts which come from the alternative looking. On the other hand, students who have enough knowledge can imagine the correct sentences. They can solve the test without such an unnecessary gaze shift. Unnecessary gaze shifts of students seem to be related their indecision. We detected the amount of unnecessary gaze shifts by the method explained in Fig 4.

During the assignment, every student would look at the hint to determine a specific card word to grasp. Every 20 milliseconds, the method identifies the direction the head faces. It is calculated from the rotation of the head mount display. The method also figures out the vector which corresponds to the direction to the word card the student grabbed next. This vector starts from the student head, and reaches to the word card. The method calculates the cosine similarity of two vectors. When the direction of the two vectors is identical, the cosine similarity takes 1.0, the highest value. It decreases, as the student gazes items located in other direction than that of the word card. We calculated the amount of unnecessary

TABLE I
RELATIONSHIP OF HAND MOVEMENT WITH CONFIDENCE

Students	Correlation Coefficient	Number of correct answers
A	-0.806	8/12
B	-0.91	8/12
C	-0.911	7/12
D	-0.568	5/12
E	-0.897	11/15
F	-0.704	10/15
G	-0.845	9/15
H	-0.765	6/15
I	-0.380	5/15
Mean	-0.754	

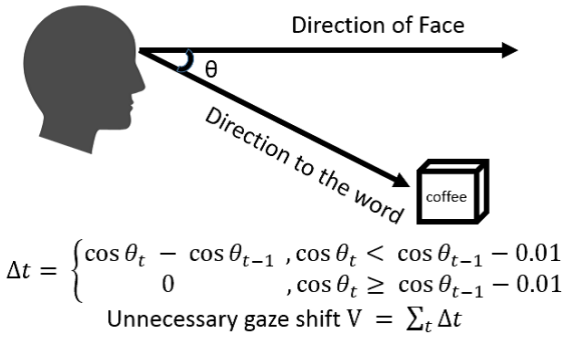

Fig. 4. How to detect a unnecessary gaze shift

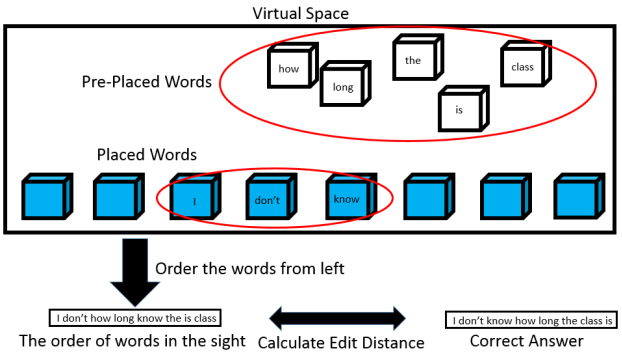

Fig. 5. Calculation of edit distance between correct answer and order of words in sight

gaze shifts as the sum of decline of the cosine similarity from the grasp of one word card to another. We ignore the difference of the cosine similarity more than -0.01 during 20 milliseconds, because it means the student gaze the same item in the duration.

When students lack enough knowledge, they would modify the word order in their answers many times, because they have poor confidence. The frequent modification increases the edit distance of their answers against the correct answers. We tried the multiple regression analysis, where the edit distance is the response variable, while the explanatory variables are the amount of gaze shifts and the time for the students use to answer. The result is showed in Table II. All students except the student E have higher P-value than 0.05. Moreover, the adjusted R-squared coefficients are very low. It means there are no relationship the gaze shift and the edit distances.

After the experiment above, we reconsider the estimation model. We review processes in which students answer assignments. Putting words one by one, students would make sentences. In the process, students would look at not only placed words but also pre-placed words the students are required to be placed in the right order. Therefore, when we estimate the cognitive load, we should consider all words, though we addressed only placed words in the previous experiment.

We re-calculate the edit distance with all words including the placed words and pre-placed words(Fig. 5). We tried the multiple regression analysis to fit this new edit distance with the amount of gaze shifts and the answer time. The result is showed in Table III. The P-value is improved to below 0.05 for about 5 of 7 students. Moreover, the adjusted R-squared coefficient is also improved, although its average is still around 0.04.

VI. DISCUSSION

A. Assessment the confidence from the behavior

The negative correlation became weaker in two of nine students. They answered fewer correct answers. After the test, we interviewed these students. This interview revealed that one of them is likely to express low confidence even for assignments he quickly gave correct answers. The student may lose confidence than usual, because of successive high-level assignments. However, the other student often expresses high confidence even for wrong answers. The mismatches of the confidence from the answers seem to be caused by lack of knowledge. That is called Dunning-Kruger effect[21]. When the test is too difficult for them, they cannot understand what is correct, which makes them misunderstand the difficulty of questions. Our method cannot estimate the confidence whose scores are low. However, we can find the confidence of students who scored well. In other words, we can choose students suitable to estimate their confidence from their scores.

The adjusted-R squared was around 0.04 in the result of multivariate regression to fit the edit distance of all words,

TABLE II
RESULT OF MULTIPLE REGRESSION ANALYSIS

students	Unnecessary Gaze Shift		Thinking time		Adjusted R-squared

using the amount of gaze shifts and the answer time. It means there are still hidden explanation variables. However, the p-value of the gaze shifts goes below 0.05. Therefore, the amount of gaze shifts certainly is one of the explanation variables for the edit distances. Note that the p-value and adjusted-R squared for the edit distance calculated from all words are better than those for the edit distance calculated from only placed words. When students answer the sort test of English, they do not stop thinking about words which have already been placed to reduce cognitive load. They would be conscious of all words to find the best combination of them.

In this experiment, we focused on movement students took to put each words. However, it seems students answers are influenced by the flow of sentences. It is expected to improve the cognitive load estimation with consideration of each chunk which is formed based on English grammar.

B. Lack of knowledge revealed with cognitive load

The result of this study shows that we can estimate the confidence of students from analysis of their behavior. Since the confidence is influenced by the cognitive load, we can estimate the cognitive load by looking behavior of students.

As we discussed in section V.A, when students answer the word sort test of English, they do not stop thinking of words they have already placed to reduce their cognitive load. They keep being conscious of all words, to find the best combination of them. Considering all words is hard work, which arises high cognitive load. Therefore, they try to combine words as chunks. The chunks correspond to confidential parts in their answer. Since each chunk occupies only one working memory, they can decrease the load of memory. Students can store all words in the assignment on the working memory, utilizing chunks. At that time, they can solve it.

Students seem to divide the whole task into small tasks. The process of their card placement appears, according to the order in which the students solve the small tasks. If one small task imposes high cognitive load on a student, the student takes either of a long time to solve it or a miss operation. Our method finds these tasks causing high cognitive load. These tasks tell what kinds of lacks in knowledges students have. Students can reduce the cognitive load when they store appropriate knowledges in their long term memory. On the other hand, if they do not have these knowledges, they have operate lots of information in their working memory. In this case, the cognitive load is high. Therefore, we can find the lack of knowledges.

Improvement of our method would enable teachers to know the lack in knowledge of each student. The method would make it easy for teachers to take care of students in the best way for each.

VII. CONCLUSION

We proposed a method which contributes to estimating students understanding level. In this method, we analyze behaviors of students in the English word sort assignment in a VR space. The analysis reveals students understanding level from their cognitive load. Students who have low confidence due to their lack of knowledge hesitate about answering the questions. Such students often stop their hands. They also show more gaze shift which come from comparison of their answers with hints. We had an experiment to confirm the relationship of the hands movements with the confidence. We examined the edit distances which represents how many correction is needed to finish English word sort assignment, We confirmed it influences the cognitive load. We also checked the relationship of the gaze shifts with the edit distances. According to the result of the experiment, we can estimate

the confidence of students from their hands movements of students except those who got poor scores. Moreover, the gaze shifts can be one explanatory variables to explain the edit distances. However, the gaze shifts cannot fully explain the edit distances. We need to find more explanatory variables.

If we can estimate the confidence of students by analyzing the observable value, we can know the cognitive load of students, while they are answering the tests. The cognitive load tells us where their weak points stay, which enables teachers to improve their teaching for each student. Consequently, this method promotes students understanding.

Efficient Discovery of Top-K Sequential Patterns in Event-Based Spatio-Temporal Data

Piotr S. Maciąg
Institute of Computer Science, Warsaw University of Technology
Nowowiejska 15/19,
00-665, Warsaw, Poland,

***Abstract*—We consider the problem of discovering sequential patterns from event-based spatio-temporal data. The dataset is described by a set of event types and their instances. Based on the given dataset, the task is to discover all significant sequential patterns denoting the attraction relation between event types occurring in a pattern. Already proposed algorithms discover all significant sequential patterns based on the significance threshold, which minimal value is given by an expert. Due to the nature of described data and complexity of discovered patterns, it may be very difficult to provide reasonable value of significance threshold. We consider the problem of effective discovering K most important patterns in a given dataset (that is, discovering top-K patterns). We propose algorithms for unlimited memory environments. Developed algorithms have been verified using synthetic and real datasets.**

I. Introduction

DISCOVERING knowledge from spatio-temporal data is gaining attention of researchers nowadays. Based on literature, we can distinguish two basic types of spatio-temporal data: event-based and trajectory-based [1]. Event-based spatio-temporal data is described by a set of event types $F = \{f_1, f_2, \ldots, f_n\}$ and a set of instances D. Each instance $e \in D$ denotes an occurrence of a particular event type from F and is associated with instance identifier, location in spatial dimension and occurrence time. Fig. 1 provides possible sets $D = \{a1, a2, \ldots, d10\}$ and $F = \{A, B, C, D\}$. The same datasets are presented in Table I. Event-based spatio-temporal data and the problem of discovering frequent sequential patterns in this type of data have been introduced in [2].

The task of mining spatio-temporal sequential patterns in given datasets F and D may be defined as follows. We assume that the *following* relation (or attraction relation) $f_{i_1} \rightarrow f_{i_2}$ between any two event types $f_{i_1}, f_{i_2} \in F$ denotes the fact, that instances of event type f_{i_1} attract in their spatial and temporal neighborhoods occurrences of instances of event type f_{i_2}. The strength of the following relation $f_{i_1} \rightarrow f_{i_2}$ is investigated by dividing the density of instances of type f_{i_2} in spatio-temporal neighborhoods of instances of type f_{i_1} and density of instances of type f_{i_2} in the whole spatio-temporal embedding space V. If obtained ratio is greater than 1, then it is possible that $f_{i_1} \rightarrow f_{i_2}$ constitute a pattern. We provide the strict definition of density in Section III. The problem introduced in [2] is to discover all significant sequential patterns defined in the form $f_{i_1} \rightarrow f_{i_2} \rightarrow \cdots \rightarrow f_{i_m}$, where the significance threshold is given by an expert. In contrary to this approach, we consider the problem of discovering K most significant patterns in the given dataset. Providing significance threshold for discovering patterns may be difficult due to the complex nature of considered task.

TABLE I
An example of a spatio-temporal event-based dataset

Identifier	Event type	Spatial location	Occurrence time
a1	A	19	1
a2	A	83	1
⋮	⋮	⋮	⋮

c2	C	15	7
⋮	⋮	⋮	⋮
d1	D	21	11
d2	D	13	12
⋮	⋮	⋮	⋮

The rest of the paper is organized as follows. Related work is described in Section II. In Section III, we provide elementary notions. Our algorithms and main results are presented in Section IV. In Section V, we provide experimental results for both real and synthetic data. In Section VI, we give conclusions and future problems. The main results of the paper are:

1) We introduce the notion of top-K patterns in event-based spatio-temporal data, namely we define the ranking of top-K sequential patterns with minimal length given by parameter *min_len* and point out the efficient pruning strategy for creating the top sequences set.
2) We formulate the algorithm discovering such top sequential patterns in event-based spatio-temporal data.
3) Proposed algorithm has been verified using both synthetic and real datasets. For experiments on synthetic data we used the same types of datasets as used in [2]. As a real datasets, we used the two types of datasets containing event instances related to air pollution data.

II. Related Work

The problem of discovering top-K most important frequent patterns in various types of data has been well investigated in literature. TFP algorithm for discovering top-K closed frequent patterns for transaction databases has been given in [3]. In this approach, the user has a possibility to provide a parameter min_len specifying minimal length of discovered patterns (that is, minimal number of items occurring in a pattern). TFP discovers top-K closed frequent patterns by means of the FP-growth algorithm (proposed in [4]) for frequent patterns mining. The authors of [5] extends approach proposed in [3], by considering the problem of effective discovering top-K closed sequential patterns for transaction databases (the notion of closed sequential patterns has been introduced in [6]) and giving algorithm TSP for that purpose. In [7], the authors provide an algorithm discovering top-K jumping emerging patterns.

The problem of discovering sequential patterns in databases containing transactions records has been well investigated. The reader may refer to [8], [9], [10], [3] for the fundamental notions in this topic. More recently, surveys on methods for mining sequential patterns are given in [11], [12]. More recent papers in the area of mining top important frequent itemsets are [13], [14], [15].

Various types of methods have been developed for discovering patterns in event-based spatio-temporal data. The authors of [2] introduce the notion of sequential pattern for event-based spatio-temporal data and provide algorithms for both limited and unlimited memory environments. Obtained results show usefulness of proposed approach, however experiments (i.e. computation time) obtained for large datasets seem to be unsatisfactory. On the other hand, results presented in [2] are not well verified using real datasets. The additional drawback of algorithms proposed in [2] is large number of noise and redundant patterns obtained during mining process. The method of discovering top-K introduced in our article eliminate these deficiencies. A survey of methods for discovering patterns in spatio-temporal data is given in [16], [17]. The problem of discovering hierarchical spatio-temporal patterns has been considered in [18]. The problem of discovering spatio-temporal patterns from trajectory data and objects movements data has been considered in [19], [20], [1], [21], [22], [23].

III. Basic Notions

The dataset given in Fig. 1 is contained in the spatio-temporal space V, which temporal dimension is of size 20 and spatial location is provided by numbers between 0 and 100. For simplicity in Fig. 1 we denote spatial location in only one dimension. Usually, spatial location is defined by two dimensions (f.e. geographical coordinates). By $|V|$ we denote the volume of space V, calculated as the product of spatial area and size of time dimension. Spatial and temporal sizes of spatio-temporal space are usually given by an expert. For example, for Fig. 1 $|V| = 20 * 100 = 2000$. In the following definitions and notions we use terms sequential patterns and sequence interchangeably.

Definition 1. Neighborhood space. By $V_{N(e)}$ we denote the neighborhood space of instance e. For $V_{N(e)}$ having cylindrical shape, R denotes the spatial radius and T temporal interval of that space. The volume $|V_{N(e)}|$ of neighborhood space is equal to $\pi * R^2 * T$.

The shape of $V_{N(e)}$ is given by an expert and may be adjusted to particular dataset. Consider example given in Fig. 1 where we denote neighborhood spaces $V_{N(a1)}, V_{N(a2)}, V_{N(a3)}$. In Fig. 2, we provide an example of cylindrical neighborhood space $V_{N(a1)}$ with spatial location specified by two coordinates. The volume of that space is $|V_{N(a1)}| \approx 384.65$.

The reader may refer to [2] for other possible definitions of neighborhood spaces.

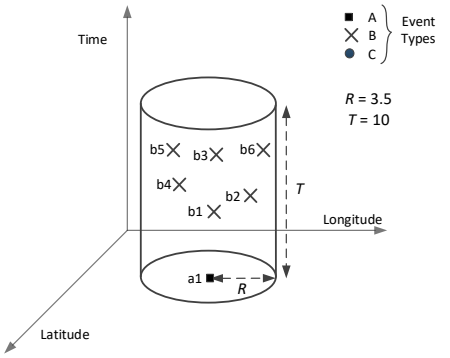

Fig. 2. Possible shape of neighborhood space $V_{N(a1)}$

Definition 2. Neighborhood [2]. For a given event type f and an occurrence of event instance e of that type, the neighborhood of e is defined as follows:

$$\begin{aligned} N(e) = &\{p | p \in D \\ &\wedge distance(p.location, e.location) \leq R \\ &\wedge (p.time - e.time) \in [0, T]\} \end{aligned} \quad (1)$$

where R denotes the spatial radius and T temporal interval of the neighborhood space $V_{N(e)}$.

As the neighborhood $N(e)$ of instance e, we denote the set of instances contained inside the neighborhood space $V_{N(e)}$.The neighborhood of instance $a1$ (shown in Fig. 2) with respect to event type B is $N(a1) = \{b1, b2, b3, b4, b5, b6\}$.

Definition 3. Density [2]. For a given spatiotemporal space V, event type f and its events instances in D, density is defined as follows:

$$Density(f, V) = \frac{|\{e | e.type = f \wedge \text{e is inside V}\}|}{|V|} \quad (2)$$

that is, density is the number of instances of type f occurring inside space V divided by the volume of that space.

Definition 4. Density ratio [2]. Density ratio for two event types f_{i_1}, f_{i_2} and their instances in D is defined as follows:

$$DR(f_{i_1} \rightarrow f_{i_2}) = \frac{avg_{e.type=f_{i_1}}(Density(f_{i_2}, V_{N(e)}))}{Density(f_{i_2}, V)} \quad (3)$$

where $\rightarrow$ denotes the *following* relation between event types f_{i_1}, f_{i_2}.
$avg_{e \in f_{i_1}}(Density(f_{i_2}, V_{N(e)}))$ specifies the average density of instances of type f_{i_2} occurring inside the neighborhood spaces $V_{N(e)}$ created for instances $e \in f_{i_1}$. V denotes the whole considered spatio-temporal space and $Density(f_{i_2}, V)$ specifies density of instances of type f_{i_2} inside that space.

If the value of density ratio for event types f_{i_1} and f_{i_2} is greater than one, then instances of type f_{i_1} attract in their spatio-temporal neighborhood spaces occurrences of instances of type f_{i_2}. If the value is below one, then they repel occurrences of instances of type f_{i_2}. If the value is equal to one, then there is no correlation between these two event types.

Definition 5. Sequence (sequential pattern) $\overrightarrow{s}$ and tailEventSet($\overrightarrow{s}$) [2]. $\overrightarrow{s}$ denotes a m-length sequence of event types: $s[1] \rightarrow s[2] \rightarrow \cdots \rightarrow s[m-1] \rightarrow s[m]$. tailEventSet($\overrightarrow{s}$) denotes the set of instances of type $\overrightarrow{s}[m]$ participating in the sequence $\overrightarrow{s}$.

Consider sequence $\overrightarrow{s_4} = A \rightarrow B$ given in Fig. 1. The length of the sequence is 2 and tailEventSet($\overrightarrow{s_4}$) = $\{b1, b2, \ldots, b14\}$ contains instances of event type B, which are in neighborhoods of instances of event type A.

Definition 6. Sequence index [2]. For a given m-length sequence $\overrightarrow{s}$, sequence index is defined as follows:

1) When $m = 2$ then:

$$SI(\overrightarrow{s}) = DR(\overrightarrow{s}[1] \rightarrow \overrightarrow{s}[2]) \quad (4)$$

2) When $m > 2$ then:

$$SI(\overrightarrow{s}) = \min \begin{cases} SI(\overrightarrow{s}[1:m-1]), \\ DR(\overrightarrow{s}[m-1] \rightarrow \overrightarrow{s}[m]) \end{cases} \quad (5)$$

where sequence $\overrightarrow{s}$ is constituted of event types $\overrightarrow{s}[1] \rightarrow \overrightarrow{s}[2] \rightarrow \cdots \rightarrow \overrightarrow{s}[m]$.

Example 1. Consider the dataset given in Fig .1. As an example let us consider the process of expanding sequence $\overrightarrow{s_1}$. One may notice that density of instances of type B is significant in the neighborhood spaces created for instances of type A. 1-length sequence $\overrightarrow{s_1} = A$ will be expanded to $\overrightarrow{s_1} = A \rightarrow B$ and as the tail event set of $\overrightarrow{s_1}$, the set of instances of type B contained in $N(a1)$ or $N(a2)$ or $N(a3)$ will be remembered (that is, tailEventSet($\overrightarrow{s_1}$) = $\{b1, b2, \ldots, b14\}$). The neighborhood spaces will be created for each instance contained in tailEventSet($\overrightarrow{s_1}$) and $\overrightarrow{s_1}$ will be expanded with event type C, to create $\overrightarrow{s_1} = A \rightarrow B \rightarrow C$. Actual will be tailEventSet($\overrightarrow{s_1}$) = $\{c1, c2, \ldots, c13\}$. In the same manner, the sequence will be expanded with event type D.

The sketch of the ST-Miner algorithm provided in [2] is as follows. First, for each event type in a dataset F, a 1-length sequence is created. Then, in a depth-first manner, each sequence is expanded with each event type in F, if the value of density ratio between the last event type in the sequence and event type considered to be appended is greater than the predefined threshold. The value of density ratio between these two event types is calculated by taking all instances from the tail event set of the sequence, creating their neighborhood spaces and verifying the ratio of the average density of instances of event type considered to be appended in these neighborhood spaces and the total density of instances of that type in the embedding space. If the value of density ratio is below given threshold, then the sequence is not expanded

any more. If the opposite is true, the sequence is expanded in the recursive way. The minimal value of density ratio between any two consecutive event types participating in the sequence is the sequence index (SI($\overrightarrow{s}$)).

IV. Discovering Top-K Patterns

In this section, we provide our algorithms discovering top-K sequential patterns.

Definition 7. For a sequence $\overrightarrow{s} \rightarrow f$ of length $m+1$, we say that f follows event type $\overrightarrow{s}[m]$. tailEventSet($\overrightarrow{s} \rightarrow f$) contains all instances of type f contained in the neighborhoods created for instances from tailEventSet($\overrightarrow{s}$).

Definition 8. Supersequence and subsequence. For two sequences $\overrightarrow{s_i} = \overrightarrow{s_i}[1] \rightarrow \overrightarrow{s_i}[2] \rightarrow \cdots \rightarrow \overrightarrow{s_i}[m_i]$ and $\overrightarrow{s_j} = \overrightarrow{s_j}[1] \rightarrow \overrightarrow{s_j}[2] \rightarrow \cdots \rightarrow \overrightarrow{s_j}[m_j]$, where $m_j > m_i$, $\overrightarrow{s_j}$ is supersequence of $\overrightarrow{s_i}$ ($\overrightarrow{s_i}$ is subsequence of $\overrightarrow{s_j}$) if only $\overrightarrow{s_i}[1] = \overrightarrow{s_j}[1] \wedge \overrightarrow{s_i}[2] = \overrightarrow{s_j}[2] \wedge \cdots \wedge \overrightarrow{s_i}[m_i] = \overrightarrow{s_j}[m_i]$.

In Fig. 1, $\overrightarrow{s_1}$ is supersequence of $\overrightarrow{s_2}$ ($\overrightarrow{s_2}$ is subsequence of $\overrightarrow{s_1}$). Please note however, that for example $\overrightarrow{s_1}$ is not supersequence of $\overrightarrow{s_3}$ (and $\overrightarrow{s_3}$ is not subsequence of $\overrightarrow{s_1}$).

Definition 9. Top-K sequence (sequential pattern). We say that sequence $\overrightarrow{s}$ of length *min_len* is the K-th top sequence (sequential pattern), if there exist K-1 sequences in the top sequences set with length *min_len* and the sequence index of each is equal or greater than $SI(\overrightarrow{s})$.

Definition 10. Pruning threshold θ. Actual pruning threshold θ for sequences considered to be in the top sequences set is equal to the sequence index of any K-th top already discovered sequence.

Lemma 1. For a given sequence $\overrightarrow{s}$ of a minimal length *min_len*, if the sequence index $SI(\overrightarrow{s})$ is below the actual pruning threshold θ, then $\overrightarrow{s}$ and any of its supersequences do not belong to top sequences and $\overrightarrow{s}$ should not be expanded with new event types any more.

Proof: If the sequence index of considered sequence $\overrightarrow{s}$ is below pruning threshold θ, then $\overrightarrow{s}$ does not belong to already discovered top sequences. By means of Definition 6 and Definition 8 any supersequence of $\overrightarrow{s}$ also does not belong to top-K sequences set, so $\overrightarrow{s}$ should not be expanded with new event types. ■

Informally the approach discovering top-K sequences is as follows: starting with 1-length sequences (that is, sequences containing singular event types) expand each sequence in a depth-first manner up to the moment when its length is at least *min_len*. We start discovering sequences with the basic value of pruning threshold θ equal to 1. At the same time we maintain the set of top-K already discovered patterns. By $D(f)$ we denote set of instances of type f in D.

In Algorithm 2, if the sequence index of considered sequence $\overrightarrow{s}$ is greater than pruning threshold θ then $\overrightarrow{s}$ will be expanded with new event types. Additionally, considering $\overrightarrow{s}$ to be inserted into top-K sequences ranking, three scenarios are possible:

Algorithm 1 Procedure for discovering top-K sequential patterns

Require: D - dataset containing event types and their instances, F - set of event types.
Ensure: A set of top-K sequential patterns.
1: **for** each event type $f \in F$ **do**
2: Create 1-length sequence $\overrightarrow{s}$ from f.
3: TailEventSet($\overrightarrow{s}$) := $D(f)$.
4: *ExpandSequence($\overrightarrow{s}$).*
5: **end for**

1) If the length of the sequence $\overrightarrow{s}$ is at least *min_len*, and if there are few than K - 1 patterns in the top-K set, then $\overrightarrow{s}$ is inserted into the set (case 1 in Fig. 3).
2) If the length of the sequence $\overrightarrow{s}$ is at least *min_len* and there are K - 1 patterns in the top-K set, then $\overrightarrow{s}$ is inserted into the set and pruning threshold θ is set to sequence index of already K-th sequence in the set (case 2 in Fig. 3).
3) If the length of the sequence $\overrightarrow{s}$ is at least *min_len* and there are K patterns in the top set, then if the sequence index of $\overrightarrow{s}$ is equal to threshold theta θ, then $\overrightarrow{s}$ is inserted into top set (cases 5, 6 in Fig. 3).
4) If the length of the sequence $\overrightarrow{s}$ is at least *min_len* and there are K patterns in the top set, then if the sequence index of $\overrightarrow{s}$ is less than threshold theta θ, then $\overrightarrow{s}$ is not inserted into the set (case 3).
5) If the length of the sequence $\overrightarrow{s}$ is at least *min_len* and there are K patterns in the top set, then if the sequence index of $\overrightarrow{s}$ is greater than threshold theta θ, then $\overrightarrow{s}$ is inserted into the set, θ is set to the value of any K-th sequences' sequence index and all the sequences with sequence indexes less than θ are deleted from the top set (case 4).

In Fig. 3, we show possible scenarios where $\overrightarrow{s}$ is considered to be inserted into top-K sequences set.

In Algorithm 2, Spatial Join procedure performed in step 2 calculates a join set between tail event set of $\overrightarrow{s}$ and set of instances $D(f)$ (that is, calculates tailEventSet($\overrightarrow{s} \rightarrow f$)). Spatial join may be performed using the *plane sweep* algorithm proposed in [24]. Algorithm 3 calculates actual sequence index of sequence $\overrightarrow{s} \rightarrow f$. DR($\overrightarrow{s}[m] \rightarrow f$) in step 1 of Algorithm 3 is calculated as follows. The nominator of ratio in Definition 4 is the average density of instances from tailEventSet($\overrightarrow{s} \rightarrow f$)) inside the neighborhood spaces created for instances from tailEventSet($\overrightarrow{s}$). The denominator is the density of instances of type f (that is, $D(f)$) inside embedding space V.

V. Experiments

We performed experiments on both generated (synthetic) and real datasets. Our experiments have been conducted using machine with Intel Core i7-6700HQ CPU, each 2.6GHz and 16GB of RAM.

Algorithm 2 ExpandSequence($\overrightarrow{s}$)

Require: $\overrightarrow{s}$ - sequence to be expanded, K - number of top sequences to discover, min_len - minimal length of discovered sequences, θ - pruning threshold for top sequences.

for each event type $f \in F$ **do**
  TailEventSet($\overrightarrow{s} \rightarrow f$) := SpatialJoin(TailEventSet($\overrightarrow{s}$), $D(f)$).
  Calculate SequenceIndex($\overrightarrow{s} \rightarrow f$).
  if SI($\overrightarrow{s} \rightarrow f$) $\geq \theta$ **then**
    if length($\overrightarrow{s} \rightarrow f$) $\geq min\_len$ **then**
      if Number of already discovered sequences $<$ K - 1 **then**
        Insert $\overrightarrow{s}$ into the top sequences set.
      else if Number of already discovered sequences $=$ K - 1 **then**
        Insert $\overrightarrow{s}$ into the top sequences set.
        θ := sequence index of the actual K-th sequence in the top-K set.
      else
        Insert $\overrightarrow{s}$ into the top sequences set.
        if $SI(\overrightarrow{s}) > \theta$ **then**
          θ := sequence index of the actual K-th sequence in the top-K set.
          Delete all sequences from the top sequences set with the sequence indexes less than θ.
        end if
      end if
    end if
    ExpandSequence($\overrightarrow{s} \rightarrow f$).
  end if
end for

Algorithm 3 Calculate SequenceIndex($\overrightarrow{s} \rightarrow f$)

Require: $\overrightarrow{s} \rightarrow f$ - a sequence of event types; $\overrightarrow{s}[m]$ - the last event type participating in $\overrightarrow{s}$.
Ensure: Actual sequence index $SI(\overrightarrow{s} \rightarrow f)$.
return min(SI($\overrightarrow{s}$), DR($\overrightarrow{s}[m] \rightarrow f$)).

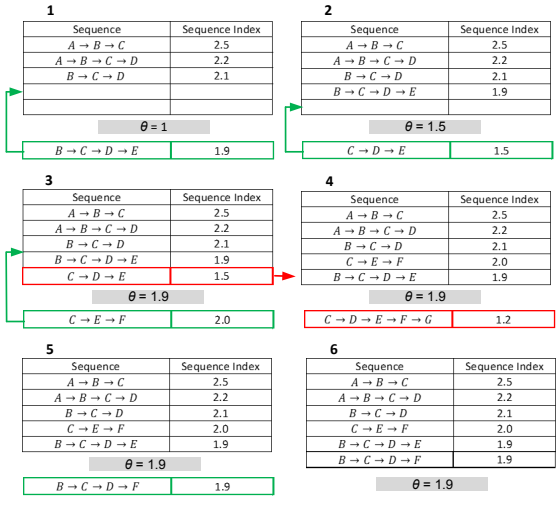

Fig. 3. Possibilities when $\overrightarrow{s}$ is considered to be inserted into top-K set with parameters min_len = 3 and K = 5

A. Experimental Results using Generated Data

We used the similar generator and notation of datasets names as proposed in [2]. In Table II, we recall parameters of data generator. In our experiments, we use cylindrical spatio-temporal neighborhood spaces $V_{N(e)}$ with parameters $R = 10$ (size of spatial dimension) and $T = 10$ (size of temporal window), similar to this one shown in Fig. 2. The whole spatio-temporal space V is given by parameters $DSize = 1000$ and $TSize = 1200$ (that is, both spatial dimensions are of size 1000 and temporal dimension is of size 1200). The total number of event instances in the dataset may be calculates as follows: $Pn * Ps * Ni * 2$, as in addition to patterns placed in a dataset we generate the same number of noise events.

We generated the same types of datasets as used in [2]. In Fig. 5, we show average computation times (we generated each dataset five times and averaged results) for three different types of datasets. In each case, computation time increases with increasing size of the dataset. We executed our algorithm for five values of K parameter (equal to 20, 40, 60, 80 and 100) and constant parameter min_len equal to 3. In Fig. 5, we are showing comparison of calculation time and the average number of discovered sequences for both STMiner proposed in [2] and our modification discovering top sequences set. The

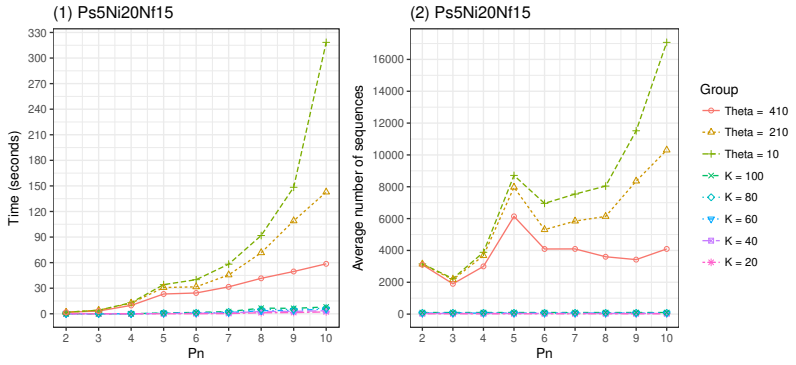

Fig. 4. The average computation times (plot 1) and average number of discovered sequences (plot 2) for both original STMiner algorithm proposed in [2] and our algorithm discovering top sequences set. The threshold $theta$ for STMiner has been set to three values: $10, 210, 410$

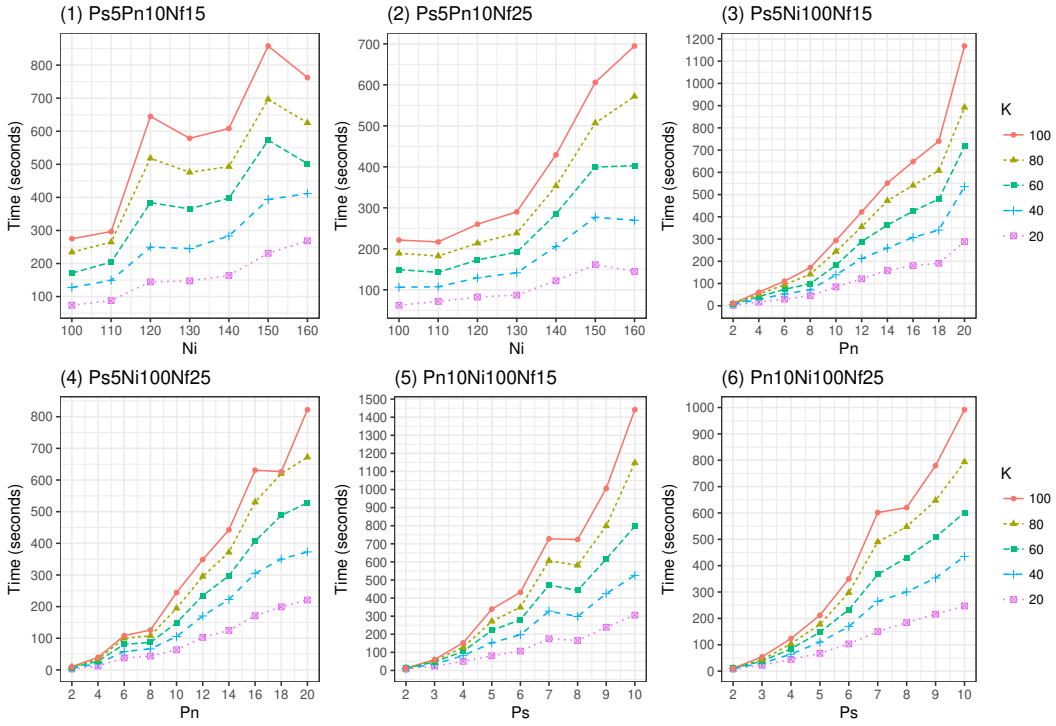

Fig. 5. Average computation times for randomly generated datasets with different number of instances per event type (diagrams (1), (2)), number of patterns (diagrams (3), (4)) and patterns lengths (diagrams (5), (6))

TABLE II
DESCRIPTION OF DATA GENERATOR PARAMETERS (ACCORDING TO [2])

Name	Description
Ps	Length (number of event types) of generated sequence
Pn	Number of sequences in generated data
$DSize$	Size of spatial dimensions of embedding space V
$TSize$	Size of temporal dimension of embedding space V
Nf	Total number of event types occurring in dataset
Ni	Number of instances per event type per sequence
R	Size of spatial dim. of neighborhood space $V_{N(e)}$
T	Size of temporal dim. of neighborhood space $V_{N(e)}$

size of the dataset for parameters $Pn = 10, Ps = 5, Ni = 20Nf = 15$ is 2000 event instances. As we may infer from Fig. 4, STMiner is impractical for even small datasets as it has a tendency to generate a huge number of redundant patterns. In Fig. 6, we show average calculation times for both STMiner and TopSTMiner when calculating exactly top 100 sequences set. To discover such sequences in STMiner algorithm we started with rather small θ threshold for sequence indexes and by its iterative increasing we obtained the set of 100 sequences.

B. Experimental Results using Real Data

For the first experiment on real data, we used the dataset of 14 types of pollutants available on the Internet repository

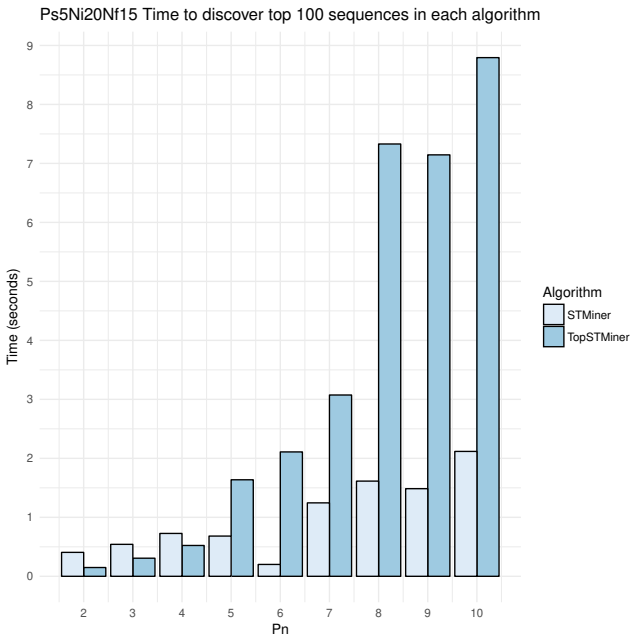

Fig. 6. The average computation times for both original STMiner algorithm proposed in [2] and our algorithm discovering top sequences set to calculate exactly top 100 sequences.

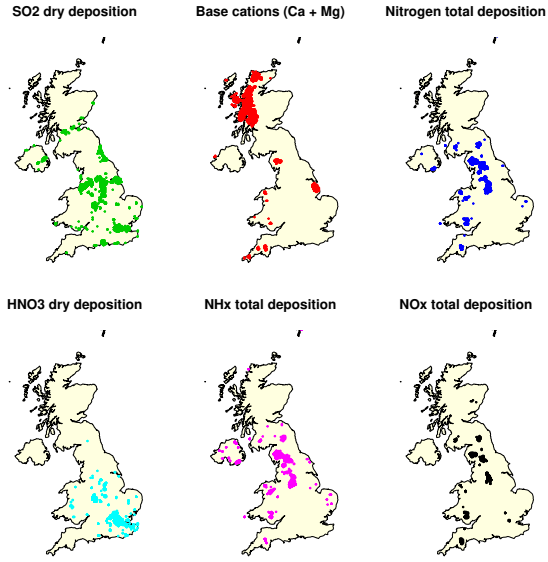

Fig. 7. Examples of extracted event types (SO2 dry deposition, base cations and total deposition of nitrogen, HNO3 dry deposition, NHx total deposition, NOx total deposition)

[25]. For each type of pollutant, the grids of resolution 5km^2 are available for years 2004-2014. Each grid contains numerical values of pollutant for United Kingdom region. For each grid and year, we calculated average value and standard deviation of pollutant. As abnormally high values of pollutants, we extracted events with values greater than three standard deviations from average. The task will be to investigate dependencies between these abnormal occurrences of pollutants. In Fig. 7, we show three types of events of pollutants extracted from the original dataset. We executed our algorithm with parameters $min\_len = 2$ and K $= 200$ and using cylindrical neighborhood space with parameters $R = 10$ km and $T = 1$ year. The types of pollutants available in the dataset and the number of abnormally high instances of each pollutant type in the final dataset are shown in Table III. In Table IV, we listed potentially interesting sequences form the top-100 set.

For the second experiment on real data we used the dataset of 6 pollutants obtained from 7 monitoring sites located in London Central: London Bloomsbury, London Eltham, London Haringey Priory Park South, London Harlington, London Hillingdon, London Marylebone, London Kensington. The name of pollutants and their numbers of instance in the extracted dataset are shown in Table V. The data have been obtained from the source [26]. Not each type of the pollutant is available for all of the stations. In Table VI, we show the name of each monitoring site, its location in the Northing, Easting system and available pollutants.

The original dataset contains hourly observations of pollutants shown in Table V for each day of 2015 for the stations mentioned above. For each type pollutant and for each station separately we extracted daily observations of such pollutant in the form of time series (that is, for each day we extracted 24 four observations respective to each hour). Then we clustered daily observations into four clusters to

TABLE III
TYPES OF POLLUTANTS USED IN THE FIRST EXPERIMENT (INST. - NUMBER OF INSTANCES)

Abbreviation	Pollutant type	Inst.
SOx-nss	Total deposition of oxidised sulphur	1989
SO4-nss	Wet deposition of sulphate	2256
SO2	Dry deposition of sulphur dioxide	1822
N	Total deposition of nitrogen	1339
NHx	Total deposition of reduced nitrogen	1252
NOx	Total deposition of oxidised nitrogen	579
NH3	Dry deposition of ammonia	1162
NH3-c	Concentration of ammonia	1292
NH4	Wet deposition of ammonium	2162
NO2	Dry deposition of nitrogen dioxide	698
HNO3	Dry deposition of nitric acid	1406
HNO3-c	Concentration of nitric acid	32
NO3	Wet deposition of nitrate	2021
Ca+Mg	Total deposition of base cations	2670
Ac	Total deposition of acidity	1406

TABLE IV
EXAMPLES OF PATTERNS DISCOVERED IN TOP-100 SET FOR REAL DATA FOR THE FIRST EXPERIMENT

Sequence	Sequence index
HNO3 $\rightarrow$ NO2	68.02
NO2 $\rightarrow$ HNO3	65.849
N $\rightarrow$ NOx $\rightarrow$ Ac $\rightarrow$ NHx $\rightarrow$ SOx	49.057
NOx $\rightarrow$ Ac $\rightarrow$ NHx $\rightarrow$ SO4	49.0339
NOx $\rightarrow$ Ac $\rightarrow$ NHx $\rightarrow$ NO3	47.8773
NOx $\rightarrow$ Ac $\rightarrow$ N $\rightarrow$ NH4	47.6831

TABLE V
TYPES OF POLLUTANTS USED IN THE SECOND EXPERIMENT

Pollutant type	Number of instances in dataset
Carbon Monoxide	52
Nitric Oxide	197
Nitrogen Dioxide	490
Ozone	534
PM10 particle deposition	161
PM2.5 particle deposition	73

obtain days with high concentration of the pollutant. For the clustering process we used R software, dtwclust package and distance time warping similarity between time series measure. The example of discovered clusters for Nitric Oxide pollutant for the London Eltham Station is shown in Fig. 8 and PM2.5 pollutant for the London Marylebone Station in Fig. 9. As the days with high concentration of pollutant we extracted these from cluster 2 for the former and cluster 4 for the latter. Each day with high pollutants' concentration has been marked as an event instance with event type corresponding to the pollutant type. The spatial location of the event instance is the location of respective monitoring station and the occurrence time is the corresponding day of occurrence.

We employed our algorithm to such dataset with parameters: $K = 100$, $min\_len = 2$, $R = 200$ meters and $T = 10$ days. The sizes of spatiotemoral space are as follows: $DSize1 = 37040$ meters, $DSize2 = 14262$ meters and $TSize$ = 364 days and are bounded by the locations of monitoring site and period of observation. The coordinates of stations are given in the Northing, Easting system. The parameter R specified as above means, that the algorithm will be looking for the interesting sequences considering events in each station separately. The set of top-15 sequences discovered from such dataset is shown in Table VII.

C. Results Discussion

For the experiments on synthetic data we show that even for small datasets our improvement discovering top sequences is more effective than the original algorithm STMiner proposed in [27]. As it has been explained, for many datasets and specific applications it may be difficult to provide a minimal sequence index threshold for discovered sequences. The algorithm proposed in the paper allows to eliminate this drawback by specifying the number of top sequences to discover. For the experimental results on real data we used two datasets, which have been preprocessed to obtain a set of event instances. For each of these datasets we obtain some potentially interesting sequences, however the additional usefulness of the proposed algorithm may be verified in the future experiments.

VI. CONCLUSIONS

In the paper, we consider the problem of effective discovering of top-K sequential patterns in event-based spatio-temporal data. In particular, we introduced the notion of top-K sequence (sequential pattern), we proposed the method creating set of top-K sequences and dynamically updating the set based on

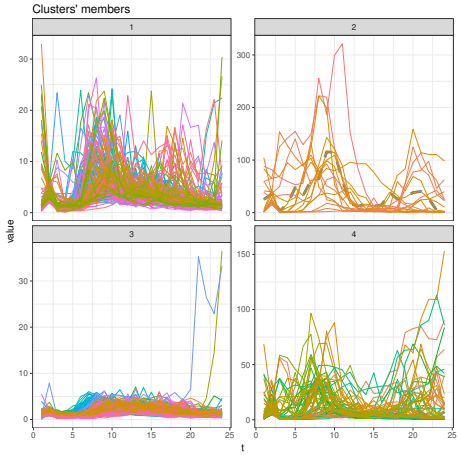

Fig. 8. Discovered clusters for Nitric Oxide pollutant for the London Eltham Station (cluster 2 contains days with high concentration of the pollutant)

***Abstract*—The usual assumption in the Evolutionary Computation field is that a cost of computing single fitness function evaluation is at last similar for all cases. Such assumption does not have to be true. In this paper we consider the recently proposed Problem Encoding Allowing Cheap Fitness Computation of Mutated Individuals (PEACh) effect that allows to significantly reduce the computation load of some of the fitness computations that occur during the evolutionary method run. To the best of our knowledge, it is the first experimental analysis that investigates the results of PEACh application to methods solving NP-hard practical problems.**

I. Introduction

THE OPTIMIZATION of computation load consumption by Evolutionary Algorithms (EAs) is a valid and important topic since these are the tools applied to solve hard computational problems. Many techniques were proposed to minimize the expenses for computing the fitness [7], [12], [6]. In this paper, we consider the Problem Encoding Allowing Cheap Fitness Computation of Mutated Individuals (PEACh) effect [17]. PEACh is a recently proposed technique that allows to significantly reduce the computation load spent on a single fitness computation without losing the precision of a result. To the best of our knowledge, except some theoretical experiments proposed in [17], there are no studies that would show the PEACh benefits obtained by applying it to Genetic Algorithms (GAs) solving a hard, practical problem. Therefore, in this paper, we apply PEACh to evolutionary methods applied to solve NP-hard flow optimization problem. The main objective of this paper is to check how significant (if any) is the PEACh influence on results quality and the method efficiency.

The other objective of this paper is to investigate which methods are more suitable to use PEACh benefits. In [17] the standard GA was pointed as a method that is capable of using PEACh optimization only for mutation operator. On the other hand, the multi-population methods employing so-called messy-coding [2], [8], [16], [15] were pointed out as those that should improve their speed more significantly.

This work was supported by the Polish National Science Centre (NCN) under Grant 2015/19/D/ST6/03115

Another important issue that was raised in [17] is the fairness of computation load measurement by using the Fitness Function Evaluation number (FFE). The application of PEACh does not change the method run, except some of the fitness value computations are performed significantly faster. Therefore, in such situations, the use of FFE as a fair computation load measure may be questioned. In this paper, by showing the speed-up, scale we verify if FFE is truly unfair computation load measure for methods using PEACh.

The rest of this paper is organized as follows. In the second section we present the related work, Section 3 contains a definition of the considered practical problem. The fourth section defines PEACh and analyses its possible applications to the considered practical problem. The research results and analysis is presented in Section 5. Finally, the last section summarizes this work and points on most promising future work directions.

II. Related work

In this section, we will present the different propositions of computation load optimization techniques employed in the Evolutionary Computation field. We will also discuss some related issues, eg. the fairness of the computation load measurement with the use of Fitness Function Evaluation number (FFE). Finally, we will briefly present the benefits of using multi-population approaches with a dynamically changed number of subpopulations since one of the methods considered in this paper is employing such techniques.

In some of the papers concerning Evolutionary Algorithms (EAs) applied to solve practical problems it is pointed that the computation load necessary to compute particular individual's fitness may be significantly decreased if the fitness value of similar (but not necessarily the same) individual is known. In [9], [10] different Resource-Constrained Scheduling Problem (RCSP) version are considered. To compute fitness of any individual, the problem solution that is represented by this individual must be constructed first. Then, the constructed solution is rated, and the fitness is computed. Some of the presented methods introduce small changes to already known and already rated individuals. Thus, the fitness of new individual that is a result of small genotype modification may be

computed in two different ways. It may be computed in a usual way by constructing and rating the solution. However, it is also possible to copy the solution of an old, already rated individual, modify it and rate it. In RCSP problem the computation load necessary for solution construction is significantly higher than the computation load required for rating the constructed solution. Thus, in NEH2 heuristic (Nawaz, Enscore, Ham) proposed in [9] the fitness of new solutions is computed by modifying the already known solutions rather than by building new solutions from scratch. In result, NEH2 can use a higher FFE number than its predecessor – NEH heuristic.

Surrogate model [6] is an interesting technique of computation load usage optimization that is useful when single fitness evaluation takes significantly long time (e.g. minutes, hours, or even days). In such situation, the use of evolutionary methods may be limited. The idea is to propose a new problem model that would mimic the real model but would be significantly cheaper to evaluate. Therefore, the use of surrogate model enables the use of EAs for problems to which they would be otherwise inapplicable due to practical reasons. The surrogate model is similar to PEACh effect considered in this paper because it optimizes the cost of fitness value computation. However, the difference is that PEACh leads to an exact fitness value, while surrogate model offers only the approximated fitness value.

Another technique that allows decreasing the computation costs is fitness caching [7], [12]. Its idea is based on storing the information about fitness values computed for the particular genotypes. When such knowledge is available instead of computing fitness the method checks if the fitness for the particular genotype was not already computed. If so, then instead of computing fitness the stored fitness value is returned. Such technique may significantly decrease FFE. However, the drawback is that checking if the fitness for the particular genotype was not computed before becomes more and more expensive in time as the list gets longer. At some point, the benefits brought by omitting the fitness computation may be exceeded by costs generated by the list search. Another issue is that the list of already rated genotypes may consume high amounts of memory. Therefore in [7] two different fitness caching techniques are described - *brutal fitness caching* (that is the technique described above) and *population fitness caching*. The population fitness caching works in the same way as its brutal version but instead using the genotypes list, the optimization is limited to the search through the current population. The research presented in [7] proposes an analysis of benefits brought by both fitness caching techniques. The research is based on modern evolutionary methods: Linkage Learning Genetic Algorithm (LTGA) [18], Dependency Structure Matrix Genetic Algorithm II (DSMGA-II) [5] and Parameter-less Population Pyramid (P3) [3]. Another important issue is shown in [7] is that when any fitness caching is used the FFE is not a reliable computation load measure when a method gets stuck. The reason for this situation is that once a method gets stuck it simply loses the capability of proposing new solutions, which have not been investigated yet. If so, then at some point all, or almost all fitness computation requests are cached. In the research presented in [7] FFE per iteration may drop to zero for the whole remaining method run. Thus, a different computation load measure than FFE number is necessary because in the described situation FFE only shows that method is not consuming any computation load at all which is not true.

The issue of fair computation load measurement is also addressed in [14]. One of the assumptions of using FFE as a fair computation load measure is that the computation load required to compute a single fitness value is the same or, at least, similar. The research presented in [14] show that this assumption is not always true. For instance, the computation load may be dependent on the genotype. Another requirement to use FFE as a fair computation load measure is that the dependency between the overall computation load used by a method and FFE should be close to linear. In other words, the computation load necessary to compute the fitness value is significantly higher than the computation load used for all other method activities. If this condition is not true, then the use of FFE as computation load measure may not be reliable. This issue is discussed in details in [8] on the base of Bayesian Optimization Algorithm (BOA). During its run, at each iteration BOA constructs the model of gene dependencies. When the genotype is long the computation load necessary for model construction significantly exceeds the computation load spent on all other method activities making it ineffective.

III. Flow assignment in computer networks

The problem of flow assignment in computer networks is one of the main problems in the field of network design [11]. The other are the capacity assignment, flow and capacity assignment, topology, flow, and capacity assignment. In the flow assignment problem, the solution shall satisfy the set of demands. Each demand defines an amount of information that is to be sent between a particular pair of network nodes. The list of demands as well as the network topology are given and cannot be modified. For each demand, a route in the network must be set to satisfy it. Thus, the solution to the problem is a list of routes (one route for one demand) that satisfy all demands and do not break the network links capacity constraint. The solution quality may be measured in many different ways. Here, we employ the Lost Flow in Link (LFL) function. LFL describes how well the network topology is prepared for the link breakdown scenario. The optimization of LFL value increases the network survivability and the quality of service. The problem denominated as WP_LFL [15] and is NP-complete [11].

The notation used to represent the WP_LFL problem is presented below.

Sets

V - set of n vertices representing the network nodes
A - set of m arcs representing network directed links
P - set of q connections in the network

$\prod_p$ - the index set of candidate working paths (routes) for connection p
X_r - set (selection) of variables x_k^p, which are equal to one. X_r determines the unique set of currently selected working paths
Indices
p - connections (demands) in the network, used as subscript
k - candidate routes, used as superscript
a - arcs (directed links), used as subscript
r - selections, used as subscript
Other
$o(a)$ - the start node of arc a
$d(a)$ - the end node of arc a
Constants
δ_{pa}^k - equal to1, if arc a belongs to path k realizing connection p; 0 otherwise
Q_p - volume (estimated bandwidth requirement) of connection p
c_a - capacity of arc a
Variables
x_p^k - decision variable, which is 1 if working route $k \in \prod_p$is selected for connection p and 0 otherwise
f_a - flow of arc a
$g_v^{in} = \sum_{i:d(i)=v} f_i$ - aggregate flow of incoming arcs of v;
$e_v^{in} = \sum_{i:d(i)=v} c_i$ - aggregate capacity of incoming arcs of v;
$g_v^{out} = \sum_{i:o(i)=v} f_i$ - aggregate flow of outgoing arcs of v;
$e_v^{out} = \sum_{i:o(i)=v} c_i$ - aggregate capacity of outgoing arcs of v;

The $o : A \to V$ and $d : A \to V$ functions denote the origin and destination node of each arc. For each $a \in A$ the set of incoming arcs of $d(a)$ except a $in(a) = \{k \in A | d(k) = d(a), k \neq a\}$, and the set of outgoing arcs of $o(a)$ except a $out(a) = \{k \in A | o(k) = o(a), k \neq a\}$ are defined.

Definition 1. *The global non-bifurcated m.c. flow denoted by $\underline{f} = [f_1, f_2, ..., f_m]$ is defined as a vector of flows in all arcs. The flow $\underline{f}$ is feasible if for every arc $a \in A$ the following inequality holds*

$$\forall a \in A : f_a \leq c_a \tag{1}$$

Inequality 1 ensures that in every arc, flow is not greater than capacity. This inequality is called the capacity constraint.

For the sake of simplicity, the following function is introduced

$$\epsilon(x) = \begin{cases} 0 & \text{for } x \leq 0 \\ 1 & \text{for } x > k \end{cases} \tag{2}$$

The analysis of local repair properties is based on a scenario where the failure of arc $k \in A$ is considered. If local repair is used then flow on the arc k must be rerouted by the origin node of k. Therefore, residual capacity of arcs outgoing from node $o(k)$ except arc k is a potential bottleneck of the restoration process. Since

$$f_k \leq \sum_{i \in out(k)} (c_i - f_i) \tag{3}$$

then the flow of the failed k can be restored using the residual capacity of other links leaving the origin node of k. Otherwise, if

$$f_k > \sum_{i \in out(k)} (c_i - f_i) \tag{4}$$

then some flow of the failed link k cannot be restored because the residual capacity of other arcs leaving the origin node of k is too small. As a consequence, the 100% restoration is not possible and some flow of k is lost. Applying formulas 3 and 4, and the $g_{o(k)}^{out}$, $e_{o(k)}^{out}$ definitions, the LA^{out} function is defined as follows.

$$LA_k^{out}(\underline{f}) = \epsilon(g_{o(k)}^{out} - (e_{o(k)}^{out} - c_k)) \tag{5}$$

Formula 5 defines the flow lost for arc k as dependent on the whole flow leaving the origin node of k. Therefore, the function of flow lost for all arcs leaving node v is defined as follows.

$$LN_v^{out}(\underline{f}) = \sum_{a:o(a)=v} \epsilon(g_v^{out} - (e_v^{out} - c_a)) = \sum_{a:o(a)=v} LA_v^{out}(\underline{f}) \tag{6}$$

Function $LN_v^{in}(\underline{f})$ is analogous to $LN_v^{out}(\underline{f})$ and defines how much flow is lost in the arcs incoming to node v. The goal of defining a function that measures the network preparation to link breakdown is realized in 7.

$$LFL(\underline{f}) = \sum_{v \in V} (LN_v^{in}(\underline{f}) + LN_v^{out}(\underline{f}))/2 \tag{7}$$

More details about the LFL may be found in [13]. The optimization problem, WP_LFL [13], [15] is defined as follows.

$$\min_{\underline{f}} \quad LFL(\underline{f}) \tag{8}$$

subject to

$$\sum_{k \in \prod_p} x_k^p = 1 \quad \forall p \in P \tag{9}$$

$$x_k^p \in \{0, 1\} \quad \forall p \in P, \forall k \in \prod_p \tag{10}$$

$$f_a = \sum_{p \in P} \sum_{k \in \prod_p} \delta_{pa}^k x_p^k Q_p \quad \forall a \in A \tag{11}$$

$$f_a \leq c_a \quad \forall a \in A \tag{12}$$

Condition (9) guarantees that the each connection can use only one working route. Constraint (10) ensures that decision variables are binary ones. Formula (11) defines a link flow. Finally, (12) denotes the link capacity constraint. The

WP_LFL problem given by (8)-(12) is a 0/1 NP problem with linear constraints. For this problem, the solution space that includes all possible paths for each connection is large even for relatively small networks. Therefore, the problem is considered hard. Let us consider 2500 demands and ten routes available for each demand. The number of solutions (not all may be feasible) 10^{2500}.

IV. PEACh effect in considered practical problem

In this section, we present PEACh idea proposed in [17]. Since PEACh benefits are strictly dependent on the problem encoding, in the second subsection we give a detailed description of solution encoding for the considered WP_LFL problem. Finally, in the last subsection, we present the two considered competing methods and discuss whether they are suitable to use PEACh benefits.

A. General PEACh description

Let us consider a situation in which fitness computation process is built from two stages - solution creation and solution rating. For some problems, the main computational cost is paid on the solution creation stage, while the process of rating the created solution is relatively cheap [17]. In such situation, if we wish to rate an individual but we know a similar solution that was already rated it is reasonable to copy the rated solution, modify it and rate the resulting solution.

Let us consider the Traveling Salesman Problem (TSP). TSP can be represented as a graph $G = (V, E)$, where V is a set of n vertices (cities) and $E = \{ei, j\}_{n\times n}$ is a set of edges that represent connections between cities. The distance function $d : E \to \Re^+$ is used to assign each edge e a distance value. The goal is to find a Hamiltonian cycle of minimal distance that visits each vertex only once. Let us assume that in the considered TSP instance we need to visit 1000 cities, the genotype encodes the solution by storing a list of genes that are city identifiers. Some individual that was already rated is being mutated by changing two genes (cities order) in its genotype. To compute fitness for the mutated version of the individual, we may compute the cost generated by using 1000 routes that are encoded by the genotype of the mutated individual. Another option is to copy the fitness of individual before mutation, subtract from it the distance of two routes that were removed and add the distance yield by two new routes. Note, that the second option requires significantly lower computation load.

We may state that PEACh benefits are used if the following condition holds

$$cost(X) \gg cost(X_{mut}, fitInfo(X)) \tag{13}$$

subject to

$$diffr(X, X_{mut}) \ll size(X) \tag{14}$$

where
X, X_{mut} - individuals genotypes
$cost(X)$ - the computation load that must be paid to compute the fitness of X without any prior knowledge
$fitInfo(X)$ - the additional information about data produced during X fitness value calculation process (including X fitness value if necessary)
$cost(X, addInfo)$ - the computation load necessary to compute the fitness of X with additional information taken from the other fitness value calculation operation
$diffr(X, Y)$ - the number of genotype positions for which genotype X is different than the genotype Y
$size(X)$ - the number of genotype positions in genotype X

If an additional information (from another fitness value computation operation) is available, then the computation load necessary for the fitness value computation will be significantly lower than if the same computation was done without the additional knowledge (inequality (13) is true). Condition (14) guarantees that the additional information is supported by the fitness calculation process for similar genotype.

The above definition proposed in [17] does not define a unit of computation load amount (returned by $cost(X, addInfo)$ and $cost(X)$). In this paper, similar as in [17], we use the computation time. Another available choice is the number of processor instructions. Note, that FFE is not an allowed choice, since the amount of computation load necessary to compute a single fitness evaluation may significantly differ.

B. PEACh in WP_LFL

In WP_LFL the network topology is given. The network links connecting the nodes are directed, so the particular link transfers data only in one direction. Therefore, the network may be represented as a directed graph. The list of demands defining the nodes pairs between the communication channels must be established is also entry information. Each demand except the start and destination node defines the volume of the demanded communication channel. Each connection is using only one route. Thus, the solution to the problem is a set of routes (each route proposed for one demand). Many communication channels may go through a single network link. The summarized volume going through a single network link may not exceed the link capacity. The example of the 4-demand problem solution encoded in the GA-like manner may be as follows: [(4) (6) (11) (13)]. In this solution the first demand will use route number 1, second demand will use the sixth route, etc. Note, that the solution does not have to be feasible, i.e. the link capacity constraint may be broken.

In Fig. 1 we present the example of the network state in the form of the two-dimensional matrix. The numbers in the matrix represent the available capacity of network links. For instance, the link from node A to node B has 24 capacity units left. For the network state presented in the upper part of the figure, we wish to set up the connection channel using the route from node A through nodes B and C to node D. The demand size (volume) of the connection channel is 4 capacity units. In the result of this operation, the available capacity in links A to B, B to C and C to D is decreased by 4. In the WP_LFL instances consider in the research present in this

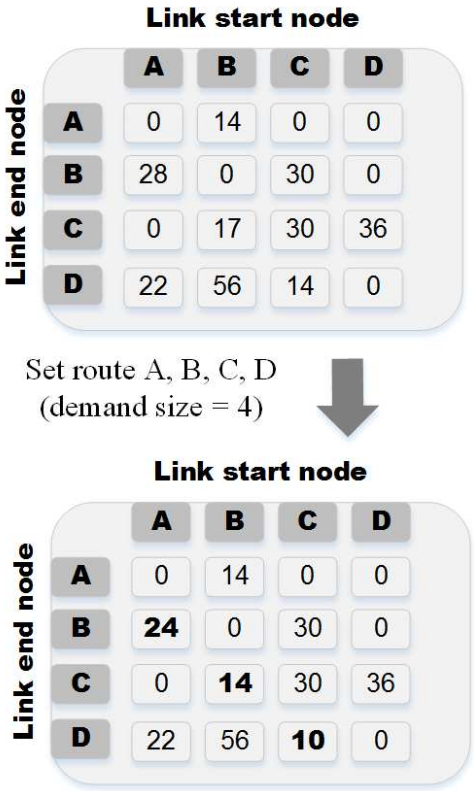

Fig. 1. The example of route establish

paper we use 1260 up to 2500 demands. To compute fitness of any individual we have to create a solution (by setting all connection channels for all demands) and then rate it (compute LFL function value for all links and summarize it). For the considered test cases the time necessary to construct the problem solution (T_{model}) is significantly larger than the time necessary to rate the constructed solution ($T_{quality}$). Therefore, the decreasing T_{model} time, shall significantly decrease the overall time necessary for fitness computation. Let us consider the following situation. The individual X encoding a solution to 2500-demands WP_LFL problem instance was rated and cost of this operation was $cost(X) = T_{model} + T_{quality}$. Then, individual X was mutated (one of its genes was modified) creating individual X_{mut}. We can compute fitness of individual X_{mut} without using any additional knowledge. If so, then $cost(X_{mut}) \approx costX$. However, we can also compute the fitness of X_{mut} differently and use the model created for individual X. It is enough to unset one connection channel that was encoded by individual X (set this channel with negative volume) and set the new channel that was defined in individual X_{mut}. In such situation we need to perform two channel setting operations instead of 2500 route setting operations $cost(X_{mut}, fitInfo(X)) = 2/2500 \cdot T_{model} + T_{quality}$. Since for the considered test cases $T_{model} \gg T_{quality}$, it is true that $cost(X) \gg cost(X_{mut}, fitInfo(X))$. Thus, we may expect that using the PEACh effect may significantly decrease the computation load consumed by a method during its run.

C. Competing methods and PEACh suitability

In this section, we present the two methods chosen for tests. The first is Hierarchical Evolutionary Algorithm for Flow Assignment in Non-bifurcated Commodity Flow (HEFAN 2.2) [13]. HEFAN 2.2 is a standard GA that is dedicated to solving flow optimization problem. The individuals are encoded in a standard GA-manner presented in the previous section. Since considering all available routes between every nodes pair would lead to the combinatorial explosion and would make the problem intractable, at the beginning of the run HEFAN 2.2 uses four shortest routes between each node pair and all routes that are not longer than 1-, 2-, 3-, and 4-hops. Such route set may be not enough to construct some high-quality solutions. Therefore, HEFAN 2.2 uses two problem-dedicated operators that were designed to propose new routes, namely the low-level crossover and low-level mutation operators. The idea behind both low-level operators is to interpret a single route (that is an ordered list of nodes) as an individual and apply to it standard GA operators. The routes resulting from low-level operators may not be feasible in the particular network topology. Therefore, the repair procedure is applied to their results. The details about dedicated operators employed by HEFAN 2.2 may be found in [13].

The second considered method is Multi Population Pattern Searching Algorithm for Flow Assignment in Non-bifurcated Commodity Flow (MuPPetS-FuN) [15], based on MuPPetS [8]. In MuPPetS-FuN two types of individual are employed. The classical GA-like individuals called *Competitive Templates* (CT) are used together with messy-coded individuals [2] called *viruses*. The messy-coded individuals do not encode the complete problem solution, but only a part of it. To rate such individual, the missing genes must be first supplemented. Therefore, each CT (complete problem solution encoded in GA-like manner) has a crowd of viruses assigned to it. The genes that are missing in each virus are supplemented from CT the virus is assigned to. Each virus population is separate, and the number of their populations is equal to the number of CTs. The virus population evolution process may be found as the optimization of the CT the viruses are assigned to - after their evolution is finished, if the fitness of best-found virus is better than its parental CT, then the genes from the virus infect the CT, improving it. The important feature of messy-coding concerning PEACh effect is that viruses encode only a small part of a complete problem solution. Thus, each virus may be interpreted as a modification of its parent CT. Since, $l_{vir} \ll size(CT)$, where l_{vir} is the genotype length of a virus, then the process of virus fitness computation seems to be suitable for using the benefits of PEACh effect.

V. Results

In this section, we present the results of experiments performed for two methods dedicated to solving the considered WP_LFL problem. HEFAN 2.2 is based on the idea of standard GA, while MuPPetS-FuN Active is a multi-population

method that uses messy-coding and dynamically manages the number of maintained subpopulations (i.e., during the method run new subpopulations are created, and some subpopulations are deleted). Since HEFAN 2.2 is based on standard GA idea, the use of PEACh effect will be limited only to mutation operator. On the other hand, MuPPetS-FuN uses messy-coding which is suitable for gaining the benefits brought by PEACh. The objective of the research is twofold. First, we wish to experimentally check how significant may be the optimization of computation load usage when PEACh is employed and how this optimization is dependent on the method type. Second, we wish to check how significantly the use of PEACh may influence the results quality for the considered WP_LFL problem.

The rest of this section is organized as follows. In the first subsection, we report the experiment setup. In the second subsection, we show and comment the differences in the computation load usage optimization brought by PEACh. The third subsection presents the influence of PEACh effect on the results quality for the two considered methods types. Finally, the last subsection contains the results discussion.

A. Experiment setup

In the experiments, the time-based stop condition was used. As pointed out in sections II and IV, since PEACh is employed, the use of FFE as a stop condition is doubtful for the research presented in this paper. The experiments were executed on PowerEdge R430 Dell Server Intel Xeon E5-2670 2.3 GHz 64GB RAM with Windows 2012 Server 64-bit installed. To ensure that the computation load used in each experiment is equal, the number of computation processes was always one less than a number of available CPU nodes. The time limit was set to 3 hours. All methods were programmed in C++, share all the possible pieces of code and are single-threaded. The experiments are executed in the clean environment – i.e., no other resource consuming processes are running, and the number of executed experiments is always one less than the number of available processor cores (1 core is spared for the operating system activities). Such assumptions are the same as in [7], [15], [8] and shall allow for fair comparison.

To compare the performance chosen methods we use ranking, defined as follows. The best method for a particular experiment receives the number of points equal to the number of competing methods; the second method receives one point less, etc. If more than one method takes the same place, then all such methods receive the same number of points as for one method. For instance, there are three competing methods A, B and C. Methods A and B were the best, and receive 3 points. Method C was the worst one – it receives 1 point.

The considered experiments may be grouped concerning the network type or flow parameters. Six different network topologies were considered. The networks parameters (minimal, maximal and average node degree) might be found as typical [19]. The mesh of five networks is irregular, the mesh of one network is grid-like. The parameters of all considered networks are presented in Table I.

TABLE I
CONSIDERED NETWORKS PARAMETERS

Network	**104**	**114**	**128**	**144**	**162**	**Grid**
Node number	36	36	36	36	36	36
Arc number	104	114	128	144	162	120
Minimal node deg.	2	2	3	3	3	2
Maximal node deg.	5	5	6	6	6	4
Average node deg.	2.89	3.17	3.56	4	4.5	3.33
Topology	Irregular mesh					Regular mesh

EXPERIMENT GROUPS PARAMETERS

Experiment group	**Group A**	**Group B**	**Group C**
Arc capacity	4800	4800	$km \cdot 1200$,where km=1,...,8
Connections to set	1260	2500	2500
Connection choice	1 for each pair	random	random
Demand size	equal for all connections	random	random

The classification using the demanded flow parameters divides the experiments into three groups: A, B and C. Each experiment group is characterized by arc capacities used, a number of connections to be set (demands) and the way the connections were chosen. The OC-12 and OC-48 standards, typical for transportation networks [4], were taken into consideration at the arc capacity design. The parameters for each experiment group are presented in Table II. The units of demands sizes and arc capacities were abandoned which is frequent for the papers concerning the problems of flow assignment in computer networks [11], [13], [15].

Ten experiments were used for each network and experiment group. Thus, the total number of test cases was $6 \cdot 3 \cdot 10 = 180$. The considered problem is NP-complete [4]. As presented in table II the number of demands is 1260 or 2500. In the employed solution encoding each gene refers to a single demand, which makes gene number equal to demand number. If for each demand we consider 10 different routes, then the number of solutions that may be encoded is equal to 10^{1260} or 10^{2500}.

The methods settings were adopted from [15] and are presented in Tables III and IV.

B. PEACh benefits depending on method type

One of the main objectives of this paper is to check how significant is the influence of PEACh effect on computation load optimization for the considered problem depending on

the method type. Therefore, we compare the amount of FFE done by MuPPetS-FuN Active and HEFAN 2.2 when using and not using the benefits of PEACh effect. To assure that the comparison is precise, each experiment was executed with the same random seed. The runs in which the optimal solution was found were excluded from the comparison. The FFE increase ratio (FFE for the run using PEACh effect is divided by FFE for the run without PEACh) is presented in Tables V and VI.

The results presented in Tables V and VI show that using PEACh effect is far more beneficial for MuPPetS-FuN Active. For MuPPetS-FuN, the minimum increase obtained in all 180 runs is over 123%, while the maximum ratio for HEFAN 2.2 is less than 112%. Such results are expected since during most of its run MuPPetS-FuN process messy-coded individuals, which genotypes are much shorter than the genotype of full GA-like coded problem solution. Thus, PEACh effect benefits may be used at every fitness computation of messy-coded individual. On the other hand, for HEFAN 2.2 whish is based on a standard GA, PEACh is only beneficial during mutation.

It is also interesting that for MuPPetS-FuN Active PEACh

effect is significantly more beneficial for some test case groups. For instance, the highest FFE increase ratio is found for networks *Grid* and *104*. On the other hand, FFE increase ratio is the lowest for experiments using networks *144* and *162*. The detailed analysis of this phenomenon is out of this paper scope and is one of the interesting future work directions. The reasonable explanation seems to be that in the experiments for networks *144* and *162* the average length of messy-individual genotypes is significantly longer than in the experiments for *Grid* and *104* networks. The longer is the messy-coded individual's genotype, the less significant is the fitness function computation speed-up caused by PEACh effect. This observation seems to be supported by the FFE ratio observed experiments in groups A, B, and C. The full GA-like encoded solution in experiments from group A contains 1260 genes, while in experiments in groups B and C this is 2500 genes. We may expect that in experiments of from group A, the average genotype of messy-individual contains a larger percentage of all necessary genes than in two other groups.

C. PEACh influence on results quality

In this section, we compare the effectiveness of both considered methods, depending on PEACh effect. In these experiments the randomizer seed was random. Thus, it is possible that a method version with PEACh may return a lower quality result than a version without PEACh. Note, that it was impossible for the experiments considered in the previous subsection because when the seed is set manually both method versions (with and without) were performing the same run. The only difference was that version with PEACh was working faster, so it was able to perform a higher number of iterations. The comparison of results quality in Table VII. In the experiments presented in this subsection the MuPPetS-FuN and HEFAN 2.2 are also compared with Lagrangian Relaxation Heuristic (LRH) [13], [15]. LRH is a hybrid algorithm that joins the Flow Deviation for Primary Routes algorithm [1] and Lagrangian Relaxation. It uses sub-gradient optimization to determine Lagrangian coefficients and was shown effective [13] in solving flow assignment problems.

As presented in Table VII the methods employing PEACh effect are the most effective for all experiment groups except two. The first is the Grid network group for which the most

114	**92.83%**	33.23%	16.62%
128	**98.94%**	7.68%	3.84%
144	**96.82%**	16.71%	8.35%
162	**98.46%**	9.63%	4.81%
Grid	73.83%	**83.18%**	41.59%
Group A	50.00%	**100.00%**	64.94%
Group B	**99.00%**	4.70%	2.35%
Group C	**99.98%**	0.09%	0.04%

effective is LRH, the second is 162 network for which the most effective MuPPetS-FuN Active without PEACh effect. In the experiments employing the Grid network, LRH simply seems to be a more suitable method. Such observation is consistent with the previous research in this area [15]. For experiments using 162 network, the explanation may be as follows. MuPPetS-FuN Active seems to be effective in solving test cases from this group. The PEACh influence on computation load used by MuPPetS-FuN Active was the lowest for these experiments (less than 150% of average ratio presented in Table V), so it is likely that such result is the effect of noise. To check if the benefits of PEACh effect are statistically significant we have used Sign Test. The results are presented in Table VIII.

As presented in Table VIII the use of PEACh effect is not statistically significant for the method effectiveness for experiments using network *144* and *162*. Such results are not surprising since for both of these subgroups the average FFE increase ration was the lowest. The third subgroup for which the influence of PEACh benefits on results quality does not seem statistically significant are experiments from Group A. Note, that for this subgroup average FFE increase ratio was the third lowest one.

The same statistical tests were performed for HEFAN 2.2. As expected, for this method the results are less convincing - the p-value of tests checking that HEFAN 2.2 effectiveness with and without PEACh is equal is significantly higher and is above 9% for 6 of 10 experiment groups. Nevertheless, when all experiments are taken into account, the results are decisive. Thus, it is allowed to state that for HEFAN 2.2 the influence of PEACh significantly affects the results quality.

D. Results discussion

The results presented in this paper show that the influence of PEACh effect may significantly optimize the computation load used by a method. Thus, it may influence the method effectiveness when the available resources are limited. The research presented in this paper show that some methods are more suitable to use PEACh benefits than other. Here, MuPPetS-FuN Active that employs messy-coding was able to perform from 123% up 311% of FFE that would be computed without using PEACh. Such change seems significant. Note, that messy-coding is not the only mechanism suitable for using PEACh. For instance, the evolutionary method may be hybridized with the local search algorithm. If the local search is based on exchanging one gene value to the other, the optimization of computation load brought by using PEACh effect may be significant as well. In this paper we also show that for some methods like standard GA the use PEACh is limited. However, its influence may also lead to statistically significant effectiveness increase.

Another interesting observation refers to computation load measurement. When an evolutionary method is applied to solve a practical problem, it seems reasonable to use PEACh effect if possible. However, when PEACh is used the FFE is not a fair computation load measure because the cost of computing a single fitness evaluation may be significantly different depending on the situation in which it is computed - if fitness is computed after a small genotype change (eg. after mutation) the cost will be low, in other cases it will be high. Thus, in such cases, FFE is not a reliable computation load measure.

VI. CONCLUSION

The objective of this paper was to check how significant may be the optimization of computation load expenses when PEACh effect is employed by methods applied to solve hard, practical problem. The presented results show that the influence of PEACh may be significant even if the method is not suitable to employ it (HEFAN 2.2). On the other hand, for methods using mechanisms like messy-coding, the efficiency increase may exceed 300%. The results supported by statistical tests point out that the result quality differences caused by PEACh are significant. Thus, for the considered methods FFE is not a fair computation load measure.

The key direction of future research is further investigation of possible PEACh utilization, for instance in hybrid methods using local optimization to improve their effectiveness. The use of PEACh may also enable significant effectiveness breakthrough for methods employing the Baldwin effect [16] as it may significantly reduce its computational costs. Finally, new techniques that use problem features for computation load reduction shall be identified and proposed.

***Abstract*—In this paper we develop a Mizar formalization of Kronecker's construction, which states that for every field F and irreducible polynomial $p \in F[X]$ there exists a field extension E of F such that p has a root over E. It turns out that to prove the correctness of the construction the field F needs to provide a disjointness condition, namely $F \cap F[X] = \emptyset$. Surprisingly this property does not hold for arbitrary representations of a field F: We construct for almost every field F another representation F', i.e. an isomorphic copy F' of F, not satisfying this condition. As a consequence to F' our formalization of Kronecker's construction cannot be applied.**
All proofs have been carried out in the Mizar system. Based on Mizar's representation of the fields $\mathbb{Z}_p, \mathbb{Q}$ and $\mathbb{R}$ we also have proven that $\mathbb{Z}_p \cap \mathbb{Z}_p[X] = \emptyset$, $\mathbb{Q} \cap \mathbb{Q}[X] = \emptyset$, and $\mathbb{R} \cap \mathbb{R}[X] = \emptyset$ respectively.

I. Introduction

INTERACTIVE theorem proving aims at developing systems to be used to formalize, that is both formulate and prove, mathematical theorems and theories in an accurate and comfortable way. The ultimate dream is a system containing all mathematical knowledge in which mathematicians develop and prove new theorems. To come at least a little closer to this goal much effort has been spent building large repositories of computer-verified theorems such as the Coq library [4], the Isabelle2017 library [15], and the Mizar Mathematical Library [17]. A number of important mathematical theorems have been proven to illustrate the capability of interactive theorem proving, the most prominent examples being the proof of Kepler's conjecture in HOL Light [13], the Feit-Thompson theorem in Coq, and the Jordan curve theorem in Mizar (see also [25]).

Another interesting challenge in this context is Artin's solution of Hilbert's 17th problem, which asks whether a (multivariate) polynomial taking only non-negative values over the real numbers can be represented as a sum of squares of rational functions. Its formalization requires the development of real algebra: the theory of ordered fields and in particular the notion of field extensions and field adjunctions [23]. A key tool in field theory is Kronecker's construction which states that for every field F and every non-constant polynomial $p \in F[X]$ there exists a field extension E of F in which p has a root. The Mizar formalization of Kronecker's construction is the topic of this paper.

One dominating subject in abstract field theory is the construction of new larger fields containing the field (or ring) one has started with, for example constructing $\mathbb{C}$ from $\mathbb{R}$ or $F(X)$ from $F[X]$. Here only the general structure of the field, not the individual representation of the field's elements, is of interest; isomorphic fields are just considered to be the same field. For example, when constructing the complex numbers by $\mathbb{R}[X]/(X^2+1)$ the result is not the usual field $\mathbb{C}$ of complex numbers, yet we have $\mathbb{R}[X]/(X^2+1) \cong \mathbb{C}$. Also $\mathbb{R}[X]/(X^2+1)$ does not contain $\mathbb{R}$ as a subfield, but an isomorphic copy of it. From a mathematician's point of view this of course does not matter, because you can get what you want by exchanging the isomorphic fields. This kind of argument is omnipresent in abstract field theory. In fact, Kronecker's construction contains a similar argument and we will see that exactly this is the hardest part in the formalization: to carry it out, we need the disjointness condition $F \cap F[X] = \emptyset$ already mentioned in the abstract.

The plan of the paper is as follows. In the next section we give a brief overview of the Mizar system and illustrate how algebraic domains are constructed. In section III we discuss our Mizar formalization of Kronecker's construction placing emphasis on the disjointness condition. In the subsequent section we present the construction of fields which do not fulfill our disjointness condition. It turns out that our construction works for every field except $\mathbb{Z}_2$. In section V and VI we provide an intuitive, though not really helpful, condition implying $F \cap F[X] = \emptyset$ and finally prove the disjointness condition for Mizar's representation of the fields $\mathbb{Z}_p, \mathbb{Q}$, and $\mathbb{R}$. In the conclusion we discuss how a formalization of Kronecker's construction without a disjointness condition might look like.

II. The Mizar System

Mizar has often been described in the literature, for example in [3], [18], [12], [9], [8] and [11]. In this paper we will present only theorems, not proofs; therefore we give only a very rough description of Mizar. Mizar's logical basis is classical first-order logic, extended with so-called schemes. Schemes

introduce free second-order variables enabling the definition of induction schemes among others. In addition, Mizar objects are typed, the types forming a hierarchy with the fundamental type `set`. The user can introduce new (sub)types describing mathematical objects such as groups, fields, vector spaces, or polynomials over rings or fields. The development of the Mizar Mathematical Library relies on Tarski-Grothendieck set theory - a variant of Zermelo-Fraenkel set theory using Tarski's axiom about arbitrarily large, strongly inaccessible cardinals which can be used to prove the axiom of choice. Mizar proofs are written in natural deduction style. The rules of the calculus are connected with corresponding (English) natural language phrases so that the Mizar language is close to the one used in mathematical textbooks [10].

To define algebraic domains Mizar provides so-called structure modes fixing the domain's sets of elements and operations. So, for example[1]

```
definition
struct (addLoopStr,multLoopStr_0) doubleLoopStr
 (# carrier -> set,
    addF, multF -> BinOp of the carrier,
    OneF, ZeroF -> Element of the carrier #);
end;
```

defines the necessary backbone of rings and fields. Note that `doubleLoopStr` inherits from both `addLoopStr` and `multLoopStr_0`, that is it joins the operations of additive and multiplicative groups. Properties such as commutativity or the existence of inverse elements are described by attribute definitions such as

```
definition
let R be addLoopStr;
attr R is right_zeroed means
  for a being Element of R holds a + 0.R = a;
end;
```

Here for elements `a` and `b` of (the `carrier`) of `R` `a+b` is a shortcut for `(the addF of R).(a,b)`. A field then is a `doubleLoopStr` with the appropriate collection of attributes (compare [21], [19]).

```
definition
mode Field is
  Abelian add-associative right_zeroed
  right_complementable associative commutative
  well-unital almost_left_invertible
  distributive non empty doubleLoopStr;
end;
```

As a consequence a Mizar object of type `Field` obtains all properties described by the defining attributes. We note here, that Mizar types have to be non-empty.

Concrete algebraic domains are built by instantiation of structures. The field of rational numbers $\mathbb{Q}$, for example, is given by the set `RAT` of rational numbers and operations `addrat` and `multrat` defining addition and multiplication for elements of `RAT`. These are then glued together by the following

[1]Throughout the paper Mizar code is written in verbatim style.

```
definition
func F_Rat -> Field equals
  doubleLoopStr(#RAT,addrat,multrat,1,0#);
end;
```

Note, that the definition of the set `RAT` gives a particular representation of the rational numbers $\mathbb{Q}$; to be used when arguing about the rational numbers using the field `F_Rat`. There are other fields, that is fields with a different set of elements, isomorphic to $\mathbb{Q}$. In fact any field of characteristic 0 contains a subfield isomorphic to $\mathbb{Q}$.

III. Kronecker's Construction

In this section we discuss our Mizar formalization of Kronecker's construction, sometimes also called the main theorem of field theory. It can be stated as follows [24], [23]:

Theorem
Let F be a field and $p \in F[X]$ irreducible. Then there exists a field extension E of F such that p has a root over E.

Note that from this theorem easily follows the existence of such an extension for every non-constant $p \in F[X]$.

A. Field Extensions

We begin with the Mizar definition of field extensions: A field E is a field extension of a field F, if F is a subfield of E [24], or equivalently if F is a subset of E, which itself is a field. It is understood that the operations $+$ and $*$ in F are the restrictions of $+$ and $*$ in E. In Mizar this is stated as follows (see [6]).

```
definition
let F be Field;
mode Subfield of F -> Field means
  the carrier of it c= the carrier of F &
  the addF of it = (the addF of F)
                        || the carrier of it &
  the multF of it = (the multF of F)
                        || the carrier of it &
  1.it = 1.F & 0.it = 0.F;
end;
```

The mode `Subring of R`, where `R` is a ring is defined analogously. Based on this definition we can introduce field extensions as follows.

```
definition
let R be Ring, E be Field;
attr E is R-field-extending means
  R is Subring of E;
end;

definition
let F be Field;
mode FieldExtension of F is
                     F-field-extending Field;
end;
```

Note that instead of postulating that F is a subfield of E we demand that a ring R is a subring of E. This way our definition gets more flexible. For example, this allows to show that $\mathbb{Q}$ extends $\mathbb{Z}$. For a field F, however, our definition is equivalent

to the one from the literature given above, in particular one proves that

```
theorem
for F,E being Field
holds E is FieldExtension of F iff
      F is Subfield of E;
```

In any case the definition implies that a field E in order to be a field extension of a field F in particular must contain the elements of F, e.g. we must have `the carrier of` $F \subseteq$ `the carrier of` E as sets.

B. The Construction

Kronecker's proof is constructive [24] and consists of two parts: The first one observes is that if p is irreducible then $<p>$ is a maximal ideal in $F[X]$, and hence $E := F[X]/<p>$ is a field. The second step consists of showing that $[X]_{<p>}$ is a root of p in $E[X]$: If $p = a_0 + a_1 * X + \ldots a_n * X^n$ we get

$$\begin{aligned} p([X]) &= a_0 + a_1 * [X] + \ldots a_n * [X]^n \\ &= a_0 + a_1 * [X] + \ldots a_n * [X^n] \\ &= a_0 + [a_1 * X] + \ldots [a_n * X^n] \\ &= [a_0 + a_1 * X + \ldots a_n * X^n] \\ &= [p] \\ &= 0. \end{aligned}$$

Between these two steps one usually finds a remark that $F[X]/<p>$ is a field extension of F. Note that formally F is no subfield of $F[X]/<p>$ just because $F \not\subseteq F[X]/<p>$ as sets; and therefore $p \in F[X]$ is not even a polynomial over $F[X]/<p>$. However, $\varphi : F \longrightarrow F[X]/<p>$ given by $a \mapsto [a()]_{<p>}$ is a monomorphism, the so-called canonical monomorphism, and gives rise to the embedding of F into $F[X]/<p>$. The remark mentioned above then reads

> *We can identify φF with F in $F[X]/<p>$ and thus consider F as a subfield of $F[X]/<p>$.*

The Mizar formalization of the two steps is quite straightforward. The quotient field $F[X]/<p>$ has been defined in [16], [20] and $p([X]) = [p]$ can be easily shown by induction on the degree of p.

The main task is to formalize the aforementioned remark: Formally, identifying φF with F in a field E if $\varphi : F \longrightarrow E$ is a monomorphism means defining a new carrier $K := (E \setminus \varphi F) \cup F$ and modifying addition and multiplication of F appropriately. For example, $a + b$ for two elements a and b of K where $a \in F$ and $b \in E \backslash \varphi F$ actually means adding $\varphi a + b$ in E. The result $a + b$ then either is $\varphi a + b$ if this is not in φF or $\varphi^{-1}(\varphi a + b)$ if this is in φF. In this way we get a new field K isomorphic to E with $F \subseteq E$:

Theorem
Let F, E be fields and $\varphi : F \longrightarrow E$ a monomorphism. Then $K := (E \backslash \varphi F) \cup F$ is a field isomorphic to E. Moreover F is a subfield of K.

This field K then is the desired field extension for Kronecker's construction. Unfortunately we were not able to prove the theorem in this general setting: the problem is that there might be elements in E, more precisely in $E \backslash \varphi F$, already appearing in F, that is $F \cap (E \backslash \varphi F)$ might be non-empty. This leads to an identification of elements during the construction, which destroys the isomorphism between $(E \backslash \varphi F) \cup F$ and E. This has to be excluded, so we require a disjointness condition. We hence come up with two slightly weaker theorems in Mizar. Here E being a F-monomorphic field just means that there exists a monomorphism $\varphi : F \longrightarrow E$ and `emb f` is the field K defined above.

```
theorem
for F being Field,
    E being F-monomorphic Field
st F /\ E = {}
for f being Monomorphism of F,E
holds E,(emb f) are_isomorphic;

theorem
for F being Field,
    E being F-monomorphic Field
st F /\ E = {}
ex E' being Field st E',E are_isomorphic &
                     F is Subfield of E';
```

The Mizar proofs are straightforward, but quite tedious due to the number of different cases. Now our Mizar version of Kronecker's construction has to take into account the disjointness condition leading to the following theorem.

```
theorem
for F being Field,
    p being non constant
                  Element of Polynom-Ring F
st F /\ (Polynom-Ring F)/({p}-Ideal) = {}
ex E being FieldExtension of F
st p is_with_roots_in E;
```

The theorem's condition

```
F /\ (Polynom-Ring F)/({p}-Ideal) = {},
```

i.e. $F \cap F[X]/<p> = \emptyset$, is not really satisfying: it depends not only on the field F, but also on the given polynomial $p \in F[x]$. This can be improved by carrying out Kronecker's construction using another representation of $F[X]/<p>$: the isomorphic copy consisting of all polynomials $f \in F[X]$ with deg $f <$ deg p (see [24]). We denote this representation by $F[p]$. For $F[p]$ we have in particular $F[p] \subseteq F[X]$ as sets, so that the condition $F \cap F[X] = \emptyset$ suffices to apply the embedding theorems from above. With `polynomial_disjoint` denoting $F \cap F[X] = \emptyset$ we now get the following Mizar version of Kronecker's construction:

```
theorem
for F being polynomial_disjoint Field,
    p being non constant
                  Element of Polynom-Ring F
ex E being FieldExtension of F
st p is_with_roots_in E;
```

IV. Constructing Negative Examples

In the last section we discussed a Mizar formalization of Kronecker's construction and ended up with a version that does not hold for all fields in the first place: To apply Kronecker's construction to a given field F we have to ensure that $F \cap F[X] = \emptyset$.

At first glance this condition should be no restriction. Intuitively a polynomial $p \in F[X]$ is a more complex object than an element a of the underlying field F. In Mizar a polynomial $p \in F[X]$ is defined as a function $p : \mathbb{N} \longrightarrow F$, which returns the coefficients of p: for $n \in \mathbb{N}$ $p.n$ denotes the coefficient of X^n. Therefore it should be easy to show that $a \neq p$ and hence $F \cap F[X] = \emptyset$ for an arbitrary field F.

This, unfortunately, is not true in general. Of course it is easy to show $a \neq p$ if p includes a as a coefficient, that is $p.n = a$ for some $n \in \mathbb{N}$. This, however, does not exclude the existence of fields F with $F \cap F[X] \neq \emptyset$, and in the following we will construct for every field F, except for $\mathbb{Z}_2$, an isomorphic copy F' of F with $F' \cap F'[X] \neq \emptyset$.

A. A First Example

Perhaps the easiest example is a three-element field isomorphic to $\mathbb{Z}_3$. One takes 0 and 1 and sets

$$F' := \{0,\ 1,\ X\}$$

where X is the identity polynomial. The idea is that the polynomial X as a function $\mathbb{N} \longrightarrow F'$ is

$$X.i = \begin{cases} 1; & i = 1 \\ 0; & i \neq 1 \end{cases}$$

Therefore, having $0 \in F'$ and $1 \in F'$ we can built this function (over F') and hence $X \in F' \cap F'[X]$. The operations $+$ and $*$ of F' are just defined to mimic the ones of $\mathbb{Z}_3$ with X playing the role of 2. As a result we have an isomorphic copy of $\mathbb{Z}_3$ our Mizar version of Kronecker's construction cannot be applied to.

B. A Class of Negative Examples

The idea of the first example can be generalized to almost arbitrary fields F by observing that we in fact changed the representation of $\mathbb{Z}_3$ by just exchanging 2 with the polynomial X. This works for almost every field F; $\mathbb{Z}_2$ is the only exception. One can exchange an arbitrary element $a \in F \backslash \{0, 1\}$ with another arbitrary object o by setting

$$F_{a,o} := (F \backslash \{a\}) \cup \{o\}.$$

Defining $+$ and $*$ appropriately $F_{a,o}$ then is an isomorphic copy of F for an arbitary object o. Substituting X for o now shows that $X \in F_{a,X} \cap F_{a,X}[X]$ and gives the Mizar

```
theorem
for F being non almost_trivial Field
ex F' being non polynomial_disjoint Field
st F',F are_isomorphic;
```

Here, the property `non almost trivial` excludes $\mathbb{Z}_2$. In other words, for every field F (except for $\mathbb{Z}_2$) we constructed a representation of F our Mizar version of Kronecker's construction cannot be applied to.

Note also that X is non-constant and hence $X \notin \varphi F$, so that identifying φF with F will not adjust the intersection. In fact - as o is arbitrary - one can substitute o with the polynomial X^n for $n \in \mathbb{N}^+$. X^n as a function is

$$(X^n).i = \begin{cases} 1; & i = n \\ 0; & i \neq n \end{cases}$$

so an analogous argument shows $X^n \in F_{a,X^n} \cap F_{a,X^n}[X]$. Hence, we get the following

```
theorem
for F being non almost_trivial Field
for n being non zero Nat
ex F' being non polynomial_disjoint Field,
   p being Polynomial of F'
st F',F are_isomorphic &
   deg p = n &
   p in (the carrier of F') /\
              (the carrier of Polynom-Ring F');
```

so that the degree of the polynomial p in the intersection $F' \cap F'[X]$ is not bounded.

As the main result from our counterexamples we get that $F' \cap F[X] = \emptyset$ is a property not invariant under isomorphisms (of fields). Consequently the application of Kronecker's theorem depends on the representation of the given field F.

V. An Intuitive "Solution"

In the last section it turned out that in order to apply Kronecker's construction with a given field F we have to ensure that $F \cap F[X] = \emptyset$, depending on the actual representation of F. This is in particular true for the basic fields $\mathbb{Q}, \mathbb{R}$, and $\mathbb{Z}_p$, where p is prime: it becomes important how these fields are represented in Mizar.

A first approach to solve this problem again relies on the intuitive feeling that a polynomial is a more complex object than an element of the underlying field. So, if all elements of a field F are of the same complexity, then $F \cap F[X]$ should be empty just because all polynomials $p \in F[X]$ are more complex than - and therefore are not equal to - all elements $a \in F$. Note, that our counterexamples from section IV do not fulfill this condition.

A possibility to measure the complexity of mathematical objects o is the so-called rank of o (see [5]). Here every object o is understood as a set and the rank of o is the least ordinal number greater than the rank of every member of the set o. In Mizar the notion of rank has been formalized as a function `the_rank_of` from objects into ordinal numbers [1]. Using this function we define

```
definition
let F be Field;
attr F is flat means
  for a,b being Element of F
  holds the_rank_of a = the_rank_of b;
end;
```

to express that all elements of a field F are of the same complexity. As already mentioned a Mizar polynomial over F is defined as a function $p : \mathbb{N} \longrightarrow F$, i.e. formally is a set of pairs $p = \{ [n, p.n] \mid n \in \mathbb{N}\}$.[2] From this immediately follows that if F is flat, then the rank of all polynomials $p \in F[X]$ is greater than the rank of all elements $a \in F$ and thus

```
theorem
for F being flat Field
              holds F is polynomial_disjoint;
```

Note that in particular the definition of functions in terms of set of pairs enabled the proof of this theorem.

Unfortunately the criterion of being flat is not really helpful, as it does not apply to standard representations of fields. The reason is that in Mizar 0 is defined as the empty set - and the empty set is the only mathematical object of rank 0. Consequently every field containing 0 is non-flat, so that in particular $\mathbb{Q}, \mathbb{R}$, and $\mathbb{Z}_p$ are non-flat.

VI. Some Positive Examples

To provide some examples our Mizar version of Kronecker's construction can be applied to, we prove $\mathbb{Z}_p \cap \mathbb{Z}_p[X] = \emptyset$, $\mathbb{Q} \cap \mathbb{Q}[X] = \emptyset$, and $\mathbb{R} \cap \mathbb{R}[X] = \emptyset$ by hand. To do so we have to rely on Mizar's representation of these fields: essentially we have to check the definitions. Note again, that for a field F the condition $F \cap F[X] = \emptyset$ suffices to apply our Mizar version of Kronecker's construction, because our formalization uses $F[p]$ instead of $F[X]/<p>$.

We already mentioned that a Mizar polynomial over F is a function $p : \mathbb{N} \longrightarrow F$, that is $p = \{[n, p.n] \mid n \in \mathbb{N}\}$ as a set. We now need to show that no Mizar polynomial p can equal any Mizar number $r \in \mathbb{R} \supseteq \mathbb{Q} \supseteq \mathbb{Z} \supseteq \mathbb{N}$. To be more precise, this has to be shown for the Mizar sets `REAL`, `RAT`, `INT`, and `NAT`, which have been used to define the fields `INT.Ring p`, `F_Rat`, and `F_Real`. To keep the following more readable we will, however, continue writing $\mathbb{N}$ for `NAT`, $\mathbb{Z}$ for `INT`, and so on.

In Mizar all numbers beginning with $\mathbb{N}$ are constructed from sets following the well-known set-theoretic approaches. So for $\mathbb{N}$ we find $0 = \emptyset,\ 1 = \{0\},\ 2 = \{0, 1\}, \ldots$ and in general $n = \{m \mid m < n\}$ for $n, m \in \mathbb{N}$.

Because the carrier of $\mathbb{Z}_n$ equals $\{0, 1, \ldots n-1\} \subset \mathbb{N}$ we already can show $\mathbb{Z}_n \cap \mathbb{Z}_n[X] = \emptyset$. For if we have $p = n$ for a polynomial p and a natural number n it follows that $\{[i, p.i] \mid i \in \mathbb{N}\} = \{m \mid m < n\}$, hence there is a $j \in \mathbb{N}$ smaller than n such that $j = [n, p.n] = \{\{n\}, \{n, p.n\}\}$. Then, because j is a natural number, j must equal $\{0, 1\} = \{\emptyset, 1\}$,[3] but neither $\{n\}$ nor $\{n, p.n\}$ equals $\emptyset$, a contradiction.

The proofs of polynomial disjointness for $\mathbb{Z}, \mathbb{Q}$ and $\mathbb{R}$ use similar set-based argumentations. To give an impression how Mizar's set-based definition of numbers is used, we briefly discuss the case of $\mathbb{Q}$. In Mizar first the non-negative rational numbers $\mathbb{Q}^+$ are introduced as pairs of natural numbers, i.e. elements of the set `NAT` (see [2]):

```
reserve i,j,k for Element of NAT;

definition
func RAT+ -> set equals
  ({[i,j]: i,j are_coprime & j <> {}}
                        \ the set of all [k,1])
  \/ NAT;
end;
```

Note that the embedding $\mathbb{N} \subseteq \mathbb{Q}^+$ is performed by hand substituting all pairs `[k,1]` for `k` $\in \mathbb{N}$. Then in a second step the rational numbers $\mathbb{Q}$ are defined as

```
definition
func RAT -> set equals
  RAT+ \/ [:{0},RAT+:] \ {[0,0]};
end;
```

that is a negative rational number r is represented as a pair $[0, r']$, where r' is a non-negative rational number.

Now assuming that there is a polynomial p and a positive rational number r with $p = r$ we get $[i, j] = \{[n, p.n] \mid n \in \mathbb{N}\}$ for some $i, j \in \mathbb{N}$, $[i, j] \in \mathbb{Q}^+$ and hence that $[i, p.i] \in [i, j] = \{\{i\}, \{i, j\}\}$. Then both cases - $[i, p.i] = \{i\}$ and $[i, p.i] = \{i, j\}$ - lead to a contradiction. Here we just mention that in one (sub) case we even use that i and j are coprime.

With $\mathbb{Q}^+ \cap \mathbb{Q}^+[X] = \emptyset$ it is then straightforward to also show $\mathbb{Q} \cap \mathbb{Q}[X] = \emptyset$: For if $p = r$ for a polynomial p and a rational number r, then r must be negative, that is $r = [0, r']$ with $r' \in \mathbb{Q}^+$. But then because $[1, p.1] \in p = r = [0, r'] = \{\{0\}, \{0, r'\}\}$ we either get $[1, p.1] = \{0\} = 1$ or $[1, p.1] = \{0, r'\} = \{\emptyset, r'\}$ - in both cases a contradiction.

Summarizing, to show that our Mizar formalization of Kronecker's construction applies to $\mathbb{Z}_p, \mathbb{Q}$, and $\mathbb{R}$ we have to provide quite involved proofs using the set-based definition of numbers in Mizar.

VII. Conclusion

We have presented a Mizar formalization of Kronecker's construction. The main drawback is the necessary disjointness condition $F \cap F[X] = \emptyset$. This condition forbids the application of the construction with an arbitrary representation of the given field F.

Though the proofs have been carried out in Mizar, we claim that similar constructions should be possible in other proof assistants such as HOL [14] or Isabelle [15] as well: From a technical point of view all that was necessary to construct our counterexamples was the possibility to aggregate arbitrary objects in a set. In this way we defined the carrier of the fields by uniting elements of F with elements of $F[X]$. This should be possible in most proof assistants - if not some rank or typing argument forbids aggregating elements of different complexities.

Mathematicians solve our disjointness problem in a somewhat intuitive way:

[2] We already mention here, that Mizar uses Kuratowski's definition of pairs, that is $[x, y] := \{\{x\}, \{x, y\}\}$. This will be used in section VI.

[3] In fact, $j = \{0\}$ is possible if $n = p.n$; but in this case we get $j = \{\{n\}\}$, and hence $\{n\} = 0 = \emptyset$.

Of course $F \cap F[X]$, and also $F \cap F[X]/<p>$, can be considered non-empty, for if not just rename elements appropriately.

is their comment, and in fact for every field F there exists another representation $F' \cong F$ such that $F' \cap F'[X] = \emptyset$. It would be desirable to eliminate the disjointness condition in such a way. The comment can be stated as a theorem with F' denoting the renamed version of F:

```
theorem
for F being Field ex F' being Field
st F',F are_isomorphic &
   F' /\ (Polynom-Ring F') = {};
```

or more general for arbitrary fields

```
theorem
for F,E being Field ex F' being Field
st F',F are_isomorphic & F' /\ E = {};
```

These theorems would allow for formalizing Kronecker's construction without any condition. To prove them, it would be necessary to exchange a possibly infinite number of elements with new ones. The emphasize here is on "new", because one has to ensure that the adjoined elements are in fact new, that is appear neither in F nor in $F[X]$ (nor in E). Note also that the construction of our counterexamples uses precisely the technique of exchanging elements. So the key of the proof is the assumption that there is always an infinite stock of new objects which can be stated as a

```
theorem
for Y being set
ex Z being infinite set st Y /\ Z = {};
```

With such a theorem one could construct the required isomorphic copy F' by taking the elements of $F \cup F[X]$ (or $F \cup E$) as Y and then exchanging the elements of F that are in $F \cap F[X]$ (or in $F \cap E$) with elements from Z. Note, however, that one has to keep track of exactly which element of F is replaced with which element of Z. This is necessary to define the operations in F' appropriately.

We believe that the above theorem follows from Zermelo's axioms of set theory, namely the axiom of power set. Carrying out these proofs would call for a non-trivial amount of additional work. Nevertheless it might be helpful when further developing abstract field theory - and in fact would give a formalization of Kronecker's construction as found in the literature. Again the proofs would make use of basics of set theory showing that field theory heavily relies on the (informally used) foundations of mathematics. Therefore the further development of abstract field theory will remain a challenge.

***Abstract*—In this paper, we present a non-deterministic strategy for searching for optimal number of trees hyperparameter in Random Forest (RF). Hyperparameter tuning in Machine Learning (ML) algorithms is essential. It optimizes predictability of an ML algorithm and/or improves computer resources utilization. However, hyperparameter tuning is a complex optimization task and time consuming. We set up experiments with the goal of maximizing predictability, minimizing number of trees and minimizing time of execution. Compared to the deterministic search algorithm, the non-deterministic search algorithm recorded an average percentage accuracy of approximately 98%, number of trees percentage average improvement of 44.64%, average time of execution mean improvement ratio of 175.62 and an average improvement of 94% iterations. Moreover, evaluations using Jackknife Estimation show stable and reliable results from several experiment runs of the non-deterministic strategy. The non-deterministic approach in searching hyperparameter shows a significant accuracy and better computer resources (i.e cpu and memory time) utilization. This approach can be adopted widely in hyperparameter tuning, and in conserving utilization of computer resources like green computing.**

I. Introduction

ML performance tuning is aimed at improving the predictability of ML algorithms. Improving performance of a ML systems can be done by configuring a set of hyperparameters. Most ML algorithms have several hyperparameters to be configured. Hyperparameters specify the interoperability of the underlying model. ML algorithms hyperparameter tuning is aimed at getting optimal values that can improve the algorithm's predictability considering minimum consumption of computer system resources [6]. When adopting ML algorithm to a specific dataset, hyperparameter tuning can be cumbersome and time consuming [13].

Manual, grid search and bayesian optimization are methods of hyperparameter optimization. Grid search is deterministic. It does an exhaustive search. It uses a predefined parameter space $S = \{0, 1, 2, ..., n\}$. The goal is to search an optimal hyperparameter s in S that records an optimal accuracy. Grid search consumes substantial amount time and is computationally expensive. However, it gives accurate results [4]. Manual search involves randomly selecting a value s in S. The value s is configured in the algorithm, the experiment executed and the accuracy observed. The process is repeated comparing the accuracy. The hyperparameter that records the optimal accuracy is selected. Manual search is cumbersome and difficult to reproduce results [1]. Bayesian optimization stochastically and efficiently trades off exploration and exploitation of the parameter space. It also explores historical information to find the parameters that maximize functions to inform user the configurations that best optimize predictability of the ML algorithm [5].

This paper introduces a non-deterministic search algorithm. The algorithm randomly selects 10% of elements in a parameter space. It then uses heuristics and termination conditions to maximize accuracy (acc) and minimize time of execution (t). This algorithm was applied and tested in selecting optimal number of trees (θ) in random forest (RF). In this paper, Section II covers related works, Section III discusses methodology and Section IV concludes this paper.

II. Related Works

In the paper by Hazan et al. (2017), large scale machine learning systems at times involves large number of parameters that are fixed manually. This is time consuming and at times inaccurate and difficult for a human expert. A hyper-parameter optimization strategy is proposed inspired by analysis of boolean function focusing on high-dimension datasets. The algorithm is an iterative application of compressed sensing techniques for orthogonal polynomials. The algorithm is tested in deep neural networks. In terms of running time, the algorithm records at least an order of magnitude faster than Hyperband and Bayesian Optimization and outperform Random Search 8x [Hazan et al., 2017]. Hazan et al. (2017) guides this work as they develops an algorithm and tests it in another algorithm; their algorithm establishes heuristics for reducing the search space.

Experiments showed that accuracy increased when number of trees in RF was doubled. However, there was a threshold beyond which there was no significance gain in accuracy. Therefore, increasing number of trees does not always mean

a better performance can be attained [15]. We note that, there was no significant variable that used to measure use of computing resources consumed when varying number of trees.

MapReduce was used to optimize regularization parameters for boosted trees and random forests (RF). For RF[2], two parameters were tuned: the number of trees in the model and the number of features selected to split each node. Experiments showed that performance was sensitive to the number of trees but less sensitive to the number of features in each split. Results showed that MapReduce could make parameter optimization feasible on a massive scale. However, it created possibilities for overfitting that could reduce accuracy and lead to inferior learning parameters [6].

In the technical report by [3], they discuss manually setting up, using and understanding RF. They note that RF grows trees rapidly and setting up a large number of trees (e.g. 1000) is okay. They further note that, if there are many variables, they can grow more trees (of up-to 5000) Beiman, (2003). From this work we can set up experiments with variable number of trees and see their effects on computing resources.

ML algorithms often involve careful tuning of learning parameters and model hyper-parameters. Parameter tuning is often a "black art" that requires expert experience, rules of thumb or sometimes brute-force search. To solve this problem, the following techniques were used: a full Bayesian treatment expected improvement, and algorithms (e.g ANN) for dealing with variable time regimes and running experiments in parallel. Results of this experiment surpassed a human expert at selecting hyper-parameters on the competitive CIFAR-10 dataset; beating the state of the art by over 3%. SVM was used as a case study algorithm [13].

A novel idea for approximate tree learning is seen in sparsity-aware algorithm for sparse data and weighted quantile sketch. The algorithm (XGBoost) proposes candidate splitting points according to percentiles of feature distribution, then maps the continuous features into buckets split, aggregates the statistics and finds the best solution among proposals based on the aggregated statistics. The algorithm also provides an insights on cache access patterns, data compression and sharing to build a scalable tree boosting system. The algorithm has been widely used and recognized in machine learning and data mining challenges e.g. Kaggle and KDDCup 2015. The algorithm can be applied to machine learning systems and in solving real-world scale problems using a minimal amount of resources [4].

Optimizing parameters of an evolutionary algorithm values is a challenging activity. CMA-ES tuning algorithms gave better results in terms of utility, in evolution algorithms. It is noted that using algorithms for tuning parameters of evolutionary algorithms does pay off in terms of performance. However, tuning algorithms gave better tuning parameter values than relying on intuitions and the usual parameter setting conventions [14].

It is challenging to create a large dataset and improve train ability of deep neural network models (DNNs). A selection of supplemental training datasets was used in fine-tuning a high-performing neural network model. Natural Language Processing system ability is improved after being evaluated by the Item Response Theory ability scores without negatively affecting generalization due to overfitting [9].

Large scale machine learning systems at times involve large number of parameters that are fixed manually. This is time consuming and at times inaccurate and difficult for a human expert. A hyper-parameter optimization strategy is proposed inspired by analysis of boolean function focusing on high-dimension datasets. The algorithm is an iterative application of compressed sensing techniques for orthogonal polynomials. The algorithm is tested in deep neural networks. In terms of running time, the algorithm records at least an order of magnitude faster than Hyperband and Bayesian Optimization and outperform Random Search 8x. The algorithm requires only uniform sampling of the hyperparameters and is easily parallelizable [7].

In the department of Soil Survey in Kenya Agriculture and Livestock Research Organization (KALRO) [10] and other soil research organizations, land evaluation is done manually, is stressful, takes a long time and is prone to human errors [11][12]. Parallel RF experiment prototypes are set up in [11] and further experiments in [12]. Parallel RF, Linear Regression, Linear Discriminant Analysis, KNN, Gaussian Naive Bayesian and Support Vector Machine are applied in predicting land suitability for crop (sorghum) production, given soil properties information. Parallel RF had a better accuracy of 0.96 and time of execution of 1.7 sec [12].

Besides assertions regarding performance reliability of default parameters in RF, many RF experiments fit using these values. An examination of parameter sensitivity of RF in computational genomic was studied. Experiments were evaluated using Area Under Curve (AUC), Root Mean Square Error (RMSE) and cross-fold validation. It was seen that RF performance was strongly affected by number of trees, sample size and number of random variables used at each split. It was noted that tuned RF gave better results than when default parameters/values are used. Effects of parameterization were analyzed using selection methods and showed that tuning can successfully improved prediction accuracy of non-parametric ML algorithms [8].

III. Methodology

In this research, we considered 14 standardized datasets collected from UCI Machine Learning website, namely: Balance Scale (1), Breast Cancer Wisconsin - Original (2), Car Evaluation (3), Habermans Survival (4), Pen-Based Recognition of Handwritten Digits (5), Website Phishing (6), Yeast (7), Banknote Authentication (8), Contraceptive Method Choice (9), Diabetic Retinopathy Debrecen (10), EEG Eye State (11), Pima Indians Diabetes (12), Wine Quality - White (13) and Wine Quality (14). In each dataset, we used simple random sampling without replacement strategy to sample 10% of elements in the search space. All experiments were run 10 times and results averaged. Number of trees (θ) was varied accordingly as we measured accuracy (acc) and time of

execution (t). The computer had the following specifications: Intel(R) Xeon(R) CPU W3505 @ 2.53GHz x 2.

A. Considering 2 to 4096 Number of Trees

We considered a finite set of sorted number of trees in the parameter space. RF predictability was evaluated by acc defined in equation 1 with n samples, where $\hat{y}_i$ is the predicted label and y_i is the original label. The results of acc and t are tabulated in Tables I and II respectively.

$$acc(y, \hat{y}) = \frac{1}{n} \sum_{i=0}^{n-1} 1(\hat{y}_i = y_i) \tag{1}$$

Table I shows a general trend of accuracy increasing steadily with increase in number of trees, then flattens. RF classification employs bagging principles, where a committee of trees each, cast a vote for the predicted class. However, RF classifier introduces modifications in bagging where it builds a large collection of de-correlated trees, and then averages them. When the number of trees become huge, we see RF accuracy varying insignificantly meaning the average accuracy of de-correlated trees varying insignificantly. Average accuracy varies because of the random nature of RF, for example, randomly selecting features when building trees. We further observed an interesting trend in the number of trees against accuracy; increasing the number of trees does not significantly contribute to a positive accuracy. The maximum accuracy values are in bold, in Table I. Moreover, we see 13 out of the 14 dataset's maximum accuracy values found between 2 and 512 trees. Dataset 6 with 2048 number of trees recorded an accuracy of 88.7% and 6.42 seconds. It's second best accuracy is 88.4% with 0.89 seconds observed at 256 number of trees. In this case, we think 256 number of trees is better because the change in accuracy rather insignificant (-0.3) while it runs faster (approximately 7x faster). Generally, we observed better results between 2 and 512, and we assume these results can be extended to other datasets. We call the region between 2 and 512, the $fertile\ region$.

Table II shows a general trend of time of execution increasing steadily with increase in number of trees. This tells us that more number of trees demand more computing resources. We also observed a relative significant change in time of execution, the threshold values are in bold. Generally, after 64 number of trees, we see a significant change in time difference. Increase in number of trees increases time of execution. More number of trees requires more computer resources to build and average the de-correlated trees in RF.

Different datasets give different values of accuracy and time of execution with the same number of trees. The selected datasets have different complexity i.e dimensionality, number of records and classes. This leads to a variation in accuracy and time of execution. For us to have an optimal number of trees hyperparameter in RF classifier, it is important we consider maximizing accuracy and minimizing number of trees.

However, we see the 6$^{\text{th}}$ dataset maximum accuracy of 88.7% and time of execution of 6.42 seconds being out of the fertile region i.e 2048 number of trees. As per our experiments, this is a probability of 0.07 i.e 1 out of 14 datasets can exhibit this. The second best accuracy of 87.9% is observed in the fertile region i.e 128 number of trees with 0.5 seconds time of execution. In such instances, we can compromise accuracy to get a better time of execution, for this case, we compromise 0.8% accuracy to gain 5.92 seconds.

B. Considering 2 to 512 Number of Trees

In the fertile region, we observed lower time of execution and maximum accuracy, therefore, we will have avoided searching out regions (> 512) that show higher time of execution and significantly same or lower accuracy. We defined a finite set of sorted number of trees from the parameter space θ. We configured, trained and tested RF with the respective θ and recorded acc and t. The results are show in Fig. 1 and 2. Fig. 1 is a box plot of accuracy for number of trees against datasets across 14 datasets in the fertile region. Most datasets had a low inter-quartile range, low difference between the low and maximum points and more outliers below the lower whiskers. Some box plots also recorded some outliers above the upper whisker. A low difference in quartile ranges means there was a low variation in accuracy from the median and 50% of the accuracy records are within this region. However, the outliers inform us that, some maximum accuracy values were very far away from the median and some lowest accuracy values were very far away from the median. The goal of any data scientist is to have the maximum accuracy when configuring RF with a specific number of trees. Nonetheless, we see variations in accuracy on different datasets, i.e. different datasets record different accuracy levels. This make the search problem more difficult because we need to have a strategy that will be dynamic to search the best accuracy in different datasets. This research was interesting in finding number of trees (i.e. the outliers in the upper whisker) that maximize accuracy.

Fig. 2 is a box plot of time of execution of number of trees against datasets across 14 datasets in the fertile region. We see the lower whisker having almost the same time of execution. This means there are some number of trees that could give almost the same minimum time of execution when configured in RF. We also see the lower whiskers being shorter than the upper whiskers. A shorter lower whisker means most lower time of executions were closer to the median. This research was interesting in these number of trees that minimize time of execution.

From these analysis, we formulated deterministic, non-deterministic and automatic configuration (having 8 number of trees by default) algorithmic approaches in searching optimal number of trees hyperparameter in the fertile region.

C. Deterministic Hyperparameter Search

Deterministic search algorithm is defined in equation 2. We developed a deterministic hyperparameter search algorithm from equation 2 as outlined in Algorithm 1. We considered number of trees θ, time t and accuracy acc descriptions and results from Section III-B. The deterministic hyperparameter search algorithm's goal is to maximize acc and minimize θ.

Table I: Accuracy (percentage) of RF with θ trees for 14 datasets (DS)

We note that, $\exists acc_{max} \in acc$ that has θ_{best}. The deterministic search algorithm is exhaustive, i.e., it does a linear search and returns acc_{max}, with θ_{best} and the time needed t. Experiment results are tabulated in Tables III, IV and V.

$$\theta^*_{best}, acc^*_{best} = \underset{\theta \in \mathcal{T}}{argmax}\ \hat{Q}\ (\theta, acc) \tag{2}$$

Algorithm 1 The Deterministic Hyperparameter Search

```
procedure DETERMINISTICSEARCH(train, test)
    t_i ← CURRENTTIME()
    T ← [θ_1, θ_2, θ_3, ..., θ_n]
    acc_max ← 0
    for each θ in T do
        rf ← RANDOMFOREST(θ, train)
        acc_new ← ACCURACY(rf, test)
        if acc_new > acc_max then
            (acc_max, θ_best) ← (acc_new, θ)
    time_spent ← CURRENTTIME() − t_i
    return (acc_max, θ_best, time_spent)
```

D. The Non-Deterministic Hyperparameter Search Algorithm

In this research, we were interested in maximizing accuracy and minimizing number of trees. Tables 1 and 2 shows almost the same accuracy but with different time of execution. Table 2 shows more NoTs require more ToE (i.e. memory and cpu time). With this analogy, this research formulated a non-deterministic search approach to converge close/to maximize accuracy and minimize number of trees and save time of execution. The algorith is outlined Algorithm 2, where $\theta_i = random(\in \mathcal{T}), \psi_1 = 1 + \frac{lim}{100},\ and\ \psi_2 = 1 - \frac{lim}{100}$.

We considered θ, acc and t descriptions and results from Section III-B. The goal of this algorithm was to maximize acc and minimize t through randomization. In this algorithm we assumption that, $\exists acc_{best} \in acc$ that has θ_{best}. Note that the function GENERATE( ) returns 26 elements which is approximately 10% of elements in the parameter space. We iterate through the random selected number of trees as we configure RF. We considered percentage upper bound and lower bound of the acc_{best}. If acc_{rand} falls in the upper boundary, then $acc_{best} \leftarrow acc_{rand}, \theta_{best} \leftarrow \theta_{rand}$ and we $break$, with the assumption that we do not anticipate further percentage Δ acc_{best}. If acc_{rand} falls in the lower boundary and θ_{rand} is less than θ_{best}, then $acc_{best} \leftarrow acc_{rand}, \theta_{best} \leftarrow \theta_{rand}$ and we also $break$, with the assumption that we have an insignificant Δ acc_{best} and we have a better t_{best}. Moreover, if acc_{rand} falls above the upper boundary, then $acc_{best} \leftarrow acc_{rand}, \theta_{best} \leftarrow \theta_{rand}$, and we continue looping with the assumption that

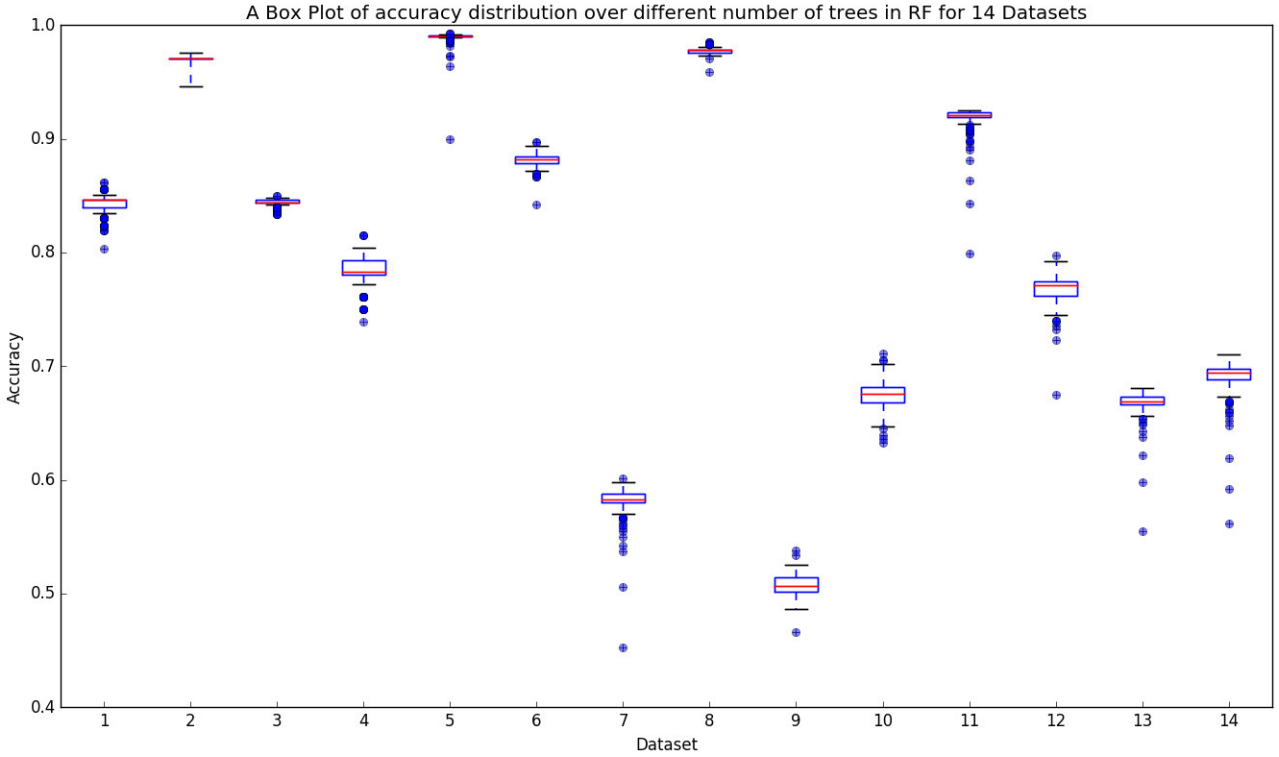

Fig. 1. Number of trees (many) against datasets of Accuracy in RF for 14 Datasets

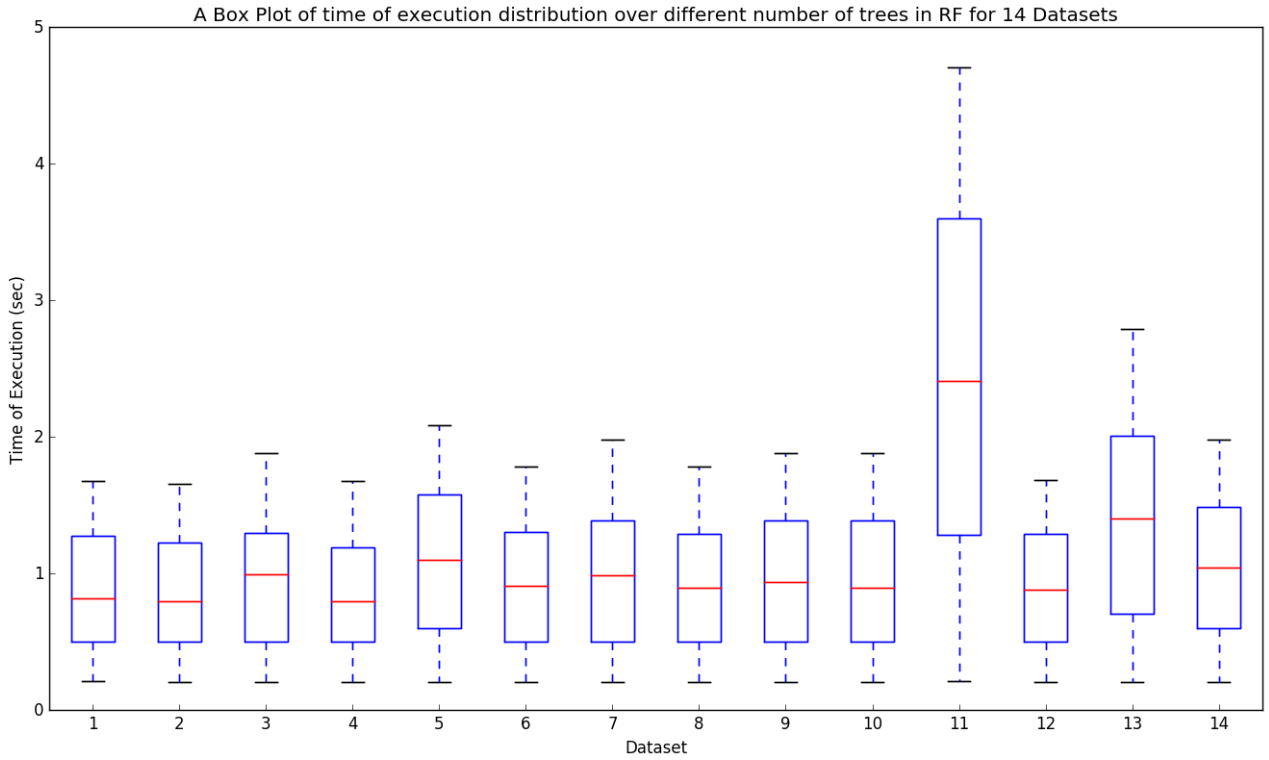

Fig. 2. Number of trees (many) against datasets of Time of Execution in RF for 14 Datasets

we anticipate further percentage $\Delta\ acc_{best}$. Lastly, we $break$ when iteration counts are 10% of the parameter space, with the assumption that we have uniformly sampled the whole parameter space. We set the percentage boundary as 1% to increase the algorithm's accuracy. Experiment results are tabulated in Tables III, IV and V.

Algorithm 2 The Non Deterministic Hyperparameter Search

```
vals = []
procedure GENERATE()
    while LEN(vals) ≤ 26 do
        val = 2 + rand()%512
        if val is not in vals then
            add val in vals
    return val
procedure NONDETERMINISTICSEARCH(train, test)
    t_i ← CURRENTTIME()
    acc_rand, θ_rand, acc_best, θ_best, count ← 0
    T ← GENERATE( )
    for each θ_rand in T do
        rf ← RANDOMFOREST(θ_rand, train)
        acc_rand ← ACCURACY(rf, test)
        if count == 0 then
            (acc_best, θ_best) ← (acc_rand, θ_rand)
        if ψ_1.acc_best > acc_rand > ψ_2.acc_best then
            if acc_rand < acc_best then
                if θ_rand < θ_best then
                    (acc_best, θ_best) ← (acc_rand, θ_rand)
                    break
            else
                (acc_best, θ_best) ← (acc_rand, θ_rand)
                break
        else if acc_rand > ψ_1.acc_best then
            (acc_best, θ_best, count) ← (acc_rand, θ_rand, 0)
        count ← count + 1
        if count >= 10 then break
    time_spent ← CURRENTTIME() − t_i
    return (acc_best, θ_best, time_spent)
```

E. Determinstic and Non-Deterministic Hyperparameter Search Algorithms, and Auto-Configured RF

Table III contains results and analysis of minimum number of trees selected by deterministic and non-deterministic hyperparameter search algorithms. We see a considerably good percentage improvement of number of trees in the non-deterministic search algorithm. At some instances, for example, in datasets 8 and 13, the non-deterministic search algorithm was able to perfectly converged to the minimum number of trees with 26 and 2 iterations respectively. In some datasets e.g dataset 1, the percentage number of trees improvement was poor. Moreover, as observed in Table III, 50% of the datasets used less than 50% (i.e. less than 5% of random values in the search space) of random values while iterating, to converge close/to maximum accuracy and minimum number of trees. With this observation, in some cases, we can have an assumption that sometimes increasing the search space would not have much scientific significance. Generally, the percentage number of trees improvement was 44.6% and the average number of iterations used were 14.5.

Table IV has results and analysis of accuracy recorded from running deterministic, non-deterministic and auto-configured RF algorithms. The auto-configured RF had a mean percentage difference -5.46 while the non-deterministic search algorithm had a considerably better percentage change of -2.1. In non-deterministic search algorithm, datasets 2, 8 and 13 recorded a zero percentage change in accuracy. 50% of the datasets recorded a percentage change of more than 1%.

Table V has results and analysis of time of execution of deterministic and non-deterministic search algorithms, and auto-configured RF. The ratio of deterministic:non-deterministic algorithms and deterministic: auto-configured RF are calculated. Their averages are also calculated. Both auto-configured RF and non-deterministic algorithm record a very high average ratio of 5623 and 176 respectively.

As discussed in Section III-C, the deterministic search algorithm is exhaustive and selects the minimum number of trees that has the maximum accuracy. With these results, we benchmark the non-deterministic search algorithm and auto-configured RF. The non-deterministic search algorithm, as discussed in Section III-D, uses the principle of randomization, heuristics and terminating policies as outlined in Algorithm 2. With this strategy, the non-deterministic search algorithm recorded $\approx 98\%$ average accuracy, and could run at an average of 175.62 faster, on an average of 14.5 iterations. Using the strategy formulated in Algorithm 2, the non-deterministic search algorithm recorded 100% accuracy at three instances and recorded zero number of trees percentage improvement on two instances. Moreover, in the non-deterministic search algorithm, we recorded number of trees that are below the number of trees threshold (64 trees), that showed a significant change in time of execution, as discussed in Section III-A. This means the formulated strategy worked quite well. Considering dataset 2, we note that 0% percentage accuracy change, was got with more number of trees (48 trees instead of 46 trees) but at 34.8 times faster. These shows 100% accuracies got, at more number trees but takes a shorter searching time. This makes the strategy formulated in this research more relevant. Despite the 1% boundary policy and breaking policies strategies, 50% of the datasets recorded less than 1% change in percentage accuracy. The other 50% scored fairly good results too. Generally, a shorter time of execution means the process will take a shorter time in memory and shorter cpu time, when tuning RF. We see the non-deterministic search algorithm run $\approx$ 175 faster on average, achieving an average of $\approx 98\%$ accuracy, on an average of 5.6% iterations (i.e 14.5 of 256 iterations in the parameter space). This is an improvement in iterations by 94.4%. Therefore, the non-deterministic search algorithm can improve utilization of computing resources while maintaining a significant accuracy.

Auto-configuring (having 8 number of trees by default) RF

Table III: Recorded minimum number of trees (θ_{best}) and iterations for deterministic and non-deterministic search algorithms across 14 datasets (DS), and their mean (μ)

F. Evaluation using Jackknife Estimation

Jackknife is used to evaluate the quality of the prediction of computational models. It uses resampling to calculate standard deviation error and estimate bias of a sample statistic, as shown in equations 3 and 4 [16]. We computed Jackknife across the 14 datasets and tabulated results as shown in Table VI. We recorded a zero for bias and standard errors across all datasets.

$$Var(\theta) = \frac{n-1}{n}\sum_{i=1}^{n}(\bar{\theta}_i - \bar{\theta}_{jack})^2, \quad \bar{\theta}_{jack} = \frac{1}{n}\sum_{i=1}^{n}(\bar{\theta}_i) \tag{3}$$

$$\bar{\theta}_{BiasCorrected} = N\bar{\theta} - (N-1)\bar{\theta}_{jack} \tag{4}$$

In Table VI we see different datasets record different values of Bias-Corrected Jackknifed Estimates. We also observe stable results are per the predictions in Table IV. Standard error is used for null hypothesis testing and for computing confidence intervals (upper and lower bounds). This explains why we observe confidence intervals deviating insignificantly. We also see the bias-corrected Jackknifed estimate deviating minimally because the standard error were zero across all the records. These results show that the non-deterministic search algorithm predictions are stable and reliable.

IV. Conclusion

In this research, we formulated a non-deterministic strategy in searching for the best hyperparameter in random forest algorithm considering number of trees, accuracy and time of searching hyper-parameter. The non-deterministic search strategy recorded significantly good results in maximizing accuracy, minimizing number of trees and minimizing searching time. Evaluations using Jackknifed Estimation show that its predictions are stable. Moreover, the non-deterministic search strategy had a significant accuracy levels and better utilization cpu processing and time in memory. This research can be widely adopted in algorithms hyperparameter search and in green computing to preserve computing resources.

ACKNOWLEDGMENT

We would like to express our appreciation to the French Embassy in Kenya and the French Government's Ministry of Foreign affairs for the financial support in this research.

***Abstract*—The paper is dedicated to a new algorithm of optimization in the sense of the area. Proposed method joins a few issues. First one is utilizing data from the set of sensors monitoring the area put into optimization. The second one is using the classification method based on two-dimensional three-state cellular automata, working on the data reported by the sensors. This method classifies all points of the area based on the data received from the sensors and designates optimal subarea. The third issue is applying the categorization layers to the data received from sensors. Such, approach gives a possibility to specify the areas in the different levels and, in consequence, after analysis, optimal subarea or subarea including the optimal point can be designated. This method can be used in different optimization tasks, starting from simple one as optimization of n-dimensional function, through specifying the contaminated area utilizing data from mobile sensors and finally estimating the contamination source-term. In this paper are presented results of testing for the proposed algorithm on a few selected functions from the set of dedicated for this purpose.**

***Index Terms*—area optimization, cellular automata, classification, sensors**

I. Introduction

In a classification problem, we wish to determine to which class new observations belong, based on the training set of data containing observations whose class is known. The binary classification deals with only two classes, whereas in a multiclass classification observations belong to one of the several classes. The well-known classifiers are neural networks, support vector machines, k-NN algorithm, decision trees, and others. The idea of using cellular automata (CA) in the classification problem was described by Maji et al. [2], Povalej et al. [3] and by Fawcett [1]. Fawcett designed the heuristic rule based on the von Neumann neighborhood (so-called voting rule); moreover, tested its performance on different sets of data. Results of Fawcett's study indicated his method, based on CA, as better than the other compared methods, like as (a) J48, a decision tree induction algorithm, (b) k-NN, a nearest-neighbor learning algorithm, (c) SMO, implementation of support vector machines. Recently, in the papers [4] were proposed and analyzed the Fawcett's method modifications into a probabilistic form of such method. These modifications were examined on the different sets of data, and obtained results show in general its higher effectiveness for classification (lower number of incorrect classifications), also in general better accuracy (the shortest scattering range).

The reconstruction of the source of an airborne contaminant may be obtained by using forward approaches, in which source characteristics are inferred from concentration or deposition measurements at different locations and time intervals by establishing source-concentration relationships. In e.g.[10] authors presented the reconstruction of the airborne contaminant source utilizing the Bayesian approach in conjunction with Markov Chain Monte Carlo (MCMC) and Sequential Monte Carlo (SMC). A comprehensive literature review of past works on solutions of the inverse problem for atmospheric contaminant releases can be found in (e.g.[9]). This class of problems is a potential area of application for the newly presented algorithm of area optimization and binary classification with use of three state 2D cellular automata.

This paper is organized as follows. Section 2 describes two-dimensional CAs, binary classification problem and binary classification methods based on 3-state CA. In Section 3 is presents the construction of the algorithm of area optimization. The stages of proposed approach examining and experimental results are presented in Section 4. The last Section concludes the paper, and is a study of application possibilities of the newly proposed algorithm and plans of future work.

II. Two-Dimensional Cellular Automata and Binary Classification Problem

CAs and they potential to efficiently perform complex computations are described by S. Wolfram in [8]. In this paper is considered two-dimensional CA. CA is a rectangular grid of $N \times M$ cells, each of which can take on k possible states. After determining initial states of all cells (i.e. the initial configuration of a CA), each cell changes its state according to a rule - transition function TF which depends on states of cells in a neighborhood around it. In this paper is considered finite CA (finite length of CA) with the periodic boundary conditions (bordered cells are neighbour cells each other).

Two types of the neighborhood are commonly used: the von Neumann neighborhood (the four cells orthogonally surrounding the central cell) which can be described as $a_{i,j}^{(t+1)} = TF[a_{i,j-1}^{(t)}, a_{i-1,j}^{(t)}, a_{i,j}^{(t)}, a_{i+1,j}^{(t)}, a_{i,j+1}^{(t)}]$, where $a_{i,j}^{(t)}$ denotes the state of a cell at position i, j in the two-dimensional cellular grid, at time step t. Also, the Moore neighborhood (the eight cells around the central cell) which can be described as $a_{i,j}^{(t+1)} = TF[a_{i-1,j-1}^{(t)}, a_{i,j-1}^{(t)}, a_{i+1,j-1}^{(t)}, a_{i-1,j}^{(t)}, a_{i,j}^{(t)}, a_{i+1,j}^{(t)}, a_{i-1,j+1}^{(t)}, a_{i,j+1}^{(t)}, a_{i+1,j+1}^{(t)}]$.

The square state of the data space in classification problem should be i.e. $[0, 1] \times [0, 1]$. Suppose that $N \times M$ data-points $p_{(i,j)}$=(x_i, y_j), where i=1, 2, ..., N and j=1, 2, ..., M are given as a training set from two classes: class 1 and class 2. When each of $p_{(i,j)}$ data-points is known as one of two classes then we have the classification. On the other hand, when even one of the data-points is not one of two known classes we have the classification problem. Moreover, to answer the question, to which of class (1 or 2) unclassified data points belong to, the classification method should be applied. In CA the data space of such problem should be mapped from $[0, 1] \times [0, 1]$ into the grid of $N \times M$ cells (in this paper $N \times N$ for the simplicity). Each cell can take one of 3 states, classified the state 1 (class 1) and state 2 (class 2) and also unclassified state (class 0). Classifier - the rule of CA will analyze the unclassified cells and changes its states into one of two known.

The classification methods based on two-dimensional three-state cellular automata was applied for classifying whole points of the area on the base data received from the sensors. The goal was expected designation of the optimal subarea. For this purpose, three kinds of the classifiers were studied. The first classification method was proposed in [1] (the rule of CA known as $n4\_V1\_stable$). The second and third one were modifications of Fawcett's rule into two patterns: partially and fully probabilistic (see, [4]). A proposed modification should strengthen an original and more accurately classify binary data, especially for large CA grid.

III. Algorithm of the Area Optimization Method

The proposed method uses the data reported by the set of sensors monitoring the area put into optimization. This data are the input for the classification method based on two-dimensional three-state cellular automata, which classifies all points of the area to designate optimal subarea. The layers are categorized based on the level of values received from sensors. The steps of the algorithm of the optimization method are presented below.

The algorithm of area optimization by layers and binary classification with use of three state 2D cellular automata:

1) Downloading input parameters:
   - CA size,
   - Threshold - the minimum value for which the recorded indication is acceptable (sensor is in positive state - class 1), the lover values recorded by the sensor are considered as 0 (sensor is in negative state - class 2),
   - Step of Threshold - the value by which the Threshold is increased during processing, it designates the levels of the layers,
   - Number of sensors,
   - Method of data classification (including type of neighborhood);
2) Preparation of cellular automaton,
   - Mapping optimizing area into (discrete) CA grid,
   - The random distribution of sensors in CA grid - CA cells with included sensors are the classified cells (class 1 or class 2), other CA cells are unclassified (class 0),
3) Searching for solution:
   - Preparation of layers for cellular automaton work (with use of Threshold and Step of Threshold): values of sensors in layer $i \in [Threshold + (i - 1) * Step; Threshold + i * Step)$, where $i = 1, 2, ...$,
   - For each layer, specify classes of CA cells with sensors: where the sensor value is $> Threshold + (i - 1) * Step$, where $i = 1, 2, ...$ Then the sensor is in a positive state (class 1). Otherwise, the sensor is in negative state - class 2,
   - For each layer perform classification - during processing of a cellular automaton are specifying classes 1 or 2 for CA cells being unclassified (class 0):
4) Elaboration of received results:
   - Designation of optimal area - development of common parts from classified as class 1 areas on each of analyzed layers,

IV. Experimental Results

The above presented and described algorithm for area optimization by layers, which apply in its work binary classification on three states two-dimensional CA should be examined in the sense of its efficiency for optimization. In this kind of test are usually used dedicated sets of different n-variables functions, as Test Functions for Unconstrained Global Optimization [7]. This set contains the testing functions with one or multi-global optima. For our problem were used functions having one optimum. Because functions have one global minimum, and proposed algorithm searching for maximum, as it was mentioned earlier, the functions $f(x)$ were inverted into $f^*(x) = f_{max}(x) - f(x)$, $f_{max}(x)$ is the maximal value of function in analyzed search domain. In the tests were used three selected and inverted functions: Booth and Matyas Function for which the results are described in this paper, and Sphere Function for which results are presented in [5], [6].

In conducted experiments, the applied CA was two-dimensional with size 500×500. The higher size of CA the more accurate results we retrieve. For proper analysis, Threshold in the algorithm was specified as: 1000 for Booth function and 10 for Matyas. The tests were conducted for a varying number of sensors ({5, 10, ..., 45, 50}) and steps of threshold ({2, 4, 6, 8, 10}).

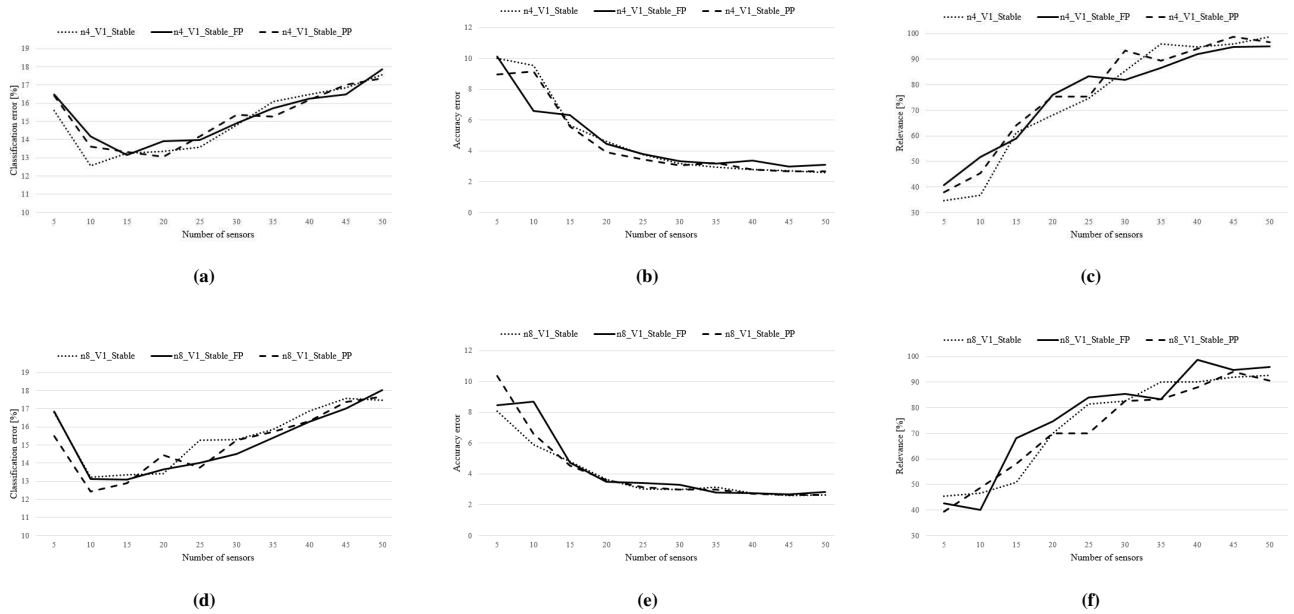

Fig. 1. Comparison of average values of **(a)** Classification error, **(b)** Accuracy error (real distance) and **(c)** Relevance (in [%]) resulted for varying number of sensors with use of each classification method ($n4\_V1\_stable$, $n4\_V1\_stable\_PP$ and $n4\_V1\_stable\_FP$) for von Neumann neighborhood on Booth function. Also, comparison of average values of **(d)** Classification error, **(e)** Accuracy error (real distance) and **(f)** Relevance (in [%]) obtained for varying number of sensors with use of each classification method ($n8\_V1\_stable$, $n8\_V1\_stable\_PP$ and $n8\_V1\_stable\_FP$) for Moore neighborhood on Booth function.

Each of tests series contains 500 single runs of the algorithm with the different random sensors spatial setup. From the set of conducted experiments were calculated the average values of classification error, accuracy error, and relevance for varying number of sensors.

A. Testing With the Booth Function

Figure 1 presents these results for Booth function with use of each classification method with von Neumann neighborhood. We can see that with growing number of sensors, the quality of results is generally getting better, except the classification error. The classification error presented in Figure 1(a) is not higher than 18% for the bordered numbers of sensors and has a parabolic trend. The lowest classification error has value about 13% for a number of sensors fluctuated from 10 to 25. This result is independent of the classification method. The error of accuracy (see, Figure 1(b)) is not higher than ~ 10 for only five sensors case and is generally going down near to 3 for 50 sensors setup. From the level of 25 sensors, accuracy error is lower than 4. The Relevance for 20 sensors is not lower than 70% and is going up. Since the setup of 40 sensors relevance being higher than 90%, where for the partially probabilistic method of classification ($n4\_V1\_stable\_PP$) and $n4\_V1\_stable$ method is near to 100% (see, Figure 1(c)).

Next step of experiments for Booth function is presented in Figure 1, where each of classification method was used with Moore neighborhood. In this case, we can see similar results and trends in particular for errors of classification and accuracy. Interesting is the fact that the fully probabilistic method of classification ($n8\_V1\_stable\_FP$) characterizes better results than for von Neumann neighborhood. Furthermore, in the case of relevance, the scores for $n8\_V1\_stable\_FP$ are slightly better than for other analyzed methods of classification. Relevance for this method and for 40 sensors is near to 100% (see, Figure 1(f)).

B. Testing With the Matyas Function

In this subsection are presented results of testing for Matyas function. Figure 2 shows these results for each of classification method with von Neumann neighborhood. As we can expect, with growing number of sensors, the quality of results is generally getting better, except the classification error. The classification error presented in Figure 2(a) is not higher than 18% only up to 15 sensor setup. For higher number of sensors classification error going up to $\sim 25\%$ for 50 sensors setup. This result is independent of the classification method. The error of accuracy (see, Figure 2(b)) is not higher than ~ 12 for only five sensors case and is generally going down near to 1 for 50 sensors setup (it is generally better than for Booth function). From the level of 20 sensors, accuracy error is lower than 4. The Relevance for 25 sensors is not lower than 70% and is going up to $\sim 90\%$, independently on the classification method (see, Figure 2(c)).

The experiments for Matyas function, where each of classification method was used with Moore neighborhood is presented in Figure 2. In this case, we can see similar results and trends to obtained for Matyas function and von Neumann neighborhood for each of assessment criteria. Moreover, classification error for the fully probabilistic method of classification ($n8\_V1\_stable\_FP$) seems to be better than other methods of classification (see, Figure 2(d)).

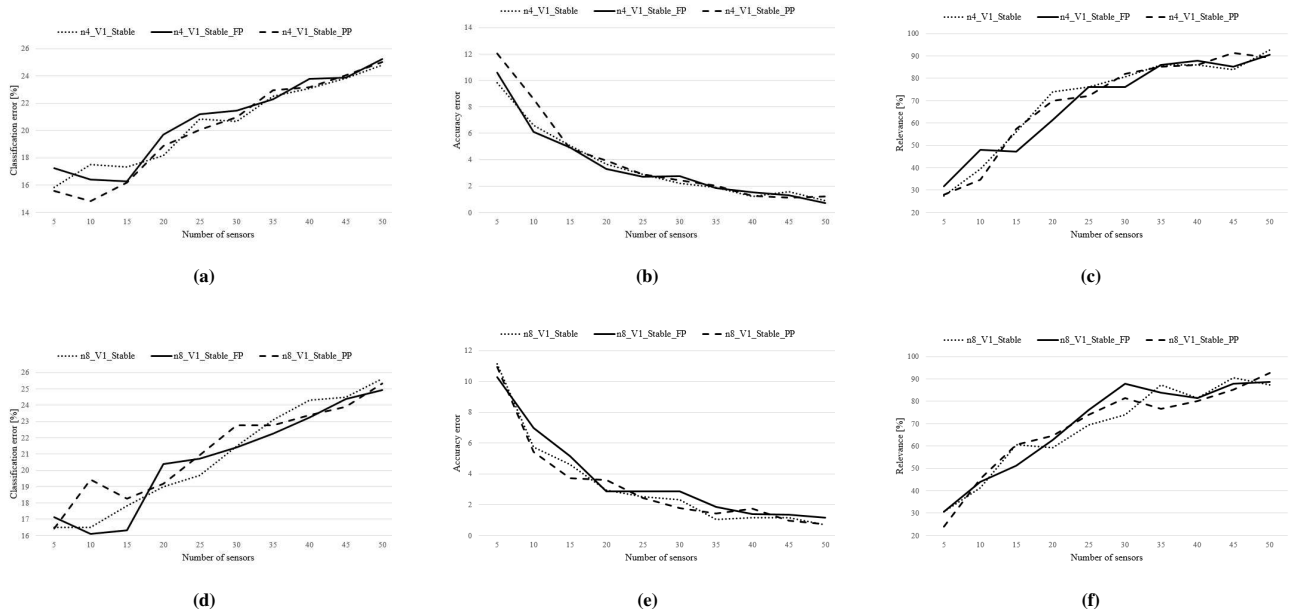

Fig. 2. Comparison of average values of **(a)** Classification error, **(b)** Accuracy error (real distance) and **(c)** Relevance (in [%]) resulted for varying number of sensors with use of each classification method ($n4\_V1\_stable$, $n4\_V1\_stable\_PP$ and $n4\_V1\_stable\_FP$) for von Neumann neighborhood on Matyas function. Also, comparison of average values of **(d)** Classification error, **(e)** Accuracy error (real distance) and **(f)** Relevance (in [%]) obtained for varying number of sensors with use of each classification method ($n8\_V1\_stable$, $n8\_V1\_stable\_PP$ and $n8\_V1\_stable\_FP$) for Moore neighborhood on Matyas function.

CONCLUSIONS

In this paper is proposed an algorithm of area optimization by layers and binary classification with use of three state 2D cellular automata. The proposed algorithm as an input utilizes the data reported by the set of sensors monitoring the area put into optimization. This data are subject to the classification based on two-dimensional three-state cellular automata, which classifies all points of the area to designate optimal subarea. The layers are categorized based on the level of values received from sensors. Such, approach gives a possibility to specify the areas in the different levels and after analysis could be selected optimal subarea or subarea included the optimal point.

The algorithm was verified and tested with use of two functions: Booth and Matyas included in the set of the functions applied for testing optimization/optimizing algorithms. The methods for interpretation of obtained results were introduced in conjunction with algorithms assessment criteria, like classification error, accuracy error, and relevance. The values of the algorithm characteristics corresponding to the algorithm run with each of three classification methods for different setups, i.e., the varying number of sensors (input data) were presented.

Conducted studies show that quite good results characterize proposed algorithm. Reasonably high relevance value, i.e. $\sim 90\%$, and higher was reached. Furthermore, the accuracy error are characterized by the low value. Performed tests show that this method could be used in different optimization problems starting from simple ones, as optimization of n-dimensional functions, and in more complicated tasks as designating the contaminated area based on the restricted number of mobile sensors data or estimating the source of airborne toxin.

Presented experiments prove that proposed algorithm is able to reduce the scanned area to the little size (even optimal). Furthermore, studies of the relevance of results obtained by the proposed algorithm indicate that it can be used as an optimization tool, which going to indicate the area including the optimum.

***Abstract*—In this work we present a method for using Deep Q-Networks (DQNs) in multi-objective environments. Deep Q-Networks provide remarkable performance in single objective problems learning from high-level visual state representations. However, in many scenarios (e.g in robotics, games), the agent needs to pursue multiple objectives simultaneously. We propose an architecture in which separate DQNs are used to control the agent's behaviour with respect to particular objectives. In this architecture we introduce *decision values* to improve the scalarization of multiple DQNs into a single action. Our architecture enables the decomposition of the agent's behaviour into controllable and replaceable sub-behaviours learned by distinct modules. Moreover, it allows to change the priorities of particular objectives post-learning, while preserving the overall performance of the agent. To evaluate our solution we used a game-like simulator in which an agent - provided with high-level visual input - pursues multiple objectives in a 2D world.**

I. Introduction

MANY recent works on Reinforcement Learning focus on single-objective methods such as Deep Q-learning [1], [2]. As those methods provide great performance in tasks such as playing video games, many real-life problems require satisfying multiple objectives simultaneously. In single objective reinforcement learning the agent receives a single reward each time it performs an action. In multi-objective reinforcement learning (MORL) the agent receives multiple rewards - one for each objective. In particular, agents dealing with complex environments, such as autonomous robots or agents playing real-time video games, need to pursue multiple, often conflicting objectives.

To have a real-life example, lets consider an autonomous cleaning robot, which is able to clean floors, navigate through obstacles and autonomously return to charging station. The observable aggregated behaviour of such robot may be decomposed into three sub-behaviours: collision avoidance (ca), floor cleaning (fc) and recharging (rg). We may describe the objectives of the robot for each identified sub-behaviour in a multi-objective manner, or we can aggregate the sub-behaviours and define a single objective. In the former case, the robot-agent will receive a set of three rewards ([r_{ca}, r_{fc}, r_{rg}]) after each action. If the robot collides with a wall, it receives a negative reward related to collision avoidance (r_{ca}), yet the rewards related to floor cleaning and recharging do not depend on this event. However, in single-objective case, the robot will receive only one reward value ([r]) dependent on any of the three sub-behaviours. In case of collision, the the single-objective robot will receive a negative reward, but it will be indistinguishable from any negative reward provided with respect to other sub-behaviours such as depletion of batteries.

In single objective scenarios, we may find an optimal policy for which the sum of rewards collected by the agent is the highest possible. Methods such as Q-learning should converge to optimal policies [3]. However, for multi-objective problems, many such optimal policies may exist, depending on the trade-offs between satisfying particular objectives [4].

Autonomous agents, such as our example cleaning robot, are not really independent - they usually have a purpose defined by another agent: human. This aspect is often neglected in the literature, but is significant when considering practical applications of intelligent agents in robotics, automation or even when designing AIs for video games (always winning AI is not the one that many humans would like to play against). Our cleaning robot may follow a policy for which collision avoidance has greater importance than floor cleaning - in such case the robot should focus on avoiding collisions even at the cost of worse performance at floor cleaning. It is however for the user of such robot to decide, what should be the proportion between carefulness and cleanliness. The user may even want to fully disable some functions (behaviours) of the robot. Yet, state of the art reinforcement learning methods, such as Deep Q-Learning, do not allow to modify the behaviour of the agent after it was trained.

We see that when considering practical applications it is desired to have a multi-objective reinforcement learning method with the following features available post-learning: 1) ability to select the sub-set of pursued objectives and 2) ability to change the impact of particular objectives on the overall policy of the agent. As we will show later, the method presented in this paper possesses those features.

Multi-objective problems may be approached using *single-policy* or *multi-policy* methods. The simplest single-policy method uses a *scalarization function* [5], which converts multiple objectives into a single objective. Scalarization methods utilize a weight matrix to obtain a single score from multiple action-value functions. Some techniques assign linear priorities to objectives [6], [7]. This allows to obtain a single optimal policy with respect to objectives ordered by those priorities.

In contrast to single-policy methods, multi-policy MORL methods are used to find a set of policies. Their aim is to

find a set of policies that contains an approximately optimal policy for every possible user's preference [4]. In multi-policy methods, the preference of objectives does not need to be set a priori as a Pareto optimal policy for any preference may be obtained at runtime [8].

A natural approach in MORL is to use separate learning modules for each objective [9]. Modularity allows to decompose the problem into components that are to some extent independent [10]; modularity may be required for providing features desired in practical applications that were listed earlier. Some works deal with transforming complex single-objective problems to many simpler objectives [11]. Such methods may be used to benefit from modular approach while solving single-objective problems.

Although Deep Q-Networks gained much attention in recent years, not many works consider the use of DQNs in multi-objective problems. Recently authors of [12] proposed a multi-policy learning framework that utilizes Deep Q-Networks.

Learning behaviours in embodied agents, such as robots, is a problem well suited for reinforcement learning methods. In *embodied artificial intelligence*, the idea of *parallel, loosely coupled processes* [13] is proposed as a principle for designing embodied agents. It states, that the control logic for embodied agents should consists of many independent components dedicated for particular aspects of the agent's behaviour. The aggregated behaviour of an agent emerges from cooperation or competence among those components.

In this work we will present a method for combining multiple Deep Q-Networks for solving multi-objective problems. We will introduce decision values used for more advanced scalarization of multiple Q-functions. Furthermore we will combine decision values with user define priorities, to have an architecture that can dynamically adapt its behaviour with respect to user's preferences.

In section II we will briefly describe single- and multi-objective reinforcement learning. Next, in section III we will describe how many separate DQNs may be used together and we will define decision values. In section IV we will present a simple 2D game - a virtual environment including an autonomous agent that has a local (situated) sensory inputs and may pursue different objectives. Finally in the last section we will evaluate our solution and present the results of our experiments.

II. Background

A. Single Objective Reinforcement Learning

In the single-objective reinforcement learning an agent interacts with the environment by perceiving the state $s_t \in S$ and performing an action $a_t \in A$ for each step t. The actions are chosen by the agent according to some policy π. After performing an action, the agent receives a reward r_t. Then the agent observes the next state s_{t+1} and the process repeats. The goal of the agent is to maximize the expected discounted reward $R_t = \sum_{k=0}^{\infty} \gamma^k r_{t+k}$, where $\gamma \in [0, 1]$ is the discount factor.

In Q-learning actions are selected based on $Q(s, a)$, which represents the expected discounted reward for performing action a in state s. For given state s, $a_t = \arg\max_a Q(s, a)$ is the optimal action. The policy of an agent, denoted by π, is the probability of selecting action a in state s. If the agent always selects the optimal action, then we say that it follows an optimal policy $\pi_\star$. Knowing the $Q(s, a)$ allows to create an optimal policy simply by selecting the action with the highest Q-value. Deep Q-learning utilizes Deep Neural Networks for approximating $Q(s, a)$ values, thus enabling this method to be used in many real-world applications. Deep Q-Networks [2] may be used used with high-level visual inputs such as those provided by video games.

B. Multi-Objective Reinforcement Learning

We may consider a more complex reinforcement learning scenario in which multiple objectives are pursued by the agent. Let O be the set of objectives of an agent. We may assign a priority p to each objective $o \in O$ such that o_k will have lower priority than o_j when $p(o_k) < p(o_j)$. For further analysis we will assume that $\forall_{o \in O} p(o) \geq 0$, so that priorities may be interpreted as weights.

The agent, instead of a single reward, receives a vector of rewards at each time-step t with respect to each objective o_i, i.e: $\vec{r}_t = [r_{1,t}, r_{2,t}, \dots r_{n,t}]$, where $r_{i,t}$ corresponds to objective o_i. For each objective o_i and step t we may define the discounted return as:

$$R_{i,t} = \sum_{k=0}^{\infty} \gamma^k r_{i,t+k} \tag{1}$$

Moreover, for each objective o_i there is a Q-function $Q_i(s, a)$ that represents the expected discounted return $R_{i,t}$, i.e: $Q_i(s, a) = \mathbb{E}\left[R_{i,t} \mid s_t = s, a_t = a\right]$.

We may define a vector of Q-functions, which includes $Q(s, a)$ for each objective o_i:

$$\vec{Q}(s, a) = [Q_1(s, a), Q_2(s, a), ..., Q_n(s, a)] \tag{2}$$

The function $Q_i(s, a)$ may be used by the agent to determine the optimal action with respect to objective o_i at time-step t, given state s_t:

$$a_{i,t} = \arg\max_a Q_i(s_t, a) \tag{3}$$

The vector $\vec{a}_t = [a_{1,t}, a_{2,t}, ..., a_{n,t}]$ consists of actions optimal with respect to particular objectives at a given time-step t. Because at each step, the agent may perform only a single action, a method of reducing $\vec{a}_t$ to a single action is required.

A common method for selecting a single action is the scalarization [5] of $\vec{Q}(s, a)$ using some scalarization function and a weight vector $\vec{w}$. Typically a linear scalarization is applied, so that:

$$SQ(s, a) = \sum_{i=1}^{N} w_i Q_i(s, a) \tag{4}$$

Then $SQ(s,a)$ may be used as in equation 3 to select an action. The weight wector in this case corresponds to priorities assigned to particular objectives.

In the further sections of this paper, we will show how to apply scalarization in Deep Q-Networks and we will introduce Decision Values to dynamically adjust the weights for improved performance of the agent. For simplicity, further in the text we will use the index i to note that a particular value or function is defined for any objective o_i, and by N we will define the number of objectives.

III. Using multiple DQNs

We have considered an agent that have multiple objectives, receives rewards with respect to those objectives and has a separate Q-function for each objective. In this section we will describe how to merge q-values obtained from Deep Q-Networks for different objectives and how the impact of particular DQNs on the behaviours of the agent may be controlled by using Decison Values. Finally we will describe the learning process utilizing DQNs with Decision Values. We will refer to our method as to Multi-Objective Deep Q-Network with Decision Values (MODQN-DV).

A. Combining Q-values

In case of multi-objective agent, we may use a separate DQN as an approximator for each $Q_i(s,a)$ in the $\vec{Q}(s,a)$ vector. Such agent would be controlled by multiple Deep Q-Networks working in parallel. Each DQN provides a list of q-values and we want to use q-values from all DQNs to select a single action a that will be performed by the agent

Let us define a vector $\vec{q_i}$ that consists of q-values provided by $Q_i(s,a)$ for each possible action $a \in A$ and a single objective o_i, i.e.:

$$\vec{q_i} = [Q_i(s,a_0), Q_i(s,a_1), ..., Q_i(s,a_j)] \tag{5}$$

In the single-objective case the optimal action a would be equal to a_j for such j that $\vec{q}_{i,j} = \max \vec{q_i}$. For multi-objective case we can use scalarization to sum up all $\vec{q}$ vectors and then select the action corresponding to the maximal value of such scaled q-value vector. In this approach, q-values may be interpreted as votes of certain DQN, which are summed-up and the highest-voted action is selected. We need to stress here that simply adding the vectors does not produce a meaningful result yet. The q-values produced by different Q-functions are not scaled. In general q-values may be any real numbers. If we want them to represent votes for particular actions, each $\vec{q_i}$ vector needs to be rescaled to $[0,1] \subseteq \mathbb{R}$. Many approaches for scaling the vector may be applied. In our experiments we use the following scaling function for which $\min(\vec{q_i})$ is mapped to 0 and $\max(\vec{q_i})$ to 1:

$$scale(\vec{x}) = \frac{\vec{x} - \min(\vec{x})}{\max(\vec{x} - \min(\vec{x}))} \tag{6}$$

The scalarized q-vector is then defined as:

$$\vec{q_s} = \sum_{i=1}^{N} w_i scale(\vec{q_i}) \tag{7}$$

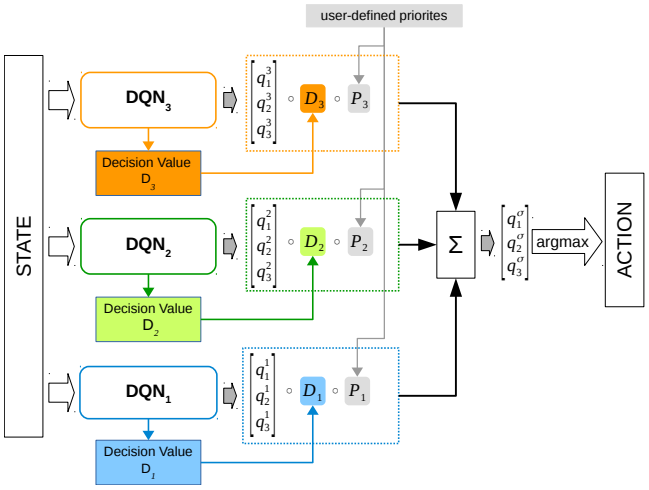

Fig. 1: Three Deep Q-Networks are working in parallel based on the same sensory input. Each DQN corresponds to different task pursued by the agent. Each DQN has an additional decision value output which acts as a dynamic weight used while summing up q-vectors from particular DQNs. User defined priorities are also used for weighting the decision from particual DQNs.

Now, using the rescaled $\vec{q_i}$ vectors we can sum them up and select one action with the highest total q-value. For example, let have actions a_1, a_2, a_3, weight vector $\vec{w} = [1,1,1]$, objectives o_1, o_2 and corresponding q-vectors $\vec{q_1} = [0, 0.6, 1]$ and $\vec{q_2} = [1, 0.5, 0]$. Adding them will result in vector $[1, 1.1, 1]$, for which the second element is the maximal, thus the corresponding action a_2 should be selected.

B. Decision Value

The scalarization allows to combine outputs from multiple DQNs. However, such a combination does not guarantee a meaningful action selection. Let us return to previous examples and consider a vacuum cleaner approaching a wall; actions a_1, a_2, a_3 correspond to turning left, going straight, and turning right respectively. If the vacuum cleaner perform the action proposed in q_1 it will turn right, alternatively if it uses q_2 then it will turn left. Using the sum will however lead to going straight forward and hitting the wall. So while both DQNs suggested a meaningful action, their sum is not meaningful at all. We see that using constant weights while summing q-values does not provide a solution for this problem.

To solve this issue, we would need to dynamically choose which q-value vectors are more important in a particular state. In other words, we would like to have a meta-policy for choosing the actual policy of the agent. However, as the agent pursues many objectives, it is hard to define this meta-policy with respect to all objectives. To overcome this problem we propose to indicate the *value* of the *decision* provided by each

DQN with respect to corresponding objective pursued by the agent.

The proposed *decision values* may be indicated independently by each DQN based on the current state and used as additional weights while summing up q-value vectors. Going back to the previous example: let assume that q_1 is the output from DQN associated with collision avoidance and q_2 is the output from DQN associated with cleaning. As the robot approaches a wall, the decision regarding collision avoidance is clearly more important than the decision regarding cleaning. This is because if the robot does not make any decision, it will collide with the wall and receive a negative reward with respect to collision avoidance objective. However, not making the decision will not affect cleaning objective (assuming that the cleanliness of the floor in front of him is not different than in other places). Thus, at this particular state the value of q_1 is higher than the value of q_2 and q_1 should be summed with a higher weight.

We may define the decision value signal $d \in [0, 1] \subseteq \mathbb{R}$, and by d_i denote the decision value associated with DQN_i. Now the scalarized q-vector would use decision values instead of constant weights:

$$\vec{q_d} = \sum_{i=1}^{N} d_i scale(\vec{q_i}) \tag{8}$$

We may additionally include the external preferences indicated by values of priorities p_i assigned to objectives as introduced in II-B. This way the q-values will be scaled both by dynamic decision values and static priorities. Moreover, for technical reasons, we need to add $\vec{\mu}$, which is a vector containing very small random values. This will ensure that in a rare cases when all decision values are equal to 0, a random action will be chosen. Finally the scaled, decision value- and priority- weighted q-value vector denoted by $\vec{q_\sigma}$ is equal to:

$$\vec{q_\sigma} = \vec{\mu} + \sum_{i=1}^{N} d_i p_i scale(\vec{q_i}) \tag{9}$$

C. Acquiring values of decisions

Now, as we have a method of applying decision values in the scalarization of multiple objectives, let us explain in more details how decision values are defined and how they can be learned by reinforcement learning.

First we should consider how objectives of an agent are defined. Again let us refer to the vacuum cleaning robot example. If the agent had only two objectives: a) to seek dirt and b) to avoid colliding with obstacles, then we could define two reward/terminal states: state A - state in which dirt is collected, state B - state in which the robot is colliding with something. There is a notable difference between those two states. In the first case, the agent should be rewarded positively, but in the latter case, it should be rewarded negatively. Moreover, if the agent is not in any of those states, it should be not rewarded at all. We can describe the first objective as being *attractive* (as it attracts the agent by positive rewards) and the second as being *repulsive* (as it repulses the agent by negative rewards). Many problems in robotics, games or other fields of AI may be presented using a set of attractive or repulsive objectives. In particular some problems may be decomposed into such set of objectives to promote more granular learning and control. Such decomposition is usually simpler and more intuitive compared to more advanced reward shaping techniques.

Let us consider an agent moving in a state-space with attractive and repulsive states. As the agent approaches one of those states, it becomes more critical to perform an action that will either move the agent towards such state or away from it. The value of the decision made with respect to an objective near a rewarding state rises as the distance to this state becomes shorter. This is a simple and intuitive heuristic: if an agent pursues multiple equally weighted objectives, then it probably should focus most on the objective that is already very close to being accomplished.

We can thus create a *decision reward* - the reward provided to the agent for performing a decision - which would be simply the absolute value of the reward provided with respect to an objective: $\rho_i = abs(r_i)$. Now we can define the decision value as a *state-value* function [3], returning the value of the state s under policy π, with respect to the decision rewards of a particular objective:

$$D_i(s) = \mathbb{E}_\pi \left[\sum_{k=0}^{\infty} \gamma^k \, \rho_{i,t+k+1} \,\middle|\, s_t = s \right] \tag{10}$$

Such defined decision value will provide high values around rewarding states (either positive or negative) and low values in states which are far from rewarding states. In any state, the decision value will provide the importance of particular objective. The proposed decision value function will hence provide values representing the chances of achieving a rewarding state (with respect to some objective o) given the current state s and following policy π. Where policy π is the policy provided by the Q-function for a particular objective.

It is important to note, that the decision value, as defined, can not be directly used for scalarization, because its value may be any positive number. Moreover, the range of the values provided for different objectives may be very broad. To overcome this problem, the decision value needs to be scaled to be in range $[0, 1]$ as noted in section III-B. However, the unscaled decision value is needed during learning as it will be shown in the next section. We will therefore denote the unscaled decision value by D_i and define the scaled decision value by d_i as follows:

$$d_i = \sigma \left(\frac{(D_i - \alpha_i)}{\beta_i} \right) \tag{11}$$

Where σ is the sigmoid function; α_i and β_i are derived during learning: α_i is an approximation of the mean value of D_i, while β_i is an approximation of the standard deviation of D_i.

D. Learning

Having defined decision values, we may move to the method of learning such values along with learning policies for particular objectives. We use Deep Q-Networks to approximate the values of Q-functions. Following the state-of-the-art in this field a DQN provides the approximated function $Q(s,a;\theta)$, where θ are the learnable parameters of the neural network. As in our model we use multiple DQNs, there is a function $Q_i(s,a;\theta_i)$ for a DQN_i related to objective o_i. Each DQN_i is optimised iteratively, using the following loss function for each iteration j:

$$L^Q_{i,j}(\theta_{i,j}) = \mathbb{E}_{(s,a,r_i,s')\sim U(M_i)}[(r_i + \\ + \gamma \max_{a'} Q_i(s',a';\theta^-_{i,j}) - Q_i(s,a;\theta_{i,j}))^2] \quad (12)$$

As introduced in [1], there are in fact two neural networks involved in the learning process of a single DQN. The *on-line network* $Q_i(s,a;\theta)$ is updated at each iteration, while the *target network* $Q_i(s',a';\theta^-)$ is updated only each K iterations. Moreover *experience replay* is used to further improve the learning process. The agent stores experienced states, actions and rewards in a *replay memory* M_i for each DQN_i respectively. Then at each iteration, each DQN_i is trained using a sample of past experiences selected uniformly at random from the corresponding replay memory M_i. Those samples are used as mini-batches for gradient descent optimization.

The Decision Value may be updated using TD-learning [3] similarly as for any state value function, by using the following update rule:

$$D_i(s_t) \leftarrow D_i(s_t) + \alpha\left[\rho_i + \gamma D_i(s_{t+1}) - D_i(s_t)\right] \quad (13)$$

As we use a neural network for approximating $D_i(s)$, we may define the loss function as follows:

$$L^D_{i,j}(\theta_{i,j}) = \mathbb{E}_{(s,\rho_i,s')\sim U(M_i)}[(\rho_i + \\ + \gamma D_i(s';\theta^-_{i,j}) - D_i(s;\theta_{i,j}))^2] \quad (14)$$

The decision value is provided by an additional output of the DQN and the learning procedure is analogical to Q-function. Moreover the decision value requires scaling, for which the parameters α and β need to be learned. If we include α and β in the neural network parameters θ, then the additional loss function for the decision value scaling would be defined as:

$$L^d_{i,j}(\theta_{i,j}) = \mathbb{E}_{(s)\sim U(M_i)}[(0.5 - \sigma(D_i(s;\theta_{i,j})))^2 + \\ + (1 - \max_s(D_i(s;\theta_{i,j})) + \min_s(D_i(s;\theta_{i,j})))^2] \quad (15)$$

The neural network is optimized using a combined loss function for Q-values, decision values and scaling of the decision values:

$$L_{i,j}(\theta_{i,j}) = L^Q_{i,j}(\theta_{i,j}) + L^D_{i,j}(\theta_{i,j}) + L^d_{i,j}(\theta_{i,j}) \quad (16)$$

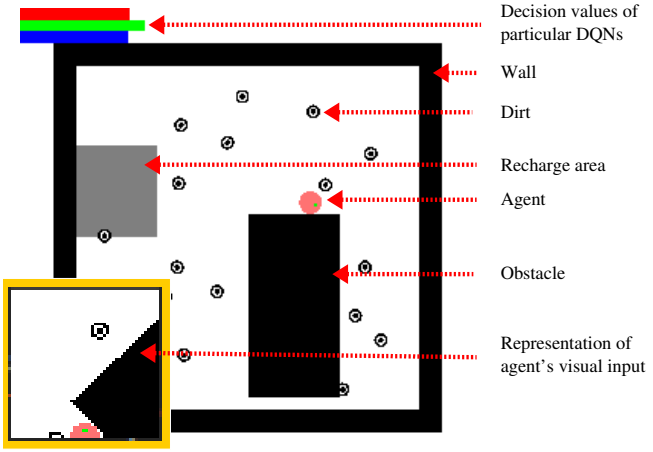

Fig. 2: Cleaner - a game-like virtual environment with agent pursuing multiple-objectives. The environment consists of the agent, walls, obstacles, recharge area and dirt. The agent perceives the environment by a visual input (a view from the top limited to a square located in the front of the agent). Agent may move forward and turn; its area of movement is limited by walls. Agent has three objectives: avoid walls, consume dirt and recharge.

IV. Evaluation

A. Cleaner - a 2D game-like virtual environment

To evaluate the solution presented in this paper we created *Cleaner* - a simple game-like virtual environment, simulating the behaviour of an autonomous vacuum cleaner. The environment consists of an agent, walls, recharge areas and dirt consumable by the agent. Cleaner is presented in Figure 2. The agent is a circular object that may move around the map by performing one of three actions: move forward, turn left and turn right. The map is a continuous space. The agent perceives the environment only by visual sense, i.e. a W x H pixel (width and height) rectangle situated in front of him. This visual input is converted to gray-scale (8bit). Agent's world (white) is surrounded by walls and filled with obstacles (black rectangles) which agent can not pass. Agent may pick up dirt and recharge itself. Dirt is indicated by three small coaxial circles (black), while recharging field is indicated by a gray rectangle. Dirt re-spawns at random positions on the map after being consumed by the agent. The quantity of dirt, recharge fields and obstacles is constant during the episode. Cleaner is a simplified simulation of a mobile robot moving on a flat surface (e.g. floor) with a video camera attached at the top of the robot pointed towards the floor.

The agent has a battery level $E \leq E_{max}$, which is decreased at each time step by E_{step}. The battery level may be increased when the agent enters the recharging area by $(1-E)\cdot 0.1$ each step. An episode ends when the agent's energy level drops to 0 or when 2000 steps pass. The agent starts each game with initial battery level $E = E_{start}$. The position of dirt, recharge

TABLE I: MODQN-DV learning hyperparameters

Parameter	Value

optimizer	Adam

fields and obstacles as well as the initial position of the agent are chosen randomly at the start of the episode.

The agent has three objectives: (ca) collision avoidance, (fc) cleaning and (rg) recharging.

The rewards for particular objectives are as follows: objective (ca): -1 for collision, 0 otherwise; objective (fc): $+1$ for collecting dirt, 0 otherwise; objective (rg): -1 for for each step when $E < 0.1$, $(1 - E) \cdot 0.1$ while charging and 0 otherwise.

In all experiments described in this chapter, the game options were as follows: $E_{start} = E_{max} = 1.0$, $E_{step} = 0.001$. The size of the agent sight rectangle is $W = 50\,\text{px}$, $H = 50\,\text{px}$. The quantity of dirt is 20. The number of obstacles varies randomly from 1 to 5, and the number of charging areas varies randomly from 1 to 3.

B. MODQN-DV implementation

Our implementation of the MODQN-DV[1] was based on the baseline DQN implementation [14] developed by OpenAI using TensorFlow[15]. We expanded the standard DQN with additional decision value outputs and mechanism for scalarizing q-values from multiple DQNs. Each single DQN in a MODQN-DV consists of a convolutional network with three convolution layers and no pooling layers, followed by a fully connected layer and the output layer. Dueling [16] and double q-learning [17] were used. The additional decision value output is a single neuron linear layer connected to the state score layer used for dueling.

The parameters of the convolution network were kept default as provided in the baselines implementation. The size of the fully connected layer in our models is set to 128, and the size of the input image is our case is 50x50x1, thus the q-values are provided based only on an image input from a single state. The memory replay was modified to store rewards with respect to all objectives separately. The prioritized experience replay[18] was not used in our implementation. The hyperparameters used for training DQNs during evaluation are presented in Table I.

During training of the MODQN-DV, loss functions are used as specified in section III-D. DQNs for all objectives are trained simultaneously and scaled decision values are used for scalarization during learning.

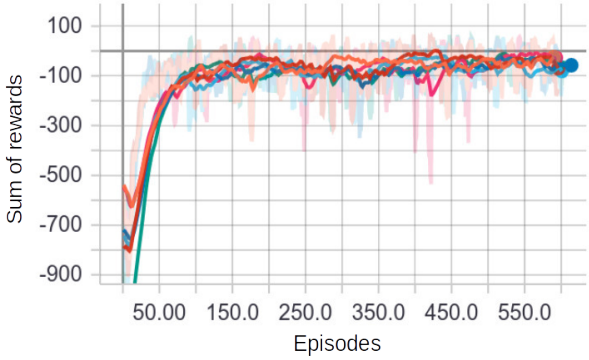

Fig. 3: The sum of rewards (smoothed) collected by MODQN-DV in cleaner over episodes of training. The plot shows data from 6 different runs.

C. Experiments

To evaluate our method we conducted a series of experiments utilizing MODQN-DV and the cleaner environment. In particular we compared the performance of multiple Deep Q-Networks for case a) where decision values were enabled for scalarization and case b) where the decision values were disabled. This comparison gave us a clear indication of the impact of decision values on the performance. We will refer to case (a) as MODQN-DV (b) as to MODQN.

The experiment for both cases (a) and (b) were conducted as follows. First the DQNs were trained using the implementation and parameters as provided in section IV-B and table I. In (a) the decision values were trained and used for scalarization. In (b) the decision values were disabled during training and their values were forcefully set to 1. During training, the user defined priorities for objectives were set to 1 in all cases (all objectives were weighted equally during scalarization). For each case the training procedure was repeated 6 times and all trained neural networks were saved. As show in figure 3, the learning of MODQN-DV is stable over time.

Next, the trained MODQN-DV and MODQN networks were used for evaluation with 10 different sets of user-defined priorities (p_{ca}, p_{fc}, p_{rg}) as provided in tables IIa and IIb. In a single evaluation, 100 episodes were played. The same sequence of randomly generated map layouts were used for each run. The sum of collected rewards were recorded for each run. For each set of priorities, 6 runs performed by 6 separately trained MODQN-DV and MODQN instances were averaged.

D. Results

The results presented in the tables IIa and IIb are averaged sums of collected rewards with respect to each objective, namely: Σr_{ca} for objective (ca) - collision avoidance, Σr_{fc} for objective (fc) - cleaning and Σr_{rg} for objective (rg) - recharging. $\Sigma\Sigma r_i$ is the sum of the sums of rewards - it indicates

TABLE II: Evaluation results - sums of collected rewards for experiments with different priorities assigned to objectives with either enabled or disable decision values. Each case is compared against the baseline agent with all priorities set to 1.0. Values in bold denote objectives with the highest priority assigned. Green/red colour of the cell indicates whether a score is higher/lower compared to a corresponding score with opposite decision values configuration (enabled/disabled).

the total performance of the agent. Priorities (p_{ca}, p_{fc}, p_{rg}) correspond to objectives (ca), (fc) and (cg).

The set of priorities: $(p_{ca} = 1, p_{fc} = 1, p_{rg} = 1)$ was used as the baseline for evaluation (also those priories were used during training). For each row in the tables IIa and IIb there is an additional row marked as $\Delta_{baseline}$ with values showing the percentage of gain or loss of collected rewards with respect to the baseline value for each case. The green and red colours of the cells indicate if the reward gain for a particular set of priorities was better compared to the corresponding case in the second table.

The aim of the evaluation was to test how the overall performance of the agent changes when priorities are different from the initial values used during training. As we can see in table IIa on 7 of 9 cases, the use of MODQN-DV helped to preserve (or even increased) the overall performance compared to the baseline (all priorities set to 1). Moreover, in almost all cases, the performance of the agent with respect to the objective with the highest priority (marked in bold in the tables) increased when decision values were used. On the contrary, when decision values were not used, changes in the priorities usually led to a decrease in the agent's performance, as presented in table IIb. The results show that the proposed solution has a significant impact on the performance when priorities are modified post-training. The average change in the agent's performance, calculated over all evaluation cases, is -27.5% when using decision values and -69.1% when decision values are not used. The average change for the objective with the highest priority is 11.3% and 4.4% respectively.

It should be noted however, that in the baseline case (all priorities set to 1), the overall performance of the agent was lower when decision values were enabled. A possible explanation of this issue is that decision values introduce additional noise to action selection. In some cases, the final q-values associated with particular actions may be very similar (e.g. when the agent does not perceive any objects). Then, action selection depends heavily on the decision values; if there is no dominating decision value, then there may be a lot of variance in action selection, thus actions may be selected based on different policies (from different DQNs) in each step. This may lead to a chaotic behaviour in states that are "far" from any rewarding states. One possible way of overcoming this issue is providing a sequence of states as the input to DQNs rather than a single state to stabilize the outputs.

It is also worth noticing how the decision values change as the agent moves. As expected, the decision value for a particular objective rises when the agent approaches a state where it could receive a reward. For instance, the value of collision avoidance rises significantly when the agent is very close to a wall or an obstacle. Moreover, the decision value

drops when the agent is in a state far from receiving a reward. For example, if the agent does not perceive any walls or obstacles, then the collision avoidance decision value is lower than average. The agent thus usually selects the action, which is related to the most promising objective at a particular state.

V. Conclusions

In this paper, we presented a method for using multiple Deep Q-Networks to approach multi-objective problems called Multi Objective Deep Q-Networks with Decision Values (MODQN-DV). We introduced decision values to DQNs in order to improve the scalarization of outputs from multiple DQNs. Our method requires only slight modification of existing DQN architectures, while it introduces a number of benefits: 1) it enables the decomposition of problems in to smaller sub-problems, for which independent DQNs may be trained simultaneously, 2) it provides a method for robust manipulation of priorities after the training, which also allows to completely disable DQNs responsible for particular behaviour/objective, 3) it allows to add new objectives to already trained agent without the need of retraining and to tune their impact on the behaviour of the agent.

In the experimental part, we shown that in most cases MODQN-DV improves the performance of the agent, that uses a different set of priorities compared to the training phase. The results are promising, however more tests should be performed using other benchmarks. Moreover, more work needs to be done to reduce the impact of the noise in decision values on the overall performance of the agent.

In this paper, we also introduce *cleaner* - a benchmark for multi-objective reinforcement learning problems that provides visual state representation. The authors are not aware of any other existing multi-objective benchmark that would be comparable to atari games benchmark or other provided by OpenAI.

In future work we want to improve the performance of MODQN-DV; one possible improvement is the use of common convolutional layers for all DQNs. It is particularly interesting to use MODQN-DV in very complex environments, such as video games. Recently published Starcraft 2 learning environment may be a good choice for further tests of MODQN-DV architecture as strategy games may be perceived as multi-objective problems.

3rd International Workshop on Artificial Intelligence in Machine Vision and Graphics

THE main objective of the 3rd Workshop on Artificial Intelligence in Machine Vision and Graphics (AIMaViG'18) is to provide an interdisciplinary forum for researchers and developers to present and discuss the latest advances of artificial intelligence in the context of machine vision and computer graphics. The workshop covers the whole range of AI-based theories, algorithms, technologies and systems for diversified and heterogeneous areas of vision and graphics.

TOPICS

The topics and areas include but are not limited to:

- image processing
- scene analysis, modeling, and understanding
- machine vision
- pattern matching and pattern recognition
- image synthesis, including three-dimensional imaging and solid modeling
- computer-aided graphic arts and animation
- mathematical approaches to image processing, analysis, and synthesis
- computational geometry
- image models and transforms
- visualization and graphical data presentation
- diagrammatic knowledge representation and reasoning
- monocular and stereo vision
- modeling of human visual perception
- innovative uses of various graphic and vision devices and systems

***Abstract*—In this paper, a classification procedure for Baker's cysts was proposed. The procedure contained two subprocedures: the image preprocessing (dual thresholding, labeling, feature extraction) and the classification (Random Forests, cross validation). In total, five features were required to classify the cysts. These geometric features represented the location, the area and the convexity of the cyst. The procedure was proven effective on a set 436 varied MRI images. The set contained 68 images with cysts ready for aspiration and was oversampled with the SMOTE approach. The proposed method operates on 2D MRI images. This reduces the time of diagnosis and, with the ever increasing demand for MRI scanners, is justified economically. The method can be employed in systems for autonomous and semi-autonomous Baker's cyst aspiration or as a standalone package for MRI images annotation. Furthermore, it can be also extended to other fluid-based medical conditions in the knee.**

I. Introduction

WITH the ageing of the world population and the ever present health sector shortages [1], automation of surgical procedures is increasingly more common and important. For some of the simpler medical conditions, it is possible to develop robotic systems to treat them nearly autonomously. This in turn offloads the medical staff – their time and experience can be devoted to difficult and complicated surgical procedures.

A Baker's cyst is a very common medical condition (see Fig. 1). The cyst is a synovial capsule filled with fluid, which often occurs when the knee is in an inflammatory state. This condition is not dangerous, but it can affect the patient's quality of life through pain and reduced range of motion of the knee. The safest and easiest method of treatment for this condition is aspiration [2]. The aspiration is usually preceded by Magnetic Resonance Imaging (MRI) [3]. Often, full 3D scans are obtained, as they can be used to precisely diagnose the cyst and chose the best approach for aspiration. Despite its simplicity, fully autonomous aspiration of Baker's cyst remains largely unexplored in the literature. To automate this procedure, it is necessary to propose a classification procedure, capable of determining whether the knee contains a Baker's cyst that is ready for aspiration.

Two major approaches to medical image classification can be distinguished. In the first one, the learning algorithm is supplied a raw image and it learns meaningful features from the image automatically [4]. This approach is intuitive but requires large training sets and time-consuming training to provide good results. Such datasets can only be obtained through scientific collaborations, which are often focused on pressing medical issues. In case of simpler medical conditions, the second approach to classification can be employed. This method involves feature extraction coupled with image processing [5]. As the features are defined by the user, smaller training sets can be used. To extract the features it is often necessary to segment the image first. While there are many methods available for the medical image segmentation [6], the thresholding remains one of the more popular approaches [7]. The threshold can be set manually by the user or automatically with one of the available methods [8], [9]. Both approaches were utilized in this study.

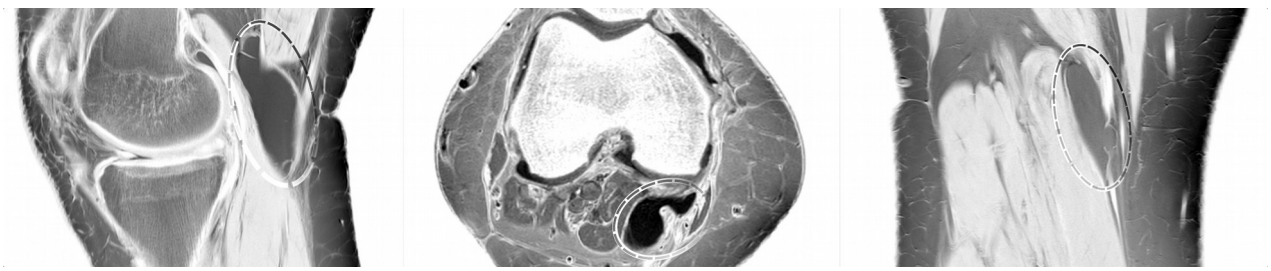

Fig 1. The Baker's cyst.

In a broader context, a classification procedure can be seen as a module in systems for autonomous and semi-autonomous surgery, in which it is used for diagnosis. The other problems in this area include: physical simulation of soft tissues and joints, medical tool path planning, surgery planning and surgery optimization [10]–[15].

In this paper, a procedure for Baker's cyst classification was proposed. The procedure was based on Random Forests and operated on 2D scans from Magnetic Resonance Imaging (MRI). The scans were preprocessed using custom, dual thresholding and labeling. Then, five geometric features were extracted from the preprocessed images. These features were then used to train the Random Forest (with cross-validation). The procedure was repeated 40 times to ensure that the obtained results were independent of the random number generator.

II. Method

A. The input dataset

The input dataset contained 12 spatial MRI sets of the knee. In total, the number of 2D MRI slices was 436. Out of them only 68 contained a Baker's cyst that was ready for aspiration. These 68 images were selected by an experienced orthopedic surgeon. The disproportion between the classes is very common in medical classification problems. Typical machine learning algorithms don't perform well with such datasets. Therefore, it is necessary to balance them. In this study, the input dataset was balanced with the Synthetic Minority Over-sampling Technique (SMOTE) [16] using Imbalanced-learn [17].

The proposed procedure was tested on three different MRI sequences: PDW SPAIR (Proton Density Weighted Spectral Attenuated Inversion Recovery), STIR (Short Tau Inversion Recovery) and PDW FatSat (Proton Density Weighted Fat Saturation) MRI sequences. In all of these sequences, the fluid-based structures appear hyper-intense, as seen in Fig. 2. The images were imported into Python using Pydicom [18].

The Baker's cysts are typically diagnosed with 3D MRI scans. The idea to use 2D slices instead of full 3D sets was partially inspired by the FAST USG, often employed in abdominal cavity diagnosis. In FAST USG the patient is diagnosed with only a few sweeps of the transducer. The diagnosis takes between 10 and 20 seconds, which is less expensive than a full sweep. These advantages also apply to MRI. With the ever growing need for MRI-based diagnosis, the availability of MRI scanners is a significant factor. Furthermore, some patients can't undergo full MRI scanning and others may feel uncomfortable during the procedure. When using singular 2D MRI scans for diagnosis, as in the proposed procedure, these issues are no a longer a concern.

B. Image processing

The initial threshold for the image segmentation was obtained using the method proposed in [9]. This threshold was then modified as follows:

$$thr_{fin} = mfn[\boldsymbol{I}(x,y) * (\boldsymbol{I}(x,y) > thr)], \quad (1)$$

where: thr_{fin} – the final threshold, thr – the threshold computed with the method presented in [9], $\boldsymbol{I}(x, y)$ – the input image, $mfn()$ – a function that computes the mean value of a matrix using only the nonzero elements.

In the next step the image was labeled with a 3 by 3 pixel mask. After the labeling, the largest object in the segmented image was selected. This object (see Fig. 3b) was assumed to be the cyst candidate. In the third step, the boundary of the knee was obtained (see Fig. 3c) using the following threshold:

$$thr_b = k\, max[\boldsymbol{I}(x,y)] + (1-k)\, min[\boldsymbol{I}(x,y)], \quad (2)$$

where: k – the thresholding parameter (here: k = 0.07). Finally, the obtained bounding box of the knee was applied to the image of the segmented object (see Fig. 3d).

C. Features

In this study, the following 5 features were used in the classification procedure:

a) $object_{area}$ – a typical feature used in medical classification procedures, which represented the area of the segmented object [mm^2],

b) *circularity* – a dimensionless measure of how circular the segmented object was; computed as a ratio between the area of the Largest Empty Circle (LEC) inside the object LEC_{area} and the object area $object_{area}$:

$$circularity = LEC_{area} / object_{area}. \quad (3)$$

The LEC (see Fig. 4b) was obtained using the method presented in [19],

c) *convexity* – a relative feature that measured the convexity of the segmented object; computed as a ratio between the object area $object_{area}$ and the area of the convex hull of the object $convexhull_{area}$ (see Fig. 4a):

$$convexity = object_{area} / convexhull_{area}. \quad (4)$$

The convex hull of the object was computed using Scipy [20],

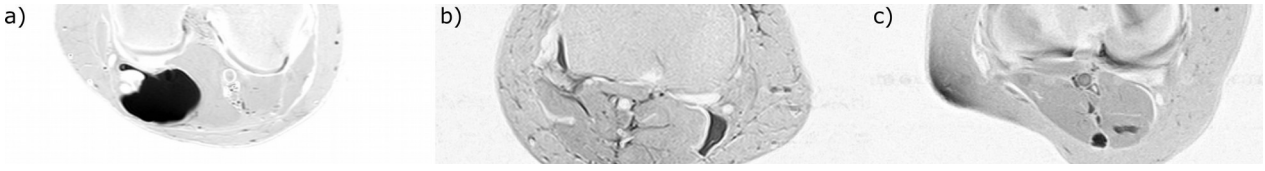

Fig 2. The supported MRI sequences: a) PDW SPAIR, b) STIR, c) PDW FatSat.

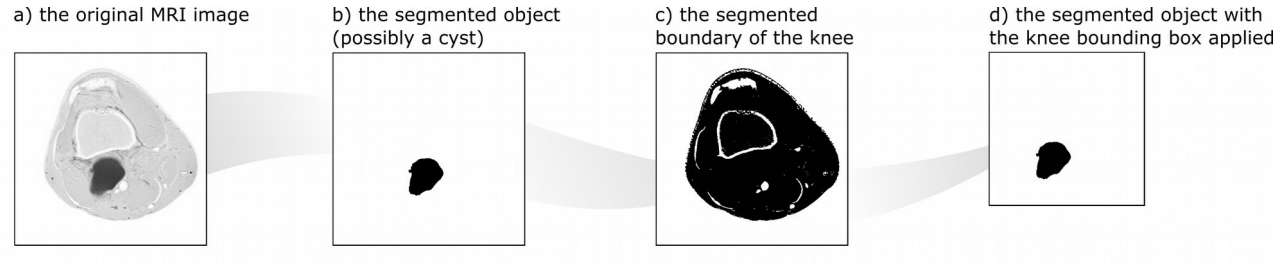

Fig 3. The image processing.

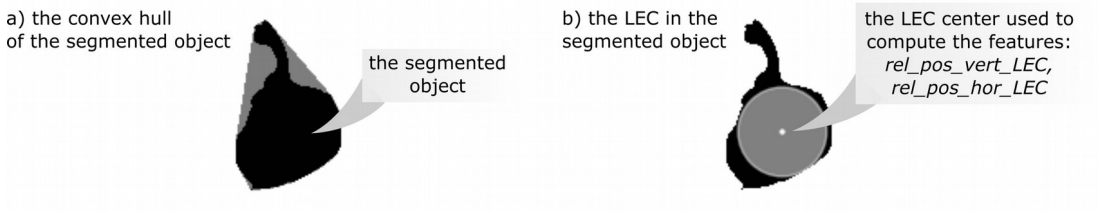

Fig 4. The convex hull and the LEC in the segmented image.

d) *rel_pos_vert_LEC* – the relative vertical position of the LEC center (see Fig. 4b),

e) *rel_pos_hor_LEC* – the relative horizontal position of the LEC center.

The first feature separated the cysts from the veins and the arteries – the cysts ready for aspiration often had larger areas. The second and the third feature helped distinguish cases with segmentation errors (multiple, small and connected objects or images with no hyper-intense objects), Furthermore, the second and the third feature were computed by dividing the area of the LEC and the convex hull respectively by the object_area. This made them independent of the first feature.

The fourth and the fifth feature differentiated the cysts from other fluid-related conditions in the knee, such as knee effusions – the cysts usually occur in the posterior side of the knee. With the proposed skin segmentation procedure, the LEC center was computed with regards to the actual boundary of the knee – not the image (see Fig. 3d). This made the procedure more general and reliable.

D. The classifier

Decision trees are among the most popular classification algorithms in machine learning. They are easy to implement and quick to train. Despite these advantages, the trees tend to overfit data. This is a serious drawback, especially when working with limited datasets. A natural extension to this approach, which addresses this flaw, is Random Forest [21]. In this algorithm several decision trees are trained on different subsets of the training dataset and the final classification is based on majority vote. It is worth mentioning that, unlike many classification algorithms, Random Forests do not require data preconditioning. This means that raw feature values can be used to train them and classify new samples.

In this study, Random Forest contained 10 decision trees, based on Gini impurity. The depth of the tress was not limited. The classifier was implemented using Scikit-learn [22]. The training and the testing were performed with a 4-fold cross validation, while the performance of the classifier was measured with the following indicators:

$$\begin{aligned} Sen &= TP/(TP+FN), \\ Spec &= TN/(TN+FP), \\ F_1 &= 2*TP/(2*TP+FN+FP), \end{aligned} \tag{5}$$

where: *Sen* – the sensitivity, *Spec* – the specificity, F_1 – the F_1 score (also referred to as balanced *F*-score), *TP* – the number of true positive cases (the knee contains a cyst ready for aspiration and is classified for aspiration), *FP* – the number of false positive cases (the knee does not contain a cyst ready for aspiration and is classified for aspiration), *TN* – the number of true negative cases (the knee does not contain a cyst ready for aspiration and is not classified for aspiration), *FN* – the number of false negative cases (the knee contains a cyst ready for aspiration and is not classified for aspiration).

III. Results and discussion

The training and test procedures were repeated 40 times to factor in the effects of shuffling and oversampling. The average and the best (based on the F1-score) results over the 40 runs were summarized in Table 1.

As seen in Table 1, the mean values of the performance indicators were higher than 95.0%. Furthermore, the best run achieved F_1 of 99.4 % and specificity of 100.0 %. This proves that the proposed method is capable of classifying the cysts for aspiration based on 2D MRI images. It is worth mentioning, that this classification problem would be easier with 3D MRI images. In three dimensions, the cyst can be easily distinguished from veins and arteries based on its spherical shape. Nevertheless, 3D MRI scanning can be time

TABLE I.
THE PERFORMANCE INDICATORS BASED ON THE 40 RUNS

	TP	*FP*	*TN*	*FN*	*Sen* [%]	*Spec* [%]	F_1 [%]
avg	88.6± 3.0	2.0± 3.0	94.0± 2.8	4.1± 3.8	95.6± 4.2	97.8 ± 3.4	96.7± 2.6
best	89	0	94	1	98.9	100.0	99.4

consuming. Furthermore, the demand for MRI scanners exceeds the supply in most medical centers in the world. Therefore, good performance using 2D slices can be seen as an advantage of the proposed procedure.

Currently, the procedure analyzes only the largest segmented object in the knee (these objects were classified by the surgeon and used to train/test the Random Forest). Nevertheless, in some rare cases the cyst may not be the largest segmented object. This issue can be solved by iteratively checking and classifying all of the segmented objects.

IV. CONCLUSION

In this paper, a classification procedure for Baker's cyst was proposed. The procedure was composed of two subroutines: the image preprocessing (coupled with feature extraction) and classification using Random Forests. The procedure was proven effective on a set 468 varied MRI images. The images were obtained using three, different MRI sequences. Good performance using 2D slices can be seen as an advantage of the proposed procedure. This reduces the time of diagnosis, improves patient's comfort and, with the ever increasing demand for MRI scanners, is justified economically. The method can be employed in systems for autonomous and semi-autonomous Baker's cyst aspiration or as a standalone package for MRI images annotation. Furthermore, it can be also extended to other fluid-based medical conditions in the knee.

***Abstract*—Varietal homogeneity is an important factor in quality of malting barley, but its inspection is difficult. Biochemical methods are expensive and inefficient, while machine vision suffers due to high variability of the grains' features. In our previous work, we have shown a convolutional neural network for simultaneous feature extraction and classification of image data basing on multiple views. It was suggested that for machine vision inspection, the observed side of a grain should be taken into account – dorsal and ventral sides of each kernel exhibit different features. In this study we present a viewpoint-aware convolutional neural network, which learns to extract specialized features from images of dorsal and ventral sides of barley grains. We show that it increases the average classification accuracy by 0.6% and sensitivity by 2.3% with respect to the viewpoint-ignorant architecture on our dataset.**

I. Introduction

In the case of food products, the quality of ingredients which they are produced from plays a significant role, hence their comprehensive inspection is necessary. The sooner the potential fault can be detected, the lower is the actual production cost including wasted materials. Therefore, effective and quick quality assessment requires automation. Among non-invasive methods, machine vision has a special significance. However, the difficulty in identifying quantitative features and their considerable variability recently draws attention to artificial intelligence methods, especially deep learning.

An example of such a natural product is barley, especially its malting varieties, which is a key ingredient in the production of beer and whiskey. Any deficiencies in its quality immediately affect quality and therefore value of the finished product. Hence, the examination of purchased barley includes detection of impurities or damage as well as moisture content and protein content measurement. Typically, such assessment is performed visually by sampled statistical process control (SPC) as it is technically infeasible to inspect all individual grains in a shipment weighing several tons. This process is however very tedious and, due to the difficulty of the task as well as the human's fatigue, error-prone.

This work was supported from the internal budget of Mechanical Faculty of WUST. The source material (barley grain) for the dataset preparation was supplied from a project financed by National Centre for Research and Development - Project PBS3/A8/38/2015.

The subtle flavors of beer and whiskey are determined, inter alia, by enzymes associated with varieties of barley. However, control of varietal homogeneity without expensive bio-chemical tests is still an unresolved problem. One possible approach, using machine vision methods, seems particularly promising due to its potential speed and no need for direct interaction with the grains. The aforementioned difficulty of feature identification becomes even more challenging in the case of barley grains, because they exhibit different features on dorsal and ventral sides.

In this study, we present a machine vision approach to recognition of barley varieties using convolutional neural networks. We propose a neural network architecture with two feature extraction streams, each specialized to process images of a specific side of the grain. This architecture is complemented with a preprocessing recognition step, in order to identify the dorsoventral orientation of each grain. The paper is arranged as follows: in section II we reintroduce a double-stream convolutional neural network from our previous work, in section III we describe the novel architecture, as well as the dataset and training methods, and in section IV we experimentally evaluate performance of the models and compare them.

II. Related works

There are several known approaches to barley grain varietal recognition. All of them rely on digital image processing and feature extraction. The features are usually hand-engineered, e.g. edges, texture descriptors, and low dimensional or reduced to a low dimension. Most works also employ some form of machine learning to perform recognition. Zapotoczny *et al.* [1] explore possibilities of classifying images of barley kernels using principal component analysis (PCA), and linear or non-linear discriminant analysis (LDA/NDA). Nowakowski *et al.* [2] use extracted features as learning vectors for an artificial neural network (a multilayer perceptron). Hailu and Meshesha [3] present a classifying ensemble of k nearest neighbors and an artificial neural network. Those approaches yield promising results, but they are only tested on very small datasets (up to several hundred images in up to 5 classes). The scope of work by Szczypiński *et al.* [4] is significantly larger, their dataset comprising over 13,000 images of 11 varieties.

In all of those works, feature extraction and classification are considered separate parts of a system, where the features remain fixed and the classifier is designed using machine learning (ML). Recent advancements in ML made it possible to learn the feature extraction function and classification as a single system. Convolutional neural networks (CNNs) can be trained on raw images, without the difficulty of manually designing the feature extractor. Despite their applications to other agriculture-related problems (e.g. [5]), there have been no attempts to classify barley varieties with CNNs.

In our previous paper [6] we have presented a CNN for detection of defects and impurities in barley grain. Our approach made use of the double-sided imaging capacity of the acquisition system presented by [7]. The double-stream CNN was able to extract features from images of both sides of the grain. Then it fused the feature vectors together, creating a single representation from both images. This enabled it to utilize the information contained within both views of the object to predict its class.

However, due to the unpredictable nature of the imaging process, it was never known which side of each grain was actually visible on which image. Therefore the network had to be robust to this unpredictability, effectively discarding the information about dorsoventral orientation of the grains.

III. Experiment Setup

A. Reference neural network architecture

As a reference model we reintroduce the double-stream convolutional neural network from our previous work [6]. This architecture consists of two streams – that is, two separate CNNs – each assigned to a specific camera in order to process one image of each grain. At some point, depending on the setup details, representations produced by those streams are merged into a single stream. Classification is performed by a feed-forward fully-connected (FC) neural network, whose input is this merged representation.

Dorsal and ventral sides of a grain may exhibit different features. However, during the imaging process the dorsoventral orientation of the grains cannot be constrained. Therefore it is not known which side of the grained is imaged by which camera - the cameras cannot be assigned to any particular viewpoint (i.e. dorsal or ventral). In order to provide robustness against this unpredictability, the two feature extraction networks have shared parameters. That means that even though these are two separate networks with different data flowing through them, their parameters are shared, i.e. constrained to always be equal (fig. 1). Since the camera viewpoints are irrelevant in this setting, we term this architecture viewpoint-ignorant.

The actual CNN implementation used in this study is derived from AlexNet [8], comprising 5 convolutional layers of decreasing kernel size (respectively, 11x11, 5x5, 3x3, 3x3 and 3x3) with 3 overlapping pooling operations between them, and 3 fully-connected layers: first two followed by dropout layers [9], the last one by a softmax operation. After each convolutional and FC layer, a ReLU nonlinearity is applied [8]. The FC layers originally consist of 4096 neurons each except the last one, which is scaled depending on the number of classes. In order to reduce overfitting we limit the capacity of the network by replacing those layers with significantly smaller ones: 64 and 16 neurons each.

A double-stream network is constructed by instantiating two copies of each convolutional layer, although the

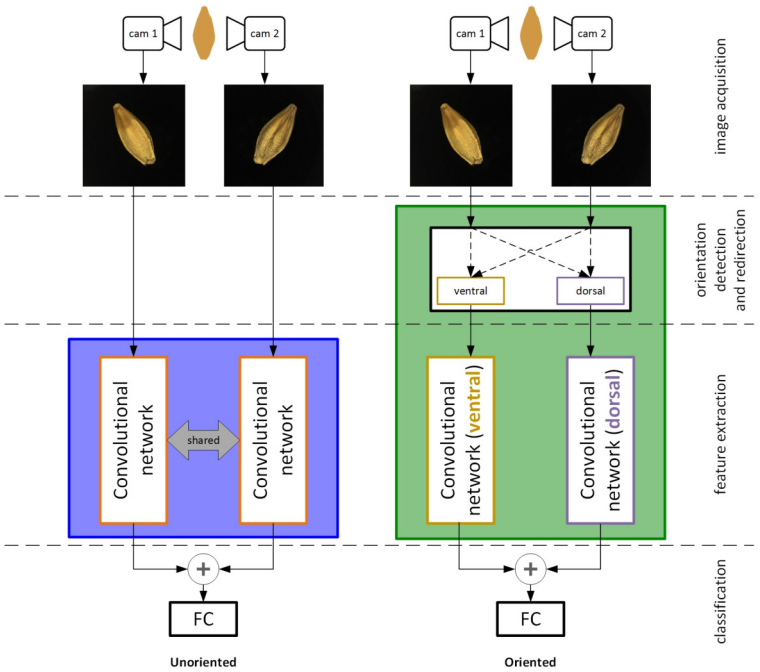

Fig 1. Double-stream CNN architectures: viewpoint-ignorant (on the left) and viewpoint-aware (on the right).

parameters (and gradients thereof) of each pair are constrained to be equal. Each stream will process an image of a different side of the grain, and during training their gradients will be summed. The streams will be merged after the last pooling operation by simple tensor concatenation. The following FC layers will proceed normally, although the input of the first FC layer will be larger to accommodate the concatenated outputs of the streams.

B. Proposed architecture

We propose a network architecture in which the streams are not robust to random dorsoventral orientation of the grains, but instead each learns to extract features specific to each side. In this setting it is assumed that each image the network receives is taken from a particular viewpoint – one of the ventral, another of the dorsal side. We term this network viewpoint-aware.

The novel architecture consists of two streams constructed exactly like in the reference architecture, except for the parameter and gradient equality constraints, which are lifted. This results in two entirely separate feature extraction networks, each associated with a specific view of the object. The rest of the architecture, particularly fusion of the streams by concatenation, and FC layers with softmax, remain structurally identical with the reference architecture.

The assumption that each stream receives a specific view of the object, as opposed to image from a specific camera, requires that the dorsoventral orientation of the object be identified before any processing. In order to achieve this, we introduce a preprocessing step in which the side of a grain is recognized, and the two images are redirected to their associated feature extraction streams according to the result. We solve the task of viewpoint recognition by reducing it to binary classification.

Both the CNN streams and the imaging cameras are ordered, so there is a natural correspondence between them – assume stream 1 is associated with ventral view, then camera 1 can capture either ventral or dorsal side. Therefore, viewpoint recognition becomes a binary classification task: either the images are acquired in the right alignment or not, in which case they need to be switched. For this, we use a CNN of the same structure as the reference architecture with shared streams, except for the final FC layer, which only has 2 outputs (correct alignment or switching needed). The complete system is shown in (fig. 1).

C. Dataset

The data used throughout this research was acquired using a prototype imaging system. The device captured RGB images of individual grains using two cameras located coaxially, opposing to each other, allowing for acquisition of top and bottom views of each grain (details in [7]). Due to the nature of the grain partitioning and transportation subsystem, the dorsoventral orientation of the objects was not predictable. For this reason, no orientation labels could be assigned to the images at the data preparation stage.

Barley was acquired from a research supply. The grains came already separated into 8 varieties, which could be grouped into spring (S) or winter (W), as well as malting (M) and fodder (F) varieties. There were exactly 2 varieties in each of the group combinations (SM, SF, WM, WF).

A total of 3169 pairs of top/bottom images were acquired, ranging between approximately 200 and 500 pairs per variety. During preprocessing, they were cropped so that the grains were visible in the center of the images, and then resized to 256x256. For the purpose of training and cross-validation, the dataset was split into 3 disjoint subsets. For every cross-validation bin, one of those subsets was used as a training set, while the two remaining ones were merged into a validation set. We applied data augmentation on each training set, appending copies of each image rotated 16 times. Table I shows the dataset composition (pre-augmentation).

TABLE I.
DATASET COMPOSITION

Variety	No. training samples	No. validation samples	Percent of total
SM Bordo	140	278	13.2%
SM Kormoran	163	327	15.5%
SF Mercada	133	266	12.6%
SF Skarb	129	257	12.2%
WM Vanessa	116	232	11.0%
WM Vincenta	166	334	15.8%
WF Kobuz	138	274	13.0%
WF Zenek	72	144	6.8%
Total	1057	2112	100%

D. Training procedure

Neural network training was performed using the Caffe framework [10], with Nvidia DIGITS front-end for task management, using a Nvidia GTX TITAN Z graphics processing unit (GPU) with 2 banks of 6 GB VRAM and 2880 CUDA cores each. To reduce the possibility of overfitting the data, the transfer learning technique was used: each of the convolutional layers was initialized from an AlexNet model pre-trained on ImageNet, a dataset of 1.5 million natural images of various origin in 1000 classes (pre-training, performed independently by Jeff Donahue, BVLC, was not a part of this study). The remaining layers' weights were initialized with Gaussian noise of mean 0 and standard deviation of 0.01, while biases were initialized with a constant of 0.1 each.

Networks were trained using multinomial logistic loss function and Nesterov Accelerated Gradient (NAG) optimization method [11], which is a variation of stochastic gradient descent with momentum. Major training hyper-parameters were: momentum $\mu = 0.9$, batch size 128 (as large as could fit in the GPU memory), initial learning rate $\alpha = 0.01$ (as high as the training could still converge at).

For variety recognition, the reference double-stream viewpoint-ignorant network was compared with the proposed viewpoint-aware network. Both networks were trained for 25 epochs: the first 2 epochs at learning rate 0.01, then until epoch 20 at rate 0.001 and for the remaining time at 0.0001. Each process was repeated 3 times for each of the cross-validation folds. Results (F1 measure and confusion

matrices) are reported by averaging of each 3 cross-validation models.

A naïve setup for the viewpoint-aware network would consist of a preprocessing network embedded into the architecture. However, since this sub-network is not being trained at this stage, its presence would only increase the memory and computation power requirement of the entire system, making the training process significantly slower. For this reason, the dorsoventral orientation recognition network was trained separately.

First, a subset of 500 images was selected from the main dataset and annotated manually (with another 500 images selected and annotated for the purpose of validation). The network was trained on this dataset for 20 epochs. After the first 8 epochs learning rate was reduced to 0.001, and after another 8 to 0.0001.

Then, the preprocessing network was queried once over the entire dataset to generate the auxiliary labels containing the information about dorsoventral orientation of each grain. The double-stream viewpoint-aware variety recognition network only read those labels at training time, reducing the preprocessing step only to redirecting images to the feature extraction streams as needed. When using such network in production environment, both the preprocessing sub-network and the variety recognition network would have to be instantiated at the same time.

IV. Results

A. Viewpoint recognition

The dorsoventral orientation recognition network reached 99.8% accuracy after 20 epochs of training. There was little to no overfitting, as both training and validation loss were equal to about -4 in logarithm. The 0.2% error rate was caused by a single image, in which the grain was not imaged from neither the dorsal nor ventral side, but from the sides (fig. 2). This is a rare occurrence which the imaging system allows, but due to an insignificant fraction of such images in the dataset, we decided to ignore their influence – those cases were not handled in any particular way.

B. Variety recognition

Training of a single variety recognition network took approximately 80 minutes (compared to less than 2 minutes for the preprocessing network). All of the models displayed a satisfactory fit – validation loss was actually lower than training, and accuracy was higher (fig. 3). Explanation for this counter-intuitive phenomenon is in dropout. During training, 50% of the fully-connected neurons are randomly deactivated, artificially increasing prediction difficulty, when during validation, no neurons are disabled (their activations are scaled down by a factor of 0.5 to preserve the total magnitude of the activation). This has a significant anti-overfitting effect.

Classification results comparing the viewpoint-ignorant and viewpoint-aware networks, averaged over cross-validation folds, are shown in Table II. Sensitivity and specificity are defined for binary classification, so the table

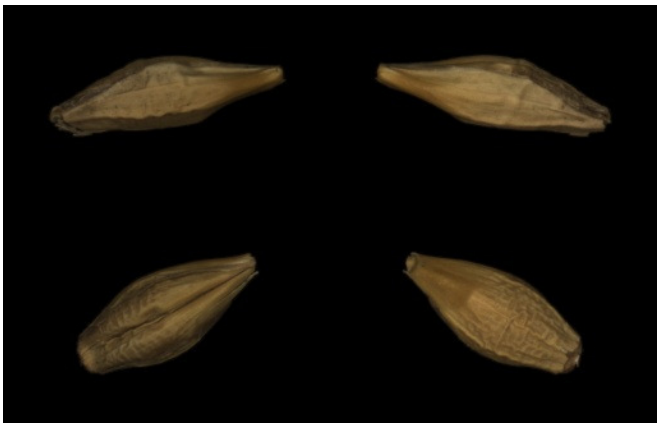

Fig 3. Difficult case of a sidewise grain orientation (top) versus normal grain exhibiting its ventral (bottom left) and dorsal sides (bottom right)

contains averages of values obtained for each class as a one-versus-all classification.

In fig. 4 we compare confusion matrices for viewpoint-ignorant and viewpoint-aware models. The matrices are normalized row-wise, so a percentage on each tile corresponds to a fraction of images from a given row that were recognized as belonging to the given column (true positive ratio on diagonal). In most cases, the TPR is higher for the viewpoint-aware network – most notably for SF Zenek, an increase from 51.9% to 69.7%. With two classes (SM Bordo, WM Vanessa) the viewpoint-aware network performed worse in terms of TPR. However, in those cases the classification precision (ratio of correct predictions to all predictions as this class, interpreted as probability that a prediction is correct) was significantly higher: 92.80% vs 91.92% for Bordo and 81.43% vs 77.60% for Vanessa.

This confirms that the viewpoint-aware approach is more powerful on average, but the scale of the difference would depend on weights assigned to errors of each kind.

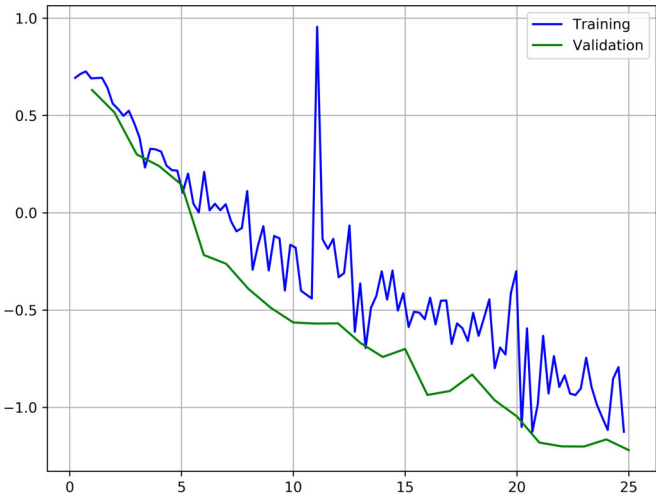

Fig 2. Loss function logarithm on training and validation sets throughout training

TABLE II.
VARIETY CLASSIFICATION RESULTS

Measure	Viewpoint-ignorant	Viewpoint-aware
Accuracy	96.65%	97.24%
Sensitivity	86.63%	88.97%
Specificity	98.09%	98.42%

V. CONCLUSIONS

We have presented a viewpoint-aware double-stream convolutional neural network and proved its superior performance at classification of barley grain varieties. The system performed better on average than a previously shown viewpoint-ignorant network, with slight variations in performance at particular classes.

Those differences might depend on the actual properties of the grains themselves. A detailed study into grain classification would have to account for many such factors, for example phenotypic variability of barley across vegetation seasons.

The system could in principle be trained in an end-to-end setup, if only the dorsal/ventral annotations were available. Due to the image acquisition technique as well as the nature of the imaged objects, obtaining those annotations during data acquisition is not trivial. This is however a limitation of the data imaging system, not our proposed machine learning system.

ACKNOWLEDGMENT

We wish to thank Piotr Lampa and Krzysztof Wall for performing data acquisition.

8th International Workshop on Artificial Intelligence in Medical Applications

THE workshop on Artificial Intelligence in Medical Applications – AIMA'2018—provides an interdisciplinary forum for researchers and developers to present and discuss latest advances in research work as well as prototyped or fielded systems of applications of Artificial Intelligence in the wide and heterogenious field of medicine, health care and surgery. The workshop covers the whole range of theoretical and practical aspects, technologies and systems based on Artificial Intelligence in the medical domain and aims to bring together specialists for exchanging ideas and promote fruitful discussions.

TOPICS

- Artificial Intelligence Techniques in Health Sciences
- Knowledge Management of Medical Data
- Data Mining and Knowledge Discovery in Medicine
- Health Care Information Systems
- Clinical Information Systems
- Agent Oriented Techniques in Medicine
- Medical Image Processing and Techniques
- Medical Expert Systems
- Diagnoses and Therapy Support Systems
- Biomedical Applications
- Applications of AI in Health Care and Surgery Systems
- Machine Learning-based Medical Systems
- Medical Data- and Knowledge Bases
- Neural Networks in Medicine

Abstract—**This paper introduces a user evaluation of several approaches for an automated similarity detection between study materials and curriculum description in the field of medical and healthcare education. Our objective is to present an effective methodology of getting relevant feedback from medical students and teachers. Two various data sets (electronic study materials represented by interactive educational algorithms on the AKUTNE.CZ platform and the curriculum of the General Medicine study programme) are processed. For the purposes of this work, text similarity between two data sets is expressed lexically, i.e. character-based (n-gram) similarity as well as term-based similarity methods are used. We present the comparison of five selected approaches to similarity calculation as well as an objective discussion covering our experience with and pitfalls of user evaluation.**

I. Introduction

Medical and healthcare studies cover a variety of useful information and sources used for learning and teaching leading to professional development. In general, any high-quality education requires that materials guaranteed by experts are available; these materials then constitute the curricula of individual study programmes. In the period between matriculation and graduation, students face a large amount of knowledge and skills to be acquired, which is repetitively emphasised in lectures, seminars and clinical practices. By way of illustration, the General Medicine master's degree programme at the Faculty of Medicine of the Masaryk University contains around 150 obligatory courses which are described by approximately 1,200 events (learning units) and 7,000 competency objects (learning outcomes); in total, this makes up more than 2,500 pages of text. Moreover, each of above-mentioned courses has a set of recommended study materials which are available either in the printed form (scripts/textbooks, atlases, monographs etc.) or in the electronic form (presentations, virtual patients/interactive educational algorithms, educational websites, etc.). With respect to human cognitive abilities, it is virtually impossible to carefully read and remember every single detail of all learning units and book chapters, including their linkages and co-dependencies [1]. This paper picks up the threads of the authors' previously published work, where the development and implementation of modern interactive tools [2], [3], as well as a complex analysis and mapping of medical and healthcare curricula [4]–[7], were introduced. There is also given a proposal of several approaches for an automated similarity detection between study materials and curriculum description in the field of medical education, including the evaluation of achieved results by users. The authors strived to get relevant feedback from medical students and teachers in terms of a systematic and objective evaluation of links between a given virtual patient and particular building blocks (learning units) of the curriculum. The following research questions were formulated in order to define and subsequently solve a particular research problem: What is the relation between the achieved results in a form of detected similarities done by computer and an evaluation by users (medical student and teachers)? Which approach of similarity detection can be effectively implemented in a particular domain of medical education?

II. Methods

A. Input data set

For the purposes of similarity detection between medical education data, we decided to process two various data sets: (i) electronic study materials represented by interactive educational algorithms on the AKUTNE.CZ platform[1] (77 virtual patients described by approximately 550 standard pages of text in total) and (ii) the curriculum of the General Medicine study programme taught at the Faculty of Medicine of the Masaryk University, represented by a full metadata description on the OPTIMED curriculum management system[2] [3] (1,232 learning units described by approximately 2,600 standard pages of text in total). Both input data sets were prepared in English language in order to eliminate problems related to a rather complicated morphology of the Czech language. As for the evaluation by users, we chose a subset of 16 learning units of a course entitled "Diagnostic imaging methods", which provides an introduction to the study of nuclear medicine, more specifically the study of radiology and imaging methods, including CT, MR, X-ray, angiography and ultrasound. All of these units are fully described by all mandatory and optional metadata, covering one complete topic and one complete course in the fourth year of study of the General Medicine. This choice of this particular course was consulted with senior experts in a field of medical education because some general overlapping

This work was not supported by any organization

[1] http://www.akutne.cz/index-en.php

[2] http://opti.med.muni.cz/en/

topics and areas with interactive algorithms were expected here. One of the main motivation given by senior teachers to select this special area was the fact that imaging methods presuppose sufficient image documentation to be used in interactive educational algorithms. Moreover, the quality and length of metadata description of all above-mentioned learning units were sufficient in terms of text-based analysis.

B. Similarity calculation

The similarity of text documents can be understood in two different ways – either semantical or lexical. The former refers to similarity in meaning and used context, whereas the latter represents similarity of character sequences. In this pilot study, we understand text similarity lexically. According to [8], we can classify lexical or string-based text similarity methods into character-based groups and term-based groups. The n-gram method is one of the character-based methods introduced in this pilot study. On the other hand, the term-based methods were implemented using several string measures – the normalised Pearson correlation, the cosine similarity, the extended Jaccard coefficient and the Dice coefficient. Each of used methods is briefly described in the following paragraphs.

C. Character based (n-gram) similarity

The comparison through a pg_trgm module (a PostgreSQL database engine that can be installed into an existing database using a simple SQL command, namely CREATE EXTENSION IF NOT EXISTS pg_trgm) is one of the approaches we used to calculate the measure of similarity between selected learning units at the OPTIMED portal and interactive educational algorithms at AKUTNE.CZ. This extension of the PostgreSQL standard database provides functions and operators to compare the similarities and distances of input text strings. Generally speaking, the pg_trgm is an n-gram (character-based) algorithm for similarity measurement [8]. In this case, N is equal to three and therefore, the measuring unit is called a trigram. In other words, a trigram is a group of three consecutive characters taken from an input string.

We are able to measure the similarity of two strings by counting the number of shared trigrams (there is a similarity to an ASCII alphanumeric text based on trigram matching). This simple idea turns out to be very effective for measuring the similarity of words in many natural languages (e.g. English) [9]. For example, the set of trigrams in the word "pet" is following: "p", " pe", "pet", "et " (the algorithm takes the input word with two spaces prefixed and one space suffixed). We expect that also in professional terminology, these similarities would be quite easily identifiable.

The pg_trgm module provides four functions and two operators. For our purposes, the function called similarity is the most interesting one, taking two strings to be compared. The function *similarity(text, text)* returns a number between 0 and 1 which indicates how similar the two inputs strings are: zero means that the two strings are completely different, whereas one indicates that the strings are completely identical. In the next step, the operator *text* <-> *text* returns the distance between two strings; it is defined as one minus the similarity of strings.

We computed all possible combinations of learning units and virtual patients/interactive algorithms using the similarity functions and stored the result in a database table (see Table 1) for further analysis and comparison with other algorithms. Similarity column represents computed trgm similarity between a learning unit and an algorithm. Correctness in interpretation of similarity results depends on our experts' expectations. If the two subjects are similar, we want to measure high similarity value.

D. Term-based similarity

Term-based similarity approaches require that a similarity measure is chosen. A similarity measure quantifies the similarity between two numeric vectors of the same length. When using this approach, text documents are represented as bags of words, and a term-frequency matrix containing the counts of a word occurrence is computed. Figure 1 represents the process of computing text similarity between two documents.

As mentioned above, four similarity measures (the normalised Pearson correlation, the cosine similarity, the extended Jaccard coefficient and the Dice coefficient) were used to compute similarities between virtual patients/interactive algorithms from the AKUTNE.CZ portal and learning units form the OPTIMED platform. Each similarity measure is computed in a slightly different way and might have a correspondingly different interpretation. The normalised Pearson correlation is a centred correlation similarity measure. The cosine similarity is a measure of similarity between two vectors of an inner product space that

TABLE I.
EXAMPLE OF DATABASE TABLE INCLUDING SIMILARITIES.

id_learning_unit	id_algorithm	title_learning_unit	title_algorithm	similarity
890	77	Protection against radiation, principle of skiagraphy and skiascopy	Car accident	0.3278
891	77	Principle of computer tomography (CT), magnetic resonance (MR) and ultrasound, new horizons	Car accident	0.1798
894	77	Abdominal radiology	Car accident	0.2433
895	77	Uroradiology	Car accident	0.1857

measures the cosine of angle between them. The extended Jaccard similarity is computed as the number of shared terms over the number of all unique terms in both vectors. And finally, the Dice coefficient is defined as twice the number of common terms in the compared vectors divided by the total number of terms in both vectors [8], [10]. These similarity measures lie between 0 and 1. Zero means that two vectors are completely different, whereas one indicates that they are completely identical.

	W_1	W_2	...	W_n
X	n_{11}	n_{12}	...	n_{1n}
Y	n_{21}	n_{22}	...	n_{2n}

Fig. 1 The process of similarity computing.

In our work, all term-based computations were conducted in the R software using the *dplyr*, *tm* and *proxy* packages. First of all, documents from both sources were preprocessed, i.e. HTML tags, punctuation, digits, other special characters and words shorter than three characters were systematically removed. Afterwards, specific words using both a Google stop-word list and a customised stop-word list were removed. In the second step, word occurrence frequencies for each single document were counted. And thirdly, similarities between individual frequency vectors of documents (virtual patients/interactive algorithms) from AKUTNE.CZ and OPTIMED educational texts/learning units were computed using all of the selected similarity measures.

E. Online evaluation tool

A web-based tool has been designed and developed in order to obtain an effective evaluation of achieved results (in a form of detected similarities) by users (medical teachers and students). Using this tool, objective opinions critically assessing the relevance between virtual patients/interactive algorithms and a particular learning unit can be systematically organised and processed. The evaluation module is integrated into the OPTIMED curriculum management system and offers the possibility to view the underlying data from both systems including an easy collection of the users' evaluation via an online form (see Fig. 2). A group of twelve evaluators (fifth and sixth year medical students, young and senior teachers) was involved for the purposes of our pilot evaluation. First of all, they needed to get acquainted with the name of the learning unit and with its brief description. Furthermore, they were invited to view the completed content of an evaluated learning unit, which was available via a direct link to the OPTIMED platform. Afterwards, the users started to evaluate the relevance of available virtual patients/interactive algorithms. Each individual Akutne.cz interactive algorithm was described by a title, a short description and keywords. The users' opinions were expressed using a marking system (grading scale) similar to that used in schools (i.e. the Likert scale from 1 to 5), where 1 meant that the interactive algorithm was very relevant to the learning unit and 5 meant that the interactive algorithm was not relevant to the learning unit at all.

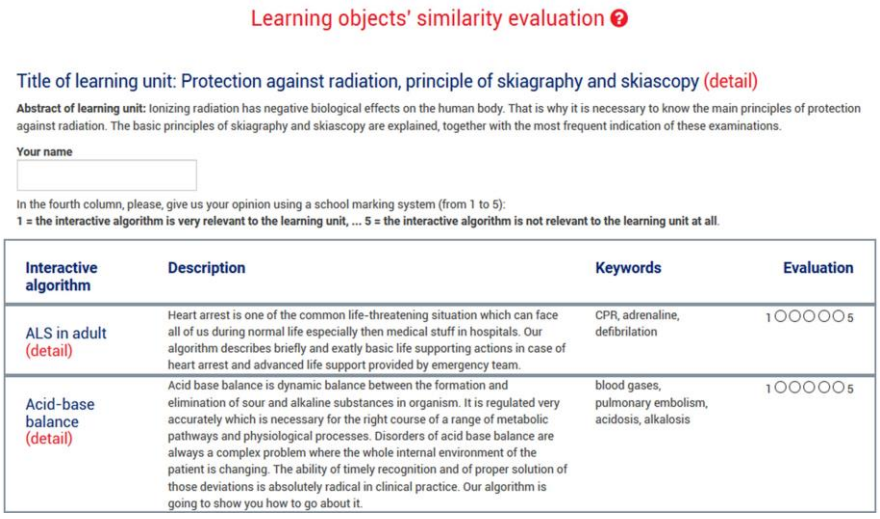

Fig. 2 Online form allowing evaluation of the teaching materials (relevancy of Akutne.cz interactive algorithms to a particular learning unit).

III. RESULTS

A. Overview of calculated similarities

The general overview (see Fig. 3 and Table 2) shows the comparison of five chosen approaches to similarity calculation in the form of a box plot chart, where the similarity measurements between all 77 interactive algorithms and 1232 learning units were taken into account. From our point of view, it is obvious that the pg_trgm module and its similarity function are very useful for cases where we expect to determine whether or not the original document and its copy are modified. It will very precisely and quickly find out whether there are differences in documents or whether the documents are identical.

On the other hand, this approach is not very appropriate for the comparison of two completely different documents, especially because it is dependent on the volume of the documents' content. Therefore, for the purposes of our pilot study, pg_trgm has been eliminated and the attention was only paid to four similarity measures (the normalised Pearson correlation, the cosine similarity, the extended Jaccard coefficient and the Dice coefficient), as described above.

After an in-depth analysis of the results, we discovered that in many cases, the cosine similarity, the extended Jaccard coefficient and the Dice coefficient indicated zero similarity because particular pairs of documents had no words in common. Nevertheless, the normalised Pearson correlation coefficient returned a non-zero value. That might be due to the fact that the correlation is a coefficient of linear dependency of two vectors. For example, let us compare a short text document (namely „What similarity measure value do we measure") with another short text document (namely „if correlation is used?)". The computed frequency vectors have the following form:

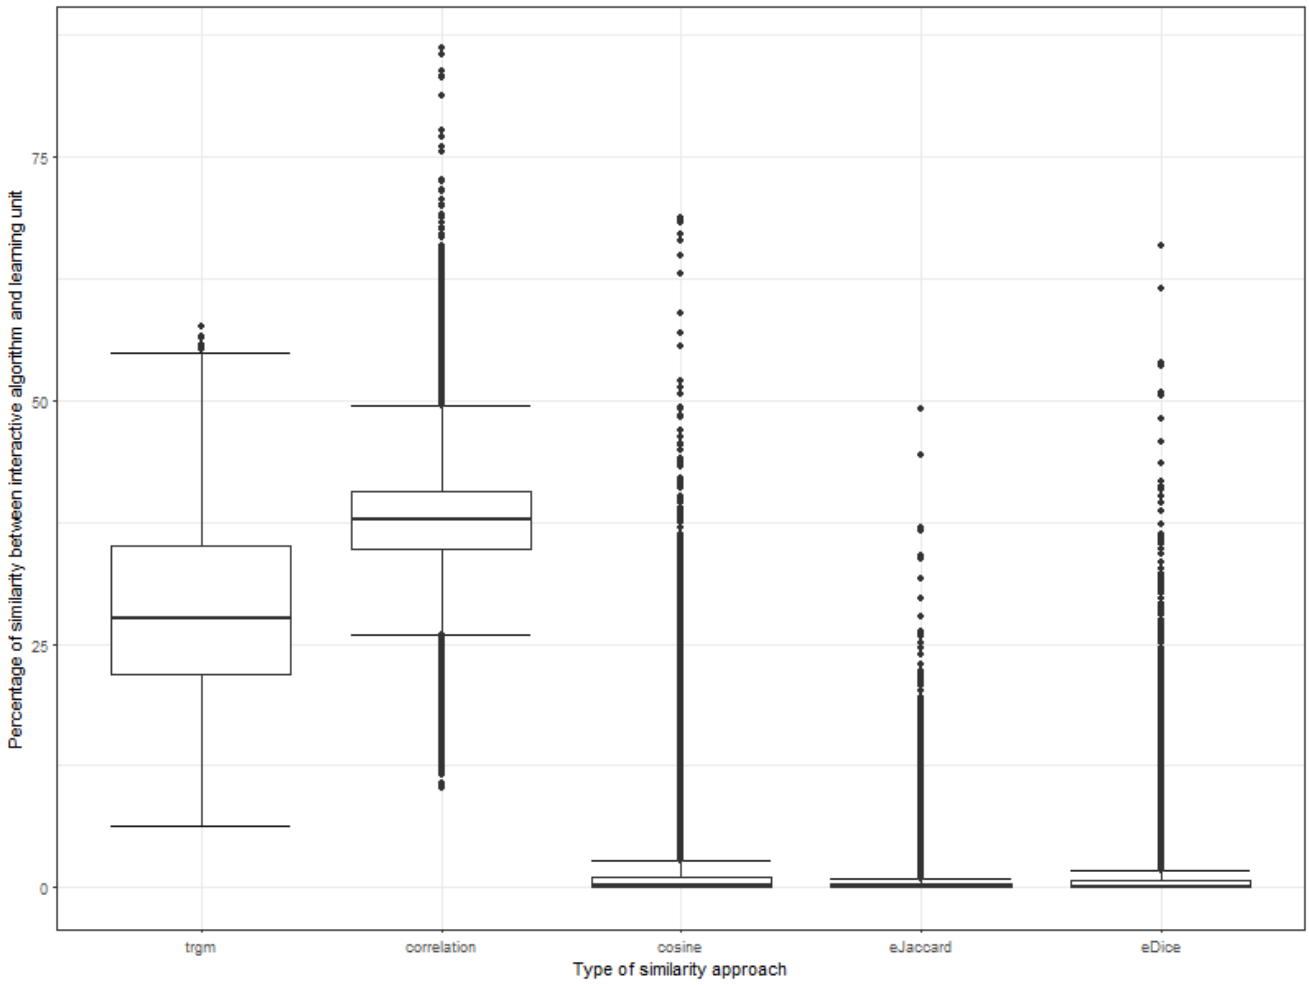

Fig. 3 Box plot representing five approaches for similarity calculation (minimum, maximum, median, average, upper and lower quartiles).

```
terms         freqs.x   freqs.y
correlation   0         1
measure       2         0
similarity    1         0
used          0         1
value         1         0
what          1         0
```

and the corresponding values of similarity measure are as follows:

```
correlation   0.07125354
cosine        0.00000000
eJaccard      0.00000000
Dice          0.00000000
```

This result shows that the correlation takes into account the whole vectors and its value depends on the vector structure rather than just intersection positions. Considering the above-described issue, we assume that the normalised Pearson correlation is not suitable for our text comparisons as out lexical understanding of term frequency in documents.
Therefore, all of our following analyses are conducted on cosine, extended Jaccard and Dice similarity measure outputs.

Figure 4 shows cosine, extended Jaccard and Dice similarity measures based on the normalised Pearson correlation coefficient, which calculates the linear correlation between two variables. The values between measures (0.923. 0.936, 0.996) imply that a linear equation describes the relationship between these measures perfectly, i.e. high positive correlation. Generally, cosine tends to return the highest values, whereas extended Jaccard tends to return the lowest ones. Nevertheless, all three measures provided very similar results.

B. Overview of calculated similarities

In terms of the pilot evaluation of achieved results (calculated similarity measures using various approaches), a set of learning units describing a complete course entitled "Diagnostic imaging methods" were used. Our users (medical students and teachers) used an online form to evaluate the relevance between learning units (OPTIMED) and interactive algorithms (AKUTNE.cz). Figure 5 represents the comparison of similarities (based on the normalised Pearson correlation coefficient) between three measures and the evaluation by users. It is immediately obvious that there is no linear correlation between any similarity measure and the evaluation by users. All algorithms used in a term-based process of similarity calculation provide very similar results, but the user evaluation of content similarity indicates no relationship or dependency between them.

IV. DISCUSSION

Based on statistical calculations, similarities and common features / terms were found between interactive algorithms in the AKUTNE.cz platform and learning units in the OPTIMED platform. Contrary to our expectations, this study did not find significant similarity between our calculated results of cosine, extended Jaccard and Dice similarity and ratings of users (medical students and teachers). We concluded that a number of factors play a role in determining the results.

Perhaps the most serious limitation of this analysis is an inappropriate choice of the course "Diagnostic imaging methods" with its very specific content and the subsequent search for similarities with a set of interactive educational algorithms in the AKUTNE.CZ platform, which were designed as teaching aids for other courses of the Medical Faculty curriculum: First Aid, Intensive Medicine, Anesthesiology and Pain Management. The fact that X-ray and other imaging methods were used in almost every algorithm only demonstrates that these are frequently used imaging techniques in acute medicine, not that X-ray should be the learning outcome of individual algorithms.

Another important confounding factor is the keywords selection. We believe that mechanically chosen keywords lead to an overinterpretation of search results; the most frequent ones do not represent the most important words, i.e. the keywords. It became obvious that keywords chosen by the machine might have not agreed and in some cases really disagreed with the algorithm's keywords. Undoubtedly, if keywords of the algorithms as defined by the creators had been used, such similarity would have not occurred and it would have increased the accuracy. Moreover, there is definitely space for a systematic improvement of a customised stop-word list. We will need to eliminate terms that do not bring the required information value.

Human evaluators may have contributed to misleading results rather significantly in several ways. Some evaluators had been involved in the design of interactive educational algorithms, which inevitably led to a bias. Some evaluators might have provided an incorrect evaluation due to a misapprehension and/or an unclear assignment. It is important to point out that human evaluators tended to focus on similarities in the meaning of concepts and terms, unlike the machine-based and statistical evaluation of similarities. One improvement to be possibly considered in future might be an optimisation of the evaluation process itself, which should be focused and implemented as a two-stage analysis in the follow-up to this pilot study. First of all, appraisers/evaluators/users would identify similarities according to established keywords, followed by their own analysis of content (abstracts and then full texts). From the methodological point of view, this process would be adopted from the process of assessing professional resources in literature reviews [11], [12]. There is also the possibility to carry out the evaluation as a three-stage process (the third stage would be a peer discussion among evaluators), but it is clear that such a process would be very time-consuming.

Yet another challenge lies in the subjective rating of significance for evaluators and users, which stems from reasoning of both practical and scholarly significance of the teaching problem as well as the scope or the respective teaching topic and issue. In other words, students' and teachers' views could differ when evaluating the learning units and interactive algorithms. Furthermore, the specialised orientation of evaluators could be the explanation for results achieved from their qualitative evaluation: most of our evaluators/users in the pilot study were professionals most familiar with acute care. In their daily practice, they are much more focused on acute and rescue interventions with the goal of saving lives rather than focusing on examination methods, especially not on radiology and imaging methods. Another possible explanation of our findings from qualitative evaluations is that users / evaluators could not see a clear link between the two assessed contents of study materials and interactive algorithms, and their views were reflected in the evaluation. What should be highlighted is that even this finding could help us improve future development of interactive algorithms: there is more space for visual documentation of a clinical condition in intensive care because there is strong evidence that imaging documentation is helpful in the education of healthcare professionals [13]–[15].

We must also emphasise that an important role was played by the fact that the volume of evaluated study materials and interactive algorithms was relatively large (n = 77 virtual patients/interactive algorithms) and that all evaluators carried out their evaluations independently, without the opportunity to communicate with others.

Despite the fact that inconsistencies were identified in our "quantitative/mathematical" and "qualitative – user view" evaluation, we are still convinced that the chosen procedure was appropriate to the above-mentioned set of objectives. We have repeatedly verified that an automated statistical evaluation must always be accompanied by an expert judgment and by an evaluation provided by target users of teaching materials [1]. At least we have verified that our methodology can reveal potential gaps as well as new possibilities of linking study materials to improve the learning process and to increase the students' preparedness for clinical practice. In the follow-up work, we would also like to approach other specialists who might provide their feedback as evaluators; as we have already mentioned, the feedback in this case was mostly provided by intensive care specialists and anaesthetists.

ACKNOWLEDGMENT

***Abstract*—Fundus images are one of the main methods for diagnosing eye diseases in modern medicine. The vascular segmentation of fundus images is an essential step in quantitative disease analysis. Based on the previous studies, we found that the category imbalance is one of the main reasons that restrict the improvement of segmentation accuracy. This paper presents a new method for supervised retinal vessel segmentation that can effectively solve the above problems. In recent years, it is a popular method that using deep learning to solve retinal vessel segmentation. We have improved the loss function for deep learning in order to better handle category imbalances. By using a multi-scale convolutional neural network structure and label processing approach, our results have reached the most advanced level. Our approach is a meaningful attempt to improve blood vessel segmentation and further improve the diagnostic level of eye diseases.**

I. Introduction

RETINAL fundus images have been widely used for diagnosis, screening and treatment of cardiovascular and ophthalmologic diseases[1], including age-related macular degeneration(AMD), diabetic retinopathy(DR), glaucoma, hypertension, arteriosclerosis and choroidal neovascularization, among which AMD and DR have been considered as two leading causes of blindness[2]. Vessel segmentation is a basic step for the quantitative analysis of retinal fundus images[3]. The segmented vascular tree can be used to extract the morphological attributes of blood vessels, such as length, width, branching and angles.

Moreover, the vascular tree has been adopted in multimodal retinal image registration [4]and retinal mosaic [5]as the most stable feature in the images. In [6], the vascular tree is also used for biometric identification due to its uniqueness. Manual segmentation of the vascular tree in retinal images is a tedious task that requires experience and skill. In the development of a computer-assisted diagnostic system for ophthalmic disorders, automatic segmentation of retinal vessels has been accepted as a vital and challenging step. The size, shape and intensity level of retinal vessels can vary hugely in different local areas. The width of a vessel often ranges from 1 to 20 pixels, depending on both the anatomical width of the vessel and the image resolution. The existence of vessel crossing, branching and centerline re?ex makes it difficult to segment the vessels accurately using artificially designed features. Pathologies in the form of lesions and exudates can further complicate the automatic segmentation. In the past decades, several methods have been proposed for the segmentation of vessels in retinal images, and they can be divided into two categories: unsupervised and supervised methods.

Both classic one-stage object detection methods, like boosted detectors [5]and DPMs(Deformable Parts Model) , and more recent methods, like SSD(Single Shot Multi-Box Detector) , face a large problem of class imbalance during training. These detectors evaluate huge candidate locations per image but only a few locations contain objects. This imbalance causes two problems: (1) training is inef?cient as most locations are easy negatives that contribute no useful learning signal; (2) Simultaneously, the negatives can overwhelm training and lead to degenerate models. A common solution is to perform some form of hard negative mining [6] that samples hard examples during training or more complex sampling/reweighing schemes[7]. In contrast, we show that our proposed focal loss naturally handles the class imbalance faced by a one-stage detector and allows us to ef?ciently train on all examples without sampling and without easy negatives overwhelming the loss and computed gradients.

This paper presents a segmentation method that is suitable for class imbalance. This paper proposes a multi-scale convolutional neural network and improves the traditional loss function, and improves the class labels. Our method outweighs the most advanced methods reported in terms of sensitivity, specificity and accuracy. (1) The proposed method solves the problem of class imbalance in the traditional segmentation method, so that deep learning can better handle the task of image segmentation of the fundus. (2) A series of procedures proposed in the article can be used not only in segmentation tasks but also in various task types such as packet classification detection, and have a wide range of versatility.

II. THE PROPOSED METHOD

A. Motivation

We carefully combed the work of related work and found that most of the previous methods used to perform the two-class task were not evenly sampled. We have found that class imbalances lead to submerged samples, which is usually not

what we want. We explore a solution to the problem from three parts: loss function, network structure and category labels.

The others have done much work in designing robust loss functions (e.g., Huber loss) that reduce the contribution of outliers by down-weighting the loss of examples with large errors (hard examples). So our focal loss functions is designed to address class imbalance by down-weighting inliers (easy examples) such that their contribution to the total loss is small even if their number is large, rather than outliers. In other words, the focal loss performs the opposite role of a robust loss: it just trains on a sparse set of hard examples.

The multi-scale network structure is mainly composed of two deep convolutional network stacks, according to Jarrett . Thus a good multi-level network model to achieve effective target recognition is an important part in our work. The network model in this paper is shown in Figure 1. However, the traditional multi-scale method scales the image segments to different scales and cannot express the boundary of the target region accurately. Thus the method in this paper is based on the selection of each pixel in the image as the center. We can see in Figure 1 two different scale image segments generate input of two deep convolutional networks. The low-level feature extraction network structure first extracts low-level feature information of large-scale image segments, and then uses local refined network structure to capture local region feature information from small-scale image segments. To compare with the traditional multi-scale method, the difference is not that multiple scales separately extract features of different size images. In this paper, the low-level features are combined with the image features extracted from the first layer of the local refinement network. After subsequent network operations, a dense and complete feature vector is obtained, which greatly improves the accuracy of image pixel category prediction.

B. Loss function improvement

The usual method in the objective function of network optimization is the cross-entropy loss function, as followed:

$$E = -\sum_{x} p(x) log(q(x)) \tag{1}$$

Where $p(x)$ is the true distribution of the sample and $q(x)$ is the estimated probability obtained through training. When the cross-entropy loss function is used for a two-category task, its form is:

$$E = \begin{cases} -loh(p), & \text{if } y = 1 \\ -log(1-p), & \text{otherwise} \end{cases} \tag{2}$$

The terrestrial truth category is specified in $y \in \{\pm 1\}$ above and $p \in [0, 1]$ is the estimated probability of the model for the category of label $y = 1$ For symbol convenience, we define p :

$$p = \begin{cases} p, & \text{if } y = 1 \\ 1-p, & \text{otherwise} \end{cases} \tag{3}$$

However, in the category imbalance problem, sometimes the difference between positive and negative sample ratios is very different. Taking a fundus image as an example, blood vessel pixels in a single image are only one-fifth that of non-vascular pixels. This imbalance leads to two kinds of situations: (1) Excessive samples of negative examples cause the information of positive examples to be difficult to be effectively learned and even concealed. (2) Simple negative factors lead to training shifts and make the model degenerate. Therefore, we propose an improvement to the cross-entropy loss function that can solve this kind imbalance problem. More crucially, this improvement can make the loss function able to calculate the difficulty in judging every sample, then we can give higher weight to those samples that are more difficult to distinguish. We call the new loss function LCE (Le Cross Entropy), LCE is defined as:

$$E = -\alpha * cos(\beta * p) * log(p) \tag{4}$$

$$\alpha = \frac{\alpha^*}{\beta} \tag{5}$$

Among them, the value ofβ is $\frac{\pi}{2}$. The reason for the value of β is that the range of p is $(0, 1)$, so that $\beta * p$can have the same mapping range as p . The weight α is the balance coefficient, usually $\alpha \in [0, 1]$. This means that the real balance coefficient is actually α^* , but for the sake of clearly, we uses α to describe it. When using LCE as a loss function, we noticed that it has the following two characteristics: (1) When an example is misclassified and p is small, the loss will not be affected. When p is larger, then α goes to zero, and the loss of well-classified examples is reduced. (2) The balance factor ęÁ effectively adjusts the weight of the instance. With the change of ęÁ, LCE can adapt to different degrees of class imbalance. In our experiment, the best results are obtained when ęÁ is taken as 0.25. About the first feature, we take a specific example to illustrate. In the case of $\alpha = 0.2$, and $p = 0.9$, the results of LCE is 33.3 times lower than CE, and the value of loss function when $p \simeq 0.2$ is 50 times lower. From the data shown in the above examples, we can find that correcting misclassification examples is necessary.

C. The Proposed Architecture

In this study, we designed a multi-scale convolutional neural network structure to segment blood vessels from fundus images. In the figure 1, we will show the details of this network in this work. The network consists of two consecutive convolution structures with input sizes of 13 * 13 and 17 * 17 respectively. The convolution kernel we have chosen on each convolutional layer is 5*5 in size and each time we move kernel one pixel. Networks of different scales have a similar convolutional layer structure. The first convolutional layer has 64 feature plots and the second convolutional layer has 128 feature plots, and the third convolutional layer has 256 feature plots. After each convolutional layer, we use a rectifying linear unit (ReLU) excitation as an activation function. As shown in this article[8], using ReLU as an activation function for the convolutional layer can speed up the training of the network. After the features are extracted from the convolution layer, we add the feature maps and connect them with the fully

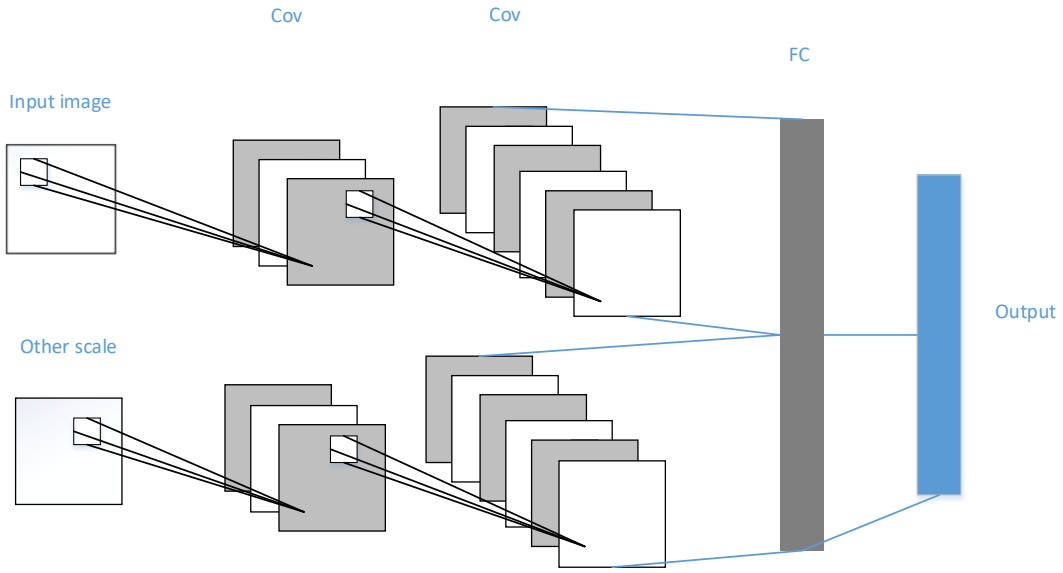

Fig. 1. The Structure of Multi-Scale Convolutional Neural Network

connected layer. It should be noted that the full-connected layer is not only one layer. Only one layer is drawn on the graph for the sake of simplicity of the view. In fact, there are three full-connected layers. We used dropout learn more powerful skills and reduce overfitting. The technique sets the output of each neuron to zero with a probability of 0.5. Finally, we use the softmax function to classify and use our improved cross-entropy function as an energy function.

D. Label Processing

In deep learning, the handling of sample tags is a part that is easily overlooked, especially in binary tasks. The tag y_- is simply designed as $y_- \in \{\pm 1\}$ or $y_- \in (0,1)$ .However, in the traditional machine method, the processing of the label has been proved to be an effective method to improve the accuracy of the classifier, and this method does not have any additional requirements for the computing power. Therefore, we try to introduce sparse variables into the label design of deep convolutional neural networks. The new tag y^* is defined as:

$$y^* = \alpha * y_- + \varepsilon \tag{6}$$

Where ęÁ is called the proportional coefficient, and its size depends on the proportion of the positive and negative samples in the training set. This coefficient was specially designed to solve the imbalance problem. ęÅ is called a sparse variable. It is to bias the same kind of sample. We usually convert segmentation tasks into classification tasks, and convolutional neural networks as a classifier, its role can be simplified to find the optimal classification plane between different types of samples. By adding sparse variables to the category labels, increasing the distance between the classes' classification planes has been used in traditional machine learning. We refer to this approach to deep convolutional neural networks.

TABLE I
PERFORMANCE OF ε-DRAGGING ON DATA POINT IN TWO CLASSES

	class	y	y after ε-Dragging	
x1	1	[1,0]	$[1+\varepsilon_{11}, -\varepsilon_{12}]$	$\varepsilon_{11}, \varepsilon_{12} > 0$
x2	1	[1,0]	$[1+\varepsilon_{21}, -\varepsilon_{22}]$	$\varepsilon_{21}, \varepsilon_{22} > 0$
x3	2	[0,1]	$[-\varepsilon_{31}, 1+\varepsilon_{32}]$	$\varepsilon_{31}, \varepsilon_{32} > 0$
x4	2	[0.1]	$[-\varepsilon_{41}, 1+\varepsilon_{42}]$	$\varepsilon_{41}, \varepsilon_{42} > 0$

Table 1 further explains our method, which reports the four data points in the two categories. Their class label vector is listed in the third column. Now, if we group together the first element of the class labeling vector, we get "1,1,0,0". In this way, a binary class partition can be obtained in which the first two is divided into one class, and the latter two classified data points are classified into another class. After label processing is performed, their image will change from "1,1,0,0" to"$1+\varepsilon_{11}$,$1+\varepsilon_{12}$,ε_{13},ε_{14}" science all are non-negative, this processing can help expand the distance between classes after data point mapping.

E. Model training

Our method does not require image preprocessing including image enhancement, which greatly simplifies the difficulty of segmentation tasks and improves the versatility of the method. According to the mask image, the fundus image part of the original image is centered on each pixel, and we can get the classification of the preset scale, and after we delete the sample of the edge part sample beyond the mask range, remain about 150 samples. Millions of sample drawings. One million of

them are training sets and 500,000 are test sets. However, our method does not use all the training set samples for training. We used a special selection method to obtain samples that was only one-tenth of the original training set. This greatly speeds up the training time without losing too much classification accuracy.

We trained and tested the network on an Intel core computer and implemented it using Anconda+TensorFlow. The processor we used was the Intel Xeon(R) CPU E5-2680V3. The training on these lasted 18 hours. Between the limits of our experimental equipment, we chose a batch size of 64.During training, the weights were updated by stochastic gradient descent algorithm with a momentum of 0.9 and a weight decay of .The biases in convolutional layers and fully-connected layer were initialized to 1. The number of epochs was tuned on a validation set consisting of patches from one randomly selected subject in the training set. The learning rate was set to initially.

III. Result

A. Implementation Details

We have evaluated the nature of our proposed method on a very popular DRIVE dataset, which consists of 40 retinal images. The dataset is divided into two subsets, training sets and test sets, each set contains 20 images. The image is 565 x 584 pixels,8 bits per color channel. Only the images of training set can be used for the training of the network. First, we clip the training image into 23x23 tiles and mark each tile by the label image. Then add a slack variable to the tag based on the method above and use the mask contained in the DRIVE database to identify the FOV. All pixels of each patch should be in the FOV area, and a total of 100000 patches are obtained for 20 training images. But not all small pieces will be trained. In fact, we only used 50,000 small pieces, which accounted for only about 2

Test the performance of the segmentation algorithm in the test set. In 20 images of the test set, four images are pathological and the other are normal images. During the testing phase, we also use the first expert's tag as a basic fact. The images in all test sets are used for testing to evaluate the performance of the algorithm.

B. Evaluation Criterion

In vessel segmentation, there are two class labels: vessel and non-vessel. By comparing the segmentation results with the manual ground truth, we obtain four measures: the vessel pixels that are predicted as vessels are denoted as true positives (TP), the vessel pixels that are predicted as non-vessels are denoted as false negatives(FN), the non-vessel pixels that are predicted as non-vessels are denoted as true negatives (TN), and the non-vessel pixels that are predicted as vessels are denoted as false positives (FP).

Usually we use three criteria to compare the performance of the proposed method with other state-of-the-art methods: sensitivity (Se), specificity (Sp) and accuracy (Acc). Evaluation indicators are only calculated for pixels within the FOV.

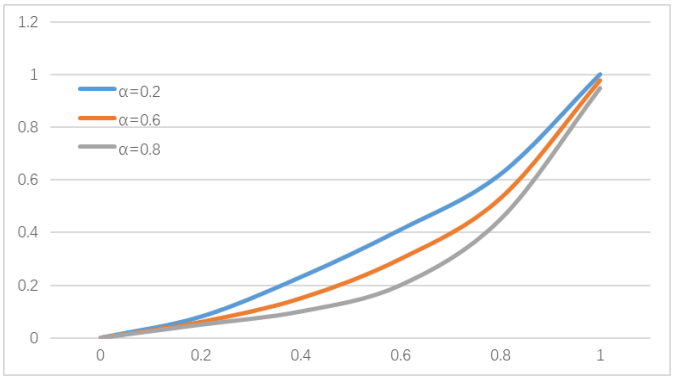

Fig. 2. Results of different segmentation methods

These metrics are defined as

$$Se = \frac{TP}{TP + FN} \tag{7}$$

$$Sp = \frac{TN}{TN + FP} \tag{8}$$

$$Acc = \frac{TP + TN}{TP + FN + TN + FP} \tag{9}$$

Because true positive score (Se) and false positive score (Sp) are sensitive to the number of sample categories. That is, when the number of samples of the binary classification problem is not balanced, these indicators cannot accurately reflect the performance of the classifier, so we also use the performance of the area under the ROC curve (AUC) evaluation method. The AUC is equal to 1 when the classifier can perfectly classify the sample. In addition, we have additionally introduced the concept of interclass accuracy.

This indicator better reflects the performance of the classifier when dealing with unbalanced categories.

C. Performance of the proposed method

Figure 2 is a comparison of our segmentation results with the traditional CNN segmentation results. Among them are (a) the original image, (b) the ground truth, (c) the segmentation result of the traditional CNN, and (d) the segmentation result of the proposed method. It can be clearly seen that our segmentation method is more delicate, and the segmentation accuracy of blood vessel details is higher and closer to the truth on the ground. The reason why our performance better is our method considers the effect of category imbalance on the segmentation of blood vessels. After modify the loss function and use multi-scale convolutional neural networks, we obviously reduce the impact of this problem on the results. In this method, the importance of the loss function is highlighted. Table III shows the comparison between the traditional CE and our proposed LCE. When using our structure at the same time, the accuracy of LCE is significantly higher than that of CE. Figure 3 shows the influence of different parameters ęÁ on the results. And through the experiments, we can get the best results when ęÁ=0.2. The proposed method is evaluated

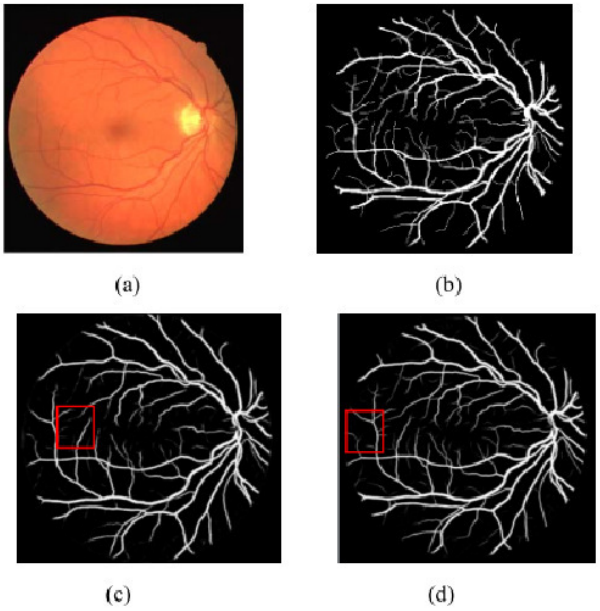

Fig. 3. The Effect of Different ęÁ Values on Loss in LCE Functions

TABLE II
COMPARISON OF CORRECT RATIOS OBTAINED BY DIFFERENT SAMPLE RATIOS ON DRIVE DATA SETS

Num	1:1	1:2	1:3	1:4
Acc	0.917	0.932	0.944	0.956

on DRIVE and STARE database images with available real ground images. The performance results are shown in TablesII and III. The performance index is calculated based on the first human observer. The accuracy, sensitivity, specificity, and AUC of the DRIVE database were 0.8347, 0.9796, 0.951, and 0.9792, respectively. The accuracy of the segmentation results of the STARE database is 0.956; the sensitivity, specificity, and AUC are 0.94471, 0.99432, and 0.988388, respectively. Figure 4 shows the performance of ROC curves on the DRIVE and STARE datasets. The average AUC of the ROC curves on the two datasets is 0.9792, 0.9743. As we know, the closer the AUC value is to 1, the better the performance of the classifier. So our retinal vessel segmentation results are excellent.

Then, we compare the proposed method with several advanced retinal vessel segmentation methods. In general, supervised learning methods have better classification accuracy than unsupervised learning methods. The methods in the reference document achieve better results than other methods because of

the use of ensemble learning methods. In a single classifier, our method has better average accuracy than other methods.

IV. DISCUSSIONS

Table II shows the accuracy of the classifier at different sample rates. On the DRIVE data set, we use the same network structure and evaluation indicators, different positive and negative sample ratios. From the above figure, we can clearly see that as the proportion of the sample much closer to the true proportion of the data set, the segmentation accuracy of our network becomes more accurate. Although it is not pursuit the unbalanced proportion on purpose, when randomly selecting small blocks from the sample set, it is actually obtained an imbalanced sample. This method can quickly classify the network, but it has no practical meaning. Because the network learning is the distribution state of the sample set itself, rather than the real characteristics of the sample.

After realizing that the above approach is not rigorous, we consider how to solve this problem. The modification of the loss function and network structure is the method that first enters our mind. Table III shows the performance of different loss functions on two data sets. After we used the improved loss function, the performance of the network has improved significantly. It is worth noting that our proposed improvement of the loss function not only has a broad prospect in this network but also in the broader field of deep learning. We are conducting experiments in this area and will soon have results. According to the definition of LCE, ęÁ is a very important hyper parameter, which determines the performance of this loss function on a specific problem. Figure 3 shows the impact of different ęÁ on network performance when we use LCE.

8	Proposed method	0.8231	0.9782	0.9560	0.9743

After our experiments, we found that when ęÁ=0.2, the best effect was obtained.

After using the method, we mentioned above, we have achieved very good results on the two data sets. The accuracy, sensitivity, specificity, and AUC of the DRIVE database were 0.8347, 0.9796, 0.951, and 0.9792, respectively. The accuracy of the segmentation results of the STARE database was 0.956; the sensitivity, specificity, and AUC were 0.94471, 0.99432, and 0.988388, respectively. In particular, except that our experiment is based on the results of a balanced sample size, other experimental results can be obtained when the sample is not balanced.

For blood vessel segmentation tasks, we are more likely to get blood vessel pixels than non-vascular pixels because blood vessel pixels are very rare and their value is much higher than non-vascular pixels. Therefore, in TableIV and Table V, our results showed a significantly higher specificity than other results. That means, in the case of a balanced sample, we only lost a little bit of accuracy, but we improved our specificity significantly. This is what we are happy to get. Our experiment has embarked on a new direction for the next study, which is not to regard accuracy as the first criterion, but rather to focus on specificity.

V. CONCLUSION

By comparing the differences of the experimental results, we found that there are unbalanced samples in the fundus image segmentation task, and we hope to improve the segmentation accuracy of blood vessels. Further we propose three solutions. By using these three methods together, we can get a better result. The deep neural network can learn hierarchically preprocessed images from it. It has a great potential in medical image processing and can help doctors easily diagnose accurately. In this paper, firstly, we use the slack variable method to increase the distance among different categories, thereby improving the performance of the classifier. Secondly, we propose a multi-scale convolutional neural network to extract the difference in information among different views, so that we can make accurate judgments. Finally, we solve the problem of unbalanced quantity among different types of samples by modifying the loss function. Our proposed method has performed well on two common data sets.

As we said above, we are conducting more tests and improvements on LCE so that it can perform well when dealing with unbalanced tasks for example target detection. The other limitation of our method is that it requires more training time than the previous method. Obviously, multi-scale networks have more parameters and the introduction of slack variables, which slows down the training speed of the network. Although the loss of time seems unavoidable, it can be acceptable to improve the accuracy. In the future, we hope to continue to improve the network structure so that it can be trained and tested more quickly.

***Abstract*—The paper is devoted to classification of MMPI (Minnesota Multiphasic Personality Inventory) profiles using fuzzy decision trees generated by means of the algorithm that uses cumulative information estimations of the initial data proposed by V. Levashenko et al. All of the stages of the classification process (i.e., fuzzification of the input data, generation of the classifier, testing the classifier) are presented and the results are discussed. A special attention is focused on determination of the center points on the MMPI scales for the fuzzification process.**

I. Introduction

OUR research, conducted for over eight years, is devoted to analysis and classification of data coming from the MMPI (Minnesota Multiphasic Personality Inventory) test (see some overview given in [1]). This test delivers psychometric data in the form of the so-called profiles (thirteen descriptive attributes corresponding to scales) used to assess patients in terms of personality traits and psychopathology. We have used several methodologies for classification of MMPI profiles which can be roughly grouped into the following categories: dissimilarity measure based classifiers, index based classifiers, classification functions, rule based classifiers, and decision tree based classifiers. A palette of classifiers has been extended by a classifier based on fuzzy decision trees. Firstly, preliminary results of research on application of fuzzy decision tress for classification of psychometric data presented in [2] are very promising in relation to results obtained for other kinds of classifiers (cf. [3]). Secondly, the character of MMPI data matches the idea of fuzzy set based approaches. For each scale included in the MMPI profile, we can define linguistic values (e.g., extremely low, very low, average, raised, high, very high, extremely high) which can be described by fuzzy sets. Fuzzy decision trees for creation of classifiers are generated by means of the algorithm based on cumulative information estimations of the initial data proposed by V. Levashenko et al. (see [4]). This algorithm is recalled in Section III-B. The main research problem, touched upon in this paper, is the determination of the intervals and/or the center points (shortly called the centers) on the MMPI scales for the fuzzification process. Therefore, we have tested different approaches which can be grouped into two categories. The first category includes approaches based on the expert knowledge used to determine intervals/centers for the fuzzification process. The second category includes approaches in which intervals/centers are induced from data.

II. Input Data

MMPI is a standardized psychometric test of adult personality and psychopathology (cf. [5]). The MMPI test delivers psychometric data in a form of the so-called profiles. Formally, a profile for the patient is a data vector consisting of values of thirteen descriptive attributes (corresponding to scales). The set of scales can be divided into two parts: the validity part (three scales: L - lying, F - infrequency, K - correction) and the clinical part (scales: $1.Hs$ - Hypochondriasis, $2.D$ - Depression, $3.Hy$ - Hysteria, $4.Pd$ - Psychopathic deviate, $5.Mf$ - Masculinity/Femininity, $6.Pa$ - Paranoia, $7.Pt$ - Psychasthenia, $8.Sc$ - Schizophrenia, $9.Ma$ - Hypomania, $0.It$ - Social introversion). In our research, we have used data coming from the WISKAD-MMPI test that is a Polish adaptation of the American test. The test originally was translated by M. Choynowski (as WIO) [6] and elaborated by Z. Płużek (as WISKAD) in 1950 [7]. The data set was collected for research by T. Kucharski and J. Gomuła in the Psychological Outpatient Clinic. It includes profiles of 1710 women. Before the profiles of women screened with the WISKAD-MMPI test formed a database for further experiments, first they had been sorted by the competent judges method - five specialists with many years of experience in the application and interpretation of the MMPI results/profiles. On the basis of these items, scores are calculated for both validity scales and clinical scales. Hence, values of descriptive attributes describing patients are expressed by the so-called T-scores [T]. The T-scores scale, which is traditionally attributed to MMPI, represents the following parameters: offset ranging from 0 to 100 T-scores, average equal to 50 T-scores, standard deviation equal to 10 T-scores. The scores are expressed as K-corrected T-Scores. The scales $1.Hs$, $4.Pd$, $7.Pt$, $8.Sc$, and $9.Ma$ are corrected by adding multiples of the scale K to them.

In our experiments, the patients' profiles are recorded in a tabular form which is formally called a decision table $DT = (U, Attr, Dec)$, where U - the set of cases (patients), $Attr = \{A_1, A_2, \ldots, A_{13}\}$ - the set of descriptive (condition) attributes corresponding to scales, $Dec = \{D\}$ - the set of decision attributes consisting of the attribute D assigning each patient from U to one of 20 classes such as the reference (*norm*) class and nosological types: neurosis (*neur*), psychopathy (*psych*), organic (*org*), schizophrenia

(*schiz*), delusion syndrome (*del.s*), reactive psychosis (*re.psy*), paranoia (*paran*), (sub)manic state (*man.st*), criminality (*crim*), alcoholism (*alcoh*), drug addiction (*drug*), simulation (*simu*), dissimulation (*dissimu*), and six deviational answering styles ($dev1$, $dev2$, $dev3$, $dev4$, $dev5$, $dev6$).

III. Methods and Tools

In this section, we present methods and tools used in experiments with classification of MMPI profiles by means of classifiers built on the basis of fuzzy decision trees.

A. Fuzzification

Fuzzification is the process that transforms the continuous value variables into linguistic variables whose domains contain linguistic values which can be described by fuzzy sets (their membership functions). Fuzzification is an important stage of the process of creation of a fuzzy decision tree based classifier. Many types of membership functions can be used to describe linguistic values, but triangular or trapezoidal shaped membership functions are the most common. In our approach, the fuzzification process consists of three stages. In the first stage, we determine intervals/centers (within the range $[0, 120]$) for each linguistic value assigned to a given descriptive attribute (scale). In the second stage, we define membership functions on the basis of centers determined in Stage 1 for each linguistic value assigned to a given descriptive attribute (scale). In the third stage, we calculate values of fuzzified descriptive attributes on the basis of membership functions defined in Stage 2. Determination of intervals/centers for the fuzzification process is one of the main research problems. In experiments, we have tested different approaches which can be grouped into two categories: approaches based on the expert knowledge used to determine intervals/centers (further, such approaches are called expert approaches) and approaches in which intervals/centers are induced from data (further, such approaches are called inductive approaches). The centers for four tested expert approaches are as follows:

- the Welsh's approach
  - all scales: 15.0, 35.0, 45.0, 55.0, 62.5, 67.5, 75.0, 85.0, 95.0, 110.0,
- the Płużek's (original) approach
  - L: 38.0, 43.0, 55.5, 75.5, 88.0,
  - F: 45.5, 60.5, 80.5, 100.5,
  - K: 36.0, 55.5, 74.5,
  - clinical scales: 34.5, 60.0, 75.5, 90.5, 105.5, 115.5,
- the Gomuła's (modified Płużek's) approach
  - validity scales: 15.0, 35.0, 42.5, 47.5, 55.0, 62.5, 67.5, 75.0, 82.5, 87.5, 100.0, 115.0,
  - clinical scales: 15.0, 37.5, 47.5, 52.5, 60.0, 67.5, 75.0, 90.0, 105.0, 115.0,
- the Gomuła's (original) approach:
  - all scales: 15.0, 35.0, 45.0, 55.0, 62.5, 67.5, 72.5, 77.5, 82.5, 87.5, 95.0, 105.0, 115.0.

The calculated centers for four tested inductive approaches are as follows:

- the K-means based approach [8]
  - L: 46.85, 55.69, 63.29, 79.58,
  - F: 56.43, 68.64, 80.82, 100.08,
  - K: 35.44, 48.60, 54.74, 66.47,
  - $1.Hs$: 53.14, 61.85, 69.29, 81.68,
  - $2.D$: 58.70, 70.22, 80.32, 92.67,
  - $3.Hy$: 55.97, 63.23, 69.61, 79.76,
  - $4.Pd$: 56.39, 65.07, 73.68, 87.68,
  - $6.Pa$: 57.45, 70.39, 83.23, 101.11,
  - $7.Pt$: 56.44, 67.28, 75.87, 95.50,
  - $8.Sc$: 58.06, 73.38, 85.22, 105.08,
  - $9.Ma$: 49.01, 58.11, 69.42, 85.47,
  - $0.It$: 51.26, 58.06, 62.39, 66.76,
- the equipotent interval approach
  - L: 46.25, 59.50, 76.25,
  - F: 55.75, 73.50, 94.75,
  - K: 38.75, 52.50, 68.75,
  - $1.Hs$: 41.25, 62.50, 89.25,
  - $2.D$: 48.75, 74.00, 99.25,
  - $3.Hy$: 42.25, 64.00, 89.75,
  - $4.Pd$: 42.25, 68.50, 95.75,
  - $6.Pa$: 44.25, 67.00, 96.25,
  - $7.Pt$: 41.75, 67.00, 88.75,
  - $8.Sc$: 45.75, 73.00, 98.75,
  - $9.Ma$: 37.25, 56.50, 83.75,
  - $0.It$: 42.25, 61.50, 75.25,
- the MDL based discretization approach (10 intervals)
  - L: 38.70, 44.10, 49.50, 54.90, 0.30, 65.70, 71.10, 76.50, 81.90, 87.30,
  - F: 47.65, 54.45, 60.75, 67.05, 73.35, 79.65, 85.95, 92.25, 98.55, 105.85,
  - K: 31.00, 37.50, 42.50, 47.50, 52.50, 57.50, 62.50, 67.50, 72.50, 79.00,
  - $1.Hs$: 36.50, 53.50, 60.50, 67.50, 74.50, 81.50, 88.50, 95.50, 102.50, 112.00,
  - $2.D$: 40.70, 57.10, 64.50, 71.90, 79.30, 86.70, 94.10, 101.50, 108.90, 116.30,
  - $3.Hy$: 37.35, 53.05, 57.75, 62.45, 67.15, 71.85, 76.55, 81.25, 85.95, 100.15,
  - $4.Pd$: 33.00, 49.50, 56.50, 63.50, 70.50, 77.50, 91.50, 84.50, 98.50, 110.50,
  - $6.Pa$: 37.65, 51.95, 59.25, 66.55, 73.85, 81.15, 88.45, 95.75, 103.05, 113.35,
  - $7.Pt$: 33.80, 50.90, 57.50, 64.10, 70.70, 77.30, 83.90, 90.50, 97.10, 103.70,
  - $8.Sc$: 35.85, 52.55, 60.25, 67.95, 75.65, 83.35, 91.05, 98.75, 106.45, 115.15,
  - $9.Ma$: 31.25, 44.75, 51.25, 57.75, 64.25, 70.75, 77.25, 83.75, 90.25, 100.75,
  - $0.It$: 31.75, 40.75, 45.25, 49.75, 54.25, 58.75, 63.25, 67.75, 72.25, 80.75,
- the MDL based discretization approach (min. 5 intervals)
  - L: 40.25, 49.50, 56.50, 62.00, 75.50, 87.75,
  - F: 52.75, 64.00, 68.00, 72.00, 78.00, 85.00, 89.50, 96.50, 106.25, 120.00,
  - K: 30.25, 36.50, 45.00, 52.00, 56.50, 64.25, 76.00, 120.00,
  - $1.Hs$: 38.25, 55.50, 58.50, 61.00, 63.50, 66.00, 70.50, 93.25, 120.00,
  - $2.D$: 44.75, 64.00, 67.50, 73.00, 85.00, 96.00, 109.75, 120.00,
  - $3.Hy$: 40.75, 58.50, 61.50, 66.00, 69.50, 73.50, 94.25, 120.00,
  - $4.Pd$: 39.75, 61.50, 65.00, 70.00, 74.50, 81.50, 103.25, 120.00,
  - $6.Pa$: 40.25, 57.50, 65.00, 70.00, 74.50, 78.50, 83.50, 97.00, 113.25, 120.00,
  - $7.Pt$: 37.75, 57.50, 61.00, 65.50, 70.50, 76.00, 85.50, 94.00, 101.75, 120.00,
  - $8.Sc$: 42.25, 62.50, 66.50, 70.00, 74.50, 81.50, 90.00, 102.50, 114.75, 120.00,
  - $9.Ma$: 33.25, 47.50, 52.50, 57.50, 61.50, 66.00, 70.50, 79.75, 97.50, 120.00,
  - $0.It$: 35.25, 53.50, 58.00, 61.00, 74.75.

In case of the K-means based approach, centers were generated for $k = 4$. In case of the equipotent interval approach, an unsupervised attribute discretization (the equal-frequency binning method) implemented in WEKA [9] was used. In this method, the same number of cases falls into each interval. Intervals are of different sizes. In case of the MDL based discretization approach, a supervised attribute discretization (the minimum length description method) implemented in WEKA was used. For more information, we refer readers to [10] and [11].

In each case, we have obtained a set (sequence) of centers located within the range $[0, 120]$. Formally, let $\{c_1, c_2, \ldots, c_{k_i}\}$ be a set of centers obtained for the i-th descriptive attribute. Triangular shaped membership functions are defined as follows.

1) For $j = 1$:

$$\mu_{c_j}(x) = \begin{cases} 1 & \text{if } x \geq 0 \text{ and } x \leq c_j, \\ 1 - \frac{x - c_j}{c_{j+1} - c_j} & \text{if } x > c_j \text{ and } x \leq c_{j+1}, \\ 0 & \text{otherwise.} \end{cases}$$

2) For $j > 1$ and $j < c_{k_i}$:

$$\mu_{c_j}(x) = \begin{cases} \frac{x-c_{j-1}}{c_j-c_{j-1}} & \text{if } x \geq c_{j-1} \text{ and } x \leq c_j, \\ 1 - \frac{x-c_j}{c_{j+1}-c_j} & \text{if } x > c_j \text{ and } x \leq c_{j+1}, \\ 0 & \text{otherwise.} \end{cases}$$

3) For $j = c_{k_i}$:

$$\mu_{c_j}(x) = \begin{cases} \frac{x-c_{j-1}}{c_j-c_{j-1}} & \text{if } x \geq c_{j-1} \text{ and } x \leq c_j, \\ 1 & \text{if } x > c_j \text{ and } x \leq 120, \\ 0 & \text{otherwise.} \end{cases}$$

Let $ls = c_j - 0.2(c_{j+1} - c_{j-1})$ and $rs = c_j + 0.2(c_{j+1} - c_{j-1})$, trapezoidal shaped membership functions are defined as follows.

1) For $j = 1$:

$$\mu_{c_j}(x) = \begin{cases} 1 & \text{if } x \geq 0 \text{ and } x \leq rs, \\ 1 - \frac{x-rs}{c_{j+1}-rs} & \text{if } x > rs \text{ and } x \leq c_{j+1}, \\ 0 & \text{otherwise.} \end{cases}$$

2) For $j > 1$ and $j < c_{k_i}$:

$$\mu_{c_j}(x) = \begin{cases} \frac{x-c_{j-1}}{ls-c_{j-1}} & \text{if } x \geq c_{j-1} \text{ and } x \leq ls, \\ 1 & \text{if } x > ls \text{ and } x < rs, \\ 1 - \frac{x-rs}{c_{j+1}-rs} & \text{if } x \geq rs \text{ and } x \leq c_{j+1}, \\ 0 & \text{otherwise.} \end{cases}$$

3) For $j = c_{k_i}$:

$$\mu_{c_j}(x) = \begin{cases} \frac{x-c_{j-1}}{ls-c_{j-1}} & \text{if } x \geq c_{j-1} \text{ and } x \leq ls, \\ 1 & \text{if } x > ls \text{ and } x \leq 120, \\ 0 & \text{otherwise.} \end{cases}$$

It is worth noting that, in each approach, intervals are disjoint. However, one can see that membership functions overlap.

Let $DT = (U, Attr, Dec)$ be a decision table containing MMPI data, where $Attr = \{A_1, A_2, \ldots, A_{13}\}$ and $Dec = \{D\}$. After fuzzification, for each descriptive attribute A_i, where $i = 1, 2, \ldots, 13$, we obtain k_i fuzzified attributes $A_i^1, A_i^2, \ldots, A_i^{k_i}$, where k_i is a number of linguistic values used for fuzzification of A_i. In case of the decision attribute D, we obtain 20 fuzzified attributes, each for one decision class, i.e., $D^{norm}, D^{neur}, \ldots, D^{dev6}$. However, values of the attributes $D^{norm}, D^{neur}, \ldots, D^{dev6}$ are binary. For example, $D^{norm}(u) = 1$ if $D(u) = norm$, and 0 otherwise, where $u \in U$.

B. Fuzzy Decision Trees

To build the classifier, we have used the algorithm for generation of fuzzy decision trees that uses cumulative information estimations of the initial data proposed by V. Levashenko et al. (see [4]). This algorithm was used by us in our preliminary experiments with the MMPI data (see [2]). The obtained results were very promising in relation to results obtained for other kinds of classifiers (cf. [3]). In general, the cumulative mutual information for a given attribute A_i, a sequence of attributes SFA, and the decision attribute D reflects the influence of the attribute A_i on the attribute D when the sequence SFA of attributes is known.

In this section, we briefly recall the algorithm used in our experiments. Let us assume the following notation: U - the set of cases, n - the number of cases, $lval(A)$ - the set of all linguistic values used for the fuzzification process of the attribute A, $cer(D^v)$ - the certainty of the decision class D^v of the attribute D, RA - the set of the remaining descriptive attributes, SFA - the set of the selected fuzzified attributes. The algorithm is recursive (see Procedure 1). There are two tuning parameters θ_{freq} and θ_{cer} used in the algorithm as the stop conditions. Expanding a tree branch is stopped when either the frequency of the branch is below θ_{freq} or when more than or equal to θ_{cer} percent of cases left in the branch has the same decision class label. Moreover, the natural stop condition is fulfilled if the set of the remaining descriptive attributes is empty (i.e., $RA = \emptyset$).

The cardinality measure of the set B of fuzzified attributes is defined as $card(B) = \sum_{u \in U} \prod_{B_i \in B} B_i(u)$. The certainty $cer(D^v)$ of the decision class D^v is calculated as $cer(D^v) = card(SFA \cup \{D^v\})$.

Procedure FDT

Data: A decision table $DT = (U, Attr, Dec)$
$RA \leftarrow Attr$; $SFA \leftarrow \emptyset$;
$E(D) \leftarrow n \log(n) - \sum_{v \in lval(D)} card(\{D^v\}) \log(card(\{D^v\}))$;
foreach $A_i \in RA$ **do**
  $E(A_i) \leftarrow n \log(n) - \sum_{v \in lval(A_i)} card(SFA \cup \{A_i^v\}) \log(card(SFA \cup \{A_i^v\}))$;
  $E(D, A_i) \leftarrow n \log(n) - \sum_{v \in lval(D), w \in lval(A_i)} card(SFA \cup \{D^v\} \cup \{A_i^w\}) \log(card(SFA \cup \{D^v\} \cup \{A_i^w\}))$;
  $CMI(A_i) \leftarrow E(D) + E(A_i) - E(D, A_i)$;
Select A_i from RA with the greatest $CMI(A_i)$;
$RA \leftarrow RA - \{A_i\}$;
foreach $v \in lval(A_i)$ **do**
  $SFA \leftarrow SFA \cup \{A_i^v\}$;
  if $\max_{cer(D_v)} < \theta_{cer}$ *and* $\frac{card(SFA)}{n} \geq \theta_{freq}$ *and* $RA \neq \emptyset$ **then**
    call FDT with $DT = (U, RA, Dec)$;
  else
    create a decision node;

C. The CLAPSS System

All of the stages of the classification process (fuzzification of the input data, generation of the classifier, testing the classifier) were performed using our software tool called CLAPSS (Classification and Prediction Software System) [12] that is a tool developed for solving different classification and prediction problems using, among others, some specialized approaches based mainly on fuzzy sets and rough sets. A new module added to CLAPSS consists of implementation of the selected methods based on fuzzy sets (especially to creation of classifiers based on fuzzy decision trees generated by means of the algorithm described in Section III-B). The user that creates classifiers based on fuzzy decision trees can select among others: a fuzzification process (*triangular*, *trapezoidal*, *Gaussian*), thresholds (*certainty* and *frequency*) to stop the process of fuzzy decision tree creation, t-norm

(*minimum*, *algebraic product*, *Lukasiewicz product*, *Einstein product*, *Hamacher product*, *drastic product*) for calculation of the certainty of rule antecedents, and a number of folds for the cross-validation procedure.

IV. Results

Our experiments were performed on real-life data described in Section II using the CLAPSS software tool (see Section III-C). In each experiment, the $5.Mf$ scale was excluded. This scale is assumed by the experts to be the weakest one. In each case, the stratified 10-cross-validation approach was used to test the classifier. In the experiments, the following settings have been used: a shape of membership functions: *triangular* and *trapezoidal*, the certainty threshold: 0.999, the frequency threshold: 0.001, the t-norm for calculation of the certainty of rule antecedents: *algebraic product*. The results of the stratified 10-cross-validation tests for all approaches (both expert and inductive) are presented in Figure 1 (for triangular shaped membership functions) and Figure 2 (for trapezoidal shaped membership functions). The results showed that expert approaches like Gomuła's (original), Gomuła's (modified Płużek's), and Welsh's are suitable for the fuzzy decision tree based classification. Among inductive approaches, good results were obtained for MDL based multi-interval discretization. It is worth noting that easy and natural diagnostic interpretation of the obtained intervals becomes the advantage of the expert approaches. Weak results obtained for the original Płużek's intervals do not seem to be surprising because this approach is recognized by the experts as rough. The approach based on equipotent intervals turned out to be inappropriate. On the basis of the results, one can see that classifiers based on fuzzy decision trees show a high effectiveness (accuracy noticeably greater than 0.9) in classification of the MMPI data. If we take into consideration solely the MMPI scales (without any additional indexes), only a few previously tested approaches are found to be such effective (cf. [3]).

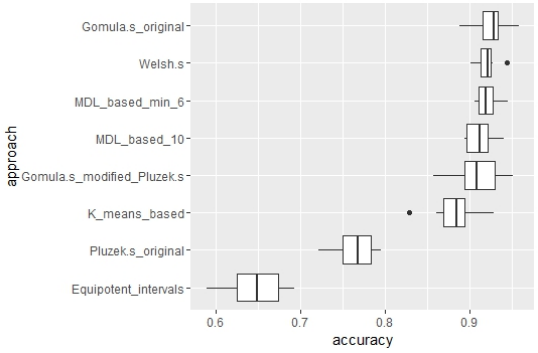

Fig. 1. Results for triangular shaped membership functions.

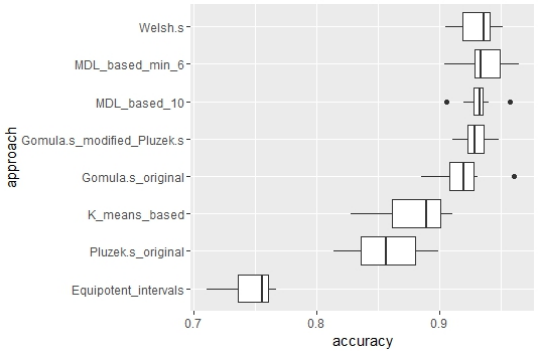

Fig. 2. Results for trapezoidal shaped membership functions.

V. Conclusions and Further Work

In general, classifiers based on fuzzy decision trees showed a high effectiveness in classification of the MMPI data. The main challenge in the future is to propose the method for searching for optimal intervals used in the fuzzification process. Simultaneously, we need to take care of diagnostic interpretation of the obtained intervals. Therefore, automated searching for optimal intervals should be aided with the expert knowledge. This fact determines the main direction of our further research. Moreover, we plan to test application of some other shapes of membership functions and some other t-norms for calculation of the certainty of rule antecedents.

***Abstract*—The paper describes the study on the problem of missing values in medical data collected to discover new dependencies between parameters in children born with intrauterine growth restriction disorder. The aim of the research is to propose a procedure that may be taken to improve the medical inference in the presence of missing data. The approach with use of unconditional mean and k-nearest neighbor imputation has been applied. The experiments proved that application of missing data imputation in original dataset yields more valuable dependencies when compared to original data, maintaining the confidence interval for goodness of fit with the original distribution above 90%. The discovered dependencies in data may establish the basis for new treatment procedures of children with intrauterine growth restriction disorder.**

***Index Terms*—missing values, imputation, medical data analysis, intrauterine growth restriction disorder**

I. Introduction

THE IMPROVEMENT of medical diagnostics and health care is based on scientific studies, which are often based on observations gathered from patients. The reliable analysis of medical dataset usually assumes that subjects of the research were chosen randomly from a greater population at the beginning of the trial. Such an approach is called a randomized controlled trial (RTC) and the analysis of its data is referred to as intention-to-treat (ITT) principle [1].

According to the ITT strategy, all the participants should be included in the analysis regardless whether their outcomes were actually collected [2]. At the same time, the ITT principle requires a complete set of data [3]. The "ideal" ITT analysis is usually not possible to perform, as the problem of missing values commonly occurs [4]. The lacking entries are basically caused by the fact that patient's data are usually gathered as a product of care actions, rather than an organized research protocol [5], [6]. Moreover, in many medical studies, the patients may withdraw or drop out from the trials, which is almost unavoidable and their data may be incomplete [1].

Therefore, appropriate procedures have been created in order to overcome the problem of missing data and estimate a treatment effect.

In most situations, a complete case analysis is considered, and the data of patient with missing vales are discarded. However, in some areas of medical research, more than 50% of missing entries may be encountered [5], [7]. Removing some instances leads to smaller datasets and as a result, to loss of statistical power of the analysis.

As an alternative to a complete case analysis, dropping variables with missing values from the analysis may be also applied [4], [8]. This approach, in turn, neglects valuable observed data and causes less beneficial data analysis.

Another common procedure, that may be a kind of compromise between a complete case analysis and dropping variables, is an available case analysis, where only a piece of patient's data, where no values are provided, is neglected. Despite the complications in analyzing such data due to differences in numbers of instances for various parameters, the method may produce biased estimates of associations [9].

The approach with use of imputation methods is of increasing importance nowadays. Many studies have been conducted on the topic of data imputation techniques [4], [10]–[12], but due to the complexity of the problem of missing data and its close relationship to inner data characteristics, no universal procedure has been discovered and researchers still strive to find standards in data imputation [13].

The aim of this paper is to verify, if appropriate imputation techniques can improve medical inference applied to the problem of intrauterine growth restriction and its relationship with metabolic disorders. There is no universal statistical method that deals with missing data as each study has its own design, measurement characteristics and different assumptions about missing data mechanisms [13]. Therefore, the research constitutes an independent contribution to the relevant literature and also attempts to find a successful way to perform accurate statistical analysis of IUGR in terms of missing data.

The rest of the paper is organized as follows. Section II corresponds to missing values imputation techniques. Section III explains the medical problem of IUGR and is followed by the description of medical data used in the research.

Next, section IV is dedicated to the experiments conducted on sample data and the results. Finally, in Section V, the concluding remarks are discussed.

II. Missing Values Imputation

The imputation methods can be divided into two categories:

- single imputation algorithms,
- multiple imputation algorithms.

A. Single Imputation Methods

In single imputation approach, missing data are imputed by single values. The most popular technique is the mean imputation (MI). The method uses mean of the values of an attribute that contains missing data. The modification of MI technique is using the mode instead of the mean, i.e. the most frequent value in the case of categorical attributes.

Two variations of MI can be distinguished: conditional and unconditional. The unconditional mean imputation (UMI) is not conditioned on the values of other parameters that describe the patient's data. Conditional mean approach (CMI) imputes a mean value that depends on the complete attributes for the analyzed record.

The widely applied single imputation technique is the hot deck [5], [14], [15]. The procedure finds the most similar object for the record that contains missing data, and the missing values are imputed from that object. If the most similar object also contains missing data for the same parameters as in the imputed record, then another closest object is found, until all the missing values are successfully imputed. To find the closest object, several distance functions can be used [16].

One of the hot deck techniques used to compensate for missing data is called kNN imputation (kNNI) [17]. It uses k closest complete instances in the dataset for imputing a missing value, assuming that the k most relevant complete objects are the k nearest neighbors of the incomplete instance in the dataset.

Another approach is based on regression (RI) of the missing values using complete data for a given record [18]. Different regression models can be used, usually depending on the types of imputed parameters, e.g. linear for numerical attributes, logistic for binary features or polytomous for discrete values.

B. Multiple Imputation Methods

Multiple imputation methods use several ordered choices for imputing the missing values [9]. The procedure is performed by creating several complete datasets, in which different imputations are based on a random draw from separately estimated underlying distributions.

One of the most popular approach to multiple imputation is multivariate imputation by chained equations (MICE) described in [19]. It provides a full spectrum of conditional distributions and related regression based methods (linear regression, logistic regression and polytomous regression). To make the application of MICE available, a missing data imputation software package was developed [20].

Multiple imputation algorithms also include:

- Markov chains [21],
- machine learning algorithms (e.g EM algorithm) [22],
- genetic algorithms [23].

Results based on those complex methods are increasingly reported, but their use needs to be applied carefully to avoid misleading conclusions. The multiple imputation procedures require modeling the distribution of each attribute with missing values based on the observed data. Therefore, the validity of results performed on the modified datasets depends on the correctness of such modelling [24].

C. Selection of Imputation Methods

The selection of imputation techniques was determined by the assumption that they should be simple and comprehensive, so that human expert could understand the underlying mechanisms. Moreover, the availability of the methods in statistical program packages such as StatSoft Statistica and SPSS facilitates their use [25]. It was also reported that unsupervised imputation methods may provide more accurate imputation for large amounts of missing data [5]. Therefore, in the experimental studies three single imputation methods were applied: unconditional mean imputation (UMI), conditional mean imputation (CMI) and k nearest neighbor with $k = 5$ (5NNI).

III. Data Description

Intrauterine growth restriction (IUGR) is a fetal disorder of growing. It is often related to fetal hypoxia and higher percentage of perinatal mortality. IUGR is a risk factor for many cardiovascular, metabolic, and pulmonologic diseases in adult life [26]. It occurs in about 3-10% of live-born newborns, but in developing countries it concerns up to 20-30% of newborn infants [27]. The comparisons of absolute measurements of the fetuses with reference values, as well as birth weight percentiles, allow detection of deviations between expected and actual fetal growth and identification of newborns being possibly at risk for adverse health events [28]. However, the diagnosis of IUGR is based on non-consistent definitions [29].

The world-wide research studies report that IUGR makes a risk factor for metabolic syndrome [30], [31], however more environmental studies are still needed to put additional treatment in practice [32]–[34].

The research was based on a study group (SG) of 113 children aged 5-10 years (average 8.1 $\pm$ 1.5) born on term with IUGR and birth weight below 10 percentile according to gestational age for the Polish population [35] and a control group (CG) of 39 children aged 4.5 - 12 (average 7.6 $\pm$ 1.2). All patients were selected during prospective studies at the Pediatric Cardiology and Rheumatology Department of Medical University of Lodz in 2010-2013. The study was approved by Medical Ethical Committee of the Health Sciences Faculty of Lodz University (No: RNN/760/10/KB).

The characteristics of all parameters subjected to further analysis included general attributes, cardiovascular parameters, lipids levels and adipocytokines values. Most of the parameters had missing values. The characteristics of the dataset is

presented in Table I, where the first column refers to the type of an attribute, the second is the name, next three columns include the range of values, the mean and standard deviation and the last column holds the percentage of missing values.

IV. Results and Discussion

The purpose of experiments was to find how the missing values imputation methods improve medical inference for the intrauterine growth restriction problem by discovering new significant correlations between attributes.

The experiments were conducted according to the methods introduced in Section II on the dataset described in Section III. Three main procedures were performed:

A. The experimental procedure that includes analysis with original but incomplete data.
B. The experimental procedure that results in choosing the best imputation technique.
C. The experimental procedure that performs the analysis with the imputed data.

A. Experimental Procedure that Includes Analysis with Original but Incomplete Data

The procedure was performed to discover the characteristics of all parameters and to perform their comparison between the control and study groups. The intention was to confirm by the epidemiological studies the hypothesis that:

- IUGR enhances the susceptibility to metabolic syndrome, and
- there is a correlation between levels of lipids and adipocytokines in IUGR group.

The results of the statistical analysis for the original dataset are presented in Table II.

The first hypothesis was successfully confirmed only for total cholesterol and triglicerides. The significant differences for the rest of parameters were not possible to obtain, mostly due to the numerous missing values and interrelated low significance level, as the level of missing values for adipocytokines was almost 50% in the study group and over 80% in the control group. Therefore, the presence of relationship between lipids and adipocytokines was not possible to be confirmed by statistical analysis as well.

B. Experimental Procedure that Results in Choosing the Best Imputation Technique

In literature the imputation methods are usually related to machine learning problems, mainly to the classification [11], [36]–[38]. Then, the validation can be based on comparisons of imputed datasets to the results obtained for the complete datasets with use of the standard classification metrics, e.g. accuracy or TP rate.

The IUGR problem described in the paper did not refer to the classification, and no class labels were available. Therefore, the choice of the best imputation technique was based on the differences between distributions for the complete sets of data and the sets with randomly dropped and artificially imputed values. The procedure involved five steps:

1) Choose the parameters that were originally complete.
2) Randomly introduce missing data into each parameter in the amounts of: 5%, 10%, 20%, 30%, 40% and 50%.
3) Impute the missing values in each dataset using three imputation methods: mean, conditional mean and kNN with k=5.
4) Compare the distributions of original and modified data for each parameter.
5) For each amount of data imputed, choose the method that built the distribution closest to the original distribution.

In our dataset only 5 parameters out of 18 were originally complete and those data were further used for verification the best suitable imputation technique.

We used missing completely at random (MCAR) approach to drop the data. Values were dropped in the amounts of 5%, 10%, 20%, 30%, 40% and 50%. Each type of missing values' generation was repeated 10 times. As a result we performed 150 experiments (5 attributes x 10 draws x 3 imputation methods). The percentage of cases, where the particular imputation technique was the closest to original distribution, taking into account the amounts of imputed data, are presented in Table III.

The results of comparison for distributions revealed that either the simplest imputation technique by mean values, or more complex with 5NN, can be used for imputation in term of our IUGR datasets. However, it can be also noticed that the imputation by mean gives better results when only small amounts of data are missing. Moreover, the experiments revealed that for smaller amount of missing data, the confidence intervals for goodness of fit with original distribution were above 95%, and at least 80% for the highest amounts of missing values.

C. Experimental procedure that performs the analysis with the imputed data

The final procedure was performed in three steps:

1) Impute the missing data with the method that resulted best for a specified amount of missing values.
2) Perform comparison of characteristics of all parameters between datasets with original and imputed values.
3) Verify the dependencies between lipids and adipocytokines with use of correlation analysis.

As the indication of the best imputation method was not clear enough (although there was a slightly higher recommendation of 5NNI), we decided to use two approaches for further analysis: unconditioned mean imputation and 5NN imputation.

The results of the analysis that includes unconditional mean imputation were presented in Table IV, whereas Table V presents the results for 5-nearest neighbor imputation.

When comparing results of statistical analysis for original dataset (Table II) and for the dataset imputed by unconditional mean (Table IV), one can notice that the statistically significant differences were attained for the parameters with rather small amount of missing data (12% for glucose - Fig. 1 and HDL - Fig. 2), whereas no additional medical conclusions could be drown for the parameters with higher levels of missing values.

TABLE I: Characteristics of attributes for the dataset

Type	Name	Range	Mean	Standard Deviation	Missing values
General	Age (years)	4.5 - 12.0	7.97	1.68	0%
	Body mass (kg)	14.5 - 73.0	25.08	7.73	0%

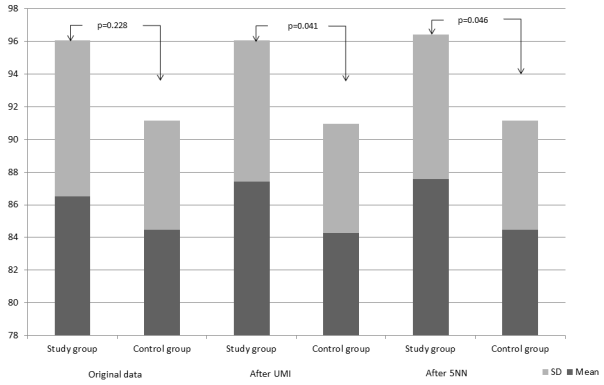

Fig. 1: Differences for glucose in study and control groups before and after performing imputation

When data were imputed with 5NN (Table V), new differences were discovered between levels of leptin and resistin, for which the percentage of missing values equaled 60%.

The correlations between lipids and adipocytokines are presented in Tables VI and VII, for datasets after imputation by unconditioned mean and 5NN respectively.

Unconditioned mean imputation enabled discovering statistically significant correlations between glucose and resistin, total cholesterol and leptin, HDL and leptin, and triglicerids and resistin. The 5NN imputation additionally revealed depen-

dencies between glucose and leptin. These relationships can build the basis for further medical diagnosis and new treatment procedures.

V. Conclusions

Missing values make one of the most common problems for real data collection and extraction in medicine. It is mainly due to the fact, that their presence excludes the intention-to-treat principle and interferes with statistically significant inference. Incomplete data may also refer to other measurements e.g. derived from modern textronic structures used in medicine or protective clothing. Their correct interpretation and analysis ensures reliable operation of intelligent sensors, and as result the entire control system of life signs of the body [41].

Each medical study has its own design, measurement characteristics and different assumptions about missing data mechanisms. Therefore, there is no universal statistical method that deals with missing data, and new investigations should be performed. In this paper, a procedure to improve medical reasoning applied to the problem of discovering new dependencies in the presence of intrauterine growth restriction in children is proposed.

The procedure consists of selecting the imputation technique that results best as applied to the characteristics of data considered and uses the chosen method to impute missing values in data subjected for further analysis. In the empirical test two imputation methods were chosen: unconditional mean and k-nearest neighbor. The statistical analysis of imputed dataset proved to yields more valuable dependencies when compared to original data, maintaining the confidence interval for goodness of fit with the original distribution above 90%. The discovered dependencies in data may establish the basis for new treatment procedures of children with intrauterine growth restriction disorder.

Further studies will involve other medical domains, e.g. monosymptomatic nocturnal enuresis in children where the problem of missing data was encountered [42]. They will also focus on investigating the impact of amounts of missing data on the validity of an imputation technique. Some other methods for dealing with missing values based on rough sets will be used, as proposed by J. Grzymala-Busse et al. [43], [44]. Moreover, the problem of high-dimensional data and feature selection techniques should be considered. More and more data are collected either by interviews, equipment [39] or extraction from text [45], speech [46] or images [47], including medical imaging [48]. In high-dimensional datasets missing data may be more frequent [49] and appropriate feature selection technique [50], [51] may improve the imputation accuracy [10]. Novel solutions of outlier detection based on linguistically quantified statements may be also considered to remove impurities from the data [52].

3rd International Workshop on AI aspects of Reasoning, Information, and Memory

THERE is general realization that computational models of human reasoning can be improved by integration of heterogeneous resources of information, e.g., multidimensional diagrams, images, language, syntax, semantics, memory. While the event targets promotion of integrated computational approaches, we invite contributions from any individual areas related to information, language, memory, reasoning.

TOPICS

We welcome submissions of papers on the following topics, without limiting to them, across approaches, methods, theories, and applications:

- Reasoning systems — theories and applications
- Proof systems and model checkers
- Theories of computation and information
- Interactive computation and reasoning
- Computation and reasoning with heterogeneous information
- Space and time in information, language, memory, and reasoning
- Partiality, underspecification, vagueness, and possibilities
- Detection of and reasoning with inconsistency
- Logic and language — approaches, theories, methods
- Computational morphology, syntax, semantics, and interfaces between these
- Constraint-based and type-theoretic approaches and grammars
- Logical approaches to multilingual processing
- Logical and computational foundations in machine learning and information retrieval
- Mathematics for linguistics and cognitive science
- Reasoning, information, and memory in computational neuroscience and life sciences
- Interdisciplinary approaches to information, language, memory, and reasoning

ul. Kolska 12, 01-045 Warsaw, Poland
Email: mateusz.krzyszton@nask.pl

***Abstract*—Reinforcement Learning (RL) is a popular approach for solving increasing number of problems. However, standard RL approach has many deficiencies. In this paper multiple approaches for addressing those deficiencies by incorporating Supervised Learning are discussed and a new approach, Reinforcement Learning with Adaptive Supervisor, is proposed. In this model, actions chosen by the RL method are rated by the supervisor and may be replaced with safer ones. The supervisor observes the results of each action and on that basis it learns the knowledge about safety of actions in various states. It helps to overcome one of the Reinforcement Learning deficiencies – risk of wrong action execution. The new approach is designed for domains, where failures are very expensive. The architecture was evaluated on a car intersection model. The proposed method eliminated around 50% of failures.**

I. Introduction

REINFORCEMENT Learning (RL) is a popular approach for solving increasing number of problems. In contrast to Supervised Learning (SL) this type of learning does not require any training data or teacher with prior knowledge. Instead, experimenting with the environemnt is performed to generate knowledge. RL has been successfully used to solve problems in multiple domains: robotics and control [1], game playinng [2] and power systems [3], just to name a few.

However, RL has many deficiencies that hinder applying it to the complex real word problems (e.g. unscalability [4], small data efficiency [5] and low human-readability of generated knowledge). Another defficiency is a risk of failures while searching optimal solution by experimenting with the environment, which requires taking random decisions from time to time. For many domains such risk is justified. However, in some domains any failure can be expensive (e.g. robot control). Thus, chance of failure should be minimized, even at the expense of the exploration. Multiple safe exploration techniques for RL were already proposed in literature [6], [7]. Most of these approaches assumes, that some prior external knowledge exists and can be used in early steps of exploration to avoid failures. However, this assumption is not always valid. Hence, need for techniques that limit risk of failures with no prior knowledge arises. It should be emphasized, however, that all failures in the exploration phase can be eliminated only if a prior knowledge is incorporeted [8].

In the literature multiple successful approaches for combining RL with Supervised Learning (SL) in form of *hybrid methods* were proposed to address various deficiencies of RL [9]–[11]. However, to the best to the Author's knowledge, no hybrid method dedicated to increasing safety of exploration has been proposed yet. In this work such approach by introducing the Adaptive Supervisor to support RL method is proposed. Adaptive Supervisor use SL approach to create knowledge about risky actions and observes states and actions that led to failures during exploration to create training set. The supervisor learns online so it can support RL and limit failures in an early phase of exploration.

The article is organized as follows. Firstly, various concepts for increasing safety of exploration are discussed. Then the novel Reinforcement Learning with Adaptive Supervisor architecture is introduced and the realisation of this architecture is proposed. The approach was verified in SInC domain [12]. Finally, results are presented and discussed. Additionally the knowledge generated by SL is verified.

II. Related Research

The comprehensive survey on Safe Reinforcement Learning can be found in [6]. The survey was recently extended in work [7]. Safe Reinforcement Learning methods can be divided into two groups. The first one involves modifying the risk-neutral optimization criterion to address possibility of failures. The modification can involve adding constraints (based on the external knowledge), optimizing performance for the worst scenario (in case the process is stochastic) or adding factor that makes safe policies more preferable over risky ones (e.g. ones with smaller variability of observed rewards). In the second group the optimization criterion remains risk-neutral, instead the exploration process is modified to avoid failures. Methods in this group can be further divided into methods that incorporates external knowledge (in the form of constraints, a set of demonstrations, a teacher that guides or supervise learning process, initial policy, etc.) and those in which exploration is directed to less risky areas by additional mechanism.

However, none of the presented works verifies possibility to increase safety of exploring process with on-line Supervisor (with no initial knowledge).

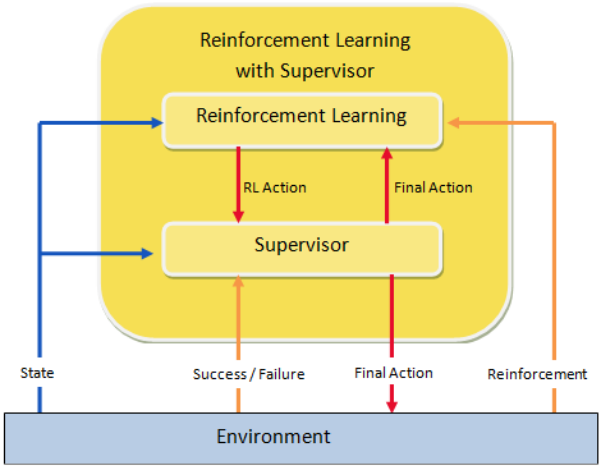

Fig. 1: General scheme of RL with Supervisor (RLS) architecture

Supervisor can be defined as additional mechanism, which role is to support RL in making better and safer decisions or in learning faster. The idea was firstly introduced in [14], where the supervisor is a set of tips, defined by expert. An idea for incorporating the supervisor (this time implemented with SL) to RL was described in [16]. The proposed solution is based on the assumption, that in some domains significant number of available actions in the given state are useless, so there is no sense in performing them. The role of the supervisor is to suggest small set of relevant actions for the given state.

In works [12], [13] SL is used to reduce state space of RL, thus increases efficiency of learning. This *hybrid method* (RLSR) is based on the assumption that two states are similar, if achieving them produces similar reward. The state is described by a set of attributes. The part of the state that is to be reduced is passed to a classifier. The classifier reduces that part of state to a single attribute. That single attribute and not reduced part of state are passed to RL module together as *reduced state*. Based on the *reduced state* the RL module chooses next action to perform. After the action a reinforcement is delivered both to the RL module and classifier for the learning purpose. The approach was tested in two domains: "Hunt the Wumpus" and "Hunter, Preys and Predators", which is the extended version of "Predators and Prey" problem. In the most of cases the conducted experiments proved the approach to be successful in shortening time necessary for learning the best solution, comparing with Q-learning. The proposed method performs well with noisy data.

III. Reinforcement Learning with Adaptive Supervisor – dealing with a risk of failures

The lack of research on applying supervised learning to implement the Supervisor concept was inspiration for developing a novel approach. The Reinforcement Learning with Adaptive Supervisor combines RL with supervisor implemented according to the SL approach.

A. General idea

To address the risk of failures the approach for combining RL with the adaptive supervisor is proposed (RLS). The architecture of the approach is presented in Fig. 1. The concept of the supervisor in this approach is similar to the one proposed in [15], where guard with explicit constraints is introduced. However, in the RLS the supervisor's knowledge is being created simultaneously with RL component. Each time the RL component chooses an action to perform, the selected action is rated by the supervisor. If the supervisor concludes, that the action chosen by RL is not safe enough (may lead to a failure) the supervisor overrides the action with the safest one (according to its current knowledge). The Supervisor observes the result of each action and on that basis it creates the knowledge about the safety of each action in each state in which that action can be preformed.

B. Realization

The proposed architecture was applied for the case where RL is implemented with the hybrid version (RLSR). This version accelerates learning, but the trade off is potentially worse quality of decision. Hence, a supervisor is introduced to minimize number of failures. Scheme of the method is presented in Fig. 2.

The supervisor is implemented as a classifier. In the process of learning the classifier receives training examples in the form: $\langle s, a, e \rangle$, where s is not reduced state, a is performed action and e is evaluation of performing the action a in the state s. e takes one of the following values: *good* or *bad*.

Asking the supervisor if the action is correct corresponds to classifying pair $\langle s, a \rangle$ as *good* or *bad*. If the action is classified as *bad* the supervisor iterates over all possible actions in state s and chooses the action with the highest certainty of being classified as *good* (the safest action). The chosen action is performed and sent back to the RL component as feedback.

To teach the supervisor rating actions, the supervisor has to store all examples gathered during learning process. As the

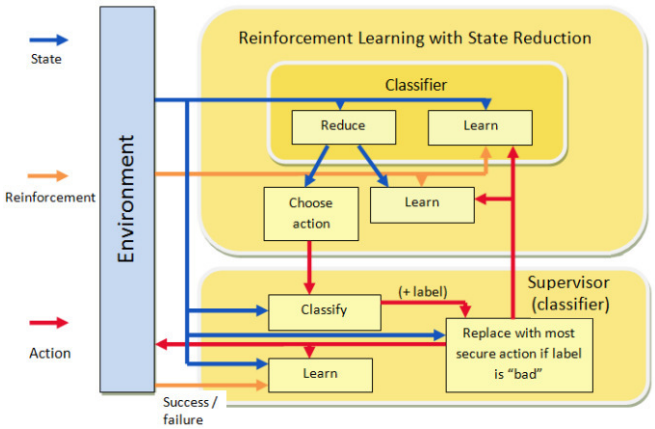

Fig. 2: Realization of RL with Supervisor architecture. First action is chosen by RL with State Reduction (RLSR). Then Supervisor rates action and replace it only if rate is *bad*.

supervisor gets information from the environment that success or failure happened, configured number of last stored examples should be labeled as *good* or *bad* respectively and added to the training set. Additionally weights of examples can be introduced — the closer example is to failure/success state, the bigger weight it should have.

The classifier used in this hybrid method should provide certainties of labels. Hence, rigor r of the supervisor can be configured. To classify action as *good* the certainty of label *good* has to be higher than r. Otherwise, action is classified as *bad*, because there were enough cases (according to the given rigor) which led to failure immediately or few steps after taking this action. It is worth noting, that too high rigor may led to rejecting action that is potentially good (there exists the list of actions following it that lead to success), but in the past that action preceded the incorrect actions that resulted in failure and hence is considered wrong.

C. Experimental domain

The approach was examined in the domain of crossing intersection by autonomous vehicles (SInC) [12]. Crossing intersection is simultaneous, therefore collisions can occur. To avoid them vehicles have to adjust their speed. In the same time vehicles should cross intersection as fast as possible. Hence, in every step of simulation an agent steering car chooses action $a_{\mathrm{i}} \in A$, which corresponds to changing speed by i[3]. The set of actions A is defined as $A := \{-a_{max}, -a_{max}+1, \ldots, a_{max}-1, a_{max}\}$, where a_{max} is the maximal speed change. In case as a result of taking action a_{i} the value of speed should be smaller than 0 or greater than v_{max}, then the speed value is set to 0 or v_{max}, respectively.

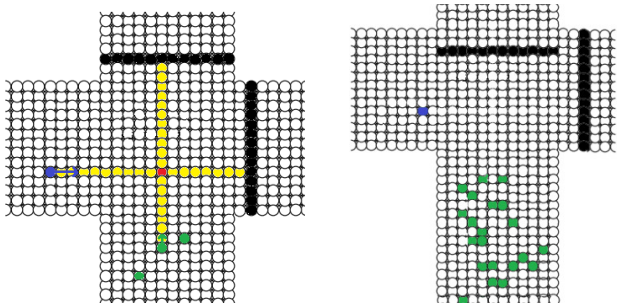
To choose an action the agent can use following information, updated in every step:

- distance to the end of intersection (d_t);
- speed of the car (v_c);
- distance between car and the nearest collision point with a car coming from the crossing road (collision car) (d_{cp});
- distance between the collision car and the collision point (d_{ccp});
- speed of the collision car (v_{cc}).

Below state s is defined as $s = \langle d_t, v_c, d_{cp}, d_{ccp}, v_{cc}\rangle$. In Fig. 3a an exemplary $s = \langle 18, 2, 10, 8, 1\rangle$ is presented.

After each step the agent observes the result of it's action. If the car reached the end of intersection successfully or collision occurred all stored pairs of states and actions ($s = \langle s, a\rangle$) are labeled by the Adaptive Supervisor as $e = good$ or $e = bad$, accordingly. Otherwise (car is still crossing intersection safely) the Adaptive Supervisor continues storing examples.

[3]the decision to change speed influences the speed of the car in the step following the step in which the decision was taken — e.g. if in the step t the speed of the car was equal to 1 field per step and the decision of the agent in that step t is to reduce speed by 1 field per step, than the car will change its position by one field in the step t and than stop (in the step $t+1$ the car won't change its position regardless the decision in the step $t+1$). Postponing result of the speed change makes the considered domain more challenging and realistic (gap between making observation and changing speed is taken into account).



(a) (b)

Fig. 3: (a) The example state at an intersection. Point where collision between the blue car (intelligent one) and the nearest moving car can happen is marked with a red color. With black line is the end of intersection (target); (b) Initial situation at intersection for experiment [12].

D. Verification scenario

Three approaches for taking decision were compared — standard RL, hybrid method RLSR, and the novel hybrid approach RLS (version described in III-B).

The first method (QRL) was based on the standard RL method (Q-learning with ϵ-greedy policy). The following rewards were introduced:

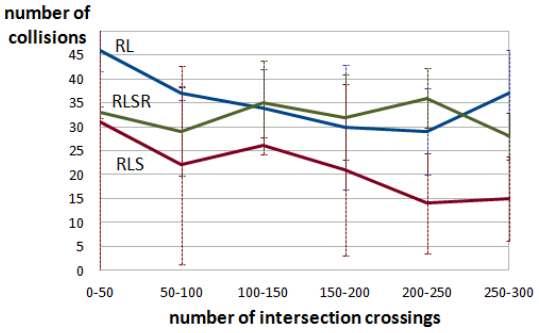
- r_c — negative reward for collision ($r_c = -100$)
- r_t — positive reward for reaching target ($r_t = 100$)
- r_s — negative reward for making move ($r_s = -2$)

Rewards r_t and r_s promote crossing intersection as quickly as possible. Reward r_c teaches the agent to avoid collisions. To implement Q-learning RLPark library was used ($\alpha = 0.25$, $\lambda = 0.4$, $\gamma = 0.55$, $\epsilon = 0.5$). All parameters were chosen with the hill climbing approach.

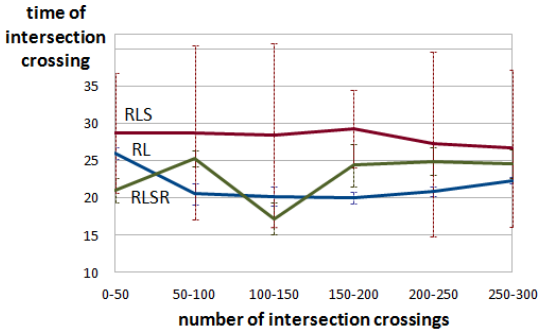
As the second method RL with state reduction with classifier (RLSR) was used. To detect similar states, the state attributes which corresponds to the possibility of collision (v_c, d_{cp}, d_{ccp}, v_{cc}) were reduced to a single bivalent attribute. The value of this attribute can be interpreted as possibility of collision in the given state. Classifier was implemented with C4.5 algorithm supplied by WEKA library. As the RL method the QRL was used.

The third approach was RLS method — to RLSR method supervisor was introduced to increase safety. For the Adaptive Supervisor success was defined as crossing intersection safely (getting to the end of intersection without collision). Any collision during crossing is considered as a failure. To implement the supervisor C4.5 algorithm was used. The rigor r of the supervisor dynamically changes with the development of agent's knowledge and is given for ith simulation of the experiment with formula:

$$r = \begin{cases} 0.5, & i < 10, \\ 0.66, & 10 \leq i < 200, \\ 0.75, & 200 \leq i < 300. \end{cases} \quad (1)$$



(a)



(b)

Fig. 4: A relationship between (a) collision number and (b) intersection crossing time and the agent experience — moving average with window size equal to 50 crossings of intersection.

The performance of methods was compared in the experiment conducted with platform MABICS [12]. The initial situation on the intersection for this experiment is shown in Fig. 3b. On the left side of the intersection a vehicle controlled by the intelligent agent is placed. On the bottom there are 21 vehicles that simulate real traffic. Each car moves with random, constant speed. Maximal speed change $a_{max} = 1$ and maximal speed $v_{max} = 3$. The experiment was repeated three times only, because of efficiency issues of the intersection crossing simulator, integrated with the MABICS. Each experiment consisted of 300 simulations. Between simulations within one experiment all gained experience of the agent was persisted.

E. Experimental results

Obtained average results of crossing time and collision numbers for all three methods are presented in Fig. 4. The RLSR method speeds up learning comparing to RL, but the number of collisions in the last periods is similar. Both RL and RLSR methods have difficulty in exploration of so complex domain, therefore only suboptimal solutions were found. The proposed RLS hybrid method proved to be safer in comparison with both standard RL and RLSR methods ($p < 0.05$ according to t-test[2]). RLS causes about 50% less collisions in the last periods of learning, which is satisfactory in so complex domain.

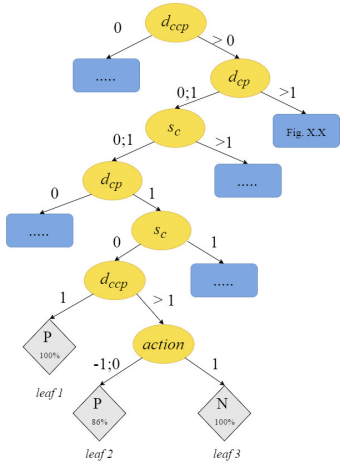


Fig. 5: Decision tree for classifying the given action in the given state as *good* or *bad* — root part

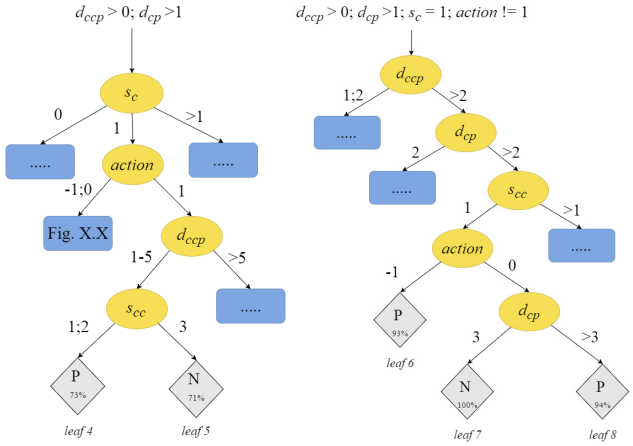

(a) (b)

Fig. 6: Decision tree for classifying the given action in the given state — (a) branch for $d_{ccp} > 0$ and $d_{cp} > 1$ and (b) branch for $d_{ccp} > 0$, $d_{cp} > 1$, $s_c = 1$ and $a < 1$

The decision tree which represents the knowledge created by the supervisor in the end of one of the experiments is presented in Fig. 5 and Fig. 6. Since the obtained tree has about 100 nodes only the most interesting branches are shown in details. With each leaf one rule for accepting or rejecting given action a in the given state(s) can be associated.

In some states any action chosen by the agent is accepted by the supervisor since collision cannot happen after visiting this state (according to the supervisor's experience). The example of such situation is represented by *leaf 1* (Fig. 5). The set of states associated with this leaf is illustrated in Fig. 7a. In this situation the speed of the car controlled by the intelligent

[2]the one sided t-test with equal variance. The equality of variance was verified with the two-sample F-test

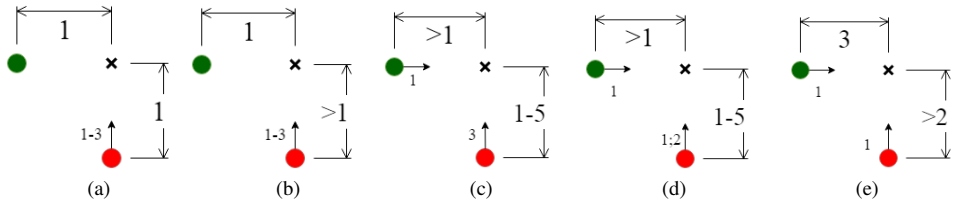

Fig. 7: Illustration of states associated with some leaves of decision tree, respectively (a) *leaf 1*, (b) *leaf 2* and *leaf 3*, (c) *leaf 5*, (d) *leaf 4*, (e) *leaf 7*. As the tree generalize examples each leaf represents set of similar states, e.g. (a) represents states satisfying $s_c = 0$, $s_{cc} \in \{1, 2, 3\}$, $d_{cp} = 1$ and $d_{ccp} = 1$.

agent is equal to zero and distance to collision point of both cars is equal to 1. Accepting each decision by supervisor is correct as the speed of collision car (v_{cc}) is greater than zero (constraint) — even if the agent decides to accelerate the car will move to the collision point in step $t+2$ whereas collision car even in the most pessimistic case ($v_{cc} = 1$) will move to collision point in step $t + 1$ and will leave this point in step $t + 2$.

Similar situation is associated with *leaf 2* and *leaf 3*. (Fig 5), but here the distance of collision car to the collision point (d_{ccp}) is greater than one (Fig. 7b). In this case accelerating is not safe anymore and supervisor will correctly reject decision to increase the speed by one and replace the action with decision to sustain speed or decrease it by one.

leaf 4 and *leaf 5* (Fig. 6a) show situation when the same action can be accepted or rejected depending on only one attribute of the state s, in this case v_{cc}. If $v_{cc} = 3$ (Fig. 7c) the supervisor reject the decision to accelerate. If the value of v_{cc} is smaller (the collision car approach to collision point slower, Fig. 7d) the decision to increase speed will be accepted as long as rigor r is smaller than 73%.

Finally, it is presented how the supervisor selects the best action in case of rejection, taking interesting rule as an example. The rejection rule is associated with *leaf 7* (Fig. 6b) and is illustrated on Fig. 7e. If the selected action is maintaining current velocity ($a = 0$) the supervisor rejects it. For simplification let choose as current state one that match the rule: $d_{ccp} = 3$, $d_{cp} = 3$, $v_c = 1$, $v_{cc} = 1$. Then, to select new action, the tree is searched for $a = 1$ and $a = -1$. For $a = -1$ the *leaf 6* (Fig. 6b) with label P and certainty equal to 93% is found, whereas for $a = 1$ the *leaf 4* (Fig. 6a) with label P and certainty 73%. As both leaves has label P the action with greater certainty is chosen ($action = -1$.). The action will cause that car will stop before reaching collision point, which is the safest option.

IV. Conclusions

This paper presents how Supervised Learning concept can be used to improve safety of the exploration process in RL, when no prior knowledge is available. The proposed method reduces number of failures, that are usually result of the space search, unavoidable part of RL method. Hence, the method should be used in domains where failures are expensive or even intolerable. The conducted experiments made it possible to verify new idea as promising since adding the Adaptive Supervisor eliminated around 50% of failures.

The presented RLS concept should be further examined in various domains, especially ones in which failures are costly and standard RL methods or hybrid methods (e.g. RLSR) are able to find good solution (it is not a case of the SInC domain) to analyze how many failures can be avoided additionally.

Combining the Syntactic and Semantic Representations of Mizar Proofs

***Abstract*—The Mizar system provides two representations of the proofs present in its library. The syntactic representation preserves the human-friendly rich Mizar language, where the meaning of structures and expressions is still influenced by their context. The semantic one, on the other hand, explicitly reflects the meaning of all elements present in the proof scripts, however many features of the Mizar language are eliminated.**

In this article, we overcome the limitations of both representations of proofs, by proposing a method combining them. We show that we can simultaneously maintain the richness of the language and provide access to the derived proof information. We discuss how such combined information closer corresponds to that present in other proof assistant languages, for example that of Isabelle/Isar.

I. Introduction

ONE of the most recognizable features of the Mizar system [1] is its highly human-oriented proof environment. For over four decades the Mizar project has developed an environment that allows to create formal reasoning similar to how it is done in informal mathematical practice. Many actions at various levels have been taken to ensure this environment:

- Linguistically motivated dependent soft type system that closely reflects how most of the mathematicians use mathematical objects and how they categorize them.
- Rich expression language that provides complex symbol overloading and notational constructs, e.g., the meaning of individual symbols is strongly influenced by the context, as in textbooks.
- The Mizar natural-deduction proof that try to approximate the way how informal proofs are written, where the deduction is not steered by an explicate list of rules that indicates how to match a statement to its proof.

These possibilities are reflected in the size of one of the largest formal libraries, the Mizar Mathematical Library (MML) [2] that includes many domains that have not been formalized elsewhere. However, the Mizar system is the only tool that can fully operate on the content of the library written in such rich language.

a) Related works: Obviously, there have been a number of attempts to explore the content of the MML by external tools. Most of them ensure access to the semantic representation of MML where many proof details are easily accessible for a human reader, starting with easy semantic searching tools as MML Query [3], variants of XML format [4], MMT logical framework [5] or provide the extensive theorems database of MPTP [6] that can be served as a tool in automated theorem proving and machine learning [7].

The Mizar system also provides two ways of access to the syntactic representation. These are *Weakly Strict Mizar* (WSX) [8] and *More Strict Mizar* (MSX) [9], where MSX is an extension of WSX. However, both human-friendly syntactic representations are still too far from semantic one and selecting access, we have to choose between these two.

A lot of work has been done to cross-verify MML by external tools that struggle with many problems such as the Mizar logic that goes a little bit beyond the first-order logic and the Mizar type system. Pioneering and the largest translation of MML to the TPTP untyped first-order language has been done by Urban [10], where higher-order problems have been verified with an extension of TPTP language [11]. Kunčar [12] has attempted to translate the MML as transparent higher-order logic theories, however, his concept was not able to cover more advanced features of the Mizar type system. Successful attempt to extract and cross-verify higher-order problems using higher-order automated theorem provers Satallax and LEO-II have been done by C. Brown [13]. However, these translations are fixed from the point of view of a further development of the MML, i.e., they do not allow any modification or further development.

Urban's MizAR system [14] facilitates the search for a given justification using machine learning and automated reasoning. It returns a list of premises needed for the current goal, which in most cases can be directly used in the script, as in the case of justification generated by the Sledgehammer subsystem for Isabelle/HOL [15]. However, in some cases to use obtained list of premises, authors need to carefully modify the

The paper has been supported by the resources of the Polish National Science Center granted by decision n°DEC-2015/19/D/ST6/01473.

Mizar proof script `environ` and/or create manually a few auxiliary steps.

b) Isabelle/Mizar: is a project whose goals are to: (1) specify the Mizar foundations fully formally in the Isabelle logical framework [16] and (2) cross-verify all the proofs in MML in resulting fully specified logic. The work on these can in the longer term lead to (3) the creation of a Mizar like environment in the Isabelle logical framework, which would provide Mizar foundations and its various mechanisms and allow users to further develop proofs in typed set theory using various Isabelle mechanisms.

There has been a lot of progress on the first goal. The environment [17], [18] has an equivalent of the Mizar dependent type system including Mizar-like structures [19], as well as higher-order concepts, such as set comprehensions and schemes [20]. We have recently developed an automated translation of the statements; however, a large gap between the syntactic and semantic Mizar representations significantly hinders work on an automatic export of the MML proofs. The proofs should be as close to the syntactic Mizar representation as possible, but at the same time, we need to use the semantics, e.g., to identify objects and reconstruct their lists of hidden arguments.

c) Contribution: This paper introduces a representation of Mizar proofs that combines the syntactic and semantic ones. Most of the original syntax is preserved, annotated by the information how particular constructs have been interpreted by Mizar, which allows the processing of the proofs by external systems. The particular contributions are:

- An elegant presentation of Mizar proofs using implicit types assigned to frequently used variable names. This combines the syntactic and semantic representation of the Mizar reserve mechanism.
- A simplification of the Mizar proof outlines to the fix–assume–show outlines present in most declarative proof languages, e.g., Isabelle/Isar [21]. This involves eliminating several constructions, such as the take steps that indicates a suitable term for instantiating an existentially quantified thesis. In particular the concept of the take step has no equivalent in most other proof languages [21].
- Lists of dedicated rules that determine the reasoning patterns for each sub-proof with the fix–assume–show proof outline present in most declarative proof languages. We propose Isabelle/Isar rules as an example.
- A human-friendly rendering of our Mizar representation.

The paper is constructed as follows. In Section II we discuss the Mizar proof concepts lost in the Mizar semantic exports. In Section III we briefly describe a method that matches syntactic and semantic representations. Then we present a reconstruction of these concepts based on the matched representations. In Section IV we present a way to simplify Mizar proofs to logical framework formats preserving reconstructed concepts. Finally in Section V we show an example formalization created in the Isabelle/Mizar environment that uses a rebuilt Mizar proof.

II. Mizar Semantic Export

The scope of this paper does not allow to fully explain the details in the Mizar system including the semantic representation (for such details see [22], [4]). We will point out the main problems and solutions using a single example that states a natural basic property of the set inclusion (Fig. 1). Additionally, the deduction used there as the property justification is quite similar to *informal* one and can be analyzed by a reader who does not have experience with the Mizar system.

a) Hidden Types and Quantifiers: According to the Mizar syntax each statement has first-order form where atomic predicative formulas are combined with classical logic connectives and quantifiers. Also note, that each quantifier has to associate a Mizar type (types correspond to first-order predicates) with all bounded variables. However, the Mizar Analyzer can not infer this type automatically based on the context of the variables as is the case for most type-theory based systems, since Mizar disambiguates the meaning of each symbol based on types of its arguments (corresponding to type inference in an intersection-type system). To avoid specifying *explicitly* the types of all bound variables at their quantifiers, the Mizar system provides a *reservation* mechanisms that allows global associating variable names with their types. For example, `object` that is the type of the variable `x` is not mentioned in the sentence ex `x` st in Fig. 1 but is imported from the reservation reserve `x,y` for `object`.

The type of a reserved variable can be skipped not only in the declaration of a quantifier, but also in each Mizar construction which requires it (compare lines 7 and 11). Moreover, for convenience, universal quantifiers that bind reserved variables can be implicit. Additionally, in many systems, free variables that correspond to *implicit* quantifiers in a given statement are automatically introduced to a sub-deduction that justifies the statement. Obviously such user support is welcome in the human-readable export, especially since the equivalent of the Mizar reserve mechanism has already been provided in Isabelle/Mizar. Unfortunately, Mizar reconstructs these quantifiers and corresponding introduction steps very early, between WSX and MSX representations and does not distinguish reconstructed objects in the XML semantic representation[1]. As a consequence, there is no difference in the semantic representation between the theorem presented in Fig. 1 and Fig. 2. On the other hand, we can easily distinguish this information in the WSX representation, but based on this representation we can not provide enough information

[1]The semantic representation of the theorem presented in Fig. 1 where hidden types and quantifiers are fully reconstructed is available in the HTMLization of the current Mizar library http://mizar.uwb.edu.pl/version/current/html/xboole_0.html#t8

to explore the MML. Note that information about disambiguating symbols and their hidden arguments are missing there and are very hard to reconstruct for any external tool.

b) Normal Form: The reservation system is one of the three main reasons why we are forced to combine information from syntactic and semantic representations. To simplify the grammar of the semantic representation, the Mizar Analyzer also transforms each formula to the Mizar normal form (MNF) which uses only selected logical connectives, such as $\neg$, a generalization of $\wedge$ for n-arguments, the universal quantifier $\forall$ and $\bot$. A lot of work has been done by Urban to minimize the consequences of normalization [4]. He built directly into the Mizar Analyzer a hint system that is visible as an additional attribute pid in selected nodes of the XML semantic representation. This system should allow the reconstruction of the original formula from the normalized one based on pid-s, e.g., every implication $\alpha \rightarrow \beta$ is replaced by the formula $\neg_{-4}(\wedge_{-5}(\alpha, \neg_{-6}(\beta)))$ where subscripts represent pid–values. However, these hints are often lost in the normalization process, since, e.g., the Analyzer eliminates double negation together with the corresponding pid-s. In consequence, there are several cases (a few percent of the library)[2], where the original formulation is different than the HTMLization generated with the pid-support even if we omit reconstructed hidden quantifiers.

It is important to note that equivalent reformulation of statements in a Mizar proof script does not affect its correctness, since most of Mizar verifier's modules are based on the MNF including the Reasoner which check the applicability of *Skeleton steps* – discussed in Section IV that operates on the thesis in a given proof. For comparison, equivalent reformulation of statements is not possible in most declarative proof languages, as all reasoning pattern must precisely correspond to the related statements and proofs.

c) More advanced pid*–problems:* The reconstruction of the original logical conjunctions and quantifiers was one of the additional tasks in the pid system created by Urban. His system mainly focused on solving the conflict between *patterns* and *constructors*, that we only sketch here (for more details see [10]). Note that every Mizar defined object (i.e, a function, a type, a predicate, an attribute or a structure) together with its list of arguments with their types (and a result type if applicable) and positions of each visible arguments constitutes the Mizar pattern. Mizar constructors are just absolute identifiers (in the environment of a given article) of Mizar objects of which the patterns are translated during their full identification by the Mizar Analyzer. Obviously, a given overloaded pattern can be translated into different constructors. Unfortunately, different patterns can be translated into the same constructor, since, e.g., synonyms and antonyms of predicates and adjectives inherit the constructor from their ancestor. To ensure full control over the many-to-many

[2] For example, the ZFMISC_1 article contains 139 theorems and the differences occur in 8 cases, i.e, theorems: 6, 19, 22, 37, 53, 58, 112, 138.

relationship, the number of constructor (nr) and pattern (pid) should be associated with each object. However, many pid-s are lost or arguments of patterns are incorrectly reconstructed. We can observe this in the HTMLization as *technical* constructors rather than the corresponding patterns or as missing values in the lists of arguments[3]. Such defects do not have a significant negative impact for the rendered HTML, but are unacceptable in every cross-verification of the MML.

III. Disambiguated Syntactic Mizar Export

The problems indicated in Section II are typical, if we want to obtain access to the MML based only on the semantic representation. Therefore we develop an application that combines the semantic and syntactic informations. Obviously there are many inconveniences in this approach, since the semantic representation is completely rewritten by the Mizar Analyzer with respect to the syntactic one and contains only the information that are absolutely necessary for the checking proof steps. We combine the information in three stages.

a) Top level: First, we match all the items from the two representations, where often a few semantic steps correspond to a single syntactic one. For example, a step that introduces variables X, Y in Fig. 2 (see 5th line) is hidden in Fig. 1, but for semantic comparison, both variables are introduced in independent steps that are followed by additional steps where the corresponding modified thesis is formulated.

b) Logic connectives and quantifiers: Next we match syntactic and semantic representation of each statement to find corresponding atomic formula. For this purpose we transform every syntactically represented statement imitating the Mizar Analyzer process such as the normalization and then we compare the obtained formula with the corresponding semantic representation of this statement. We transform also all formulas into a system of abstractions and applications in meta logic

```
<logic id=("ball"|"hidden_ball"|"bex"|"iff"|
  "impl"|"or"|"and"|"not"|"False"|"True")\>
```

that should be easy-to-read by external tools, since e.g., our system directly corresponds to logical framework application and abstraction. Note that the constant hidden_ball is semantically equivalent to ball but corresponds to a universal quantifier that is originally hidden. Additionally, we distinguish types of variables that are imported form *reservations*. For example, hidden quantifiers that bind variables with types imported from *reservations* in the statement of theorem presented in Fig. 1 obtained the following our representation:

[3] See for example http://mizar.uwb.edu.pl/version/current/html/pboole.html#CC4 where the expression includes V8 rather than non-empty, V9 rather than empty-yielding, and the argument A is missing in the type ManySortedSet of A.

```
<proposition label="xboole_0_th_8">
 <app>
  <logic id="hidden_ball" type="o" args="2"
     argsType="ty_abs"/>
  <ReservationType id="X">
   <const id="HIDDENM2" type="ty" args="0"
      argsType="set"/>
  </ReservationType>
  <abs id="X" type="set" args="0">
   <app>
    <logic id="hidden_ball" type="o" args="2"
       argsType="ty_abs"/>
    <ReservationType id="Y">
     <const id="HIDDENM2" type="ty" args="0"
        argsType="set"/>
    </ReservationType>
    <abs id="Y" type="set" args="0">
    ...
```

where the constant HIDDENM2 corresponds to the Mizar set that is the second type definition (called mode in Mizar) in article HIDDEN. Note that the name directly corresponds to the absolute constructor name proposed in [10] and the OMDoc node <OMS module="HIDDEN"name="M2"/> (according to the
naming scheme proposed in [5]).

c) Atomic propositions: Matching at the atomic proposition level is quite natural. Generally, we just match predicates and then recursively terms and subterms to disambiguate them. However, we have to take into account Mizar local abbreviations that are fully unfolded in the semantic representation. It is also important to note that most of the Mizar objects have different numbers and order of arguments in compared representations, since the semantic representation contains visible arguments of each Mizar object, but also their hidden arguments calculated by the Mizar Analyzer. We explore these differences to access hidden arguments at the syntactic level, and use them just like visible arguments. Additionally, as in the case of logic connectives, we present every object using an application of meta-constant that corresponds to unique pattern of the object and list of its arguments.

For example, let us consider the statement of theorem SUBSET_1:13 presented in Fig. 3. It states that the set difference of sets A and B is equal to the intersection of A and the complement of B in the given universal set E.

The universal set E does not appear *explicitly* in the statement, but is necessary to determine the complement set B`. Additionally, the difference (represented as \) and the intersection (/\) are originally defined for arbitrary sets, however the Mizar redefinitions (for more detail see [22]) change types of return values in these functors for Subset of E, if both arguments are also Subset of E. Therefore, E is a hidden argument of these three functors if we want to fully reflect the meaning of this statement. The representation of the fact is presented in Fig. 4.

To provide a human-friendly access to our representation we also build an initial system that automatically generate pdf files that visualize our representation as well as HTMLization of the MML

```
reserve E for set,
        A,B for Subset of E;
theorem :: SUBSET_1:13
  A \ B = A /\ B`;
```

Fig. 3. An example Mizar theorem whose statement contains hidden arguments.

```

 </app>
</app>
```

Fig. 4. The formula `A \ B = A /\ B`` represented in our format. These are necessary to decode the complete information. `SUBSET_1K7` corresponds to the pattern `_ \ _`, defined in the Mizar article `SUBSET_1` to represent the difference of sets in an universe, where the universe is a hidden argument and is calculated by Mizar from types of the sets. Similarly, `SUBSET_1K9` and `SUBSET_1K3` correspond to patterns `_ /\ _` and `_`, respectively.

visualize the semantic representation. We use a presentation inspired by that of Isabelle rendering of its formalizations, in particular applied to Isabelle/Mizar that combines selected components of Isabelle/Isar and Mizar[4]. In particular, the theorem presented in Fig. 3 is expressed as follows:

mtheorem subset_1_th_13:
∀E: ⟨ set HIDDENM2 ⟩ .
∀A: ⟨ Subset SUBSET_1M2 of E ⟩ .
∀B: ⟨ Subset SUBSET_1M2 of E ⟩ .
A \ SUBSET_1K7⟨E⟩ B = XBOOLE_0R4
A /\ SUBSET_1K9⟨E⟩ B ` SUBSET_1K3⟨E⟩

where hidden quantifiers and types imported from reservations are highlighted as well as hidden arguments are visible in subscripts. Additionally, identifiers indicate absolute patterns and links indicate absolute constructors in the HTMLization of the current MML.

[4] Readers can check automatically generated pdf files (generated now for 104 initial Mizar articles) at the author's web site http://alioth.uwb.edu.pl/~pakkarol/fedcsis2018/, stylized for the Isabelle/Isar language.

```
reserve x for object, X,Y for set;
theorem
  X/\Y = X implies X c= Y
proof
  assume that A1: for x st x in X/\Y holds x in  X and
              A2: X c= X/\Y and
              A3: ex x st x in X & not x in Y;
```

Fig. 5. An example Mizar assumption where two predicates (equality and inclusion) are unfolded in one skeleton step.

IV. Simplification of Mizar proofs by cut introduction

The Mizar proof style, inspired by Jaśkowski [23], provides various natural deduction steps (called *Skeleton steps* in Mizar). The steps generally modify the current part of a given *thesis* that still remains to be proven. Thesis is the same as the current goal at the beginning of every proof, but further it becomes *implicit*, as is done in informal proofs. Indeed, mathematicians do not often indicate what has been done or what is left in the middle of proofs. It means that Mizar authors must know the current thesis and predict how it will be changed by a particular skeleton step to finish a given proof. Mizar proof is finished if the thesis is reduced to `verum` (*true*). Then the Mizar Reasoner tries to adapt the skeleton steps proposed by authors even if this requires unfolding the definitions of several predicates.

A. Unfolded Predicates

An example of an *implicit* unfolded definition is presented in Fig. 1 in line 11. The generalization step (keyword let) can be used if the current thesis is a universally quantified formula, but the current thesis after line 10 is a formula (`X c= Y\{x}`) that becomes a universally quantified formula if we unfold a definition of set inclusion. Such an approach gives a lot of freedom for authors, but is very hard to control by existing external tools. It is important to note that the Mizar semantic representation has been enriched by Urban with a list of definitions that the Mizar Reasoner actually needs to unfold in every step. Such information is sufficient to cross-verify a given thesis modification done by Reasoner (for more detail see, [24]). However this information is not sufficient to determine reasoning pattern, since it does not determine positions of unfolded predicates, or even their number. An example of an assumption accepted by Reasoner supported by two definitions, namely the definition of equality as two inclusions and the definition of inclusion is presented in Fig. 5. The equality `X/\Y = X` is introduced as two inclusions, where the first one `X/\Y c= X` has been unfolded, and further the indirect proof is started where the inclusion in the indirect assumption not `X c= Y` has been unfolded. Determination of a reasoning pattern for such an assumption is a severe problem. However, combining the syntactic and semantic information we can automatically

eliminate the more advanced skeleton steps, generating the corresponding reasoning patterns while introducing fewest changes in the reasoning.

B. Procedure Overview

Note that we can transform modified thesis by a given reasoning step back to the thesis before this step or to an equivalent formula, if we take into account the meaning of the definitions unfolded there (for more details see [24]). It means that we can reconstruct an equivalent of the thesis by analyzing the skeleton steps from the end of a given proof, if there are only *simple* (i.e., without definitional expansions) kinds of steps, such as generalizations, assumptions, conclusions (or shorter let–assume–thus) that correspond directly to the Isar fix–assume–show. Moreover, in such cases we can indicate a list of natural deduction rules that precisely correspond to the related created thesis and proof. In our representation we only use implication introduction and the following four rules (expressed in the Isabelle syntax):

lemma impMI: (A1 ⟹ A2 ⟶ C) ⟹
  A1 ∧ A2 ⟶ C
lemma conjMI: C2 ⟹ C1 ⟹ C1 ∧ C2
lemma ballI: (⋀x. x be D ⟹ P(x)) ⟹
  inhabited(D) ⟹ ∀x:D. P(x)
lemma bexI: P(x) ⟹ x be D ⟹
  inhabited(D) ⟹ ∃x:D. P(x)

where impMI connects uncurry and impI; conjMI is a modification of conjI; ballI, bexI are bounded quantifier introduction and elimination rules which apart from the condition ensure that the given Mizar types are inhabited. These correctly correspond to the Mizar foundations (see [17]). Note that conjMI corresponds to the Mizar conclusion where a given proposition is a conjunct of the current thesis and impI separates a list of conjunctions in an assumption to give them independent labels as follows:

have A ∧ B ∧ C
proof(rule conjMI,rule conjMI)
  show A ⟨proof⟩
  show B ⟨proof⟩
  show C ⟨proof⟩
qed
have A ∧ B ∧ C ⟶ D
proof(rule impMI,rule impMI,rule impI)
  assume a: A **and** b: B **and** c: C
  show D ⟨proof⟩
qed

As shown in Fig. 5, a reconstructed thesis can not be easily matched to a given thesis in a proof, if some definitions have been unfolded in a let–assume–thus step. Therefore, in our approach we introduce a cut in the reasoning at every place where such steps occur. Let us fix such a let–assume–thus step. We encapsulate a part of deduction beginning from the step using the created list of rules as a sub-deduction that proves the reconstructed thesis (the correctness condition of such cut introduction have been developed in [25]). Then we replace this step by a conclusion where the original thesis is given as the proposition and we refer to the sub-deduction and unfolded definitions and as the justification. An example of such a cut introduced to our representation is presented in Fig. 6.

```
have ∀ y : ⟨ object HIDDENM1 ⟩ .
    y in HIDDENR3 X →
     y in HIDDENR3 Y \ XBOOLE_0K4 { TARSKI1 x }
proof(rule ballI,rule impI)
 fix y being ⟨ object HIDDENM1 ⟩
 assume A4: y in HIDDENR3 X
 hence y <> HIDDENR2 x using A3;
 hence A5: ¬ y in HIDDENR3 { TARSKI1 x }
    using tarski_def_1;
 have X c= TARSKIR1 Y using A1;
 hence y in HIDDENR3 Y using A4;
 thus y in HIDDENR3 Y \ XBOOLE_0K4 { TARSKI1 x }
    using xboole_0_def_5, A5;
qed
thus X c= TARSKIR1 Y \ XBOOLE_0K4 { TARSKI1 x }
   using tarski_def_3;
```

Fig. 6. An example of a cut introduction related to the skeleton step located in line 11 in Fig. 1.

C. take *steps*

The Mizar take is a kind of skeleton step that is a challenge for other declarative proof languages, including expressing the proofs in Isabelle/Mizar, as such steps cannot be omitted. take indicates terms suitable for instantiating an existentially quantified thesis. Such terms can be constructed using any available constants in Mizar. For comparison, there is a limitation for kinds of constants in the Isabelle/Isar language i.e., constants introduced inside obtain steps have to be available before a deduction where we use them to construct such suitable term. Unfortunately, the obtain step is the only equivalent of the Mizar consider (for more detail see [21]) and most of take steps are using consider constants. A cut introduction is one and only one solution that we introduce in our representation. For example, we can introduce the following cut

```
show ∃ t : object HIDDENM1 .
 t in HIDDENR3 Y ∧
   X c= TARSKIR1 Y \ XBOOLE_0K4 { TARSKI1 t }
proof(rule bexI[of _ x],rule conjMI)
 show x in HIDDENR3 Y using A2;
 have ∀ y : ⟨ object HIDDENM1 ⟩ .
    y in HIDDENR3 X →
    y in HIDDENR3 Y \ XBOOLE_0K4 { TARSKI1 x }
 proof(rule ballI,rule impI)...
 thus X c= TARSKIR1 Y \ XBOOLE_0K4 { TARSKI1 x }
    using tarski_def_3;
qed
```

in relation to the step take x; presented in Fig. 1.

Note that to introduce such cut we have to extract a given term and also its type, but the type can be *implicit* even in the semantic representation. Generally, we can extract this type comparing the thesis before and after a given take step, but not in most cases where some definitions have been unfolded. For them we use the following solution. Let us regard t as such take step and

denote by `f` the first skeleton step after `t` that is not a take step where we can not extract a type. First, we encapsulate a part of deduction beginning from `f` as a sub-deduction that proves a thesis that corresponds to `f`. Then we formulate a conclusion with the original thesis of `t` and as a justification we refer to the sub-deduction, unfolded definitions in `t`, but also in all skeleton steps between `t` and `f`; and a list of bexl rules substituted by terms given in `t` and skeleton steps between `t` and `f`. In the case of the take step presented in Fig. 1. proposed solution should introduce the following cut:

```
show ∃ t : object HIDDENM1 .
 t in HIDDENR3 Y ∧
   X c= TARSKIR1 Y \ XBOOLE_0K4 { TARSKIK1 t }
proof-
 have x in HIDDENR3 Y ∧
    X c= TARSKIR1 Y \ XBOOLE_0K4 { TARSKIK1 x }
 proof(rule conjMI)...
 thus ?thesis using unfolded definitions bexI[of _ x];
qed
```

D. The rest of skeleton steps

The remaining Mizar skeleton steps not explained so far are: given, hereby and also per cases steps that play a similar role as skeleton steps, but do not modify a considered thesis.

The given step is an abbreviation for an assume step that as a valid proposition introduces an existential statement and a consider step that creates a fresh constant and provides access to the instantiated existential statement with the constant. We replace every such step via assume, consider/obtain.

To describe the hereby step, we must first introduce the now concept, since hereby is a simply abbreviation of thus now. In the Mizar language now opens a sub-deduction where the proved statement is not written explicitly but is reconstructed from the sub-deduction. The sub-deduction can be conducted with the support of all kinds of skeleton steps with only one restriction that each take steps have to be formulated as "take *new constant=term*" to indicate all terms that should be replaced by a variable bounded by the appropriate existential quantifier. Weaker equivalent of the now blocks are present in some proof languages, for example the Isabelle/Isar `{...}` concept supports only deduction via fix–assume where the last `have` step is chosen as the conclusion. Therefore we replace the now blocks by *normal* steps with reconstructed statements in our export.

The per cases step is a kind of step that generally reflects the idea of the informal proof by cases, where a thesis has to be justified under each of logically complementary alternatives, but not necessarily with identical skeleton steps. We encapsulate the sub-deduction in each case as a justification of the corresponding implication "*case assumption* implies *reconstructed thesis*".

V. Our representation as a next stage to cross-verify MML in Isabelle

In this section we describe possibilities of our representation in relation to the needs of the Isabelle logical framework and in particular Isar reasoning patterns. In our previous work [18], we defined a unique and faithful equivalent of the Mizar dependent type system and higher-order concepts as an Isabelle object logic. This equivalent has been tested so far only on a manually reformalized part of the MML. However, the experience gained during manual re-formalization showed directions in which we can bring the Isar language closer to the Mizar one as well as unattainable goals, e.g., the take step. Our manual attempts to generate Isar reasoning patterns also showed that with enough effort, we can indicate corresponding lists of rules even for very intricate deductions. However, such list are too sensitive to minor changes, even in *simple* deductions. Our representation of proofs is an attempt to solve these problems on the MML side.

Opportunities offered by this representation at the moment have been visualized on a re-formalization of the theorem presented in Fig. 1 created in our Isabelle environment. The re-formalization is presented in Fig. 7 and reflects all elements contained in the automatically generated visualization[5].

The example demonstrates the usefulness of the reconstructed reserve concept (Section III) that is welcome in the human-readable export. Note that the reserve command is our Isabelle/Mizar equivalent of the Mizar reserve mechanism that collects variable names with their types. Therefore, we do not need mention the types of `X`, `Y`, `x` in quantified formulas same as in the Mizar proof scripts. Additionally, we can hide the first two quantifiers in the statement of the theorem, since the mtheorem command automatically binds free reserve variables, introduces them into the sub-deduction, and adds corresponding propositions of the shape "*term* is *type*" to the *background knowledge* of the proof stored by a designated theorem list (`ty`). Then the knowledge, extended by some additional informations is added to the list of premises by the proof method mauto before auto call (more detail in our formalization).

We can also observe consequences of the introduced cuts and the simplicity of the generated reasoning pattern described in Section IV. Note that Isabelle/Isar does not accept a given sub-deduction as the justification of a particular statement, even if it accepts justifications for all the steps in a sub-deduction, since the given reasoning pattern does not precisely correspond to the statement and the sub-deduction.

VI. Conclusion

We have introduced a combination of the Mizar syntactic and semantic proof representations and presented

[5]See http://alioth.uwb.edu.pl/~pakkarol/fedcsis2018/mispdf/xboole_0.pdf

```
reserve X,Y for set
reserve x for object
mtheorem xboole_0_th_8:
 ∀ X. ∀ Y. X c< Y ⟶
   (∃ x. x in Y ∧ X c= Y\{x} )
proof -
 have ∀ X. ∀ Y. X c< Y ⟶
   (∃ t:object. t in Y ∧ X c= Y\{t} )
 proof(rule balll,rule balll,rule impl)
  fix X assume [ty]:X be set
  fix Y assume [ty]:Y be set
  assume A1: X c= Y
  then obtain x where [ty]: x be object and
   A2: x in Y and A3: ¬ x in X using xboole_0_th_6
   by mauto
  show ∃ t : object. t in Y ∧ X c= Y\{t}
  proof(rule bexI[of _ x],rule conjMI)
   show x in Y using A2 by auto
   have ∀ y : object. y in X ⟶ y in Y\{x}
   proof(rule balll,rule impl)
    fix y assume [ty]:y be object
    assume A4: y in X
    hence y <> x using A3 by auto
    hence A5: ¬ y in {x} using tarski_def_1
     by auto
    have X c= Y using A1 xboole_0_def_8
     by mauto
    hence y in Y using A4 tarski_def_3 by mauto
    thus y in  Y\{x} using xboole_0_def_5 A5
     by mauto
   qed mauto
   thus X c= Y\{x} using tarski_def_3 by mauto
  qed mauto
 qed mauto
 thus ?thesis by mauto
qed
```

Fig. 7. An example Isabelle/Mizar reasoning that exactly corresponds to the combined representation of the proof script presented in Fig. 1. Note that the highlighted part of reasoning can be removed from the script without influence for its correctness just like in the Mizar proof scripts (for more detail see our formalization)

a number of possibilities that such combined data offers. We rebuild the Mizar natural deduction style to the fix–assume–thus proof outlines present in declarative proof modes, including that of Isabelle/Isar. The transformation preserves all Mizar components using cut introduction. This eliminates all the Mizar natural deduction constructions for which adequate equivalent constructs do not exist in other systems. In particular, it reduces the distance between the Mizar and Isabelle/Isar proof styles, which we showed in an experiment in which a transformed MML proof could be directly cross-verified in Isabelle/Mizar. The original and transformed proofs for the first 50 Mizar articles are available at:

http://alioth.uwb.edu.pl/~pakkarol/fedcsis2018/

Future work could target a further reduction of the distance between Mizar and Isabelle. The MML export combining the syntactic and semantic representations, as well as the Isabelle/Mizar object logic and its packages are under active development. Many Mizar concepts are still not completely expressed in Isabelle (e.g., the Mizar reconsider construction) or they have not been sufficiently verified (e.g., the Mizar structures [22] which are used directly or indirectly in the latter 74% of the MML). We believe that under a suitable proof translation ATPs are strong enough to accept all justifications accepted by the Mizar checker. However, to make the automation more efficient and practical, it might be necessary to extract additional knowledge from the semantic representation used as an initial information by the checker.

***Abstract*—The paper discusses the problem of formal modeling of the interpretation of statutory legal norms. The authors propose a comprehensive framework that allows the representation of the interpretation process. The authors' proposal is illustrated by a real-life example.**

Introduction

LEGAL interpretation is one of the most important problems in legal theory and practice. The aim of our paper is to develop formalized descriptive model of statutory interpretation. We are interested in formal modelling of actual interpretive argumentation rather than in developing its idealized picture. The second aim of our work is to integrate our model of legal interpretation with one of the most popular formal model of argumentation (ASPIC+ [1]). The development of a fully-fledged descriptive model of legal interpretation is a complex research project, and perhaps rather a regulative idea rather than an operational goal. The realisation of such a goal requires dealing with certain problems that remain unsolved in the current state of the art. In this contribution we model an actual case involving statutory interpretation to represent different arguments developed by different agents for the sake of the realisation of goals important for these agents.

I. Interpretive agents

The authors of [2] notice that a significant role in the argumentation process is played not only by the interpretive argument itself, but also by the agent putting forward the argument, since in legal discourse every agent plays a particular role with his/her own preferences and goals. In [2] a semi-formal framework is presented which permits to model the agent's role in interpretive arguments. This framework will constitute the grounds for the model of agent in our argumentative system.

II. Argumentation framework

ASPIC$^+$ is a well-developed framework for structured argumentation representation ([1], [3] and many others). As such, it does not specify any logical language to represent arguments, but argumentation represented in this framework may be instantiated in different languages.

III. The Model for Legal Interpretation

Let $\mathscr{L}$ be any well-defined and closed under negation language. First, let us define certain postulated sets. Let S be a legal system in question, let C be a concrete or a hypothetical case in question, and let $\mathscr{L}$ be the language under consideration.

Definition 1 (Source Set): Let K be a knowledge base in argumentation system AS. Then $SRC(S,C)$ (Source Set under a legal system S in the context of a case C) consists of:

1) $ST(S)$ is the set of all explicit statutory norms under a system S. $ST(S) \subset K_p$. Each norm in $ST(S)$ is represented by a predicate $norm(\alpha,\beta,\gamma)$, where $\alpha \in \mathscr{L}$ is the name of the norm, β is a wff in $\mathscr{L}$ which represents the conditional part of the norm, and γ is a wff in $\mathscr{L}$ which represents the conclusion of the norm;
2) $Cases(S)$ is the set of wff in $\mathscr{L}$ which represents all accessible judicial opinions ruled under a system S. $Cases(S) \subset K_p$;
3) $Doctrine(S)$ is the set of wff in $\mathscr{L}$ which represents all scholarly opinions concerning legal issues arising under a legal system S. $Doctrine(S) \subset K_p$;
4) $Materials(S)$ is the set of wff in $\mathscr{L}$ which represents the remaining official materials that may be relevant for the sake of interpretation of statutory law under a system S, such as legislative opinions, soft law and the like. $Materials(S) \subset K_p$;
5) CSK is the set of wff in $\mathscr{L}$ which represents all available common sense knowledge propositions. $CSK \subset K_p$;
6) SK is the set encompassing propositions which are referred to as Scientific Knowledge. $SK \subset K_p$;
7) $Facts(C)$ is the complete set of propositions describing the facts of a case C in question. $Facts(C) \subset K_n$;
8) $IT(\mathscr{L})$ is the set of all Interpretive Terms in a language $\mathscr{L}$, that is, terms that may be used for the sake of the interpretation of any term of $ST(S)$. $IT(\mathscr{L}) \subset K_p$;

9) $R_i \subset R_d$ is the set of all argumentation schemes (represented as defeasible inference rules) used to generate interpretive arguments from the knowledge contained in sets 1)-8) above, hereafter referred to as Source Sets.

Definition 2 (Extensional relations): Extensional relation $INC \subset \mathscr{L}$ is a set of binary relations encompassing inclusion relation $\sqsubseteq$, strict inclusion relation $\sqsubset$, and equivalence relation ($\equiv$) defined on the set $\mathscr{L}$.
If $X \sqsubseteq Y$ and X and Y are two expressions in $\mathscr{L}$, then we claim that X is within the scope (semantic extension) of Y.

Definition 3 (Interpretation): $\bullet \in \mathscr{L}$ is a binary relation word denoting "legally counts as" or "is interpreted as". We introduce this relation in order to grasp the phenomenon in which, in certain cases, an expression may legally count as an instance of another expression even though it is situated outside its semantic extension. It it worth to notice that the relation "is interpreted as" should be understood as a presumptive (defeasible) one.
Relation $\bullet$ is reflexive (because $\phi \bullet \phi$), not symmetric (because if $\phi \bullet \psi$ then it is not necessary that $\psi \bullet \phi$), and transitive (because if $\phi \bullet \psi$ and $\psi \bullet \delta$ then $\phi \bullet \delta$)
Each of the sources from a Source Set can be interpreted as a kind of a knowledge base which allows to infer and examine whether a given proposition is in the scope of meaning of a certain expression.

Definition 4 (Interpretive Sentences): All complex expressions of a language $\mathscr{L}$ constructed by means of any of the elements from the set INC or by means of the relation word $\bullet$ will be referred to as Interpretive Sentences.
The legal theory points out that Interpretive Sentences are justified by means of interpretive arguments or canons. In our work interpretive canons will be represented by interpretive inference rules:

Definition 5 (Interpretive Inference rules): All inference rules whose conclusions are interpretive sentences or undercutters of other interpretive inference rules will be referred to as interpretive inference rules. The set of all Interpretive Inference Rules will be denoted as R_i ($R_i \subset R_d$)

Definition 6 (Interpetive Arguments): If A is an argument constructed by means of a knowledge base K in AS and the last inference rule in A is built on the basis of an interpretive inference rule ($TopRule(A) \in R_i$), then argument A is an interpretive argument.
Although we assumed that the sources of justifications do not have to be consistent, we assume that an interpretive argument should be internally consistent. By an internally consistent argument we understand an argument in which:
$\nexists_{\varphi,\psi}(\varphi \in Prem(A) \wedge (\psi \in Prem(A) \vee Conc(A) = \psi) \wedge \psi \in \overline{\varphi})$.

A. Authorship of interpretive arguments

The authors of [2] point out that the notion of interpreting agent plays a crucial role in a descriptive model of legal interpretation. The notion of interpreting agents enables us to attibute certain statements and arguments to a given agent, which allows for a more fine-grained representation of argumentation in real-life cases.

Definition 7 (Set of Agents): Let $IA \subseteq K_n$ be a collection of the agents' names. Each $ia \in IA$ will be the name of the agent present in a legal case c.

Definition 8 (Authorship of an argument): The relation of authorship is a subset of a Cartesian product:
$\mathscr{R} \subseteq IA \times \mathscr{A}$, i.e. a set of pairs: (ia, A), where $ia \in IA$ and $A \in \mathscr{A}$.
This relation shows who the author of a given argument is. The argument can have many authors; one agent may be the author of many arguments.
To consider the issue of argument authorship in structured argumentation framework, the *SAF* from [1] definition must be adjusted:

Definition 9: A structured authored argumentation framework (*SAAF*) is a tuple $\langle \mathscr{A}, \mathscr{C}, \preceq, \mathscr{R} \rangle$ where:

- $\mathscr{A}$ is the smallest set of all finite arguments constructed from a knowledge base in AS;
- $\preceq$ is an ordering on $\mathscr{A}$;
- $(X,Y) \in \mathscr{C}$ iff X attacks (is in conflict with) Y.
- $\mathscr{R}$ is an authorship relation on sets $IA \subset K_n$ and $\mathscr{A}$.

B. Model of Interpreting Agent

Definition 10 (Agent): Basing on the model from [2], it is assumed that an agent ia in a structured authored argumentation framework *SAAF* will be a tuple:
$(KB(ia), preferences(ia), authority(ia))$
Where:

- $KB(ia) \subseteq SRC(S,C)$ The knowledge base of an agent IA is a subset of the Source Set
- $preferences(ia) \subseteq K_n$ and $preferences(ia) = NormPref(ia) \cup SubPref(ia)$
  - $NormPref(ia) = (<_{NP(ia)}, \mathscr{L})$ $NormPref(ia)_t$ is a partial order on set wff in $\mathscr{L}$
  - $SubPref(ia) = (<_{SP(ia)}, \mathscr{L})$ $SubPref(ia)$ is a partial order on set wff in $\mathscr{L}$
- $authority(ia) \subseteq K_n$ The relation of Authority is a subset of a Cartesian product $authority(ia) \subseteq S(ia) \times IA$, where $S(ia)$ is the set of all sentences stated by an Interpretive Agent in the case c (formally: $S(ia) = \{Conc(A_n) : (Conc(A_n), ia) \in \mathscr{R}\}$, i.e. a set of pairs of statements given by the agent in a case c and agents formally bound by these sentences).

On the basis of the relations $preferences(ia)$, $authority(ia)$, and the relevant inference rules (to appear in future work), it will be possible to establish a relation of order between conflicting arguments in a structured argumentation framework (relation $\preceq$).

IV. Example

This section presents a modelling of interpretation in an actual case also discussed in [2]. However, here, in addition to presentation of the knowledge bases of the relevant agents, we also reconstruct the arguments developed and used by them. The legal issue at stake was as follows. Generally, according to the Personal Income Tax Act (PITA), the taxpayer's total

revenue is taken into account in the calculation of taxable income, unless this revenue is exempted. Pursuant to the provision of 21.1.47c of the PITA, revenues raised by a natural person from a governmental or an executive agency, where the agency is financed from the state budget, are exempted from tax. The protagonist of the case obtained a housing benefit from the Military Housing Agency and claimed that this revenue was exempted from tax. However, the tax authorities disagreed, pointing out that the legislative materials suggested that the exemption is question was intended to apply to entrepreneurs, while the protagonist of the case was not one. The assessment of the Court is that the opinions presented by the tax office are not sufficiently justified both in relation with the provisions of tax law and the factual circumstances of the case. Such a conclusion results primarily from the outcomes of the linguistic interpretation of the Act. It follows from this regulation that in order to apply the exemption in question, two conditions must be fulfilled: first, the taxpayer is to receive a specific amount from a government or executive agency; second, this agency is to receive funds for this purpose from the state budget. In the view of the Court, both conditions which determine the exemption are fulfilled in this case. It should be highlighted that in the interpretation of tax law provisions, the linguistic interpretation of the text of the Act has the primary and dominant weight. Under no circumstances is it permitted in the tax law system to apply teleological, systemic, or historical interpretation of a provision of tax law to the factual circumstances should its result (even if obtained correctly) be inconsistent with the result of the linguistic interpretation.

Basics:

First, the alphabet of the language is defined:

- Propositional atoms: $\{housing\_benefit, natural\_person, person, enterprise, revenue\_from\_agency, revenue, agency\_financed\_from\_the\_state\_budget, tax\_law, tax, d_{ling}, d_{hist}, d_{mod}, r1, r2\}$
- symbols: $\{\neg, \wedge, \vee, \supset, \sqsubseteq, \sqsubset, \equiv, \bullet, norm(,,)\}$
- Interpreting Agents: $IA = \{ia_{person}, ia_{taxOffice}, ia_{judge}\}$

Knowledge Base

The authors of [4] (section 4.0) distinguish two ways of utilization of the $ASPIC^+$ framework: domain-specific vs. general inference rules. In order to model our example, we will use the second one.

Facts of the case:
$Facts(C) = \{housing\_benefit, natural\_person, revenue\_from\_agency, agency\_financed\_from\_the\_state\_budget, tax\_law\}$
Commonsense knowledge:
$CSK(S) = \{revenue\_from\_agency \sqsubseteq revenue\}$
Applicable law:
$ST(S) = \{$
$norm(r1, housing\_benefit \wedge revenue\_from\_agency \wedge agency\_financed\_from\_the\_state\_budget, \neg tax,$
$norm(r2, revenue, tax)\}$
There are two legal rules: it follows from the first one that revenues raised from a governmental or an executive agency, where the agency is financed from the state budget, are exempted from tax, whereas the other rule states that all kinds of revenue are taxable.
Historical materials:
$Materials(S) : \{norm(r1, \alpha, \beta) \wedge natural\_person \supset \neg(natural\_person \wedge \alpha \bullet \alpha)\}$
According to historical materials, the legal rule $r1$ is not intended for natural persons, but for companies: a natural person does not fulfill the conditions of rule $r1$.
Doctrine:
$Doctrine(S) = \{(n(A) = d_{hist} \wedge tax\_law) \supset \neg A)\}$
The use of historical interpretation is forbidden in tax law.
Inference Rules:
Interpretive inference rules $R_i =$

- linguistic interpretation $d_{ling} : \alpha, \alpha \between \beta \Rightarrow \alpha \bullet \beta$, where $\between$ is one of the extensional relations: $\sqsubseteq, \sqsubset, \equiv$.
- historical interpretation $d_{hist} : \alpha, (\alpha \bullet \beta) \in Materials(S) \Rightarrow \alpha \bullet \beta$
- interpretation $d_{int} : \alpha, \alpha \bullet \beta \Rightarrow \beta$

Defeasible inference rules $R_d =$

- defeasible modus ponens $d_{mod} : \alpha, (\alpha \supset \beta) \Rightarrow \beta$
- legal rule application: $d_{legal} : \alpha, norm(r, \alpha, \beta) \Rightarrow \beta$

Where α, β are formulae in $\mathscr{L}$, $r \in \mathscr{L}$ is a legal rule name.

Interpreting Agents

The models of interpreting agents are adapted from [2]:
Since none of the agents from our case built arguments on the basis of the sets *Cases*, *CSK*, and *SK*, we assume that they are empty for all agents.
Agent: ia_{judge} $KB(ia_{judge})$:

- $ST(ia_{judge}) = \{$ $norm(r1, housing\_benefit \wedge revenue\_from\_agency \wedge agency\_financed\_from\_the\_state\_budget, \neg tax),$ $norm(r2, revenue, tax)\}$
- $Doctrine(ia_{judge}) = \{(InfRule(A) = d_{hist} \wedge tax\_law) \supset \neg A)\}$
- $Materials(ia_{judge}) = \varnothing$
- $Facts(ia_{judge}) = Facts(C)$
- $R_d(ia_{judge}) = R_d$

Preferences: In the analyzed case, the agent does not use his/her preferences
Authority: Interpretive statements made by the judge are binding on the tax office and the person:
If $\alpha \in S(ia_{judge})$ then $(\alpha, ia_{person}) \in authority(ia_{judge})$ and $(\alpha, ia_{taxOffice}) \in authority(ia_{judge})$
Agent: $ia_{taxOffice}$
$KB(ia_{taxOffice})$:

- $ST(ia_{taxOffice}) = \{$ $norm(r1, housing\_benefit \wedge revenue\_from\_agency \wedge agency\_financed\_from\_the\_state\_budget, \neg tax),$ $norm(r2, revenue, tax)\}$
- $Doctrine(ia_{taxOffice}) = \varnothing$

- $Materials(ia_{taxOffice}) : \{norm(r1,\alpha,\beta) \wedge natural\_person \supset \neg(natural\_person \wedge \alpha \bullet \alpha)\}$
- $Facts(ia_{taxOffice}) = Facts(C)$
- $R_d(ia_{taxOffice}) = R_d$

Preferences: $NormPref(ia_{taxOffice} = SubPref(ia_{taxOffice})$.
The agent prefers rules which increas the collected tax:
$NormPref(ia_{taxOffice}) = \{r1 <_{NP(ia_{taxOffice})} r2\}$
In the analyzed case, the agent does not use his/her preferences.

Authority: Interpreting statements made by the tax office are binding on the person:
If $\alpha \in S(ia_{taxOffice})$ then $(\alpha, ia_{person}) \in authority(ia_{taxOffice})$

Agent: ia_{person}
$KB(ia_{person})$:

- $ST(ia_{person}) = \{$ $norm(r1, housing\_benefit \wedge revenue\_from\_agency \wedge agency\_financed\_from\_the\_state\_budget, \neg tax)$, $norm(r2, revenue, tax)\}$
- $Doctrine(ia_{person}) = \varnothing$
- $Materials(ia_{person}) = \varnothing$
- $Facts(ia_{person}) = Facts(C)$
- $R_d(ia_{person}) = R_d$

Preferences: In the analyzed case, the agent does not use his/her preferences

Authority: Interpreting statements made by a person are not binding on anyone:
$authority(ia_{person}) = \varnothing$

Arguments:

First of all, the arguments of the agent *person* are presented:

A_1 : $natural\_person$
A_2 : $housing\_benefit$
A_3 : $revenue\_from\_agency$
A_4 : $agency\_financed\_from\_the\_state\_budget$
A_5 : $norm(r1,\alpha,\beta)$ where: $\alpha = housing\_benefit \wedge revenue\_from\_agency \wedge agency\_financed\_from\_the\_state\_budget$, $\beta = \neg tax$,
A_6 : $A_1, A_2, A_3, A_4 \sqsubseteq \alpha$
A_7 : $A_6 \Rightarrow (A_1 \wedge A_2 \wedge A_3 \wedge A_4) \bullet \alpha$ (Inference rule: d_{ling})
A_8 : $A_7 \Rightarrow \alpha$ (Inference rule: d_{int})
A_9 : $A_8, A_5 \Rightarrow \neg tax$ (Inference rule: d_{legal})

It follows from the above arguments that since the conditions of the legal rule $r1$ are fulfilled, the revenue should not be taxable.

Next, the arguments of agent $taxOffice$ are presented:

B_1 : $Materials(ia_{taxOffice}) : norm(r1,\alpha,\beta) \wedge natural\_person \supset \neg(natural\_person \wedge \alpha \bullet \alpha)$
B_2 : $B_1, A_1, A_2, A_3, A_4, A_5 \Rightarrow \neg((A_1 \wedge A_2 \wedge A_3 \wedge A_4) \bullet \alpha)$ (Inference rule: d_{hist})

The arguments of tax authorities are based on historical materials from which it can be concluded that the legal rule $r1$ does not apply to natural persons, and therefore the natural person (even if theoretically the conditions of $r1$ are fulfilled) cannot be interpreted as fulfilling the conditions of $r1$.

Arguments A_7 and B_2 are in conflict (B_2 rebuts A_7), and hence the case is decided by the judge:

The arguments of the agent *judge*:

C_1 : $Doctrine(ia_{judge}) = \{(InfRule(A) = d_{hist} \wedge tax\_law) \supset \neg A)\}$
C_2 : $InfRule(B_2) = d_{hist}$
C_3 : tax_law
C_4 : $C_1, C_2, C_3 \Rightarrow \neg B_2$ (Inference rule: d_{mod}).

Arguments A_7 i B_2 are, on the basis on definition 11, contradictory.

According to the doctrine (arg C_1), it is forbidden to use historical interpretation in tax law, and hence argument C_4 attacks (undercuts) argument B_2.

Since argument B_2 is undercuted by argument C_4 and:

- $(ia_{judge}, C_4) \in \mathscr{R}$
- $(Conc(C_4), ia_{person}) \in authority(ia_{judge})$,
- $(Conc(C_4), ia_{taxOffice}) \in authority(ia_{judge})$

then C_4 defeats B_2.

Since C_4 defeats B_2, then C_4 defends A_7.

V. Conclusions

The main aim of our work was to develop a formal descriptive model of statutory interpretation which can be integrated with one of the most popular argumentation frameworks (ASPIC+ [1]). Our proposal was illustrated by a model of a real life example of a legal case. Compared to the models presented in [5], [6], [7], our model is more comprehensive and abstract. We focused on the problem of integrating interpretation with the entire argumentation process, on the roles played by agents, disregarding the discussion of the structure of interpretive arguments.

8th International Workshop on Advances in Semantic Information Retrieval

THE International Workshop on Advances in Semantic Information Retrieval is organized as an event within FedCSIS. In 2018, we are running our eighth workshop. It is gaining popularity among researchers from Europe and Asia.

We are doing our best to follow the changes in the area of semantic information retrieval and making the necessary adjustments in the set of topics of interests. We shift the focus of this workshop on the most challenging problems. The ASIR'18 workshop will continue to maintain high standards of quality and organization, set in the previous years.

Characterizing the current tendency in development of semantic technologies, we point out that recent advances form a solid basis for a variety of methods and instruments used in multimedia information retrieval, knowledge representation, discovery and analysis. They influence the way and form of representing documents in the memory of computers, approaches to analyze documents, and techniques to mine and retrieve knowledge. In its turn, gathered knowledge is used to build problem domain models and support decision making. The abundance of video, voice and speech data also raises new challenging problems in developing multimedia information retrieval systems.

We believe that the ASIR'18 workshop will facilitate discussions of new research results in this area, and will serve as a meeting place for researchers from all over the world. Our aim is to create an atmosphere of friendship and cooperation for everyone, interested in computational linguistics, data-driven decision making, data analytics and semantic information retrieval. We welcome all interested researchers to join this event.

Topics

The topics and areas include but not limited to:

- Data analytics.
- Data-driven decision making.
- Domain-specific semantic applications.
- Evaluation methodologies for semantic search and retrieval.
- Knowledge representation and management.
- Models for document representation.
- Natural language semantic processing.
- Ontology for semantic information retrieval.
- Ontology alignment, mapping and merging.
- Query interfaces.
- Searching and ranking.
- Semantic multimedia retrieval.
- Visualization of retrieved results.

***Abstract*—Document retrieval from digital libraries based on user's query is highly affected by the terms appeared in the query. In many cases, there are some documents in the digital libraries that do not share exactly the same terms with the query, but they are related to the user's need. We address this challenge in this paper by introducing a new subject-based retrieval approach in which, apart from ranking documents based on the terms in the query, a new subject-based scoring scheme is defined between the query and a document. We define this score by introducing a new vector space model in which a vectorized subject-based representation is defined for each document and its keywords, and the terms in the query, as well. We have tested the new subject-based scoring scheme on a database of scientific papers obtained from Web of Science. Our Experimental results show that in 83% of times users prefer the proposed scoring scheme with respect to the classic scoring ones.**

I. Introduction

NOWADAYS a considerable amount of information is spread over billions of various documents saved in digital libraries. Although, various retrieval tools and algorithms have been developed to address accessing such information easily, in many cases these algorithms and tools are limited by the user's query. Many of the retrieval methods try to go beyond the exact terms in user's query. In other words, instead of only relying on Bag-of-Words (BoW) representation of the query, new approaches have been developed such as interactive query refinement, relevance feedback from user, word sense disambiguation, and clustering search results [1], [2], [3], [4], [5] to guid the user in his/her *journey of information retrieval*. More specifically, some of these methods are based on improving user involvement (implicitly or explicitly) in the retrieval process by receiving relevance feedback or providing interactive search tools. Some other methods rely on expanding user's query using query expansion techniques [6].

In this paper, we address these challenges by introducing a new *subject-based* document retrieval approach. Instead of applying query expansion techniques or using semantic relations between words and terms based on ontologies, we introduce a new subject-based representation for each document in the digital library, using vector space model. By the use of the proposed approach, we can measure how much a document and a given query are similar and share same subjects, even if they do not share same terms. The proposed approach is applicable in specialized, scientific digital libraries in which in addition to a set of keywords/tags usually assigned to each document, a set of predefined disciplines/subjects are also available and each document usually falls into a specific discipline, subject or category. In such specialized libraries, documents are usually indexed based on subjects and keywords assigned to them, to improve the indexing, retrieval and archiving tasks.

In the proposed method, first, a new subject-based vectorized representation for each keyword is introduced by relying on the knowledge obtained from all documents that have been already indexed in the digital library. Then, a probabilistic, vectorized subject-based representation for each document is estimated. Each element of this vector shows how much each document belongs to a specific subject. This consideration is based on the assumption that each document might belongs to more than one subject/category. This is a valid assumption that is usually considered in well-known retrieval/indexing approach such as topic modeling. Then we use these vectors in order to calculate subject-based similarity between a given query and documents.

After a brief literature review in section two, we describe our method in details in section three. Then, in section four, a series of experiments are presented to show the effectiveness of our approach, and The experimental results are analyzed. Finally, we present our conclusions in section five.

II. Literature Review

Different types of research have been done in order to improve the performance of retrieval algorithms, by considering semantic relationship between the query and documents. Tai et al. used supervised learning to improve vector space information retrieval model [7] by using matrices with 1s and 0s to show the relevance of queries and documents. Hofmann presented a statistical model based on Latent Semantic Analysis (LSA) leading to probabilistic latent Semantic Analysis

(PLSA) [8]. Maitah et al. investigated the use of an adaptive algorithm under vector space model, extended Boolean model, and language model in information retrieval [9]. Wang et al. presented a new document retrieval framework that learns a probabilistic knowledge model for improving document retrieval [10]. The model was represented by a network of association among concepts defining key domain entities and is extracted from a corpus of documents or from a domain knowledge base. Campos et al. proposed a probabilistic model based on Bayesian network for document retrieval [11] and used the network to compute posterior probabilities for the relevance of the documents. Mohebi et al. proposed a new subject-based retrieval method to retrieve all documents from a scientific digital library related to that subject. Their proposed method does not rely on user's query, rather the user specifies a specific topic or subject, and all related scientific documents related to this subject are retrieved [12]. Siddiqui proposed a hybrid IR model with two stages: first, the document collection is downsized using vector model based on a given query, second a conceptual graph based representation is used to rank the documents [13].

Sometimes retrieving the relevant text is hard because the query and the document may use different vocabularies. Mitra et al. trained a word2vec embedding model to improve the ranking of retrieved documents. In their model they map the query words into the input space and the document words into output space, and compute a relevance score by aggregating the cosine similarities across all word pairs [14].

Relevant document may be clustered together with other relevant items that may not contain query terms and could be retrieved through a clustered search [15].

Most of the methods in the literature rely completely or partially on the terms presented in the user's query. However, when a document does not contain any of the terms in the query, but is related to the query, then that document has a low chance to appear in the top retrieved documents. We address this challenge in this research by proposing a new method based on Vector Space Model. In this model a new subject-based representation for each document and the query is defined, that is independent of the query terms. Subject-based mapping of all documents in this method is a pre-processing activity that should be done once for all documents in the data-base.

III. Proposed subject-based scoring scheme

The proposed scoring scheme can be applied on a basic retrieval model such as BM25, in order to re-order the ranking of a set of retrieved documents. The proposed scheme calculates a new subject-based distance between a document and a query. This distance is a semantic-based one which calculates the relationship between a query and a given document apart from their joint terms. For this purpose, we assume that $\mathcal{D}$ is the document collection, with N documents, while every document has a set of keywords and a set of subjects associated with it. We aggregate all subjects and all keywords of all documents in set $\mathcal{S}$ and $\mathcal{K}$, respectively, i.e.:

$$\mathcal{D} = \{d_1, \ldots, d_N\}, \mathcal{S} = \{s_1, \ldots, s_M\}, \mathcal{K} = \{k_1, \ldots, k_L\}. \quad (1)$$

Our ultimate goal is to define a vector space model in order to represent each document as a subject-based vector. Consequently, the subject-based vector for each document can be compared with the subject-based vector of a given query to compute their relationship. In order to do so, we rely on the keywords for each document. In other words, we introduce a method to represent each keyword as a subject-based vector, with the size of M, to reflect how much the keyword is related to every subject. For a keyword k_l, this vector is defined as:

$$\mathbf{vk}_l = \Big(p_l(s_1),\ p_l(s_2), \ldots,\ p_l(s_M)\Big), \quad (2)$$

where $p_l(s_m)$ shows how much keyword k_l is related to subject s_m. In other words, $p_l(s_m)$ can be considered as the conditional probability that a given keyword belongs to a specific subject, defined by:

$$p_l(s_m) = P(s_m|k_l) = \frac{P(s_m, k_l)}{P(k_l)}. \quad (3)$$

We estimate this probability based on the data available in $\mathcal{D}$, as follows:

$$\hat{P}(s_m|k_l) = \frac{\sum_{d_i \in D_l} ds^i_m}{|D_l|}, \quad (4)$$

where D_l is the set of all documents with keyword k_l, and ds^i_m denotes the number of documents in D_l containing subject s_m. Finally, for a document d_i with L_i keywords, we represent d_i as a $L_i \times M$ matrix (X_i) where each row corresponds to each keyword of d_i and each column corresponds to a subject. For the sake of simplicity, we assume that $k_1, k_2, \ldots, k_{L_i}$ are keywords of d_i, then we have:

$$\mathbf{X_i} = \begin{bmatrix} \mathbf{vk}_1 \\ \vdots \\ \mathbf{vk}_{L_i} \end{bmatrix} = \begin{bmatrix} p_1(s_1) & p_1(s_2) & \ldots & p_1(s_M) \\ \vdots & & & \\ p_{L_i}(s_1) & p_{L_i}(s_2) & \ldots & p_{L_i}(s_M) \end{bmatrix}. \quad (5)$$

Now we can define a subject-based representation vector for every document, based on the matrix in 5. We call this vector $\mathbf{vs_l}$. Each component in this vector corresponds to a subject in $\mathcal{S}$, showing how much the document is related to that subject. Thus, each document d_i is mapped to a subject-based vector:

$$\mathbf{vs_i} = \frac{\sum_{l=1}^{L_i} \mathbf{vk_l}}{L_i} = \Big(\frac{\sum_{l=1}^{L_i} p_l(s_1)}{L_i}, \ldots, \frac{\sum_{l=1}^{L_i} p_l(s_M)}{L_i}\Big). \quad (6)$$

Every query Q, can also be mapped to a subject-based, M-sized, vector too. For this purpose, the query is processed first in order to extract its distinguished terms, i.e. $q_1, q_2, \ldots, q_r$. Thus, we have:

$$\mathbf{vs_q} = \frac{\sum_{l=1}^{r} \mathbf{vk_l}}{r} = \Big(\frac{\sum_{l=1}^{r} p_l(s_1)}{r}, \ldots, \frac{\sum_{l=1}^{r} p_l(s_M)}{r}\Big). \quad (7)$$

Based on the subject-based vectors for d_i and Q, a new subject-based scoring function is defined:

$$Score_{subject}(d_i, Q) = \frac{1}{\|\mathbf{vs_q} - \mathbf{vs_i}\|}. \quad (8)$$

A. Final combined scoring scheme

The proposed subject-based scoring scheme can be combined with different basic retrieval scoring schemes such as Okapi BM25 which is based on the probabilistic retrieval framework and ranks a set of documents based on the query terms appearing in each document. Given a query Q with r distinct terms, BM25 score is:

$$Score_{BM25}(d, Q) = \sum_{j=1}^{r} IDF(q_m) \frac{freq(q, d)(c+1)}{freq(q, d) + c(1 - b + b\frac{|d_j|}{avgdl})}, \quad (9)$$

where q_i is i-th term of query, $freq(q_i, d)$ is term frequency of q_i in document d, $|d|$ is the length of d in words and $avgdl$ is the average document length in the whole collection. Parameters c and b are usually chosen as $c \in [1.2, 2.0]$ and $b = 0.75$. $IDF(q_i)$ is the inverse document frequency (IDF) weight of the query term q_i and is usually calculated as:

$$IDF(q_i) = \log \frac{(N - n(q_i) + 0.5)}{(n(q_i) + 0.5)}, \quad (10)$$

where N is the total number of documents in the collection, and $n(q_i)$ is the number of documents containing term q_i. Now, we can define a combined scoring scheme based on the subject-based and BM25 scores:

$$Score_{final}(d, Q) = \alpha\ Score_{subject}(d, Q) + (1 - \alpha)\ Score_{BM25}(d, Q), \quad (11)$$

where $\alpha \in [0, 1]$ is a weighing parameter that need to be tuned. This score is applied on a set of documents retrieved based on a basic model such as BM25, in order to represent a new ranking for the retrieved documents.

IV. Experiments and Results

In order to examine the proposed method, we have considered a collection of scientific documents (articles) extracted from Web of Science (WoS) which contains all papers published from Iran in years $2013-2017$. The collection contains 98497 documents. Each document has a title, abstract, author, keywords and subjects. The subjects are assigned for each document by WoS, based on a list of predetermined categories in WoS. The collection contains 340836 keywords and 1200 different subjects. Two domain experts have classified 1200 subjects to eight main subjects including Art, Biosciences and Natural Sciences, Basic Sciences, Empirical Sciences, Humanities Sciences, Medicine and Treatment, Engineering.

In our experiment, we choose the top 100 documents for our query. Then, the top selected documents are ranked again based on $Score_{final}$. The subject-based vectors for keywords and documents in the database are calculated once. Thus, all vectors are calculated offline, and for every query presented to the system, only the corresponding vector for the query is calculated. For instance, given the following query:
"A Robust optimization for the milkrun problem under demand and travel time uncertainty",
the subject-based vector for the query is calculated based on the vectors of each term in the query, after stop word removal, as shown in Table I. $Score_{final}$ is calculated for the selected top documents based on the query $\mathbf{vs_q}$. Table II shows the $Score_{BM25}$, $Score_{subject}$, and $Score_{final}$ for the top retrieved documents, when $\alpha = 0.3$. Thus, we calculated retrieved documents changes as following:

$$Change(\%) = n_q \sum_{i=1}^{n_q} \min |R_i - i|, \quad (12)$$

while R_i is rank of i-th result in BM25 ranking and n_q is number of queries in experiment. In Fig. 1 we show how the ranking changes based on (12) in terms of α. In the proposed scoring scheme, when α is very small, the contribution of subject-based score is small, thus BM25 plays the key role in ranking the results. Alternatively, when α is large, near 1, the subject-based scoring share the most contribution in the final score. However, in a specific range, i.e. when $\alpha \in [0.25, 0.55]$, there is a competition between BM25 ranking and subject-based ranking. In this range, we see the maximum changes in the ranking between these two ranking schemes.

In order to evaluate the proposed approach on users' opinion, we have launched our model on a server and represented users the ranking obtained based on BM25 and proposed approach for a set of queries, while α changes. Then, we have asked the users to choose the best ranking. We have observed that the users prefer more the results based on the proposed scoring scheme than BM25 scoring scheme, when $\alpha = 0.3$.

TABLE I
SUBJECT-BASED VECTOR FOR QUERY: *"Robust optimization for the milkrun problem under demand and travel time uncertainty".*

Query term	s_1	s_2	s_3	s_4	s_5	s_6	s_7	s_8
Robust	0	0	0	0	0	0	1	0
Optimization	0	1	0	1	0	0	1	0
Milkrun	0	0	0	0	0	0	0	0
problem	0	0	0	0	0	0	0	0
demand	0	0	0	0	0	0	1	0
travel	0	0	0	0	0	0	1	0
time	0	0	0	0	0	0	0	0
uncertainty	1	1	0	0	1	1	1	0
$\overrightarrow{\mathbf{vs_q}}$	0.125	0.25	0	0.125	0.125	0.125	0.625	0

TABLE II
BM25 RANKING VERSUS PROPOSED RANKING FOR TOP 5 RETRIEVED DOCUMENTS WITH $\alpha = 0.3$

BM25 ranking	$Score_{BM25}$	$Score_{final}$	**Proposed ranking**
1	0.628	0.637	1
2	0.508	0.436	2
3	0.358	0.157	**5**
4	0.357	0.193	**3**
5	0.348	0.167	**4**

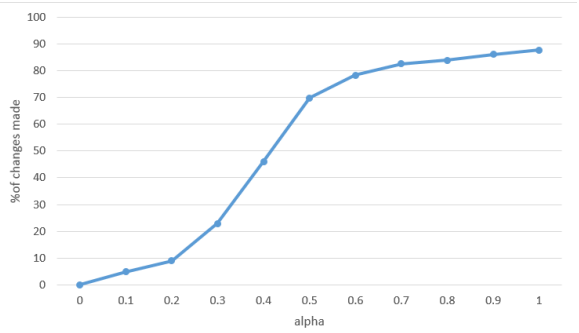

Fig. 1. How much the proposed method is able to change the ranking, when α changes. The vertical axis reflects the ranking difference between proposed method and BM25.

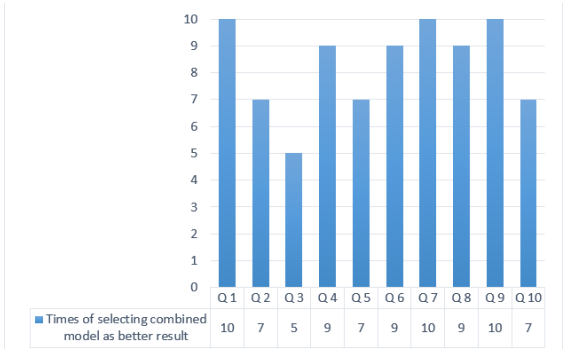

Fig. 2. How much different users prefer the proposed method versus BM25, in 100 experiments

We have also represented 10 users, 10 different queries (users and queries are independent) with both BM25 and proposed ranking scheme and ask them to choose the best results.

Based, on 100 experiments and results, we have obtained that in 83% of times, users preferred the proposed ranking scheme, as shown in Fig. 2.

V. Conclusions

This paper introduced a new vector based model for improving document retrieval, specifically when the documents are from a set of scientific databases, and each contains a set of keywords, and subjects assigned to it. A new scoring scheme is defined in which each document is represented as a vector of subjects. Based on this vector, a new subject-based scoring scheme is defined that can be combined with a basic scoring scheme such as BM25 in order to assign a new score for each document. The new scoring scheme is specifically practical when some terms in the user's query have not been appeared in the database. Thus, rather than retrieving documents based on the exact appearance of the user's term in the database, the proposed approach looks for documents related to the query conceptually, by comparing the subject-based vectorized representation. We have evaluated our proposed scoring scheme to examine how much it is able to change the results effectively, comparing with BM25. In addition we have evaluated the proposed approach based on user's satisfaction, and obtained that in 83% of times the users prefer the proposed scoring scheme than the basic frequency-based scoring scheme. For future research directions, we propose to examine other basic retrieval method rather than BM25, and combine them with the subject-based scoring scheme.

***Abstract*—This paper examines the perspectives of intonation processing for automatic keyword extraction. Based on a discourse intonation model from D. Brazil, automatic tone pattern recognition in speech stream is performed. It is shown that automatic classification of tone patterns can be done using simple polynomials and correlation. The original software tool *PitchKeywordExtractor (PKE)* was applied to academic discourse (on-line lectures) to extract keywords. The results were compared to the output of popular tools for speech analytics: *VoiceBase* and *IBM Watson*. All the records were processed also with Praat software and annotated by human experts. Experiments show that none of the automatic systems outperforms the others and PKE, VoiceBase and IBM Watson have the identical error rates with respect to human expert opinion. It motivates further research and supports the tendency to integrate intonation and, more generally, prosody processing in automatic keyword extraction.**

I. Introduction

AUTOMATIC keyword extraction is an important operation of textual information processing, e.g., information retrieval, summarizing, indexing, etc. Speech content occupies a large share in the overall information environment being therefore a matter for automatic keyword extraction [1]. The common practice to retrieve the keywords from speech is limited to text-based supervised and unsupervised methods applied to automatic speech recognition (ASR) output. Meanwhile, speech has its inherent feature, namely, speech prosody, that can be processed automatically to leverage keyword extraction.

Prosody processing for keyword extraction has not been thoroughly studied so far. Nevetheless, during past decades, it was repeatedly highlighted that the involvement of prosody knowledge into speech processing frameworks contributes to their performance. Even though there exists a significant diversity in phonetic and phonological approaches to prosody modelling, it is widely acknowledged, that speech prosodic markers are stable. They can be directly measured and reliably classified by means of machine learning [2], [3], [4].

Speech prosody encompasses all suprasegmental speech phenomena, but the present research is focused on only one aspect of prosody, i.e., intonation, in terms of pitch or fundamental frequency F_0. This paper addresses speech intonation in context of automatic keyword extraction in English academic discourse and contributes to the approach presented in [5] towards better understanding of applicability of computational prosodic modelling for keyword extraction and possible benefits for existing speech keyword extraction techniques.

The rest of the paper is organized as follows: Section I establishes the research background; Section II describes automatic tone pattern recognition using polynomials; Section III outlines word-to-frame mapping; Section IV presents the results of polynomial model (p-model) accuracy evaluation and cross-validation of *PitchKeywordExtractor* [5] along with two popular speech processing tools, *VoiceBase* and *Watson*; Section V summarizes the paper.

Research background for this work originates from three areas: automatic keyword extraction techniques, integration of prosody knowledge into speech processing and automatic tone pattern recognition:

A. Automatic keyword extraction techniques

Automatic keyword extraction has been a subject of extensive and detailed research in the past. An extreme demand for fast, cost-effective and accurate keyword extraction algorithms is motivated by a growing amount of digital text information. Text mining, automatic data collection indexing, extractive and abstractive text summarization, keyword-based information retrieval as well as other related tasks and applications strongly rely upon the sets of keywords (e.g., [6]).

Detailed surveys of the state-of-the-art keyword extraction techniques can be found in [7], [8], [9]. A comparative analysis of automatic keyword extraction algorithms along with text summarization challenges was presented in [10]. Existing techniques can be classified by approach as supervised and unsupervised, the latter including simple statistic, linguistics, graph-based and hybrid. Supervised techniques require annotated training data, while unsupervised operate without preliminary annotation or labelling (e.g., [7]). A comprehensive study of performance for supervised ensemble methods and base learning algorithms (Naive Bayes, support vector machines, etc.) can be found in [11].

Unsupervised methods were shown to be not less powerful than supervised ones; e.g., unsupervised morphology learning was found to produce similar results compared to a rule-based system [12]. In [9] automatic keyword extraction was performed very effectively with unsupervised graph-based keyword ranking. Keyword extraction from conversations using particle swarm optimization was shown to produce highly accurate query results [13].

B. Prosodic models in speech processing

Computational prosodic modeling integrated into speech processing workflow is a promising yet challenging area. Prosodic models have been reported to be helpful for various speech processing areas [14], e.g., automatic speech understanding (ASU), speech synthesis (TTS, text-to-speech) [15], [3], discourse tagging and segmentation [4] and automatic speaker verification [16]. It was shown that the combination of word and prosodic knowledge yielded the best results, with significant improvements over either knowledge source taken separately.

Prosodic models were found to increase speech recognition accuracy, having not been optimized for word recognition [4]. An impressive result in speech segmentation, where the prosodic model alone performed better than the language model alone [4], makes it reasonable to investigate the segmentation ability of prosodic models for keyword location within ASR output.

One of the key concepts of any prosodic model is a tone unit. In [17] the tone unit is defined as the realization of the information unit, which is extremely valuable in the context of keyword search. Both units are generated in the flow of discourse, referring to the phonological and grammatical levels respectively.

Prosodic models which motivated this research were Discourse Intonation model from D. Brazil et al. (communicative approach) [18] and Systemic Functional Linguistics of M. Hallidey et al. (grammatical approach) [17]. Both models operate with a set of tonal patterns, e.g., in Brazil model these are: *falling*, *rising*, *rising-falling*, *falling-rising* and *level*, each having a specific communicative payload. These tone patterns are connected to the categories of "given/new information" [17] or deemed to be "referring/proclaiming" [18], [19], [20], [21] This explicit relationship between intonation and meaning is exploited to search for keywords in speech.

C. Automatic tone pattern recognition

Location and classifying of tone units can be performed automatically. In [2] a 4-point model to approximate tone patterns is proposed and examined in contrast with other approximation models for tones (e.g., Bezier curves). [2] also presents a detailed study on 4-point model cascaded with several supervised classifiers and was shown to perform the best with a rule-based classifier. In [5] a continuous polynomial tone model (p-model) for Brazil tones was proposed. Functions inside p-model are used not to approximate pitch contours, but as ideal tone pattern sets to calculate correlations. Both models will be evaluated together to check p-model tone pattern recognition accuracy (see Experiment 1 in Section IV).

II. Automatic tone pattern recognition using polynomial model

Automatic tone pattern recognition implemented in PitchKeywordExtractor [5] is applied to locate a pitch pattern within a part of a record to retrieve a frame with a significant tone move. The task is to make a decision what pattern type is the closest to a frame of a record containing n readings of fundamental frequency (pitch) $F_0[k], 0 \leq k \leq n$ taken at the sample rate of f_d. $w_{min} \leq w \leq w_{max}$ is frame length range; $0 \leq l \leq n - w$ is frame shift from the first frame element. Thus, each frame contains lw-windowed signal $F_0[l : l + w]$ and one can easily see that these frames are of different length. To cope with it, a polynomial model can be easily scaled and shifted. Due to the pitch detection algorithm if for k-th sample $F_0[k]$ cannot be measured, it is defined as $F_0[k] = -1$. Median filtering is applied to smooth single pitch discontinuities.

A. Polynomial model (p-model)

We define 5 model functions ϕ_k, $k = 1..5$, which correspond to 5 Brazil tones - *falling*, *rising*, *rising-falling*, *falling-rising* and *level*. These functions are the 1st and 2nd order polynomials (Fig. 1).

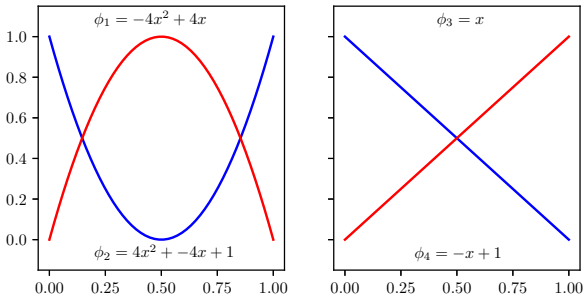

Fig. 1. p-model for Brazil tones

B. Classifier

To classify a frame by pattern type we evaluate its proximity to 4 model functions (except ϕ_5, "level"). ϕ_k, $k = 1..5$ define 5 decision regions separated by surfaces (Fig. 2).

Decision criterion to classify a frame to a region ϕ_i is

$$a_i = \frac{\sum_{k=l,F_0[k]\neq -1}^{w+l}(F_0[k] - \overline{F_0})(\phi_i((k-l)/w) - \overline{\phi_i})}{\sqrt{\sum_{k=l}^{w+l}(\phi_i((k-l)/w) - \overline{\phi_i})^2}},$$

and

$$\frac{a_i}{\sqrt{\sum_{k=l,F_0[k]\neq -1}^{w+l}(F_0[k] - \overline{F_0})}} = r_i \leq 1,$$

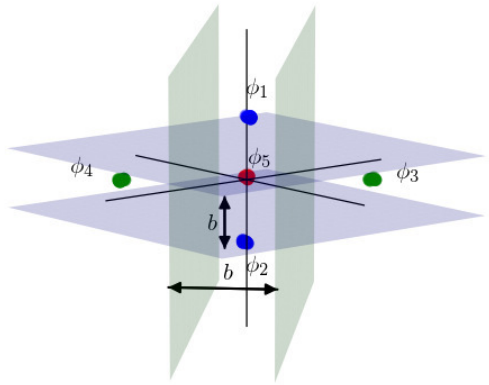

Fig. 2. Classifier decision regions $\phi_1 - \phi_4$. Parameter b sets the boundaries for *level* region ϕ_5.

where $\overline{F_0}$ is frame mean, $\overline{\phi_i}$ is model mean, r_i is normalized correlation; a_i is scaled correlation to distinguish any significant tone move from almost *level*. Decision criterion is scale and shift-invariant, thus, a_i are time and timbre-independent.

Decision is made as $k = argmax_i(a_i)$. If $max(a_k, b) \leq b$, where b is adjustable significance threshold and sets the *level* region, frame is classified as *level*, ϕ_5.

Thus, classifier outputs a pair (k, r). Frame overlaps are resolved [5] and the final frame set is successively transmitted to word-to-frame mapping.

III. WORD-TO-FRAME MAPPING

Frames where a tone move was detected during automatic tone pattern recognition and ASR output file are mapped to each other to locate a word within a frame. The goal of word-to-frame mapping is to find a word that was pronounced during a given interval defined by the frame boundaries; this word is deemed to be a keyword. Partial coincidence between segments and word timestamps is allowed and can be set as a parameter p.

Mapping in [5] could extract single words only. i. e. if one frame contained several matches with ASR output words, they were processed independently: e.g. for "computer science" the output list included both words one after another:"computer", "science". But very often a tone move refers to word collocation. Mapping is modified in order to extract keyphrases and word collocations as a single keywordlist entry. The following condition is checked sequentially for every frame:

If

$$\frac{L_{frame}}{t_2^{This_{word}} - t_1^{This_{word}}} \geq (1+p), \qquad (1)$$

then $[This_{word} \quad Next_{word}]$ is added to keyword list. This way keyphrases, e.g. of type "noun+noun" are constructed: "computer science", "artificial intelligence", "graduate student", etc.).

If

$$\frac{L_{frame}}{t_2^{This_{word}} - t_1^{Next_{word}}} \geq (1+p),$$

then $[This_{word}, Next_{word}, Next\_next_{word}]$ is added to the list to produce constructions like "noun+preposition+noun" or "particle+verb+particle/attributive construction" (e.g. "place of interest", "to follow up", "to examine closely").

A further improvement of mapping may be achieved by *break* indices processing if ToBI annotated data are available.

IV. EXPERIMENTS

PitchKeywordExtractor implementation details, libraries and tools are described in [5]. New experiments are aimed at checking the applicability of proposed p-model in comparison with one of the best existing models (4-point model) and to disclose abilities of intonation-based keyword extraction to contribute to existing speech keyword extraction techniques.

Publicly available online lectures were used as samples of academic discourse to retrieve automatically pitch patterns (Experiment 1) and extract keywords (Experiment 2). Results on three speakers are shown in Table I, II:

Speaker 1 is Benjamin Elman from Harvard University's Fairbank Center for Chinese Studies The Great Reversal: The "Rise of Japan" and the "Fall of China" after 1895 as Historical Fables.

Speaker 2 is JoAnne Stubbe, MIT 5.07SC Biological Chemistry, MIT OpenCourseWare Lexicon of Biochemical Reactions: Cofactors Formed from Vitamin B12.

Speaker 3 is Patrick Winston, MIT 6.034 Artificial Intelligence, MIT OpenCourseWare, Introduction and Scope

All the records were processed with Praat software and annotated by human experts. *Expert* row in Table II is the absolute value of agreement between two human experts about tone patterns and keyword set for each *Speaker*.

A. Experiment 1. Pattern recognition

In Experiment 1 samples of academic speech were processed to check pattern recognition ability of p-model. p-model and 4-point model [2] are evaluated together to check p-model applicability for tone pattern recognition (Table I). Both models reveal almost identical recognition recall, calculated as

$$R = \frac{T_2}{T_1} 100\%,$$

where T_1 is a number of tones in total (tone units pointed out by *Expert*), T_2 is a number of tones found automatically.

TABLE I
PATTERN RECOGNITION WITH P-MODEL AND 4-POINT MODEL

Speaker	Tones in total	$A_{p-model}$	$A_{4-point}$
Speaker 1	50	52%	49%
Speaker 2	22	36%	36%
Speaker 3	40	22%	25%

B. Experiment 2. Intonation-based keyword extraction vs. other algorithms

Cross-validation of PitchKeywordExtractor (PKE) algorithm [5] vs. *Expert* and two popular speech processing tools, *VoiceBase* and *Watson* was performed. All the sets of

TABLE II
INTONATION-BASED KEYWORD EXTRACTION VS. HUMAN EXPERTS, VOICEBASE AND WATSON

Experiment	Speaker 1	Speaker 2	Speaker 3
E (human experts)	51	53	26
PKE	54	40	24
W(Watson)	58	51	18
VB(VoiceBase)	26	50	33
$PKE \cap E$	15	12	9
$W \cap E$	16	30	10
$VB \cap E$	10	11	4
$PKE \cap VB$	8	5	1
$PKE \cap W$	9	13	4
$VB \cap W$	16	9	3

keywords were compared and their intersections were counted. Numbers in cells show absolute value of keywords found. The observations that can be done based on Table II:

1) None of the systems outperforms the others
2) All the keyword sets found by the systems of automatic extraction (*PKE*, *W* and *VB*) have nearly the same intersection with *Expert*
3) All the keyword sets found by the systems of automatic extraction (*PKE*, *W* and *VB*) have nearly the same intersections with each other
4) There exist "core" keywords, extracted by either of the systems

V. CONCLUSION

Keywords are informative milestones of speech, therefore, they are frequently marked by prosodical emphasis; that is why specific discernible prosodic characteristics (tone moves) can mark keyword presence. Prosodic features in the form of F0 estimates allow computation of pitch contours along the utterances or single words, or over the length of windows positioned in a location of interest (e.g., around a word boundary). The algorithm is based on tone and information unit boundaries juxtaposition.

The goal of this paper is to provide evidence that automatic keyword extraction systems can benefit from intonation analysis. A software tool *PitchKeywordExtractor* was evaluated along with popular tools for speech analytics and revealed the identical ability to locate the keywords. A moderate percentage in intersections of human and automatic keyword sets, pointed out either by intonation-based and other algorithms, motivates further research towards the elaboration of a hybrid approach to automatic keyword extraction.

***Abstract*—We address the Lithuanian author profiling task in two dimensions (AGE and GENDER) using two deep learning methods (i.e., Long Short-Term Memory – LSTM) and Convolutional Neural Network – CNN) applied on the top of Lithuanian neural word embeddings. We also investigate an impact of the training dataset size on the author profiling accuracy. The best results are achieved with the largest datasets, containing 5,000 instances in each class. Besides, LSTM was more effective on the smaller datasets, and CNN – on the larger ones. We compare the deep learning methods with the traditional machine learning methods (in particular, Naive Bayes Multinomial and Support Vector Machine), and frequencies of elements as the feature representation). The comparison revealed that the deep learning is not the best solution for our author profiling task.**

I. Introduction and Related Work

AUTHOR Profiling (AP) is a specific subfield of Authorship Identification that aims at revealing characteristics of authors (e.g., age, gender, psychometric traits, etc.) from their writing style: synonymy and sentence structures used, grammatical or syntax errors made, etc. Thus, the AP task is solvable due to the stylometric "fingerprint" (so-called human stylome [1]): a phenomenon of individuals to express their thoughts in the written text in the specific unique ways. The stylome is also valid for the groups of individuals sharing the same demographic or psychometric characteristics. In some cases, the stylome is even attributed to the other human biometrics, as handwriting, gait or voice, and it tends to develop over time [2], depending on the age, education, social status of a person. Due to a number of potential applications in such fields as forensics, security or e-commerce, the importance of AP is constantly growing. These tasks are tackled with the automatic methods and continuous improvements of these methods contribute to the increase of the AP accuracy.

The majority of AP tasks are solved with the traditional machine learning methods and the weight vectors of features [3], [4]. The most influential examples of this field refer to Support Vector Machines (SVMs) [5], Multi-Class Real Winnow [6], Mean Proximity Clustering [7] and Holomorphic Transforms [8]. While a range of explored feature types usually covers stylistic (e.g., average sentence length, standardized type/token ratio), lexical (e.g., bag-of-words, function words), character (e.g., document or word-level character n-grams), morphological (e.g., part-of-speech tags) levels of feature representation types. The detailed description of these techniques can be found in [9].

Since methods are usually tested under different experimental conditions (various languages, profiling dimensions or datasets) it is difficult to determine, which one is the best. It is the reason why the scientific PAN competition of shared tasks plays an important role in the AP research field.[1] The comprehensive comparative analysis on the benchmark datasets reveals potential of tested methods and the new trends.

In 2013 [10], 2014 [11] and 2015 [12] PAN competition age and gender profiling was done on the English and Spanish datasets with the traditional supervised machine learning approaches: Logistic Regression, Random Forest, SVMs, etc. In 2016 PAN competition [13] the goal was to test the robustness of methods from the cross-genre perspective and SVMs were the dominant paradigm. In 2017 [14] two more languages (i.e., Arabic and Portuguese) were added to the dataset. Despite SVMs were still chosen by many participants, deep neural networks (in particular, Windowed Recurrent Convolutional Neural Network as an extension of Recurrent Convolutional Neural Network) achieved state-of-the-art performance on the gender dimension.

In the whole area of authorship identification, authorship attribution is the most explored topic for the morphologically complex Lithuanian language (the recent research work is described in [15], [16]). Unfortunately, the deep learning methods have never been applied on the Lithuanian language in any of these tasks, including AP. The aim of this research is: 1) to test their robustness on the AGE and GENDER dimensions; 2) to compare obtained results with the results produced by the traditional machine learning methods, described in [17].

II. Deep Learning Methods

Our solving task can be formulated as the supervised machine learning, where classifiers are the deep learning methods:

- *Long Short Term Memory* (LSTM) [18]. This method is a modification of Recurrent Neural Network (RNN) having a memory unit and able to learn long-term dependencies. The memory unit with input, output and forget gates is used to remember the values over arbitrary time intervals. The output with 256 nodes in the LSTM layer is an input to the fully connected softmax layer which output is the probability distribution over classes.

[1]More information about the PAN competition is in http://pan.webis.de/.

- *Convolutional Neural Network* (CNN) [19]. The convolution is performed on the sequentially connected word vectors (the detailed description is in [20]). The feature map is produced when the filters (in particular, of 3, 4, and 5 widths) are applied on each possible window of words in the text. The max-over-pooling operation on the feature map generates a single maximum value for each filter. Values from different filters are passed to a fully connected layer which outputs the probability distribution over classes.

The LSTM and CNN methods were tested using *deeplearning4j*[2] – the open-source distributed deep learning library for the Java Virtual Machine. Original method implementations were adjusted to solve only binary classification problems, therefore necessary adjustments to multi-class classification were done by the authors of this paper. All parameters were set to their default values, except for the maximum text length: i.e., it was set to 300 tokens (i.e., words or other text elements separated by spaces or punctuation) to match the maximum possible length of the input text (described in Section III-A).

Both deep learning methods were applied on the top of Lithuanian neural word embeddings (the description is in [21]), in particular, continuous bag-of-words of 300 dimensions generated with the negative sampling as the training algorithm. Since Seimas transcripts of ∼23.9 million tokens (described in Section III-A) are also the part of word embeddings corpora, our deep learning methods are protected from the out-of-vocabulary problem in all AP tasks. Despite we analyze the spoken edited language, the vocabulary of each speaker remains untouched. Since the vocabulary itself becomes one of the strongest evidence of the authorship, word embeddings should be the proper feature type for our solving task.

III. Experimental Set-Up and Results

A. Datasets

The datasets for our AP tasks are composed of the Lithuanian parliamentary text transcripts, representing speeches and debates by the Lithuanian Seimas members produced at regular parliamentary sessions and cover the period of 7 parliamentary terms from 1990 till 2013.

All texts perfectly represent formal spoken Lithuanian language, because: 1) the language of transcripts is unedited (texts match soundtracks), 2) words are grammatically correct. Only texts of the length between 100 and 300 tokens are considered, because: 1) very short texts are less informative; 2) too long texts might have the unclear authorship, i.e., long parliamentary speeches for parliamentarians might be written by someone else.

The experiments are carried out on the datasets for these dimensions:

- *AGE* dimension was composed of 6 classes (25,439 texts, 5,395,677 tokens, 161,010 types, ∼212.10 tokens/per text) related with the age intervals: *to-29* (inclusive), *30-39*, *40-49*, *50-59*, *60-69*, and *from-70* (inclusive).[3]
- *GENDER* dimension was composed of 2 classes (10,000 texts, 2,168,664 tokens, 101,951 types, ∼216.87 tokens/per text): *male* and *female*.

Each dimension was tested with 6 balanced datasets of 100, 300, 500, 1,000, 2,000, and 5,000 texts (i.e., instances) in each class. Except for the AGE dimension: the *to-29* class contained 707 and *from-70* class contained 4,732 instances at most. All datasets were composed by randomly selecting the determined number of text documents from the whole set of texts.[4]

The experiments with AGE and GENDER dimensions were performed with relevant datasets (described in Section III-A) of different sizes, containing 100, 300, 500, 1,000, 2,000, and 5,000 instances in each class.

B. Evaluation

We have tested two deep learning methods (in particular, LSTM and CNN) with the Lithuanian neural word embeddings (described in Section II) on the dataset described in Section III-A. Rough texts (without any normalization and dimensionality reduction) were given as the input. The stratified 10-fold cross-validation was used in all our experiments. The effectiveness of methods was evaluated with the *macro-accuracy* and *macro-f-score* measures (explanation is in [22]) averaged over classes and folds.

To determine if 1) obtained results are reasonable, and 2) differences between results are statistically significant, we have 1) calculated random and majority baselines, and 2) performed McNemar [23] test with one degree of freedom, respectively. The random ($\sum(P(c_j)^2)$) and majority ($max(P(c_j))$) baselines are the same in all datasets except for the AGE dimension with 1,000, 2,000 and 5,000 instances in each class (because it's classes *to-29* and *from-70* contained 707 and 4,732 instances, respectively). For the McNemar test, we have set the significance level equal to 95%, which means that the differences are considered statistically significant, if the calculated *p-value* is lower than 0.05.

The results produced by the deep learning methods with the neural word embeddings were compared to the results of the traditional classification methods (in particular, Naive Bayes Multinomial – NBM and Support Vector Machine - SVM) with the frequencies of elements as the text document feature representation. The results for NBM and SVM were taken from [17]. NBM and SVM were tested with the different feature representation types: ultimate style markers, document-level character n-grams (with *n*=[2,7]), function words, token n-grams (with *n*=[1,3]), token lemmas (with *n*=[1,3]), part-of-speech tag n-grams (with *n*=[1,3]), and n-grams of concatenated lexical and morphological features. There is no single the

[2]The deep learning library is in https://deeplearning4j.org/.

[3]The chosen grouping is also used in the largest European data archive (http://www.gesis.org) and in the Lithuanian Data Archive for Social Science and Humanities (http://www.lidata.eu).

[4]The *AMŽIUS_PROF* and *LYTIS_PROF* datasets of the *AGE* and *GENDER* dimensions, respectively, can be downloaded from http://dangus.vdu.lt/~jkd/eng/?page_id=16.

best feature representation type: it depends on the classification method and the dataset size (for the best types see Table I). Here *lemmorf* denotes lemmas + fine-grained POS information; *lex* – tokens, *lexpos* – tokens + coarse-grained POS; *lem* – lemmas; *lempos* – lemmas + coarse-grained POS; *lexmorf* – tokens + fine-grained POS information; *chr* – characters. The number next to each tag represents *n* of their n-gram.

C. Results

The results of the deep learning on the top of neural word embeddings and traditional machine learning methods with the best feature types (presented in Table I) are summarized in Figure 1. The figures do not present the *f-score* values, demonstrating the same trend as the *accuracy* values.

Figure 1 allow us to make the following claims. All obtained results are reasonable, because exceed random and majority baselines, except for LSTM with the dataset size of 100 in the GENDER dimension.

Marginally the best accuracies of 0.316 and 0.609 with the AGE and GENDER, respectively, were achieved with the CNN method and the largest datasets of 5,000 instances in each class. Besides, CNN method achieves higher profiling accuracy compared to LSTM on the larger datasets for all dimensions (with 1,000-5,000 for AGE and GENDER). Whereas, CNN is often outperformed by LSTM on the smaller datasets: with 100-500 for the AGE dimension; with 300-500 for GENDER.

According to the McNemar test, the differences in accuracies between tested LSTM and CNN methods are significant with $p < 0.05$ for the AGE and GENDER dimensions with 1,000, 2,000 and 5,000 instances in each class. For 100, 300, and 500 instance datasets for the AGE dimension are not statistically significant with $p = 0.32, 0.22, 0.19$, respectively. The p values for 100, 300, and 500 instance datasets for GENDER are 0.37, 0.99, and 0.38, respectively.

The comparison of LSTM or CNN + neural word embeddings with NBM or SVM + element frequencies as the feature representation type revealed that the deep learning methods are not the best choice for our AP tasks. The neural methods are significantly outperformed by the traditional machine learning methods: i.e., except for GENDER with 100 or 300 datasets.

The accuracies improve by increasing a number of instances in each class. In this research the purpose was to equalize the experimental conditions (in terms of dataset sizes) and to compare the effectiveness of deep learning methods with traditional machine learning methods. However, the deep learning results improve with the increase of the dataset size, whereas, e.g., NBM seems already have reached its limits (i.e., the peak on AGE and GENDER, are with 500 instance datasets, respectively). Maybe it is possible to find the breaking point where the deep learning methods reach or even bypass the effectiveness of traditional methods. Thus, the deep learning experiments with the larger datasets could be possible accuracy improvement direction for the future research.

Despite the experiments are performed with the grammatically correct texts and in-the-vocabulary words, for NBM and SVM lexical features (bag-of-words) are not always the best representation. The deep learning methods are applied on the top of neural word embeddings, however, in the future research would be useful to test the other types of embeddings (e.g., based on characters or lemmas). Moreover, the parameter (i.e., the numbers of layers, filters, or neurons in each hidden layer) tuning of LSTM and CNN could result in the higher AP accuracy, therefore this important step is also on the list of our future plans.

IV. Conclusions and Future Work

The main contribution of this research – the Lithuanian author profiling experiments with the AGE and GENDER dimensions, performed using the deep learning methods (applied on the top of neural word embeddings) that have never been tested for this task on the Lithuanian language. During this research the impact of the dataset size (with 100, 300, 500, 1,000, 2,000, 5,000 instances in each class) was also investigated. Moreover, the achieved results were compared with the traditional machine learning methods with element frequencies as the feature representation type.

The experiments on the grammatically correct texts of the Lithuanian parliamentary transcripts revealed the superiority of the Convolutional Neural Network over the Long Short-Term Memory method with the larger datasets on both profiling dimensions.

The highest accuracies of 0.316 and 0.609 on the AGE and GENDER, respectively, do not exceed the accuracies achieved by the traditional machine learning methods. Summarizing, deep learning methods are not the best choice for our profiling tasks with AGE and GENDER. Despite that in the future research we are planning to continue exploring the deep learning methods (by increasing training set sizes, tuning parameters, selecting different types of word embeddings) for the author profiling.

***Abstract*—The amount of information that is stored and processed by computer systems is constantly increasing. The relational model is still popular. Unfortunately, despite its simplicity, it has many disadvantages, which more often exclude it from large-scale applications. The property graph model seems to be a good alternative for describing real world data with its relationships. Therefore, property graph based databases become more and more popular every day. In this paper we introduce Named Property Graph model that allows to group graphs into separate units and describe information about them. We also present Cypher$_n$ query language that supports our proposal, mapping algorithms, use cases with the chemical data, and SDFEater that is our tool for processing data. Presented solutions are fully backward compatible with existing databases.**

I. Introduction and Motivation

THE amount of information that is stored and processed by computer systems is constantly increasing. The way they are stored becomes more and more important. The relational model is still popular. Unfortunately, despite its simplicity, it has many disadvantages, which more often exclude it from large-scale applications. Today, with much more attention is also looking at alternatives, e.g. graph and document databases [1], [2], [3], [4]. The graph data model is often very well suited for describing real relationships. It can be successfully used for example, on social networks. Presenting of the relationships between users, as well as the relationship of their posts, seems much more natural in this model. Users are represented by vertices, and the edges describe relationships between them. Using property graphs [5], we can additionally add some information about each person, and even that, from when they are friends.

Importantly, the property graph data model can be simply mapped back to other data models [5], [6], [7], [8]. This means that the presentation of data, for example in tabular and semi-structured form, is also possible.

The property graphs model [5], unlike the Resource Description Framework (RDF) [9], does not support named graphs [10]. In this article, we present our solution that allows to group property graphs, and give them a name and properties. This solution allows to describe graphs (context, provenance information, graph hashes and graph signatures or other metadata).

A similar approach was presented in [11], [12]. The authors propose graph collections that are logical partitions of a graph called logical graphs. These graphs are subsets of shared sets of vertices and edges. Unfortunately, logical graphs may have common vertices and edges, so it in not possible to unambiguously hash and sign these graphs.

Another approach was presented in [13] and [14]. In the first paper, Levene et al. present hypergraph which is a generalization of graphs where the concept of edge is extended to hyperedge, which relates an arbitrary set of nodes. In the second paper, the authors propose hypernodes that are directed graphs whose nodes can themselves be graphs, allowing nesting of graphs. Unfortunately, these both solutions do not support the property graph model, which is used most widely in databases.

In [15] the authors present the GOOD data model with directed labeled graph and object in database as nodes. In this model, nodes can be printable or not. In addition, two edge types are distinguished – functional and non-functional. Functional edges allow to define functional relationships between objects. GOOD data model supports edge and node labeling. Another data model was presented in [16]. The LDM data model is based on labeled directed multigraph which means graph that can have one and more edge between pair of nodes. All edges have one specific type: Basic, Product, Power or Union. LDM supports only node labels, edge labels are not supported. Unfortunately, GOOD and LDM data models do not support properties.

The GRAD data model presented in [17] is based on property graphs and extends property graphs by specific semantics. Ghrab et al. define different types of nodes, eg. entity, attribute, and literal node. Authors also introduced four types of entity edges such as association, generalization, aggregation, and composition edges. GRAD supports hypernodes which are represented as subgraphs. Unfortunately, authors do not provide any algorithms for mapping from their proposal into existing databases and query languages. Furthermore, hypernodes in GRAD do not support properties that can be used in storing metadata about subgraphs.

The paper is constructed as follows. In Section II we formalize Named Property Graph data model and propose how to map our approach into Property Graphs. Section III is devoted to a use case that presents our proposal in a molecular entities scenario. In Section IV we present tested datasets and our experiments. The paper ends with conclusions.

II. Named Property Graph

This section describes the Named Property Graph (NPG) model and shows how to map our proposal to property graphs

(Subsection II-A). Then, we discuss the possible use of our proposal. In Subsection II-B we present Cypher$_n$ that is a query language for NPGs. Then, we show a mapping algorithm that transforms our proposal into openCypher [18].

Our following proposal allows to group graphs into separate units and describe information about them. The ability to express metainformation about graphs can be required for:

- access control – ability to add additional metadata for precise access control,
- information usage control – ability to add additional metadata about authorship, license, and policy to graph in order to limit information usage,
- data syndication – ability to store and update original information,
- graph singing – allows to apply good practices, where all singing data is kept in a different graph,
- aggregation or encapsulation of graph elements – provide a wider view of the graph as it enables a higher level design and analysis,
- expressing propositional attitudes – such as trust and temporal metrics.

Potential drawbacks of Named Property Graph model is data redundancy. However, there are mechanisms for removing redundant vertices [19], [20].

A. Named Property Graph Model

According to [5], we provide a formal definition below.

Definition 1 (Property Graph): A *Property Graph* is a tuple $PG = \langle V, E, S, P, h_e, t_e, l_v, l_e, p_v, p_e \rangle$, where:

1) V is a non-empty set of vertices,
2) E is a multiset of edges, which are elements of $V \times V$,
3) S is a non-empty set of character strings,
4) P is a Cartesian product $S \times S$, where each member has a form $p = \langle k, v \rangle$,
5) $h_e : E \to V$ is a function that yields the source of each edge (head),
6) $t_e : E \to V$ is a function that yields the target of each edge (tail),
7) $l_v : V \to S$ is a function mapping each vertex to a label,
8) $l_e : E \to S$ is a function mapping each edge to a label,
9) $p_v : V \to 2^P$ is a function that assigns vertices to their multiple properties, and
10) $p_e : E \to 2^P$ is a function that assigns edges to their multiple properties.

We propose a general and simple variation on PG model, called Named Property Graphs. A named property graph is a property graph which is assigned a name (label), and properties. A name should be in the form of a string, and properties should be in the form of a set of key-value.

Definition 2 (Named Property Graph): A *Named Property Graph* is a tuple $NPG = \langle PG, N, l_n, p_n \rangle$, where:

1) PG is a Property Graph (see Definition 1),
2) N is a non-empty set of named nodes,
3) $l_n : N \to S$ is a function mapping each named node to a label, and
4) $p_n : N \to 2^P$ is a function that assigns named nodes to their multiple properties.

Algorithm 1: Mapping Named Property Graph into Property Graph

input : Named Property Graph NPG
output: Property Graph PG

```
n ← getName(NPG) ;
foreach g ∈ NPG do
    v ← getVertex(g) ;
    PG ← addVertex(v) ;
    PG ← addEdge(n, "related", v) ;
return PG;
```

Named nodes, unlike vertices, cannot connect to each other using edges. The set of all PG and NPG graphs is the Named Property Graph Database that allows to group graphs into separate units and describe information about them.

Definition 3 (Named Property Graph Database): A *Named Property Graph database* consists of a (possible empty) set of Named Property Graphs (with distinct labels) and a set of Property Graphs.

In order for our solution to work on current databases, we show the transformation of our NPG into PG in Algorithm 1. The algorithm adds one additional vertex, with the same label as the name of the PG graph, and leaves the properties assigned to it. The next step is to assign an edge to the label related to each of the vertices.

B. Cypher$_n$ Query Language

Named Property Graphs need a query language. We propose Cypher$_n$ that supports our proposal. It is a simple extension of openCypher [18]. OpenCypher a high-level declarative graph query language with an ongoing standardization work. We add `FROM` clause which specify name of property graph. Listing 1 presents Cypher$_n$.

```
MATCH (n)
FROM (m)
RETURN n, m
```

Listing 1. Cypher$_n$ example

The extension of openCypher grammar[1] that defines our query language consists of one production, which adds a FROM clause. A fragment of grammar is presented in Listing 2 in EBNF. The key fragment of grammar is shown in Fig. 1 in the form of a railroad diagram.

```
From = ((F,R,O,M), SP, NodePattern);
```

Listing 2. Extension of openCypher grammar

In order to ensure interoperability with solutions that already exist, we present Algorithm 2 that transforms our Cypher$_n$ into openCypher. The algorithm gets the name of the graph from the `FROM` clause and modifies the `MATCH` clauses so that the

[1]https://www.opencypher.org/resources

Algorithm 2: Mapping Cypher$_n$ into openCypher

input : Cypher$_n$ query CN
output: openCypher query C

$f \leftarrow$ getFormClause(CN) ;
if $f \notin \emptyset$ **then**
  $P \leftarrow$ getMatchPattern(CN) ;
  foreach $p \in P$ **do**
    $C \leftarrow$ addRelationship(p, f) ;
  $C \leftarrow$ cloneWhereAndReturnClause(CN) ;
  return C;
else
  return CR ◁ `From clause is optional` ;
return PG;

relation selects all the paths connecting the special vertex with the metadata with other vertices. The algorithm allows some graphs to be unnamed, thanks to which we retain backward compatibility with existing solutions. Listing 3 shows how openCypher query is generated from a Cypher$_n$ query given in Listing 1.

```
MATCH (n)<-[:RELATED]-(m)
RETURN n, m
```

Listing 3. OpenCypher after transformation

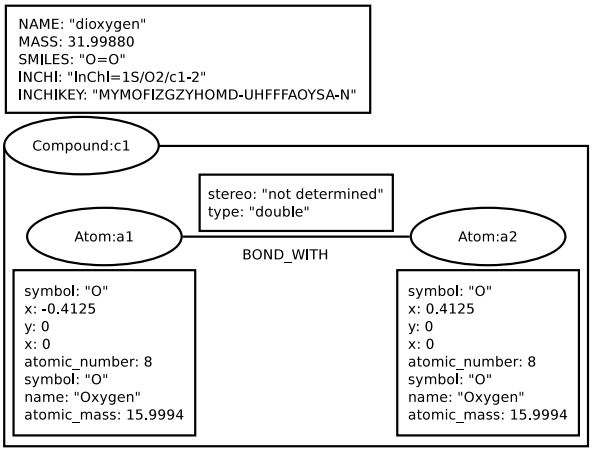

Fig. 2. Example of a named property graph

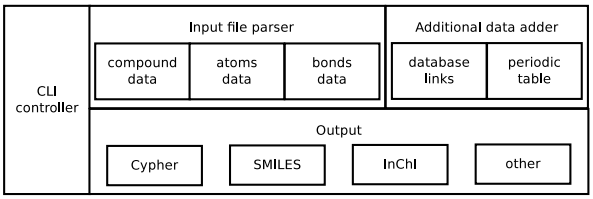

Fig. 3. Parser architecture

III. Use Case: Molecular Entity Representation

Our approach may have many practical applications. One of them is the molecular entity representation. In the standard property graphs, it is possible to describe individual atoms and their relationships. Using our solution, it is also possible to describe the entire molecule as shown in Fig. 2. In this particular case, we have compound "dioxygen" with the properties describing it. All atoms and chemical bonds are also additionally described with properties.

We have developed chemical data parser called SDFEater, available on GitHub[2] under MIT license. Our cross-platform parser is written in Java and works from the command line. It reads molecules, atoms, and bonds data from the file, and then places it in the appropriate program structures. Moreover, the program can add additional atoms data from periodic table, and tries to match the hyperlinks to the database identifiers placed in the input file. The parser accepts Structure-data file (SDF), which is part of Chemical Table file (CT File) [21] family. CT File is the collection of text formats describing chemical data. Among them there is Molfile that contains information about atoms and bonds which is stored in the tabular form. SDF, in addition to Molfile, may also contain additional information about the whole molecule such as description, Simplified Molecular Input Line Entry Specification (SMILES), International Chemical Identifier (InChI), mass, and others in the key-value form. Parser supports four output formats. One of them is the output to the openCypher query language. This allows to easily import data into the Neo4J[3] graph database.

The parser architecture is shown in Fig. 3. SDFEater has 4 main modules – CLI controller, input file parser, additional data adder, and output. The first one is responsible for operating of the command line, writing help, and running of the appropriate parts of the code depending on the selected options. In the second, the data from the source file is parsed and saved to the appropriate program structures. In the next module, additional data not included in the input file is added. Depending on the options chosen by the user, the program tries to replace the IDs listed in the compound properties with full database URL. It can also add additional information about atoms by searching the built-in data from the periodic table of chemical elements. Finally, there is the output module, where the program prints data in the appropriate format depending on the option chosen by the user.

TABLE I
TEST QUERIES

Name	Query	Description
$\mathbf{Q}_1$	MATCH (c:Compound) RETURN c.CASNumber	Selects CAS number from Compound data
$\mathbf{Q}_2$	MATCH ()−[r:BOND_WITH]−>() RETURN r	Displays all information about atoms bonds
$\mathbf{Q}_3$	MATCH (a1:Atom)−[r:BOND_WITH]−>(a2:Atom) WHERE r.type = 'double' RETURN a2	Chooses second atom with "double" bond type

IV. EXPERIMENTS AND EVALUATION

In this section we evaluate the creating, loading, and querying openCypher based on our Cypher$_n$, presented in Section III. We performed Cypher$_n$ generation tests, importing data to the Neo4j graph database, as well as query tests.

The loading and query tests were performed using the cypher-shell command-line tool[4].

All experiments were executed on a laptop with quad-core AMD A6-6310 APU with AMD Radeon R4 Graphics @ 2.4 GHz (4 cores, 4 threads), single channel 2x4GB RAM (clock speed: 800 MHz, available: 6.77 GB) and 5400 RPM HDD with reading speed rated at about 95 MB/sec[5]. The system used was Ubuntu 16.04.4 LTS with Oracle Java 1.8.0_171 and Neo4j 3.3.5 graph database (community server edition).

We prepared two SDF datasets based on ChEBI [22] (subset of ChEBI complete 3-star dataset[6]) and DrugBank [23] (subset of DrugBank open structures[7]).

In the first step, we measured the performance of generating Cypher$_n$ based on the prepared SDF subsets. We used our SDFEater which is publicly available on GitHub under MIT license. The generated data in openCypher has been published on Figshare [24] under Creative Commons (CC BY 4.0) license. In total, we created 8 datasets in openCypher (2 SDF subsets and 4 variants) marked as $\mathrm{DB}_{card}^{parm}$ and $\mathrm{CB}_{card}^{parm}$, where $parm$ represents one of four variants and $card$ is the number of compounds. For example, CB_{4000}^{r} means `r` variant of ChEBI subset with 4000 compounds. Similarly, DB_{7000}^{p} is `p` variant of DrugBank subset with 7000 compounds. We distinguish the following variants of sets:

- **r** – standard SDF to openCypher,
- **p** – standard SDF with added additional periodic table data to atoms,
- **u** – standard SDF with `-u` parser option enabled (try to generate URLs to other databases instead of IDs),
- **up** – standard SDF with added additional periodic table data to atoms and `-u` parser option enabled,

The **r** variant contains only data present in SDF files. In other cases, we add extra data that are not present in the SDF datasets.

Table II shows openCypher generation times for all discussed openCypher datasets. In the case of DrugBank, a huge increase in execution time is noticeable when additional data is added to atoms. In the case of the ChEBI subset, this is visible for CB_{4000}^{u} and CB_{4000}^{up}. We also provide SDF to PubChem JSON (pcj) [25] conversion times using OpenBabel 2.4.1[8]. Comparing execution times, we can see that our parser is much faster in processing DrugBank and slower in generating ChEBI Cypher$_n$ dataset. In the case of the DB_{7000}^{r}, the Cypher$_n$ is generated almost 11.5 times faster than PubChem JSON.

In the next step, we tested importing data to Neo4j graph database. Mapping Named Property Graph into Property Graph was based on Algorithm 1. Table III shows that for both sets, the importing time grows significantly only in the case of the variant with additional data from the periodic table.

In the last step, we prepare 3 openCypher queries based on Algorithm 2. The prepared queries are representative and checks all features. These queries are presented in Table I.

Table IV shows the execution times for discussed queries. The execution times do not change significantly even in the case of different openCypher datasets variants. The exception to this are subsets with added additional periodic table data (DB_{7000}^{p}, CB_{4000}^{p}, DB_{7000}^{up}, and CB_{4000}^{up}). This is noticeable only for `Q3`.

V. Conclusions

The property graph model is increasingly used in databases. We present a Named Property Graph model which allows to group graphs into separate units and describe information about them. Named Property Graphs provide a high-value and incremental change to the property graph model. We also introduce Cypher$_n$ query language that supports our proposal. In the paper we also present mapping algorithms, use cases with the chemical data, and SDFEater that is our tool for processing data. Our proposal can be easily applied to existing databases. The results of the experiments show the good potential of the presented solutions.

The future work will focus on providing support for temporal, uncertainty, and trust metrics. Another challenge is to find a relationship between our solution and hypernodes. We would also like to focus on developing methods for transforming our solution into other query languages.

1st International Workshop on AI Methods in Data Mining Challenges

THE scope of DMGATE is to establish a forum for data scientists working at the edge of academic research and commercial applications, keen on developing and using AI-based methods in data mining projects and challenges. DMGATE continues the tradition of data mining competitions organized at FedCSIS.

This year's competition starts on April 3 and lasts until May 7. The task is to predict win-rates of Hearthstone decks used by players with various skill and experience. Details are available here.

As usual, competition winners will be granted with financial awards and/or free conference registration. Moreover, we will invite a small group of authors of the most interesting competition solutions to submit papers that will be reviewed on special fast-track basis.

Starting from this year, we also welcome regular paper submissions describing new approaches for analyzing data sets published online during previous competitions. These papers will be peer-reviewed by top specialists in the area of data science and – if accepted – they will be presented at the DMGATE session together with the papers prepared by this year's competition winners.

We believe that it is highly important for the data science community to keep up the discussion on both current and past data mining competitions, in order to jointly develop a firm knowledge base on how to apply AI-based data mining methods in real life.

***Abstract*—Designing a robust and adaptable Artificial Intelligence (AI) opponent in a computer game would ensure the game continues to challenge, immerse and excite the players at any stage. The outcomes of card based games such as "Heartstone: Heroes of Warcraft", aside the player skills, heavily depend on the initial composition of player card decks. To evaluate this impact we have developed a new robust regression network in a context of the AAIA Data Mining Competition 2018, which tries to predict the average win-rates of the specific combinations of bot-player and card decks. Our network is composed of 2 levels: the entry level with an array of finely optimized state of the art regression models including Extreme Learning Machines (ELM), Extreme Gradient Boosted decision tree (XGBOOST), and Least Absolute Shrinkage and Selection Operator (LASSO) regression trained via supervised learning on the labeled training dataset; and just a single ELM at the 2^{nd} level installed to learn to correct the predictions from the 1^{st} level. The final solution received the root of the mean squared error (RMSE) of just 5.65% and scored the 2^{nd} place in AAIA'2018 competition. This paper also presents two other runner-up models receiving RMSE of 5.7% and 5.86%, scoring the 4^{th} and the 6^{th} place respectively.**

I. Introduction

Computer games, or more precisely computer-controlled games where players interact with objects displayed on computer screens, provide entertainment [1] and challenge players' physical and mental abilities. Beside entertainment, playing computer games has been found to combat stress, promote health and keep brain fit and active [2]. In recent years, fast development and penetration of Internet, multi-medial graphic devices, emergence of virtual reality, on-line open games led to the rapid growth of gaming popularity and combined with improved affordability, accessibility, ease and customization of gameplay, opponents choices, have driven the game industry to the enormous success and a bright future ahead [2].

To keep players interested and enthralled, computer games usually offer various stages and complexity levels to suit people from beginners to masters, and keeping them equally entertained for as long as possible. The fun of computer games is magnified when players play against their friends or other opponents from all over the world in on-line games since human opponents guarantee fresh, distinctive and engaging challenge [2]. With the recent advancement in Machine Learning (ML) and the Internet of Things (IoT), Artificial Intelligence (AI) has attracted increasing attention and heavily penetrated many industries including gaming industry. In many computer games, designing a robust and adaptable AI opponent would ensure the games continues to challenge, immerse and excite the players at any stage, which is one of the most important aspects of success.

In the card based games such as Heartstone: Heros of Warcraft, aside the player skills, the outcomes heavily depend on the initial composition of card decks. To evaluate this impact, 2018 Advances in Artificial Intelligence and Applications (AAIA) Data Mining Competition was proposed and focused on the prediction of win-rates of 4 AI bot players, playing the Heartstone game among each other with different initial decks of cards and hero characters. The objective of the competition was to use these data to build the prediction model capable of accurately estimating win-rates of the same 4 AI bots but playing with one of the 200 new test card decks, gameplay of which and their results were not available to the contestants.

This paper presents a new robust shallow regression network to predict the average win-rates of the specific combinations of bot-player and card decks in a response to the context of AAIA Data Mining Competition 2018. Our network is composed of two levels. The first level is built with an array of individually trained regression models that have proven to be effective for sparse binary regression problems, including Extreme Learning Machine (ELM), Extreme Gradient Boosted Decision Tree (XGBOOST) and the Least Absolute Shrinkage and Selection Operator (LASSO) regression models, while the second level contains only a single ELM that learns to correct the predictions from the preceding level. The final solution submitted as a competitive entry in the AAIA'2018 Data Mining Competition received the RMSE of 5.65% and scored the 2^{nd} place, marginally trailing the winning solution.

The remainder of the paper is organized as follows. AAIA Data Mining Competition 2018 is introduced in Section II. The feature extraction method and regression network for predicting the average win-rates of the specific combinations of bot-player and card decks are presented in Sections III and IV, respectively. The experimental results obtained through model evaluation are summarized in Section V, followed with a discussion in VI and the concluding remarks provided in Section VII.

II. Competition Description

The AAIA Data Mining Competition 2018 is related to the turn-based card game of "Heartstone: Heros of Warcraft". In this game, two players choose their heroes with a unique power and compose a deck of thirty cards that represent various spells, weapons, and minions, and can be summoned in order to attack the opponent with the goal of reducing the opponent's health to zero and win the game. The outcomes of the game, aside the player skills, heavily depend on the initial composition of player card decks. To evaluate this impact, the competitors were expected to predict win-rates of four AI bot players, automatically playing many games against each other with different initial decks of cards and hero characters.

The training data provided by the competition contained a collection of JSON files describing in detail more than 300k games played by all pairs from the set of 4 different bots, each starting with one of 400 unique Hearthstone card decks. The data included the initial composition of card decks, heroes selected, the results of each game, and detailed turn-by-turn gameplay states and related statistics. The objective of the competition was to utilize these datasets to build the prediction model capable of accurately predicting win-rates of the 4 AI bots assigned to any previously unseen composition of card decks and related class of hero character. To evaluate the competitive models the win rates of all 4 bots were tested in combinations with specific 200 new test decks, however this time provided without any gameplay nor game results details to the contestants to properly simulate realistic predictive power of competing win-rates prediction models.

The solutions were evaluated using the root of the mean squared error (RMSE) measure. The preliminary score of each submitted solution was evaluated externally on a fixed 10% subset of the full test records and published on the competition leaderboard. The final evaluation on the complete testing set was performed after the completion, i.e. when the competitors submitted their final solutions with no further changes allowed.

III. Feature Engineering

Estimation of average win-rates of the specific combination of bot-player and card decks can be solved via regression analysis that is a methodology for estimating the relationships between a dependent variable (response) and one or multiple independent variables (predictors). The dependent variable here was the win-rate expressed as a continuous real number from the $[0, 1]$ interval.

From the outset it has been decided, that since no gameplay details, beyond the initial deck, was available in the test stage, the training data need to be trimmed consistently down to the same content. It included the id of the player-bot and the initial Heartstone deck composition, i.e. the id of one of the 9 distinct hero characters and the cardinalities (0,1, or 2) of other cards from the pool of over 300 available card types. All above were cascaded to form a feature vector as shown in Fig. 1.

The initial modeling tasks involved generating features from the available data and after a brief experimentation with simple

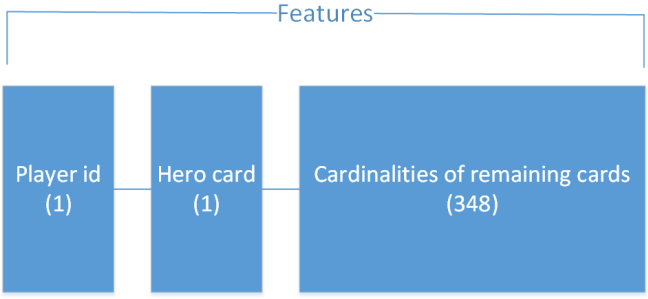

Figure 1. Feature representation.

linear regression models, the highest predictive power associated with the win-rate predictions appeared to come from numerical encoding of raw categorical features. The player id took the values of [1,2,3,4] representing the 4 bot-players, and the hero card took the values of [1,2,...,9] representing the 9 hero characters. The remaining card features took the values of [0,1,2] depending on the cardinality of specific card types in the decks. For each data record associated with a single game, this formed a sparse 348-dimensional vector describing the cardinalities of card types appearing both in the training and test sets. The final feature set included $1 + 1 + 348 = 350$ features as shown in Fig. 1.

Initial feature selection experiments did not result in any improvement of the cross-validated performance measure, although in-sample (training-set) RMSE was reduced significantly after selection of around 100 greedily found card features. To prevent model overfitting, it was decided to include all 350 features in the model building phase. With these features, a robust regression network has been developed for predicting win-rates of four AI bots playing the "Heartstone: Heros of Warcraft" game against each other with different initial decks of cards and hero characters, which will be elaborated further in the following section.

IV. Regression Networks

Artificial neural networks (ANNs) have been successfully applied in various fields due to their ability to approximate complex nonlinear mappings directly from input samples as well as model natural and artificial phenomena that are difficult to express using classical parametric techniques. Gradient-based learning algorithms are commonly used to train neural networks and tune the parameters iteratively, which, however, requires long training time.

To improve learning efficiency of neural networks, Huang and his colleagues proposed extreme learning machines (ELMs) that are feed-forward neural networks with a single or multiple layers of hidden nodes. Instead of tuning the parameters of hidden nodes, the ELMs randomly choose hidden nodes and analytically determine the output weights of the network [6]. In Comparison to many state-of-the-art computational intelligence methods, such as the conventional back-propagation (BP) algorithm and Support Vector Machines

(SVM), ELMs have the advantage of much faster learning rate, ease of implementation, the least human intervention, and better generalization performance in terms of lower training error and smaller norm of weights. It has been reported by Huang et al. based on their experimental results that ELMs are able to achieve better generalization performance and learn thousands of times faster than traditional learning algorithms for feed-forward neural networks [6].

In order to extend the generalization performance of the ELM, a novel shallow regression network composed of 2 stages has been developed. In the first stage an array of finely optimized state-of-the-art regression models are trained directly on the input data to predict the desired regression outputs. The models shortlisted for this stage based on best preliminary ad-hoc evaluation included beside kernelized ELMs, XGBOOST, LASSO, SVM, Gaussian process (GP) and simple Multi-Layer Perceptron (MLP) models.

The outputs of all base models, i.e. the proposed regression outputs are passed on to the second and final stage of the shallow network in which just a single or multiple regression are trained again, however this time their inputs are multiple propositions of the predicted outputs, hence their role is just to learn to optimally correct multiple predictions to minimize final regression error. The decision to limit such corrective layers to just a single 2^{nd} layer follows from extensive experimentations which confirmed that adding more corrective layers does not improve the performance but only contributes to the network complexity.

We have dedicated a lot of experimentation to the selection of the best subset of primary regressors as well as the final stage corrective models. We have, however consistently received ELM to be the single most effective 2^{nd} stage corrective regressor, while also in the primary first layer ELM appeared to dominate in terms of performance but showed the best overall results if combined in the first layer with XGBOOST and LASSO regression models only.

A structure of the best performing network with 9 base kernelized ELMs, 1 LASSO and 1 XGBOOST models in the primary layer and a single ELM in the final layer is shown in Fig. 2.

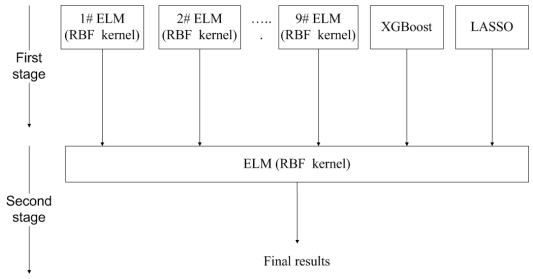

Figure 2. A sample structure of the learning model.

Multiple ELM models with radial-basis-kernels of increasing width parameter (gamma) from 20 to 60 dominated the first layer of the network. The RBF kernel is defined as [7]

$$K_{\text{RBF}}(x, x') = exp(-\frac{||x - x'||^2}{2\sigma^2}), \quad (1)$$

where $\gamma = 2\sigma^2$.

As mentioned above, these 9 ELM models in the optimized network setup have been complemented with just a single XGBOOST and LASSO models, therefore for completeness few details on only the added models are provided below.

- A decision tree builds a regression model in the form of a tree structure, which breaks down a dataset into multiple smaller subsets and incrementally builds a tree with decision nodes and leaf nodes for the purpose of classification or regression. XGBOOST, based on Extreme Gradient Boosting model [3], is an implementation of the gradient boosted decision trees algorithm with a goal of pushing the limit of compute resources for boosted tree algorithms [4]. In recent years, XGBOOST, due to its advantages of fast processing speed and high prediction accuracy, has been employed by many winning teams of a number of machine learning competitions, e.g. [5].
- LASSO regression is a shrinkage and variable selection technique aimed at enhancing the prediction accuracy and interpretability of the linear regression model it produces [8], [9], [10]. It attempts to find a subset of predictors that minimize the prediction error of the response variable, which is achieved by imposing a constraint on model parameters to make regression coefficients for some predictor variables shrink down to 0. Given the feature vectors encoding cardinalities of cards are very sparse, LASSO is employed as another base regression model in the first stage of our network. It attenuates and effectively excludes certain variables from the model, while the variables with non-zero coefficients are considered as strongly associated with the target variable.

Among other primary models that deserve some attention despite not being selected to the final network was a Multi-Layer Perceptron (MLP) with variable number of neurons. Among a wide range of configurations trialled we found a network with 50 input neurons, one hidden layer of size 20, and a single linear-activation output neuron to be the best performing model of this kind. Rectified Linear Unit (ReLU) activation [11] was set for all input- and hidden-layer neurons. It should be noted however, that we managed to maximize the generalization performance of this network only after introduction of recently popular regularization techniques: batch normalization and dropout [12] after the first two dense layers. We decided to use this particular model as a benchmark model for our regression network, yet did not include it in the network itself.

Each of the base regression models in the first stage was individually trained over the whole training set. The second stage was built on top of the first stage with a goal of learning to correct its predictions. Experimentations concluded very decisively that just a single ELM with optimized hyper-parameters is best at learning to correct the primary regressors'

outputs and hence to further improve the generalization ability of the whole network. As a result, the entire regression network became a hybrid model with a decision level fusion in the top layer realized using the ELMs. It was very important, however, for the robustness of the emerging 2-level regression network to train the second layer on the cross-validated outputs of the first layer such that the second layer regression used only out-of-sample rather than in-sample prediction outputs.

V. Experiment Results

As already partly explained in the previous section, many experimental trials were performed to determine the best composition of the first and the second stages of the regression network as well as optimize all the individual and joint hyper-parameters. All the experiments were based upon both k-fold cross-validation over the training dataset and the external feedback in a form of performance scores published in the web-based KnowledgePit platform and calculated for only 10% of the test examples. Eventually, the best structure of the network consists of 9 kernelized ELMs, an XGBOOST, and a LASSO regression models in the first level that are connected to another ELM model in the 2^{nd} level, is shown schematically in Fig. 2.

The parameters of the individual regression models were optimized over the k-fold cross-validated training set using Bayesian or grid optimization. The optimal network setup included 9 ELM models with radial-basis-function kernels of width [20,25,30,35,40,45,50,55,60], XGBOOST model with learning rate 0.01, re-sampling rate 0.2, maximum tree depth 2 and 100000 iterations, and the LASSO regression model with 100 lambdas and up to 100 non-zero weights. The ELM in the second stage used RBF kernel with a small width $\gamma < 1$.

The final solution that we submitted to the competition received the RMSE of 5.0% based on the preliminary evaluation on the 10% of all test examples, and the final score of 5.65% on the whole test set. The best RMSE scores on the preliminary leaderboard evaluation achieved individually using each base regression model were 5.88% for ELM with 40-wide RBF kernel, 6.64% for XGBOOST, and 6.87% for LASSO. For comparison, our benchmark single-stage MLP regression model achieved RMSE of 5.69% on the same 10% subset of the test set and 5.86% on the whole test set (6^{th} best score), showing robustness to over-fitting yet still remaining slightly behind the proposed two-level regression network.

The above figures prove that the introduction of the shallow hierarchy with just a single regressor in the 2^{nd} level was an adequate choice leading to a noticeable performance improvement compared to the base models.

VI. Discussion

It is found that better individual performers of base models may not lead to better combined output. Indeed the removal of GP and SVM regressors, although individually top in-sample performers, surprisingly led to improved performance of the whole network.

To further improve the network performance we have introduce specific regularization filter applied on the final test outputs in order to enforce similar global (higher order) statistics observed in the training set. The filter included 3 constraints: shift towards the desired mean, stretching or compressing the variance around the desired mean and forcing the shift of the differences among bot-player individual win-rates towards the same relative differences observed in the training set.

Deeper structures with multiple concatenated ELMs in the 2^{nd} level have also been tested to no statistically significant improvement in the generalization ability of the network compared to the architecture shown in Fig. 2. If 2 ELMs were concatenated in the 2^{nd} stage, with different kernel widths, the resulting preliminary test RMSE was in a range of $[5.05, 5.1]$. Similarly, a network with a 4-ELMs chain in the second level received the same RMSE of 5.1%. These observations indicate that further attempts to correct regression errors bring no additional value to the design instead just modeling propagated noise and bringing re-optimization overhead.

VII. Conclusions

The regression network presented in this paper has been developed and submitted as a competitive entry to the AAIA Data Mining Competition 2018, concerned with the prediction of win-rates of four AI bot players, playing the game "Heartstone: Heros of Warcraft" among each other with different initial decks of cards and hero characters. The proposed regression was hierarchically designed to combine the advantages of Extreme Learning Machine and few other complementary state-of-the-art regression models in the first level and improve the final performance through supervised decision fusion and error correction in the second level. Our solution received the final RMSE of 5.65% and scored the 2^{nd} place in AAIA'2018 Data Mining Competition.

A Neural Network Approach to Hearthstone Win Rate Prediction

Jan Jakubik
Wrocław University of Science and Technology
Faculty of Computer Science and Management, Department of Computational Intelligence
Wrocław, Poland
Email: jan.jakubik@pwr.edu.pl

***Abstract*—This paper describes a solution to the AAIA'18 data mining challenge, which concerns prediction of win rates for decks in Hearthstone collectible card game. A neural network model assigning win rate to decks is learned based on maximisation of log probability of observed match results. A representation of deck contents is based on a second network, which performs the role of a dual-task encoder. Two tasks learned by the encoding networks are encoding decks in such a way that the full deck can be reconstructed, and encoding individual cards so that their specific properties can be decoded. Shared representation for these tasks allows the knowledge of individual cards to be taken into account.**

I. Introduction

COMPETETIVE multiplayer video games have been a thriving market in recent years, posing new challenges in areas of artificial intelligence and data analysis. In online game communities, the search for optimal tactics has lead to the development of "metagaming" - an entire layer of strategy related to the knowledge of certain playing styles and changes in their popularity on a community level.

The collectible card game (CCG) landscape, which includes popular and highly profitable games such as Hearthstone and Magic: The Gathering, naturally leads to the development of a particular type of metagame. In these games, players compete using decks which consist of a limited number of cards selected from a much larger pool of cards possible to collect. In a realistic scenario, the flow of knowledge between players leads to rapid development of popular deck types, with players often directly copying known well-performing decks. Any practical approach to applying artificial intelligence methods in such an environment has to consider not only the typical issues of moment-to-moment gameplay but also the metagame information.

In this paper, we explore the problem of predicting win rates for Hearthstone decks within a particular metagame environment. The proposed approach was developed as a submission to the AAIA'18 data mining challenge organised by Silver Bullet Labs and Knowledge Pit as part of the FedCSIS 2018 conference. The paper is arranged as follows: Section II describes the competition and available challenge data, Section III explains the use of external data not provided by organisers. Neural networks which serve as core components of the proposed approach are described in Sections IV and V. Section VI describes how ensembling was used to improve the results and Section VII summarises the conclusions.

II. Competition Description

The competition posed the task of predicting deck win rates for a set of 200 decks based on the record of 300000 games between another set 400 decks. The decks were played by four distinct AI agents, with the AI choice influencing win rates significantly. The goal of the prediction model was to compute win rates for all possible AI-deck pairs in the test dataset. This equates to 800 test samples. The training dataset included:

- name and the number of copies for each card present in the deck
- basic description of games including AIs playing, decks being played and the winning player
- detailed description of games - a recorded data of all turns, including actions taken by respective players

The proposed solution uses the basic descriptions of games while utilising an external dataset to represent cards present in the test, but not training set.

During the contest, it was possible to upload solutions and receive an evaluation of RMSE on an evaluation subset of 10% test samples (i.e. 80 AI-deck pairs randomly sampled from all possible 800). This influenced the chosen approach, as "over-tuning" parameters to increase fitness on the evaluation subset of the test set was possible. In fact, the order of top 4 results on the competition leaderboard was reversed in the final results, suggesting multiple submissions including the one described here were over-tuned to some extent. The solution described in this paper was in 2nd place on the competition leaderboard when the submissions closed but placed 3rd in the final evaluation. Possible causes are discussed in the Conclusions section.

III. External Data Use

The proposed solution employs a set of data from the hearthstonejson database [1]. This database contains information on all cards present in the training and test decks. All numerical properties such as life and attack of minions, weapon durability etc. are accounted for. Keywords such as Battlecry, Taunt, Adapt etc. are recognized as binary variables (whether the card has a keyword or does not). Full card text

(a) Minion (b) Weapon (c) Spell (d) Quest (e) Hero

Fig. 1: Types of cards available in Hearthstone CCG [2]

for every hearthstone card present in the challenge datasets is also available. The dataset also contains certain conditions that need to be met to play the cards (such as "there needs to be a valid minion target").

IV. Encoding Network

To build an encoding of hearthstone decks, first, an encoding of a card is created. The goal of this encoding is to represent cards present in the test, but not training data. There are 330 unique cards in all training decks, and 18 unique cards in test decks that do not appear in training set. These cards include both spells and minions.

Types of cards available in Hearthstone CCG are shown in Fig. 1. Note that minions (a) and weapons (b) have informative numerical properties of attack, health, and durability. However, even when these properties are accounted for, card text can still have a significant effect on the gameplay. In the case of the presented minion, Deathwing, its battlecry ability drastically alters the game state by destroying all minions on the game board. In case of spells (c), the only available information is the card text. Finally, quest (d) and hero (e) cards can alter the overarching game strategy of the entire deck by replacing the player's hero or offering a powerful reward for fulfilling the quest condition. For these cards, even card text does not offer a sufficient explanation. However, no quests or heroes that are not in the training data appear in the test dataset.

Taking this knowledge into account, we build the representation of a card as a concatenation of two vectors. First contains numeric properties, mechanics and other data available from hearthstonejson.com. Each numeric property is encoded as a continuous variable, each keyword is encoded as a binary variable, and all conditions required to play a card are encoded as binary variables. We use all properties available in hearthstonejson descriptions, as long they actually occur in training and test dataset.

The second vector is a word occurrence vector based on the card text. Card text is cleaned by removing punctuation, after which we build a dictionary of all strings that occur in the dataset (separated by whitespace characters) and count their occurrences in each card's text. Word occurrence serves as a simplified way to contain information regarding card function. Terms such as "destroy" or "heal" describe the interactions of a card to some extent, and can be relevant to the AI's ability to efficiently use the card. Without actually simulating the game logic, this is an easy way to represent effects such as the Deathwing battlecry mentioned above.

The representation of decks is then built by a neural network trained on all 600 training and test decks. The encoding network's loss function is defined as a sum of two terms, representing two distinct tasks. First is a standard autoencoder [3], i.e., the loss is based on the network's ability to reconstruct exact input vectors from a lower-dimensional encoding in the hidden layer. Inputs used in optimising this objective are decks from both training and test sets, represented as simple card occurrence vectors - each dimension in the input space represents the count of a particular unique card in the deck.

The second task is to learn an encoding which makes it possible to decode the properties of each card. For this purpose, we use the matrix of card properties C, in which each row represents hearthstonejson information of a single card. The assumption here is that encoding a single card in the same space as full decks can be decoded as card's specific properties. Given shared encoding Enc, autoencoder decoding Dec_1 and card property decoding Dec_2, the combined loss for both tasks can be calculated as:

$$\|Dec_1(Enc(X)) - X\|_F^2 + \|Dec_2(Enc(I)) - C\|_F^2 \quad (1)$$

Where X is the matrix of deck vectors, C is the matrix of card property vectors and I is an identity matrix of a size corresponding to the number of cards. Combining both tasks ensures the network encodes decks in a way that retains full information, but also encodes similar cards in a similar way.

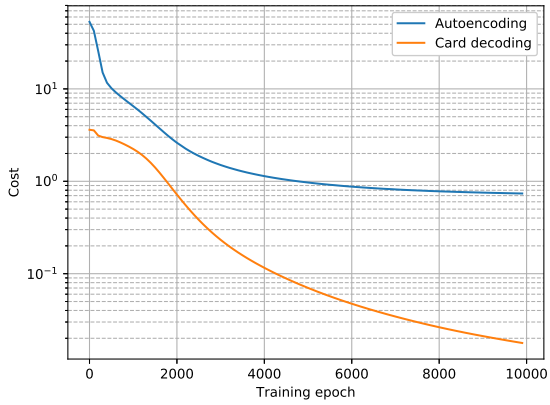

Fig. 2: Training curves of two objectives in the encoding network

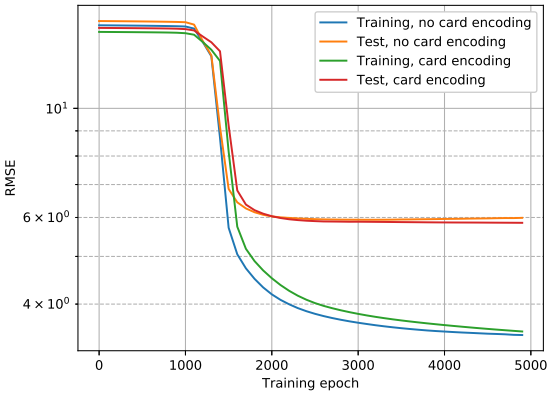

Fig. 3: Training curves of the prediction network, with and without using the card decoding objective in the encoding network

The latter is relevant for the cards that do not appear in training data.

Each of the functions: Enc, Dec_1, Dec_2, is learned by a single neural network layer, resulting in a network with one hidden layer and two separate output layers. The encoding layer uses ReLU nonlinearity [4], and decoders are linear layers. The dimensionality of encoding was set to 200 after preliminary tests. The number of training epochs for encoding network was set to 10000, and the network was trained with a gradient-based method Adadelta [5] with $\rho = 0.9$. Using a Theano [6] implementation, training this network takes approximately 3.5 seconds per 1000 epochs on a Nvidia GTX970 GPU.

Training curves of the encoding network are presented in Fig.1. While autoencoding objective reaches a visible plateau, card decoding objective could still be trained beyond 10000 epochs. However, we found this did not improve the prediction network results.

V. Prediction Network

Features encoded by the encoding network are used as and input to the prediction network. Prediction network is a standard feedforward neural network [7] with three hidden layers, respectively 300, 200 and 100 neurons. ReLU nonlinearity is used for activation in hidden layers. The network is optimized with Adadelta, using $\rho = 0.9$. To avoid errors (loss function can return NaN values if the output is outside of $(0, 1)$ interval), final layer activation was implemented as:

$$\sigma(x) = 1 - ReLU(1 - ReLU(x)) \tag{2}$$

However, in practice, outputs do not exceed 1.0 or 0.0 during optimisation if the hyperparameters are tuned for the task, i.e., the bias of final layer is initialised to 0.5 and other parameters to very small values. Therefore, the final layer effectively works as linear.

A basic loss function over all outputs, where o_i denotes the prediction for i-th deck that approximates a known win rate y_i, is defined as:

$$\sum_i -d_i(y_i \log(o_i) + (1 - y_i) \log(1 - o_i)) \tag{3}$$

where d_i represents the number of observations based on which the y_i win rate was calculated. In other words, the solution maximises log probability of the observed sequence of games, assuming all games by any particular deck can be modelled as a win-loss boolean random variable. Note that this completely ignores the two-sided nature of games and the essential property of decks having varying win rate against specific enemies. However, attempts to estimate matchup-specific win rates resulted in worse performance, possibly caused by to overfitting due to an insufficient number of games for each specific matchup.

Additionally, decks from the test set were employed in training of the network to counteract the positive win rate bias which appeared when using training data. When the number of games per deck is not distributed uniformly, it is possible for the average win rate to be over or under 0.5, thus creating an unwanted bias in the model. In the training set for the competition, the average deck has a win rate of 0.517, leading models trained on the data to overestimate win rates of test decks. Using prediction for test games, this bias can be removed. Assuming u_j is the output for j-th test set game, the full loss is defined as:

$$\sum_i -d_i(y_i \log(o_i) + (1-y_i) \log(1-o_i)) + (\lambda - \sum_j \frac{u_j}{200})^2 \tag{4}$$

The second term leads the average predicted win rate over the test set to be close to λ. This also works as regularisation for training. The λ value was chosen experimentally to maximize performance on leaderboard evaluation. We tested a range of values from 0.48 to 0.51, with 0.005 step size, and set $\lambda = 0.49$.

In Fig. 3, the training curve for the prediction network is shown. We compare the prediction network's performance

TABLE I: Results of the competition - top 5 submissions

Team	RMSE
hieuvq	5.57339852
amy	5.6482014
jj	**5.66759451**
dymitrruta	5.696228
amorgun	5.8473786

using two different encodings of training data. First is using the dual-task encoder described in Section IV, while the second one is encoded by a standard autoencoder, with no card decoding objective (i.e. the loss function is equal to the first term in Eq. 1). Training-test split for these experiments was the same, using 300 decks for training and 100 for tests. It is noticeable that the prediction network starts on a plateau and requires more than 1000 epochs to escape it, then rapidly improves the results. Past 2000 epochs little improvement is seen in test results although the minimum on the training set is not yet reached. Because of this, we set the early stopping point at 5000 epochs. Training time for this network was approximately 8 seconds per 1000 epochs on a GTX970 GPU.

Moreover, the improvement from using card decoding objective can also be seen in Fig.3. Prediction network performs better on training set but worse on test set when the card encoding objective is ignored. This indicates worse generalization without using the card decoding objective.

VI. Ensembling

The best performing single network achieved RMSE of approximately 5.0 on the 10% of the test data used to calculate leaderboard results. This result was further improved by ensembling, averaging results over multiple deep network models. Since throughout the competition we uploaded multiple results, models for the final ensemble were chosen from these according to their leaderboard evaluation results. The parameters given in sections IV and V describe the best single-network model. Other models in the final ensemble were variants of the described one with minor alterations, previously tested during parameter tuning: one with a larger number of training epochs (100000 for the encoder, 10000 for prediction network), one with added l2 regularization term in loss function (0.01 weight), and one with card matrix ignoring properties of cards other than word occurrence. These four best single-network models were averaged to obtain the final submission, resulting in approximately 0.2 RMSE improvement on the evaluation subset of test data.

VII. Conclusions

The final result placed the proposed solution as third in the competition. Results for other top submissions can be seen in Table I. It is worth noting that during the competition, two top solutions on the evalutation leaderboard reached RMSE below 5.0.

It can be argued that the chosen approach to representing Hearthstone decks was not sufficient to represent all intricacies of cards present in the test, but not training data. However, the change between results on the evaluation subset and final leaderboard suggests another explanation of the results, namely, that the described approach (along with some other top submissions) was over-tuned for the evaluation subset of test data.

While identifying the exact cause of this over-tuning is not possible without extensive tests on full data, the most likely explanation lies in the chosen approach to reducing positive win rate bias. As mentioned in Section V, the bias reduction is achieved by explicitly forcing the average win rate over test data to be close to an experimentally chosen value. The value 0.49 was set to maximise the performance according to the leaderboard. This means an implicit assumption was made that the 10% evaluation subset provides an accurate estimate of mean win rate for the entire test set.

Additionally, the choice of models to build an ensemble was based on the evaluation leaderboard, further contributing to the exact fitting of the model to evaluation subset of test data. A more refined ensemble building strategy would likely improve the results.

Regarding future work, the possibilities of the proposed approach are somewhat limited. The chosen model predicts win rates given a specific opponent distribution while using an unrealistic assumption that the test decks themselves are not part of the metagame. In a practical setting, due to fluctuating opponent distribution, a model that computes win rate for a matchup between two specific decks should be more applicable. We attempted to build such a model during the competition, however, since its training was significantly more computationally expensive than the prediction of win rates, the described approach was chosen instead. Nevertheless, predicting matchup-specific win rates remains a possible goal for further development that would require designing a new prediction network. The encoding network, on the other hand, can be potentially re-used without changes for any task that requires deck representation.

Acknowledgements

We would like to thank Silver Bullet Labs and Knowledge Pit for providing the simulation data and a platform for the competition.

I. Introduction

AAIA'18 Data Mining Challenge: *Predicting Win-rates of Hearthstone Decks* was the fifth contest organized in association with the FedCSIS conference series. The topic was a follow-up of the previous edition of the challenge, related to a popular collectible card game *Hearthstone: Heroes of Warcraft* [1]. This time, participants were asked to predict win-rates of various Hearthstone (further abbreviated as HS) decks played by AI bots, based on games played with similar decks.

HS is a good framework for carrying out AI research. One kind of research is development of autonomous game-playing agents. The game is popular (more than 70M active players), highly competitive (one of the biggest eSport games) and yet it has combinatorial-game-like structure. Some notable bots reported in the literature are MetaStone (https://github.com/demilich1/metastone), Hearthranger (http://www.hearthranger.com), HearthBot [2] and Silverfish [3]. The second type of research revolves around analysis of the game in order to, e.g., help the players build better decks [4], [5]. A common need in all such investigations refers to an appropriate data representation that can be considered with respect to cards, decks or players. As one could see in the entries in the '17 installment of the competition, a good card representation is the backbone of ML-based playing agents. This aspect is even more crucial when it comes to win-rates prediction.

The competition outlined in this paper refers to both bot and non-bot research. On the one hand, we employ our AI algorithms [6] to generate massive bot vs. bot game logs data set. Our bots play using different decks and simulate different levels of real players. On the other hand, the competition task is related to another thread of our investigations, i.e., designing an advisory platform that helps players compose better decks [7]. Indeed, the top competition solutions, especially those taking into account the importance of the aforementioned card representations, can lead us toward new insights with respect to what decides about the win-rates of particular decks.

The rest of the paper is organized as follows: In Section II, we summarize the competition. In Section III, we discuss several approaches to constructing hybrid vector representations of HS decks and compare empirically usefulness of the obtained representations for predicting the win-rates. In Section IV, we draw some directions for future research.

II. AAIA'18 Data Mining Challenge

The competition (https://knowledgepit.fedcsis.org/contest/view.php?id=123) took place on April 3 – May 7, 2018, under the auspices of 13^{th} International Symposium on Advances in Artificial Intelligence and Applications (https://fedcsis.org/2018/aaia) which is a part of the FedCSIS conference series. The purpose of this challenge was to discover reliable methods for predicting win-rates of HS decks. The task was to construct a prediction model that can learn win chances of new decks, based on the history of match-ups between AI bots playing with similar decks. To give participants freedom of choosing a representation of the data, apart from a preprocessed data set in a tabular format, there were provided JSON files with detailed descriptions of each game. We were interested whether the data regarding the way in which cards are played during the game can be useful in the proposed task.

The training data set contained logs from 299680 games played between four bots which used 400 decks. Another 200 decks – combined with the same bots as in the training set – were used as a test set. The win-rates of the bot-deck pairs from the test set were computed based on 300000 simulated play-outs. In those games, one of the bots used a deck from the training set, and the other one – from the test set. The decks were created by randomly mutating a set of 13 deck archetypes that at the time of the competition were commonly used in ladder matches by human players (12 top-rated archetypes and one group of decks consisting of only basic cards).

To generate the games, we defined four HS bots that differed in: a) available time limit for performing a move and b) available knowledge about the opponent hand (*full_info* or *limited_info*). Eventually, the following configurations were used: A1 – limited_info & 1 second per move, A2 – limited_info & 2 seconds per move, B1 – full_info & 1 second per move, B2 – full_info & 2 seconds per move.

TABLE I: Final RMSE results and number of submissions from top-ranked teams. The last row shows the result obtained by a baseline solution – a fully-connected neural network with two hidden layers, trained on the bag-of-cards representations of decks.

...	...	...	...
baseline	26	–	8.8645

A. Evaluation of results and participation in the challenge

Submissions from participants were managed by Knowledge Pit [8]. Each submission had to be properly formatted, containing predictions of win-rates for every deck-bot pair from the test set. Each of the teams could submit multiple solutions. As a quality criterion for submissions, we selected the RMSE measure. The submitted solutions were evaluated on-line and the preliminary results were published on the competition leaderboard. The preliminary scores were computed on a subset of the test set, fixed for all participants. The size of this subset corresponded to randomly chosen 10% of the test decks. The final evaluation was conducted after competition's completion using the remaining part of the data.

Apart from submitting their predictions, each team was obligated by competition rules to provide a brief report describing the approach used. The description had to cover utilized learning models, as well as the steps of data preprocessing and feature extraction. Only teams which sent a valid report qualified for the final evaluation. In this way, we were able to collect a vast amount of information regarding various representations of HS decks and the state-of-the-art approaches to this type of prediction problems. After completion of the challenge, the final results were published on-line. The scores obtained by top-ranked teams are presented in Table I.

B. Summary of the competition results

Our contest attracted 204 teams from 28 countries. The countries with the highest number of registrations in the challenge were Poland (119), Russia (28), United Kingdom (9), United States (8) and India (5). Among the participating teams, 82 submitted at least one solution file which was ranked at the public leaderboard. Over a half of those teams decided to disclose their approach by uploading short reports.

The top solutions were obtained by ensembles of regression models. The winners combined linear regression with deep neural networks. The second team blended a tree-based boosting model (XGBoost) with Extreme Learning Machines and LASSO regression. Other models that performed well were SVR (SVM ϵ-regression) and Gaussian processes.

To represent the decks as vectors, many of the top-ranked teams encoded them as bags-of-cards, i.e., vectors of a size equal to the number of distinct cards in the data, where each element indicates how many cards of a corresponding type are present in a deck. The winners augmented such a representation using aggregated card properties, e.g., the total health of minions in a deck, the number of spells, the number of minions with a taunt ability, etc. A few teams incorporated into their representations advanced knowledge about HS, e.g., indicators of cards' relative strength defined by experts. Still, none of the top 20 teams used information from game logs to augment their representations of decks.

III. Representations of Hearthstone Decks

Since one of our objectives for this competition was to find out whether information regarding the way cards are played during HS duel can be useful for predicting win-rates of decks, we further investigated this problem in a series of experiments. We created various card representations using three different data sources. Based on those representations, we built vector embeddings of decks and compared their usefulness by measuring performance of several prediction models. Let us discuss the obtained results.

A. Bag-of-cards and its transformations

The most common representation of HS decks is a bag-of-cards – by an analogy to a bag-of-words representation of textual documents. A deck is regarded as a set of card IDs. Its vector representation has a length equal to the number of available cards. The i-th vector's position expresses the amount of copies of the i-th card in the given deck.

Such a simple representation turned out to be very effective for predicting win-rates. It was utilized by many of competition entrants, including all the top three teams. However, in nearly all cases, it was augmented by additional information extracted from the cards, e.g., a distribution of card mana costs. The augmentation was usually done by aggregating properties of cards included in the deck. For this purpose, participants often used external knowledge bases, such as the one provided by HearthstoneJSON API (https://hearthstonejson.com/).

The dimensionality of bag-of-cards representation can be reduced using some text mining techniques, such as SVD. A deck representation in the space of latent concepts can be used by itself. It can be also combined with the others to express combinations of cards often appearing in the same deck.

B. Aggregation of cards represented in a vector space

Representation of a deck can also be created by aggregating representations of individual cards. Information about the cards can be acquired from various sources, such as:

- a database with card properties and textual descriptions (e.g.: HearthstoneJSON, Wiki)
- a database of players' decks (e.g.: HearthPWN.com)
- logs from games between human players or AI bots (e.g.: the data used in our competition)

Specific algorithms for creating vector embeddings of HS decks based on the data from the first two of the above sources are described in [7]. Game logs can be utilized to generate embeddings of cards, e.g., using a word2vec model [9] in which card IDs correspond to terms and their use sequences extracted from game logs are treated as documents.

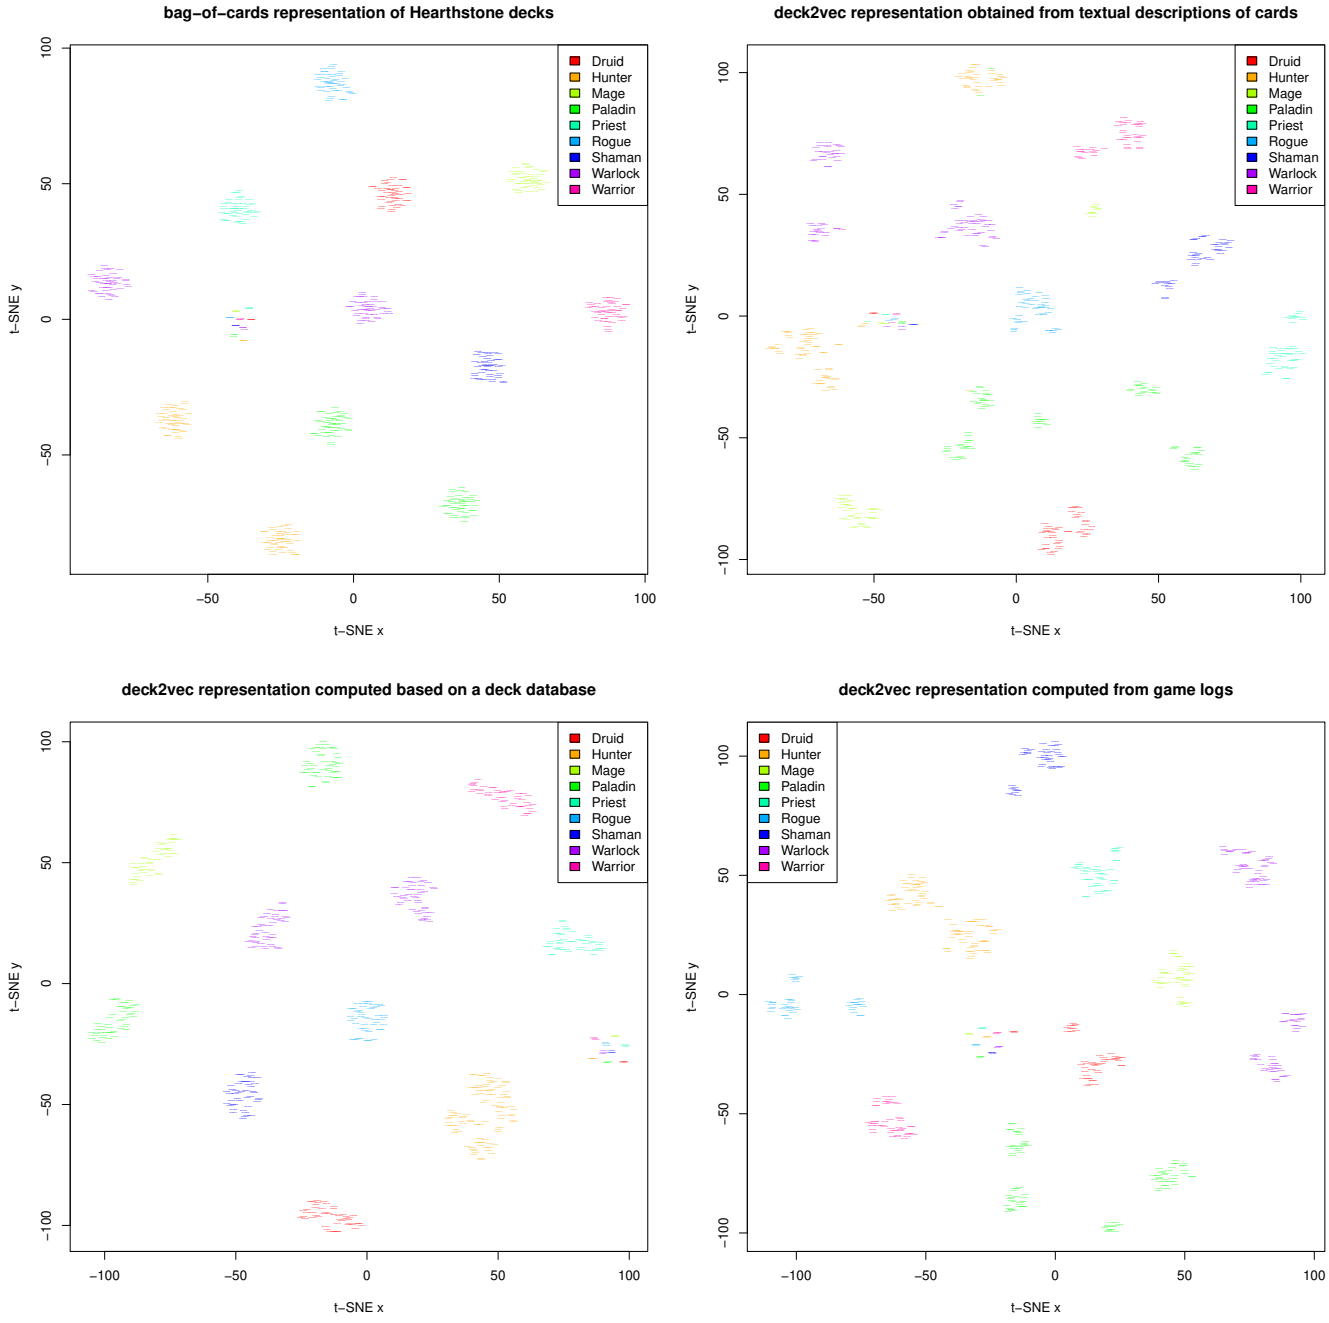

Fig. 1: A t-SNE-based visualization of four deck representations. Top-left: bag-of-cards. Top-right: aggregated embeddings derived from textual descriptions. Bottom-left: representation based on an on-line deck database. Bottom-right: representation based on the competition game logs.

The derived representations may cover different aspects of card similarity. For instance, the word2vec embeddings of cards computed from their descriptions can capture information about their basic properties. A representation derived from compositions of decks created by players may be better at expressing the aforementioned interchangeability [7]. Finally, a representation created from game logs may convey more information about the way cards are used during a game.

The aggregation of cards can be performed in many ways too. The simplest approach is to take a mean of the card vectors. To prevent losing too much information, such a deck representation can be extended by, e.g., min, max and standard deviation of card vectors (computed dimension-wise).

To visualize differences between the above approaches, we used them to represent the decks from our competition. Figure 1 shows these representations embedded into a two-

dimensional space using the t-SNE algorithm [10]. Only the bag-of-cards method allows to identify all deck archetypes which we used to generate the data (12 visible groups of decks for nine hero classes and one mixed group with decks containing only basic cards). For the representation obtained by analyzing a deck database, two groups of decks for the Hunter hero class were merged together. This is quite a good indicator given the fact that these archetypes were *FaceHunter* and *AggroBeast*, which share significant portion of cards and have a similar game plan. For the representation derived from textual descriptions, some archetypes were split into separate groups. Such a division is also visible when using representations extracted from game logs. Therein, however, apart from the group of decks composed of basic cards, there are no clusters with mixed decks from different hero classes.

C. Predictive power – experimental evaluation

We performed a series of experiments to evaluate the impact of the deck representation methods on a predictive performance of various regression models. We trained four models, namely the aforementioned Gaussian Process Regression (GPR) [11], SVR [12], Multi-Layer Perceptron (MLP) and K-Nearest Neighbors (KNN) on the competition data and compared their results obtained for four representations of decks. Table II shows the final scores.

The best score was achieved by combination of the bag-of-cards and GPR. On the other hand, the same representation combined with KNN regression was the worst. This fact highlights a need of adjusting data representation for a given prediction model. The second best representation was the one derived from a deck data set. Its score was even slightly better than for the bag-of-cards used together with MLP and KNN. The most disappointing were results of the representation based on game logs. It suggests that more advanced methods of learning deck representations from logs need to be developed to fully utilize this source of information.

Nevertheless, motivated by a diversity of the deck clustering results, we decided to check if the learned representations can contribute some additional knowledge to prediction models. We concatenated each of the vector representations with the bag-of-cards and evaluated their performance in a combination with GPR. These results are included in Table II. Surprisingly, for every representation we obtained considerably better results than for the plain bag-of-cards. Moreover, when we concatenated all four representations, we achieved the best score (RMSE 5.465) among all entries in our challenge (see Table I). This confirms the benefit of using diverse sources of the data for constructing prediction models.

TABLE II: RMSE scores obtained for four prediction models and discussed deck representation methods, where BC stands for bag-of-cards and DD, TD and GL denote representations derived from a deck data set, textual card descriptions and game logs, respectively. The last row shows results for selected concatenated vector representations.

representation:	BC	DD	TD	GL
GPR model	5.812	7.059	7.768	9.274
SVR model	6.185	7.107	7.435	7.873
MLP model	7.035	6.823	8.573	8.018
KNN model	10.158	9.152	9.348	8.960
representation:	BC+DD+TD+GL	BC+DD	BC+TD	BC+GL
GPR model	**5.465**	5.503	5.733	5.629

IV. Conclusions

We summarized AAIA'18 Data Mining Competition organized at the Knowledge Pit platform, whose topic was predicting win-rates of Hearthstone decks. The outcomes of the competition show that various machine learning models are capable to accurately assess the quality of new decks, based on the data regarding performance of similar decks.

Our own comparison of deck representations created using various sources of information about cards revealed that the simplest approach, i.e., the bag-of-cards, can be successfully employed. Moreover, our experiments show that it is possible to considerably improve performance of prediction models by training them on combined representations from different sources. We believe that such a hybrid approach will move us one step further in our ultimate goal of designing an advisory platform for helping players in composing their decks.

***Abstract*—This paper describes our solution for the AAIA'18 Data Mining Challenge: Predicting Win-rates of Hearthstone Decks. Train and test decks were clustered by DBSCAN algorithm with precomputed distance matrix dependent on the number of common cards. We observed that each cluster can be represented by an archetype deck - one of popular decks used by human players. For each deck we created features describing cards quality and types. Additionally we used differences of these features with respect to archetype decks. Finally we used XGBoost to build a model predicting outcome of a game played between two decks.**

I. Introduction

Hearthstone is the most popular online collectible card video game[1]. Despite simple rules, game requires high strategic skills, of two separate types:

- Ability to create a high quality deck (set of cards)
- Ability to use given deck as well as possible

Article describes our solution to AAIA'18 Data Mining Challenge, where teams were asked to predict winrates of different decks, played by different bots. Full data about deck composition was easily available, while bots strategies could be only guessed from training games history. Because of that, of the two factors (deck variability and player variability), corresponding to the two skills mentioned, we decided to focus on the first, using bot type only as a control variable dividing training/testing data into 16 subsets (4 bots playing against each other).

In Hearthstone, every deck has a strategy - a way to beat the opponent. The three main strategy types are aggro, control and combo. An aggro deck tries to kill the opponent as fast as possible. A control deck tries to destroy minions played by the opponent and finish the game with strong, high-cost minons. A combo deck uses a special combination of cards that work very well together to gain great advantage or even kill the opponent in one turn.

[1]While describing Hearthstone mechanics is clearly out of the scope of this work, some basic rules are enough to make it understandable. There are two players, each of them starts with deck of 30 cards and a 'hero' card. They play alternating rounds, in each round player may play any number of cards, limited by their costs and the resource called 'mana'. Cards have different types, most important being spells and minions. Played cards more or less directly contribute to dealing damage to the other player, and the only goal is to be the first player to deal 30 damage.

Although there is virtually infinite set of possible hearthstone decks, only few of them are good enough to be played on at least semi-professional level. One of the most popular webpages with hearthstone statistics, https://hsreplay.net/decks/, currently defines 48 deck "archetypes" (exact number varies in time), such as "Aggro Hunter" or "Cube Warlock". Archetypes are based on existence of certain key cards, cleverly matched to other key cards. Those connections build deck strength, and with some of those cards missing deck would become unplayable.

Archetypes usually define the only one correct strategy. Without going too much into detail, strategy is about maximizing played card value by playing them in the right moment. E.g. strategy for Aggro Hunter is to deal as much damage as possible as fast as possible, while Cube Warlock defends until he has enough mana to play very strong cards cheaply. Each strategy has a counter strategy that might be more or less available to the opponent, so most decks - even top quality ones - do much better against some certain decks, and much worse against other.

II. Problem statement

The goal of the competition was to predict winrates (percentage of games won) of 200 test decks played by bots[2]. There were 4 different bots (denoted by $A1, A2, B1, B2$). A priori nothing was known about the bots, in particular it was not known what algorithms were used by the bots (a bot could just use a set of simple heuristics to play the game, or it can be a deep neural network, like AlphaGo) The training set consisted of results of 299680 games played between 400 training decks. For each game, we had a tuple (bot1, deck1, bot2, deck2) and the result of the game. This tuple denoted that bot1 played deck1 against bot2 using deck2.

The winrates that we had to predict were calculated based on a large number of games played between test decks and the training decks. The score was calculated as RMSE between the actual winrate and the predicted winrate for each bot, deck pair (so there were 800 numbers to predict).

[2]bot is a computer program that plays a game, here Hearthstone

III. Bot winrates

While we knew nothing about specific bot strategies[3], they were certainly different. Overall winrates for each bot are presented in Table I.

TABLE I
Bot winrates - overall, as first/second player, vs others

bot	overall	1st	2nd	vs A1	vs A2	vs B1	vs B2
A1	0.45	0.51	0.39	0.50	0.44	0.38	0.40
A2	0.52	0.57	0.47	0.56	0.50	0.45	0.43
B1	0.54	0.58	0.50	0.62	0.55	0.50	0.46
B2	0.56	0.61	0.51	0.60	0.57	0.54	0.50

It is obvious that every reasonable predicting model must include information about bots playing, and - when predicting single game result - also about starting deck/bot. Having stated that, later in this article we won't be explicitly referring to bots and starting positions - they are present in every model, but our solution is based entirely on differences between decks.

IV. Deck archetypes via clustering

A natural question is: are the given decks just random collections of available cards, or are they created from some archetypes? We used clustering to answer this question. We defined a distance between decks as

$$d = \frac{30 - n_c}{30} \tag{1}$$

where n_c is the number of common cards (counting with repetitions) in both decks.

Then we used DBSCAN [1] algorithm from scikit-learn library [2] with this metric. The parameters of the algorithm were eps = 0.4 and min_samples = 5. The algorithm found 11 clusters:

- 2 different clusters for Paladin and Warlock heroes;
- 1 cluster for each other hero

There were also 25 decks that did not have any cluster assigned. Each cluster had 47 or 48 decks, except for the Hunter cluster which had 96 decks.

This result looked promising — if the decks were random, because of the big number of possible cards, there would be no meaningful clusters.

A. Deck archetypes

For each cluster we calculated the most frequent cards used in the decks from this cluster. In each cluster there were from 5 to 10 cards that appeared in almost every deck of the cluster. For example, in one of the Paladin clusters cards Vilefin Inquisitor, Murloc Tidecaller, Bluegill Warrior, Grimscale Chum, Murloc Warleader and Rockpool Hunter that are all murloc minions were among top 10 most frequent cards (see Table II). This fact combined with the knowledge that there exists a popular Murloc Paladin deck allows to easily classify decks from this cluster as being of this archetype.

Based on the most frequent cards and domain knowledge (one of the authors used to play a lot of Hearthstone) we determined the archetype of the decks in every cluster. The archetypes were: dead man's hand warrior, inner fire priest, jade shaman, aggro hunter, jade druid, zoo warlock, cube warlock, tempo rogue, secret mage, murloc paladin, and dude paladin.

[3]Competition data included full training games courses, so those strategies could be somehow extracted, but we did not use them

TABLE II
Top 10 most frequent cards in the Murloc Paladin cluster.

card name	frequency
Vilefin Inquisitor	97.92 %
Murloc Tidecaller	95.83 %
Righteous Protector	95.83 %
Bluegill Warrior	93.75 %
Corridor Creeper	93.75 %
Grimscale Chum	93.75 %
Call to Arms	91.67 %
Murloc Warleader	91.67 %
Rockpool Hunter	91.67 %
Unidentified Maul	91.67 %

B. Model decks

We had decks clustered and we knew their archetypes. We were interested in how much the given decks differ from decks of those archetypes played by professional human players. Ideally, we would prefer to compare provided decks with 'optimal' decklists but there is no such thing as a "perfect" deck — optimal decklist depends on the decks played by the opponents. For example, there is a card Golakka Crawler that is very effective against decks that use pirates. If the decks with pirates are popular, then the decks with the Golakka Crawler will be more successful than those without it. On the other hand, if no one uses pirates, then the card is useless. [4]

For each cluster (except of 'other') we chose one model deck from the website Tempostorm (https://tempostorm.com/hearthstone/meta-snapshot/standard/2018-01-08) that creates reports about popular/strong decks. One problem with this approach was that the used decklists change every week and we did not know the date from which we should take the decklists. We used the report from the beginning of January 2018, based on the following observations:

1) the decks contained cards from the Kobolds & Catacombs expansion, released in December 2017;
2) the decks did not have any cards from The Witchwood expansion, released in April 2018; and
3) high percentage of the decks contained cards Corridor Creeper (46%) and Patches the Pirate (28%) which were changed in February 2018 and lost a lot of popularity as an effect [5]

In Table IV (column average distance) we give the average distance of decks from each cluster to the model decks. The distance function is the same as the one used in the clustering.

Note the huge discrepancies in the average distances between clusters. This can be simply a matter of the prepared decks: maybe the Shaman decks were generated differently

[4]For human players it is therefore very important to know "the meta" — that is, which decks are strong and which are popular.

[5]changing a card to a weaker version is called a nerf in the Hearthstone terminology.

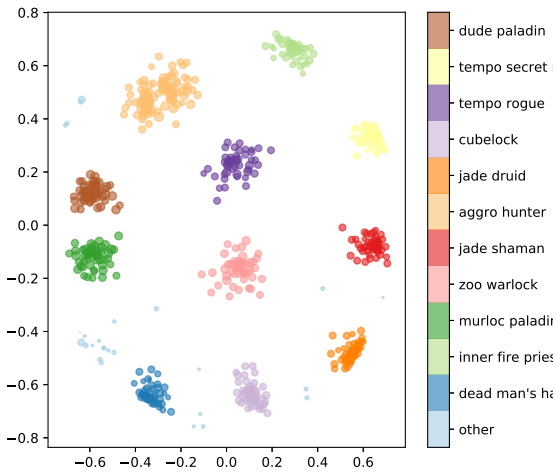

Fig. 1. 2-D decks embedding based on distance matrix using t-SNE ($perplexity = 2$, $angle = 0.9$)

than the Aggro Paladin ones. Of course this can be also a matter of poor choice of the model decks for some archetypes. We did not try to find other model decks.

To better visualize the clusters, we created a 2-D embedding using the t-SNE algorithm [4] with precomputed distance matrix. The clusters are visualised in Figure 1, Decks are coloured according to clusters found by DBSCAN. The size of dots is proportional to win-rates (with 50% substituted for test decks). In the figure we can see that clusters are clearly visible with except of the 'other' cluster. The only one unexpected fact is the division of the Hunter cluster into two groups. The number of decks in "aggro hunter" cluster is roughly two times greater than the number of decks in other clusters. Therefore it is possible that this cluster should be further divided into two clusters. However, neither DBSCAN nor multidimensional scaling (MDS) visualization confirm this division.

C. Simple cluster-based model

With established clusters, we tried the simplest possible model: for each deck D, predict the average winrate of the training decks from D's cluster as its winrate. For example, if in the training set there are 3 "murloc paladin" decks with winrates $65\%, 56\%$ and 55% respectively, each murloc paladin deck from test set gets winrate $\frac{(55+56+65)}{3} = 58.66\%$. Averaged winrates per clusters are shown in Table IV (column winrates). We can observe significant differences between clusters and poor performance of decks classified as "other". This model ignored any differences between decks in the same cluster, so it could not achieve a good score.

Another approach we tried was to use the metric given by Equation (1) directly, take the 10 training decks closest to the test deck and predict the average winrate of those 10 decks, but this gave much worse results. We decided to use more standard predictive models, improving them with features based on the clusters and model decks.

V. Predicting the winrates

A. Basic deck features

For each deck we generated a number of features that tried to capture the 'goodness' of the deck. Those included e.g.

- Average card cost
- Number of cards with cost of 0/1/2/3 or more
- Number of free/common/rare/epic/legendary cards[6]
- Number of neutral/single-hero cards[7]
- Number of minions/spells/weapons/other cards[8]
- Average overall card winrates[9]
- Number of special cards such as murlocs, beasts, minons with divine shield, taunt minions, etc.

We also gathered data from few webpages with Hearthstone statistics:

- "Card value" - overall card value when playing in arena mode[10] [http://www.heartharena.com/tierlist]
- "Card played winrate" - chance of winning the game, under condition that given card was played [https://hsreplay.net/cards]
- 2821 most popular decks [https://hsreplay.net/decks]

First and second datasets were averaged into deck "mean card value" and "mean card winrate" features. Most popular decks were used to estimate "how well cards in deck are connected". For each card pair we calculated:

- How often they appear in external decks
- How often they appear together in external decks
- "Card pair connection strength" as quotient of the above values

Deck feature "card connection strength" was calculated as a mean of connection strength between all card pairs in deck.

B. Differences with the model decks

In addition to deck-only based features, we created a set of features describing how different the deck is from the model deck of the same archetype, such as:

- General distance (as described in 1),
- How many 1-mana cards were added/removed
- Difference between added/removed card's arena value

This way we wanted to approximate how big is the "real" impact of the differences between decks and their archetypes. E.g. if deck uses many cheap minions, replacing some of them with other cheap minions is a small difference, while replacing them with expensive cards would be a drastic change.

[6]Every Hearthstone card fits into one of those categories, they approximately describe card strength

[7]Neutral card may be played by any hero, in the contrast to cards that may be played only by specific hero

[8]Every Hearthstone card has its type, "minions", "spells" and "weapons" are the most popular

[9]Taken from https://hsreplay.net/cards/

[10]Arena mode is a specific hearthstone variant, played with more or less random decks

TABLE III
FEATURES IMPORTANCES

feature	f-score
deck2 winrate	1198
mean card value p2	470
mean card value p1	442
mean minion health p2	436
mean card winrate p2	409
mean minion attack p2	387
who plays first	366
mean minion attack p1	363
mean minion health p1	352
mean card winrate p1	349
diff mean minion health p2	337
diff mean minion attack p2	334
card connection strength p1	328
diff arena value p2	327
diff arena value p1	320
card connection strength p2	320
mean minion cost p1	315
diff mean minion health p1	314
diff mean minion attack p1	308
mean minion cost p2	289

C. Final model

We considered two approaches for generating final predictions:

(a) train a regression model predicting winrate of each deck,
(b) train a classification model predicting result (win, lose) of a game between the deck and a particular opponent.

We tested both approaches and we decided on (b) due to larger training set available (300K training games versus 400 train decks) and more promising preliminary results. Since the test decks were evaluated based on the games against training decks, we added the feature "opponent's winrate" which was by far the most important one (see Table III).

Classification model was trained using XGBoost library [3], which is an implementation of gradient boosting algorithm. After training we predicted results of 4 million random games between train and test decks. Final winrates were averages of these games results.

Using XGBoost model we analysed features importances given by f-score, which is a measure of how often given variable was used to split node of a decision tree. Table III shows twenty most important features with respect to f-score. Each deck feature was repeated for both players, p1 and p2 denote player1 and player2 respectively. Features with diff prefix are differences between deck and its archetype.

VI. RESULT PER CLUSTER

After preparing the final model we tested how did the model work on particular clusters. Since we did not have the ground truth, the test was done taking 100 random training decks as the validation decks and training the model on the games played with the remaining 300 decks. We then calculated for each cluster the mean absolute error for the validation decks. The results are shown in Table IV (column mae).

We expected that we will not do so well on the 'other' cluster, since for those decks we did not have the model decks. One possible explanation is that the 'other' decks were quite weak (27% average winrate) and quite different from the other decks and therefore easier to predict.

TABLE IV
RESULTS FOR EACH CLUSTER SEPARATELY: AVERAGE WINRATE PER CLUSTER, AVERAGE DISTANCE FROM EACH CLUSTER TO THE MODEL DECK AND MEAN ABSOLUTE ERROR

cluster	winrate	average distance	mae
dude paladin	0.6482	5.33	3.90
murloc paladin	0.6141	11.98	3.13
zoo warlock	0.5871	6.46	5.08
aggro hunter	0.5860	8.13	5.54
cubelock	0.5074	5.83	4.70
tempo rogue	0.5013	6.62	5.79
jade shaman	0.4680	14.51	3.53
jade druid	0.4510	9.28	3.93
dead man's hand warrior	0.4174	12.04	5.24
tempo secret mage	0.4084	8.85	3.38
inner fire priest	0.3888	11.56	5.78
other	0.2651	-	3.01

VII. CONCLUSIONS

Our idea was to explore if the decks were generated randomly or followed the pattern of human players decks. Clustering revealed existence of groups. Each group can be represented by an archetype deck selected from decks of successful human players. Our final solution was generated by XGBoost model using features describing differences between each deck and its archetype. These distance features improved model results significantly with comparison to the model using only basic features. Our model achieved the RMSE score 6.349 which gave us 10th place in the competition.

The solution could be further improved by:

- building ensemble of different models,
- exploring other clustering algorithms,
- XGBoost hyper-parameter tuning.

Final result of our model evaluated on all test decks was slightly worse than on a fraction of test decks available for early evaluation of submissions, which can be caused by overfitting of the solution to the test data available. It would probably be beneficial to leave part of training decks for validation and comparison of different solutions.

***Abstract*—Success of many computer games depends on designing a robust and adaptable AI opponent that would ensure the games continue to challenge, immerse and excite the players at any stage. The outcomes of card based games like "Heartstone: Heros of Warcraft", aside the player skills heavily depend on the initial composition of player card decks. To evaluate this impact we have developed an ensemble prediction model that tries to predict the average win-rates of the specific combination of bot-player and card decks. Our ensemble model consists of three sub-models: two Logistic Regression models and one Deep Learning model. The models are trained with both provided data and additional data about the cards, their health, attack power and cost. To avoid overfitting, we employ a trick to generate predictions for all possible combinations of opponent players and decks and obtain the result as the average of all these predictions.**

I. Introduction

Success of many computer games depends on designing a robust and adaptable AI opponent that would ensure the games continue to challenge, immerse and excite the players at any stage. In the history of game development, much efforts have been dedicated to the design and implementation of such a bot player. There are some very powerful examples of AI robots already, such as the famous "Deep Blue" that has defeated the world chess human champion. "Heartstone: Heros of Warcraft" is a turn-based card games between two players who select their heroes with a unique power and construct a deck of thirty cards that represent various spells, weapons, and minions, and can be summoned in order to attack the opponent with the goal of reducing the opponents health to zero and win. The outcomes of this game, aside the player skills, heavily depend on the initial composition of player card decks.

With the purpose of designing such robust and adaptable AI opponent for Heartstone, an important task is to correctly predict the marginal winning probability of AI players, given unseen decks. This very task has been defined as the target of the AAIA'18 data mining challenge. Specifically, the objective was to construct a prediction model that can learn win chances of the specific AI bots assigned to specific new card decks, based on the historic evidence of same AI bots playing with similar decks [1] against all kinds of players and decks extracted from hundreds of thousands of automated games. In this competition setup the training stage involved observing four AI players assigned to one of 400 available decks of 30 cards, battling each other in over 300000 automated games. The deviced prediction models were expected to use this data to learn how particular cards are played by the bots and evaluate their contribution or impact on the final win-rate estimate of specific decks-players. The competitive models are evaluated on the games with the configurations of the same 4 bot-players and 200 new card decks.

To solve the challenge we followed a pragmatic sequence of steps that could be in fact considered generic best practices for any competition involving predictive model build from data: understand the data, perform exploratory data analysis, conduct feature engineering and select features for the model, construct models, evaluate them and optimize the complete pipeline to maximally improve the predictive performance.

Since our solution turned out to be the best and won the 1^{st} place in AAIA'2018 data mining competition, we provide detailed information of how we follow these steps to design the top model. In addition, we also introduce a key technique that we have employed to avoid overfitting, which we believe was instrumental in winning the challenge. In general, our paper offers the following two major contributions:

- We provide a clear demonstration of how basic steps in designing a machine learning model should be executed: from data understanding and feature engineering to model design, parameter tunning and model's improvement.
- We present a critical method to avoid the overfitting in reconstructing regression based win-rate from large number of simple classification models and experimentally verify how it results in significant gains in testing set performance.

In rest of the paper is organized as follows. In Section II, we introduce related work. In Section III, we describe the problem, available data and features that we generated from the dataset to train our models. In Section IV, we present both our single models and how to combine them to form an ensemble model. We discuss how we avoid overfitting to improve model's accuracy in Section V. Finally, we conclude the paper in Section VII.

II. Related Work

In this section, we briefly introduce the machine learning techniques used in our model: Deep Learning, Logistic Re-

gression and Ensemble model.

A. Deep Learning

Deep Learning (DL) refers to a class of machine learning tech- niques and architectures, where many layers of non-linear information processing stages in hierarchical architectures are exploited for representation learning [2]. In particular, a DL network represents a multi-layer neural network with the deeper structures compared to the shallow models like Support Vector Machines and a specific method where the data is processed at and in between layers. Even though the concept of DL was introduced long time ago, it has only recently gained enormous popularity due the lower cost of computing hardware, the increased speed of chip processing, and recent advances in DL algorithms. DL has been successfully employed for computer vision, optimization, pattern recognition, signal processing, and natural language processing [3].

B. Logistic Regression

Logistic regression, developed by David Cox in 1958 [4], is a statistical method for regression analysis to describe the relationship between one dichotomous dependent variable (outcome) and one or more independent variables (predictors or features). Binary logistic model can be used for estimating the probability of a binary response based on predictors and gain insights on the presence of which factors increase the probability of a given outcome by a specific percentage.

Logistic regression has been widely used in medicine, e.g. to assess injury mortality or severity for patients [5], [6], [7], [8], [9], or help to diagnose some diseases like diabetes and coronary heart disease based on characteristics and physiological data of patients such like age, sex, body mass index, blood test results, etc. [10]. It has also been successfully applied in various areas, e.g. predicting votes of American voters based on their characteristics like age, income, sex, race, state of residence, previous votes, etc. [11], estimating probability of failure in various processes, systems or products [12], [13], predicting customers' propensity to purchase a product or cease a subscription in marketing applications [14]. Conditional random fields, the extended, sequential version of logistic regression for labeling or parsing sequential data, have been commonly used in natural language processing, biological sequences prediction, computer vision, etc. [15], [16], [17].

C. Ensemble method

Ensemble methods are learning algorithms that construct a set of classifiers and then classify new data points by taking a (weighted) vote of their predictions [18]. Similar to XGBoost, ensemble method is a popular technique employed by winning teams in Kaggle's machine learning competitions [19]. In our work, we employ a simple average ensemble method from a deep learning model and a wide learning model. While the idea of leveraging deep and wide learning has already been introduced by Cheng et al. in [20], our work is very different from their work because we combine deep and wide learning in an "ensemble method" to serve the purpose of binary classification. Cheng et al. do not utilize ensemble method, instead, they jointly train wide linear models and deep neural networks to combine the benefits of memorization and generalization for recommender systems.

III. Data Description and Feature Engineering

Before performing feature engineering, it is important to understand the original data in detail and exploit all available prior knowledge. Thus, the first part of this section is reserved for data description followed with a discussion of important features used in our model.

A. Data description

Available training data represented a collection of a total of 299680 labelled games played between 2 players from a set of total 4 bots: {A1,A2,B1,B2}. In each game, both bot-players, used one of 400 card decks, each including exactly 30 cards associated with specific hero class. Throughout the games 348 distinct cards and 9 distincts hero classses were observed. In each deck, a card must belong to either the hero class which the deck relates to or the neutral class.

The testing set included in turn only the composition of 200 new testing card decks linked to the same set of up to 9 hero classes and again the same 4 bot-players {A1,A2,B1,B2}. No details of the testing games were provided and the competition task was to estimate accurate win-rates for all 800 combinations of 4 bot-players playing off 200 testing decks.

In addition to the games inital setup data of players, decks and the result, training data also included detailed turn-by-turn gameplay data but since the same was not available for the testing set it was simply ignored.

B. Important features

Given that the task was to predict the likelihood of wining a game played by a particular bot using a specific deck, it was clear that the bot-player, hero class and the cards from the linked deck were the first choices for important features. Two types of features were extracted from the cards as follows:

- Card cardinality features: represented simply the number of cards of each type present in the deck and their observed values: {0,1,2} were mostly capturing just the presence of a specific card in a deck. We have narrowed the available set of cards down to 296 that appear in both training set and testing set since it does not help the model if we train on certain cards that do not exist in the testing set and vice versa.
- Card property features: each card has a set of properties that describe the *cost*, *health*, *attack* and *armor* of the card. In addition, there are properties to specify the card type (*hero*, *minion*, *spell*, and *weapon* [1]) and card rarity (*free*, *common*, *rare*, *epic*, and *legendary*). Since these properties are good indicators of the card's strength, we also consider them as features. However, if we build such a set of features for each individual card as card cardinality features, our number of features will increase significantly and is not manageable. Thus, we chose to generate card property features from the statistics of card properties in terms of the summary of card property values and maximum values

[1]Note that we do not consider two card types: *enchantment* and *hero power* because they do not help to improve our model's performance.

from certain card properties. In total, we generated 17 card property statistics features for each deck.

Given that the card properties are not provided in the dataset, we have to collect such information from a Hearthstone API website http://hearthstoneapi.com/.

IV. Win-rates Prediction Model

In our previous work, we proved that ensemble model usually outperforms single models in binary classification [21]. Thus, we continue to choose ensemble as our final model. In this competition, we constructed the ensemble model from three different models: two logistic regression models and one deep learning model.

A. Logistic regression models

Our first two models are based on the basic logistic regression method. As discussed in the above section, we have a total of 316 features: 1 feature for the bot id, 1 feature for the deck's hero and 297 cardinality features for the cards themselves and 17 statistics features from card properties. Initially, we trained a single logistic regression model on all features. However, we soon realized that training the model separately on either players or heroes leads to better result. Thus, we decided to employ two different logistic regression models as follows:

- The first logistic regression model consists of 4 sub-models trained separately on 4 different bots, each using 300 features KBest selected from 316 available features. Note that while we chose to use 300 features for the sub-models, these features are not the same for all sub-models. In our implementation, we used KBest to select 300 features from the training data for each sub-model and the selected features are slightly different from sub-model to sub-model.
- The second logistic regression model includes 9 sub-models trained separately on 9 different heroes of the deck, each using 100 features KBest selected from 316 available features. Similar to the above 4 sub-models trained separately for each bot, the 100 feature sets of each sub-model here are also different based on the feature selection returned from KBest method executed before training the sub-models.

It is interesting to see that the number of features used by the second model is much smaller than the number of features used by the first model (100 compared to 300). It is simply because for each sub-model of the second model, since the main difference between training data are only in cards belonging to the deck's hero or neutral cards, the total number of useful features is small.

B. Deep learning model

The third model is a deep learning model. For this model, we simply constructed a network with 5 Dense layers: 200, 100, 50, 25 and 1. For the first four layers, we used the basic *relu* activation. With the last layer, since this prediction issue is a binary classification, as expected, we used *sigmoid* for it. We compiled the model with *adam* optimizer. Our model was trained on all 316 features. For the epoch and batch size, we implemented a grid search to search for optimal parameter settings among epoch 5, 10, 15 and batch size 1,000, 2,000, 3,000, 4,000, 5,000, 10,000, 15,000, 20,000 and based on the experimental results, we chose to train the model in 5 epochs using batch size 5,000.

V. Overfiting prevention and model improvement

In this section, we will introduce several tricks we used to improve the model performance as well as to prevent overfitting.

A. Model improvement

We observed that we have two players in each game. However, so far we have only used data of the first player to train the model. We know that having more training data usually improves the model's performance. Thus, we simply tried to include training data for the model from both players of the games. It means that for each game, we use features of player 1 as the first sample and features of player 2 as the second sample. This way, the training set doubled in size up to 599,360 samples and the accuracy of our models improved from 0.4 to 0.5 point.

B. Overfitting prevention

Since the task of the competition challenge is to predict the likelihood of winning a game played by a bot using a specific deck, our initial models were trained using only data of a single bot or deck's hero as described in the above section. However, it is generally expected that the prediction accuracy would be better if we also consider information/features of the opponent player (as in practice some particular player may have better result when playing with certain players and vice versa). The problem of having extra features from the opponent player, however, is that we do not have opponent information in the test set to generate predictions. It means that to leverage information of the opponents in training the model, we need to find a way address this issue.

Fortunately, since the competition challenge description says that the opponents of games in the testing set are only selected from the set of provided 400 decks used in the training set, we decided to use a brute-force strategy to generate extra information for a test sample by considering all possible combinations of opponents, which gave us 4 * 400 = 1.600 test cases. The prediction results of these 1.600 test cases are then averaged to obtain the final prediction of the test sample. It means that given a test case of a bot and a deck, we generate a total of 1.600 test cases for that pair of bot and deck again 1.600 possible cases. It also means that we increase the size of our test size 1.600 times. In summary, the following changes were made in model training and predictions generation processes:

- We double the size of the features used in our training models, considering similar features of the opponent, in addition to features of the players. Specifically, for the two logistic regression models, we respectively used a total of 600 and 200 features selected by KBest selection method. On the the hand, the total number of features used by the deep learning model is 632.

- Given that the input size of the deep learning model has been double, we added an extra Dense layer size 400, again with *relu* activation, to the existing model, making the total number of layers to 6 instead of 5 as in the previous one.
- For the predictions, given each pair of a bot and a deck in the test set, we generated predictions for all 1,600 possible games between the bot using the deck against 4 bots * 400 decks. The final prediction is the average result obtained from these games's predictions

Note that while we double the size of the features by considering features from both the player and its opponent, we keep the number of training samples unchanged at 599,360 samples. It is because we see that training data of a bot *X* playing in a game with a bot *Y* is still different from training data of the bot *Y* in a game playing with the bot *X*.

From our submissions to the public board, we could see that this technique helped to improve our scores from 0.3 to 0.5. In addition, while we were only in the 4^{th} position of the public leader board with a gap of almost 1.0 point (a big gap) compared to the team in the 1st position, since our solution did not suffer much overfitting (which we believe that due to this strategy), we jumped to the 1st position and became the winner of the competition when the final ranking list was released.

VI. Implementation and Evaluation

We implemented all models in Python. For the logistic regression models, we relied on scikit-learn library, http://scikit-learn.org/stable/index.html. On the other hand, for the deep learning model, we employed keras.io library, https://keras.io/. Our single models respectively got score of -5.8892, -5.9148 and -6.0017 and the final ensemble model, which used a simple weighted average with coefficients 1.1, 1.08 and 1.0, reached the score of -5.4017 in the public leader board, a good improvement of approximately 0.5 compared to the results of single models. Note that we simply chose the co-efficients of the ensemble model based on the performance/scores of single models in the public leader board. Actually, if we had had more time, we could have tried a stacking technique to implement the second final layer model getting results from the first prediction models. In this way, we can also optimize the co-efficients and could even lead to a better result.

VII. Conclusion and Future Work

This paper has introduced not only our winning model from the AAIA'2018 data mining challenge, but also details of a step-by-step model building process, from the early problem and data understanding through feature engineering up to the model fine-tuning and ensembling the single models for improvements. We also prsented several techniques that we used to improve the model performance avoided model overfitting with that seemed to be critical in receiving excellent final testing score and wining the competition.

A. Future work

Even though our final result is good, as discussed in Section VI, we believe that there is still room for improvement if we have a better approach to ensemble our three single models into a final one. Besides, as discussed earlier, we did not try to utilize the massive amount of data on how games are played between the two players. Actually, we believe that the detailed game information once extracted and mined properly can provide some useful information about the tactics of the bots on playing with certain decks, and hence could be also useful to improve the model's performance.

6th International Workshop on Smart Energy Networks & Multi-Agent Systems

OUR energy supply infrastructure is in the middle of a transition from a conventional star-like energy supply topology with a manageable number of well-structured power plants towards a grid topology with a myriad of different generation units that are geographically widely distributed. Additionally, the increasing integration of volatile and intermittent renewable energy resources brings massive challenges to grid operations and its composition with respect to power system commitment, dispatching and reserve requirements.

The fact that renewable energy generation units will increase their share in the overall energy production, calls for technologies to be developed in the next decades to deal with the transition of the energy supply system and the distribution of renewable energy generation units. This includes technologies to integrate, handle and intelligently manage energy storage systems, grid load peak-shaving, smart supply system components, more efficient and intelligent coupling of heating with electrical power, heat storage, intelligent load shifting and balancing, to name only a few here.

All these have in common that the future power grid has to be intelligent, where generation and consumption units communicate or even negotiate their offer or their demand of energy through an 'internet of energy'. Thus, to efficiently design and develop those distributed energy management systems is one of the key challenges to be solved to transform the energy supply system, addressing distributed coordination, as well as different forms of energy like electricity, heat, natural gas and other.

Information and communication technologies are the key enablers of such envisioned systems, where especially the agent-paradigm provides an excellent modelling approach for the distributed character of energy systems. Although significant efforts and investments have already been allocated into the development of smart grids, there are, however, still significant research challenges to be addressed before the promised efficiencies or visions can be realised. This includes distributed, collaborative, autonomous and intelligent software solutions for simulation, monitoring, control and optimization of smart energy networks and interactions between them.

TOPICS

The SEN-MAS'18 Workshop aims at providing a forum for presenting and discussing recent advances and experiences in building and using multi-agent systems for modelling, simulation and management of smart energy networks. In particular, it includes (but is not limited to) the following topics of interest:

- Experiences of Smart Grid implementations by using MAS
- Applications of Smart Grid technologies
- Distributed energy management of distributed generation and storage based on MAS
- Examples of design patterns for MAS in distributed energy management systems
- Microgrids, Islands Power Systems
- Real time control of energy networks
- Distributed planning process for energy networks by using MAS
- Self-configuring or self-healing energy systems
- Load modelling and control with MAS
- Simulations of Smart Energy Networks
- Software Tools for Smart Energy Networks
- Energy Storage
- Electrical Vehicles
- Charge scheduling for electric vehicles (and fleets) based on MAS
- Interactions and exchange between networks for electricity, gas and heat
- Stability in Energy Networks
- Distributed Optimization in Energy Networks
- Safety and security issues for MAS in Smart Grids

TUTORIAL

Beside the scientific exchange, the event will provide a practical tutorial for building so called Energy Agents. Based on the open-source framework Agent.GUI, the JADE agent platform and the experiences in the project Agent.HyGrid, the tutorial will guide you through the development process that enables you to build agents that can be installed and executed beside distributed energy systems.

***Abstract*—Energy distribution as a main part of energy management in self-powered micro-scale networks like sensor networks is a challenge with the goal to satisfy a safe and reliable operational state on system and node level. Under the assumption that nodes are arranged in mesh-like networks with links posing the capability to transfer data and energy between nodes a self-organizing Mulit-agent System based on divide-and-conquer is deployed in this work successfully to distribute energy without a system/world level model and knowledge of single nodes about the system state. Different agent behaviour were investigated and the emergence evaluated. An exploring help strategy with energy deliver child agents showed the best and efficient overall behaviour. Mobile agents were programmed in JavaScript using the JavaScript Agent Platform that can be deployed in strong heterogeneous environments.**

I. Introduction

AMONG energy supply and consumer networks on a macro-scale level there are sensor networks with self-powered sensor nodes consisting of an energy storage and energy supply. Both classes of networks require distributed, adaptive and self-organizing energy management to satisfy (1) A balance of energy supply and energy consumption, and (2) Operational stability on system level **[1]**. The energy management addressing the control of consumption and production is basically a distributed resource sharing and scheduling problem **[2]**. Sensor networks consists of nodes optionally equipped with an energy harvester collecting energy from the environment from different sources posing varying availability that cannot be controlled, in contrast to macro-scale energy sources (power engines, ..). Power management and energy harvesting are central issues in sensor networks **[3]**. Additionally, self-powered nodes can be supplied by external energy sources not directly attached to the node using other nodes to transfer energy. Nodes in a sensor network can use communication links to transfer energy, for example, optical links are capable of transferring energy using Laser or LE diodes in conjunction with photo diodes on the destination side, with a data signal modulated on an energy supply signal.

Typically, energy management is performed by a central controller on software level **[1]**, with limited fault robustness and the requirement of a well-known environment world model for energy sources, sinks, and storage. In a centralized approach, energy is only transferred on node level. With a distributed approach, energy management in a network involves the transfer of energy between node instances, too. In **[4]**, multi-agent systems (MAS) are used to perform energy management (between sinks and sources) in a renewable energy grid by solving a (global) optimization problem by the MAS. In **[1]**, a MAS performs energy distribution by a token-based approach solving an optimization problem, too. In **[5]**, MAS based on the Belief-Desire-Intention architecture (BDI) are deployed in distributed sensor networks to perform goal and knowledge orientated energy management (but without considering energy distribution). These examples pose the benefit of agent-based systems solving energy management and distribution in large-scale networks. Agents are already deployed in industrial applications and the Industrial IoT **[6]**.

We propose a smart energy management and distribution approach for a broad range of applications ranging from micro-scale sensor network architectures to large-scale energy networks with nodes supplied by 1. energy collected from a local source (energy harvesting, **[3]**), and 2. by energy collected from neighbour nodes using smart energy management (SEM) and self-organization, based on early work investigating primarily technological aspects in sensorial materials and agent-on-chip hardware architectures **[7]**. For the sake of simplicity, nodes are arranged in a n-dimensional grid with connections to their direct neighbours, i.e., in a three-dimensional network there exist up to six connections in directions North, South, East, West, Up, and Down. It is assumed that the network is irregular (missing nodes) and incomplete (missing links). Each node can store collected energy and distribute energy to neighbour nodes via communication links.

Each autonomous node provides communication, data processing, and energy management. There is a focus on single System-On-Chip (SoC) design satisfying low-power and high miniaturization requirements addressing the micro-level as well as macro-scale networks with power supplies and consumers.

Energy management is performed 1. For the control of local energy consumption, and 2. For collection and dis-

tribution of energy by using the data links to transfer energy.

Considering strong heterogeneous networks and host platforms with a loosely coupling of nodes arranged in grids the distributed data processing is a challenge. Multi-agent systems (MAS) poses a distributed computation and communication model providing autonomy, self-organization, and group behaviour. MAS are already deployed in energy management and energy distribution systems**[8][9][1]**. Most published MAS perform negotiation between energy producer and consumer under varying environmental, node and system level states. The negotiation results effect and control energy production and consumption. In contrast to public energy markets, self-powered sensor networks do not provide such a control as energy harvesting is strongly influenced by not controllable environmental conditions (e.g., sun shine duration influencing solar cell harvesting efficiency).

This work investigates and evaluate the emergence behaviour of self-organizing energy management agents that are capable to transfer (virtually carry) energy between nodes of networks and that are deployed in large-scale decentralized energy supply and consumer networks under resources and reliability constraints, e.g., self-powered sensor networks**[10]**. The desired emergence is the efficient improvement of the energy distribution in such networks to satisfy operational stability of the entire network on system level and in bounded regions, i.e., avoiding nodes with too low energy being operational. Agents perform decision making based on actual and past node energy, reward, and interaction with other agents.

The next sections introduce the underlying energy model on node level, energy management and distribution, the MAS and the agent processing platform (APP), finally used in an evaluation of a large-scale network simulation.

II. Energy Model

There is no system level model in this work considering only the node level energy. The total energy of a network node is a balance of energy loss due to computation, communication, and agent creation, and energy harvesting via energy delivery by agents and local energy harvesters (power supplies). The energy balance equation is shown in Eq. **1.** and used throughout this work.

$$\begin{aligned} E_{node}(t) \quad = \quad & e_0(t_0) - \sum k_{decay}(t) \\ & - \sum k_{comp}\tau(Ac_i) \\ & - \sum k_{create}Ag_i(AC) \\ & - \sum k_{comm}k_{link}\sigma(msg_i) \\ & + \sum l_{conv}l_{link}e_{i,deliver} + \sum l_{conv}ha_i \end{aligned} \tag{1}$$

It is assumed that the time variable of the energy E is a discrete variable with a time resolution between milliseconds and seconds. The initial energy is e_0 with a time-dependent decay k_{decay} due to losses in the energy storage of a node. The energy is reduced by agent activity Ac_i(with $\tau(Ac)$ as the execution time of an agent activity scaled by a parameter k_{comp}), agent creation $Ag(AC)$ from class AC (can be expressed by a computational time, too). Communication further requires energy and depends on the size of the message$\sigma(msg)$ scaled with the parameter k_{comm} and the link specific energy consumption given by the parameter k_{link}. Finally, energy is increased by agents delivering energy via the communication links (amount can vary, and energy conversion losses are covered by the parameter l_{conv} and the loss of the link by l_{link}) and from local power sources (ha, again covering conversion losses by the parameter l_{conv}).

Nodes are classified by their *energy deposit* and operational state:

1. A node with very low energy $E<E_{Alarm}$, with restricted node operation (only agents arriving with energy are processed, only help emergency agents are sent out).
2. A node with low energy $E<E_{Thres1}$, resulting in a basically normal node operation but with execution limits (number of agents, agent processing time, agent creation, agent migration, agent class restrictions, increased barriers of processing negotiation).
3. A node with normal energy deposit $E<E_{Thres2}$ and a normal node operation state with some resource limitations. All agents are processed and the node agent can create any type of energy agents.
4. A node with very high energy $E>E_{Alarm}$, with node operation being normal with only a few or no resource limitations. All agents are processed and the node agent will only create distribute energy agents (if behaviour was enabled).

For the sake of simplicity a three-dimensional grid network connecting spatial neighbour nodes is assumed, shown in Fig. **1**. Connected nodes can exchange data and energy. The shown example network consists of three layers (z-axis, levels) and each layer consists of 5x8 nodes. Each node has any time t an energy deposit $0>E(t)>E_{max}$, illustrated in Fig. **1** by different colors (blue: low energy, red: high energy).

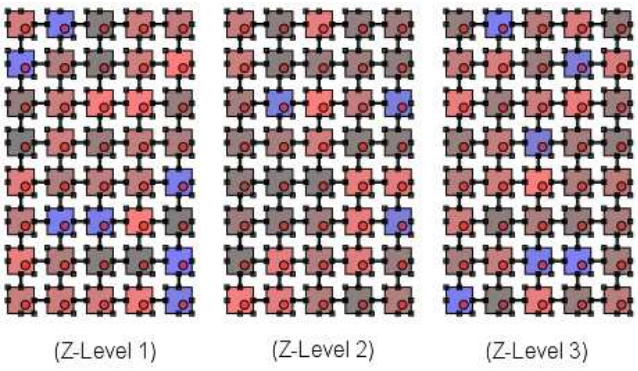

Figure 1: Example of an energy distribution in a three-dimensional network. Squares: Nodes (red color indicates enough node energy - good node - to be operational, blue color indicates critical low energy capacity - bad node), Circles: Agents, Lines: Communication and Energy links. The different z-levels are connected by up- and down links.

III. Energy Management and Distribution

In this work mobile agents perform energy management and distribution, discussed in detail in Sec. IV. The energy management relies on three main principles:

A. Adaptive Routing

Agents are responsible to find an appropriate path between a source and a distinct destination node by using adaptive routing or by using data centric routing linking an information (energy) supplier and an information (energy) sink.

B. Energy Transport

Mobile agents can carry energy tokens being able to be transferred between nodes. An energy token is requested on a node (granted or negotiated by the node agent) and can be migrated to other nodes. Each time an agent arrives on a new node it delivers its energy to the node energy deposit. If the agent has to transport the energy token to another node the agent has to collect the energy token again reduced by some technical conversion losses, shown in Fig. **2**. This approach is reasonable with respect to a technical representation of energy transfer in networks via communication links.

C. Negotiation

To avoid a high density of help and request agent populations on a specific neighbour node each help and request agent places temporary markings on the node indicating energy demand on this (good or very good) node (aka. synthetic pheromones) by other nodes. These markings are placed in the tuple space of the node and removed after a time-out automatically. If a new help or request agents arrives on this nodes and this node has a strong marking it will continue traveling (help behaviour) or dies (request behaviour). Each help and request agent negotiates energy demand with the node agent via the tuple space (by accessing active tuples using the evaluate operation and placed by the node agent using a listen operation).

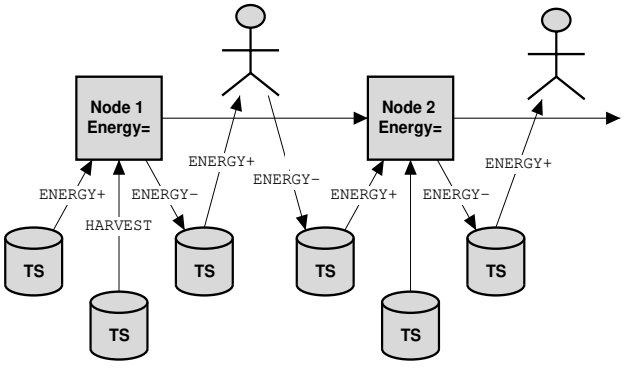

Figure 2: Energy transport by agents: Each time an agent carrying energy tokens arrives at a new node the energy is stored in the node deposit and a virtual energy tuple is stored in the tuple space. If the agent continues travelling it has to collect the energy token again.

D. Energy Management

The following parameters are used for the dynamic energy management (which can be changed at run-time) performed by the MAS:

Energy Thresholds: $E_{Alarm}<E_{Thres0}<E_{Thres1}$, $E_{Deposit}$
Energy Transfer Tokens: E_{Req},E_{Dist}
Efficiencies: k_{Conv},k_{Comm}
Exploration Radius: r_{expl}
Agent Lifetime: τ_{max}
Maximal hop-count: h_{max}

IV. MAS

The Multi-agent system (MAS) used for distributed energy management and energy distribution consists of different agent classes posing different behaviour and goals. Each network node part of the distributed energy management system provides an agent processing platform (APP). At least one stationary (non-mobile) node agent is created on each node to initialize the sensor processing and energy management. Based on the current state of the node and the power history of the node the node agent will create further energy management agents, summarized in Tab. **I**. All other energy management agents are mobile and can migrate (travel) along a path in the network crossing multiple nodes.

The node management agent can choose different energy management strategies: *Help*, *request*, and *distribute*. Depending on the operational and energy state of the node one or multiple strategies are applied to improve the energy deposit.

The different behaviour of the energy management agent is shown in the activity-transition diagram in Fig. **3**. Different parameters have an impact on each behaviour at run-time. Each agent owns a set of body variables, e.g., a delta vector indicating the position in the network, a charge and energy variable for distributed energy management. Most central parameters are the current positionΔ(relative to a source node) and the energy deposit of the current node *E* that is retrieved via the tuple space and provided by the node agent that interacts with power components via a HAL of the physical node. Energy agents are either created by the node agent (*help*, *request*, *distribute*) or by already created energy agents (*reply*, *deliver*).

Each agent can carry virtual energy as outlined in Sec. III. Since agents are mobile they can transfer energy from a node *A* to a new node *B* via the communication link (or any other power link between these nodes) just by migration. The energy transfer is handled by the APP on migration if the*charge* agent body variable holding a mobile energy token is greater than zero. Before travelling the *charge* value is transferred to the *energy* body variable of the agent to store the energy virtually. After the arrival on a new node the value of the*energy* variable is transferred back to the *charge* variable. There are now two possible cases: The agent delivers the energy finally on the current node (technically the energy was already transferred to the local energy storage), or it continues travelling and transfers the energy again to the next node via links.

Agent Class	Behaviour
`Node`	This stationary agent monitors the node state and power history. It has to initiate appropriate actions, i.e., creation of energy request, help, or distribute agents. The node agents has to asses the quality of the SEM locally and can change SEM strategies.
`Request`	*Point-to-point agent*: This mobile agent requests energy from a specific destination node, returned with a `Reply` agent. If the destination node cannot deliver energy (bad node), the request agent dies without a reply.
`Reply`	*Point-to-point agent*: Mobile reply agent created by a `Request` agent, which has reached its destination node. This agent carries energy from one node to another.
`Help`	*ROI agent*: This mobile agent explores a path starting with an initial direction and searches a good node having enough energy to satisfy the energy request from a bad node. This agent resides on the final good node (found by random walk within a region) for a couple of times and creates multiple deliver agents periodically in dependence of the energy state of the current node. If the current node is not suitable anymore, it travels to another good node.
`Deliver`	*Path agent*: This mobile agent carries energy from a good node to a bad node (response to `Help` agent). Depending on selected sub-behaviour (`HELPONWAY`), this agent can supply bad nodes first, found on the back path to the original requesting node.
`Distribute`	*ROI agent*: This mobile agent carries energy from the source node to the neighbourhood and is instantiated on a good node. It explores a path starting with an initial direction and searches a bad nodes to supply them with the energy from the agent virtual energy deposit.

Table I: SEM agents with different behaviour used to manage and distribute energy in bounded regions (ROI: region of interest) based on negotiation.

The movement of mobile agents are constrained by three parameters: The maximal hop count, the maximal mobility radius relative to the source node, and a maximal lifetime. The constrained mobility ensures a relaxation and limitation of the population of the MAS after a stimulus occurred, i.e., energy decrease or increase that can trigger the creation of energy agents.

The request and distribute strategies are the most simple ones that can be performed by bad and good nodes, respectively. The help strategy is more advanced usually performed by bad and very bad nodes. A variation of the help strategy adds help-on-way behaviour performed by the deliver agents to charge bad nodes on the way back to original requesting bad node, too.

Agents perform decision making based primarily on the node energy class (bad/good), but also on actual and past node energy recording, reward and utility feedback for charging their home node, and interaction with other agents.

V. Agent Platform

In this work agents are programmed and implemented in *JavaScript* using the *JavaScript* Agent Machine platform (*JAM*) and the *AgentJS* programming language used for the implementation of the state-based reactive agents.

In the considered use-case scenario the MAS is deployed in a large-scale strongly heterogeneous network environment, which can be additionally extended with mobile devices. This heterogeneous network requires a unified agent processing platform (APP), which can be deployed on a wide variety of host platforms, ranging from embedded devices, mobile devices, to desktop and server computers. E.g., some measuring stations are attached to buoy or installed on small islands, equipped only with low-power low-resource computers. To enable seamless integration of mobile MAS in Web and Cloud environments, agents are implemented in *JavaScript*(*JS*), executed by the *JS* Agent Machine (*JAM*), implemented entirely in *JS*, too. *JAM* can be executed on any *JavaScript* engine, including browser engines (Mozilla's *SpiderMonkey*), or from command line using*node.js*(based on *V8*) or *jxcore*(*V8* or *SpiderMonkey*), or a low-resource engine *JVM*. The last three extend the *JS* engine with an event-based (asynchronous using callback functions) IO system, providing access of the local file system and providing Internet access. But these*JS* engines have high resource requirements (memory), preventing the deployment of *JAM* on low-power and low-resources embedded devices. For this reason,*JVM* was invented. This engine is based on *jerryscript* and *iot.js* from Samsung, discussed in **[11]**. *JVM* is a Bytecode engine that compiles*JS* directly to Bytecode from a parsed AST. This Bytecode can be stored in a file and loaded at run-time. *JVM* is well suited for embedded and mobile systems, e.g., the Raspberry PI Zero equipped with an ARM processor.*JVM* has approximately 10 times lower memory requirement and start-up time compared with *nodes.js*.

JAM consists of a set of modules, with the Agent Input Output System (*AIOS*) module as the central agent API and execution level. The deployment of agents in the Internet requires an additional Distributed Organization Layer (*DOS* with capability-based security). *JAM* is available as an embeddable library (*JAMLIB*). The entire *JAM* and *DOS* application requires about 600kB of compacted text code (500kB Bytecode), and the *JAMLIB* requires about 400kB (300kB Bytecode), which is small compared to other application programs and commonly used Java-based platforms like *JADE*/*AgentSpeak*. *JVM+JAMLIB* requires only 3 MB total RAM memory on start-up.

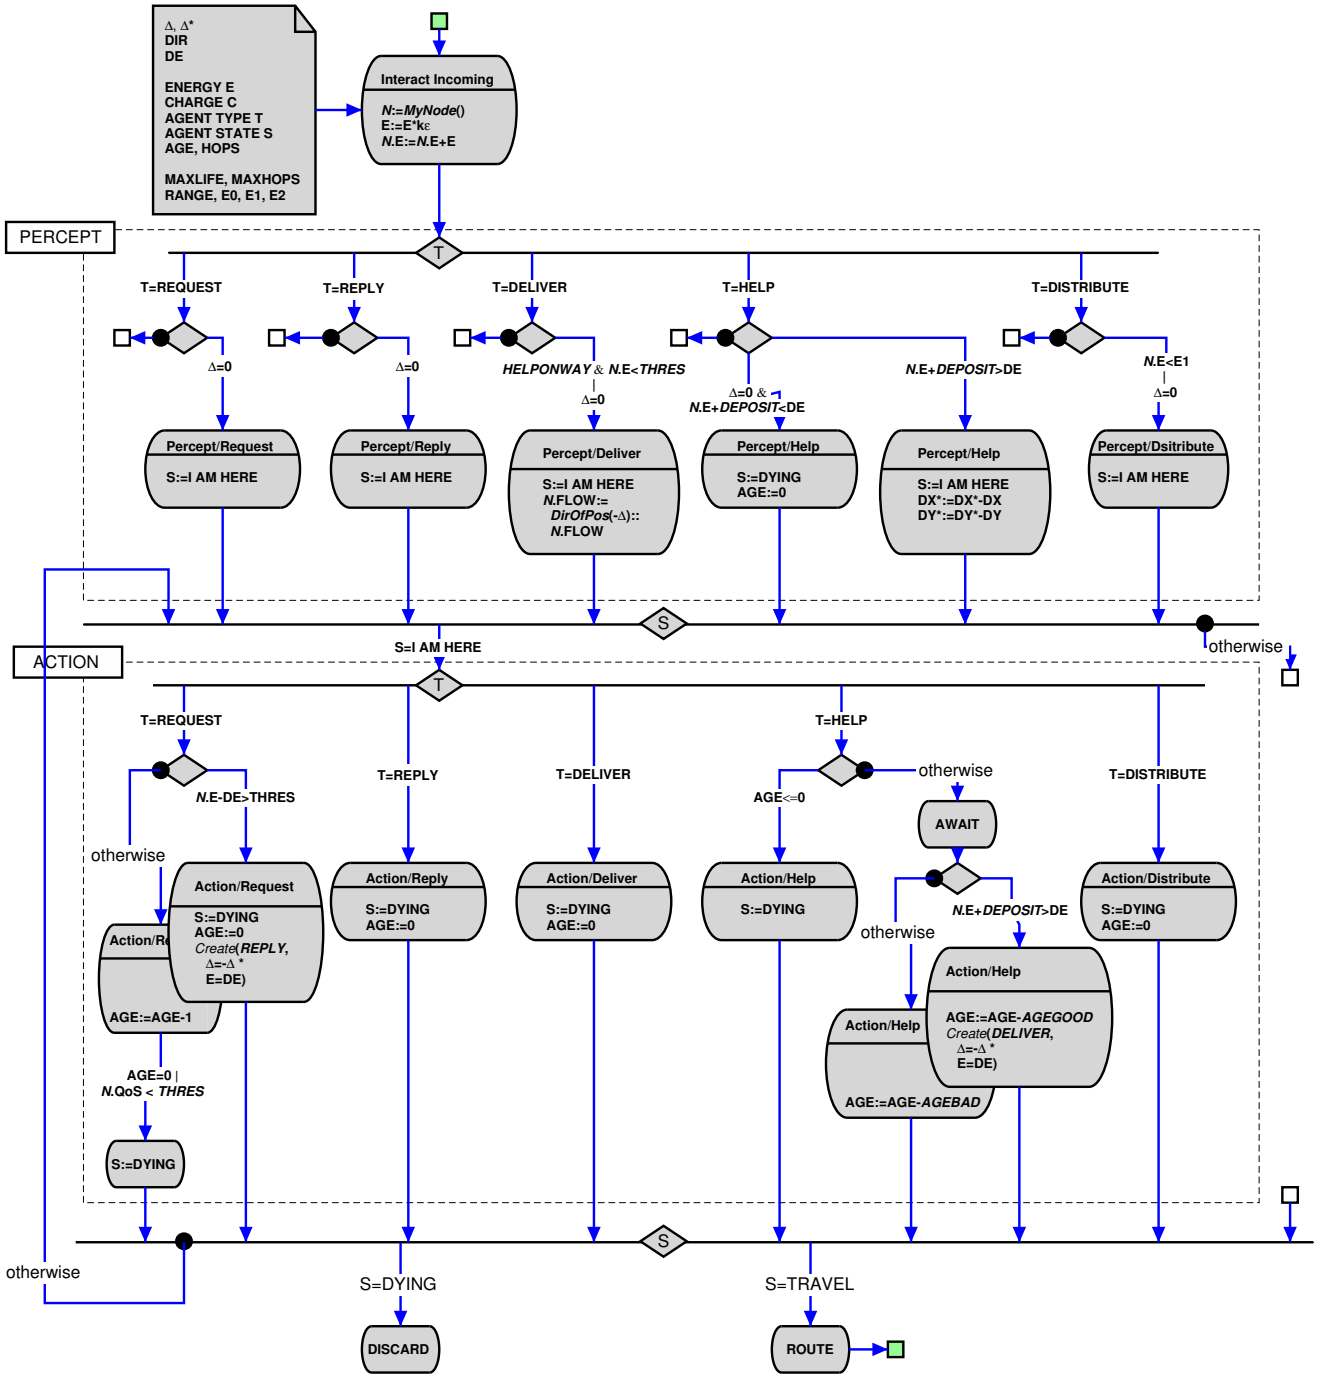

Figure 3: Principle activity diagram of the Energy Agent behaviour. There are five different agent classes (or sub-classes of the energy management agent) differing in their behaviour: Request, Reply, Help, Deliver, and Distribute.

JAM is capable of handling thousands of agents per node, supporting virtualization and resource management. JAM agents can migrate between different (physical) node APPs supporting true agent mobility with process snapshots preserving and embedding the entire agent state with low-resource overhead. Depending on the used*JS* VM, agent processes can be executed with nearly native code speed. *JAM* provides Machine Learning as a service that can be used by agents. The agent only saves a learned model, but not the learner code. Agent interaction and synchronization is provided by exchanging data tuples stored in a tuple space on each*JAM* node.

The agent behaviour is modelled according to an Activity-Transition Graph (ATG) model. The behaviour is composed of different activities representing sub-goals of the agent, and activities perform perception, computation, and inter-action with the environment (other agents).

Agent interaction (communication) is performed by using tuple spaces and mobile signals (point-to-point or point-to-N messages). Using tuple spaces is a common approach for agent communication, as proposed by**[12]**, much simpler than **[13]** proposed with *AgentSpeak*. The transition to another activity depends on internal agent data (body variables). The ATG is entirely programmed in *JavaScript* (*AgentJS*, see **[14]** for details). The ATG can be modified by agents at run-time enabling code morphing and optimization (behaviour adaptation or sub-classing).

JAM agents are mobile, i.e., a snapshot of an agent process containing the entire data an control state including the behaviour program, can migrate to another *JAM* platform. *JAM* provides a broad variety of connectivity, available on a broad range of host platforms. Although *JAM* is used in this work as a simulation platform in the *SeJAM* simulator only, it is ready to use in real-world networks and is capable to execute thousands of agents. The *SeJAM* simulator is built on top of a *JAM* node adding simulation control and visualization, and can be included in a real-world closed-loop simulation with real devices. Since *JAM* can be embedded in any host application and its capability to be easily extended enables the binding of *JAM* to low-level power management and technical energy components (conversion, storage, transfer). A hardware abstraction layer (HAL) enables the access of the power components by agents completely via the tuple space or by extended *AIOS* functions.

VI. Simulation and Evaluation

The simulation was carried out with the *SeJAM* simulator and a three-dimensional grid network consisting of three z-levels (layers), 8 rows, and 5 columns, as already shown in Fig.**1**. Each node of the network is a virtual *JAM* instance connected with up to six neighbouring nodes via serial links. Each node is associated with a virtual energy storage and energy harvester. The links are capable to transfer data and energy as introduced. Each node is populated with at least one node agent. An artificial world agent controls the simulation, perform monitoring, and reforms Monte Carlo simulation of the energy harvesting, and the initial start condition with respect to the initial energy deposit of each node. The randomized energy distribution assign nodes with an initial energy storage in the range [e_1=50,e_2=300](arb. energy units). Depending on the energy threshold settings there is initially a fraction of bad and very bad nodes about 20% of the total number of 120 nodes. In periodic intervals the nodes are charged with randomized energy amounts in the interval [0,e_Δ=0.3].

Each simulation run consists of 3000 simulation steps (in all considered cases the SEM converged either during this simulation range or never).

A typical parameter set used by the MAS is shown below.

```
parameter:{
 energy1:50, Energy range of nodes
 energy2:300,
 energyAlarm:50,   e < e_Alarm: Very Bad Node
 energyThres0:100,  e < e_Thres0: Bad Node
 energyThres1:200,  e > e_Thre1: Very Good Node
 energyDeposit:50,  Reservoir
 energyRequest:50, Def. en. to requeste
 energyDistribute:20, Def. en. to distribute
 explorationRange:4,
 maxLife: 4,
 maxHops: 8,
 Inhibit request/help agent send out
 inhibitTime: 20,
 Internal energy conversing efficiency
 energyK: 0.95,
 energyCommK: 0.8, Energy transfer efficiency
 sem: ['help'],  Energy management strategy
 doHarvest:true,
 harvest:0.3,
 cpuK:0.3,
 createK:3,
}
```

One important outcome of the simulation was the observation that the emergent behaviour on system level depends on the starting condition of the network, i.e., the initial energy distribution. That means the result of the MAS operation can vary significantly under different situations discussed below.

Typical examples of the run and progress of different energy management strategies with respect to the node classification population (very bad, bad, good, very good) are shown in Fig. **5**. Without SEM (not shown), there is commonly no change in the network situation, i.e., the number of bad nodes (typically about 20%) remains unchanged. Using SEM, the MAS is capable to decrease the fraction of all bad nodes below 1%. All three SEM strategies request, help, and help-on-way, show a fast convergence and reaching of the goal to minimize bad nodes but still preserving a high amount of good and very good nodes. The help behaviour has the fastest convergence time, usually eliminating all bad and very bad node states, whereas the request behaviour has a slower convergence time. The help-on-way behaviour can create a remaining fraction of bad and very bad nodes and seems not be appropriate to satisfy the system level goal.

Typical variations of the run and progress of different energy management strategies are shown in Fig. **6**. The request behaviour poses a lower stability in the final outcome of the MAS than the help and help-on-way behaviour. Although help-on-way seems to be more reliable, it tends to create very bad node cluster as shown in Fig. **4**.

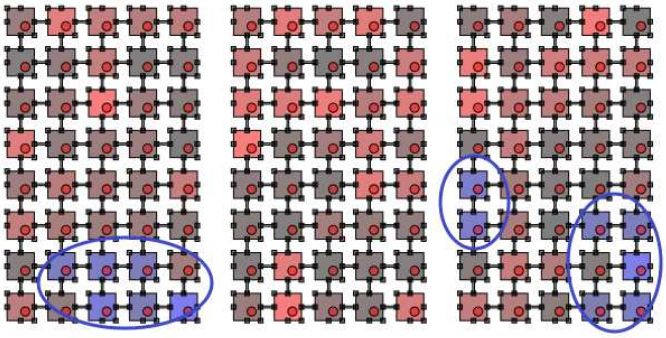

Figure 4: Formation of isolated very bad node clusters

One important measure is the temporal development of energy agents during a SEM run and the total number of created energy agents (help, request, distribute, deliver, reply), shown in Fig. **7**. The help behaviour performs optimally (both concerning the convergence time and the number of agents required). The help-on-way behaviour shows the aforementioned instability and missing convergence.

Fig. **7** summarizes the evaluation of the impact of different SEM agent parameters (parameter sets *B*-*F*). The parameter sets are explained in App. A. Parameter sets *B*-*E* are used to investigate the help MAS behaviour with different maximal help agent life times (staying on a good node and sending out deliver agents). Increasing the lifetime increases the total number of created energy agents without decreasing the fraction of bad nodes significantly. A fraction about 4% still remains (with large variations). But increasing the exploration range and the maximal number of agent hops results always (regardless of the initial start condition) in 0% bad nodes!

Finally, the energy efficiency of the MAS (defined as the fraction of start+harvest energy/final energy) was analyzed and is shown in the center plot of Fig. **8**. All parameter sets show a high efficiency between 87-92%.

The energy equation Eq. **1.** is updated during simulation about every 50 simulation step providing a sufficient smooth change of E based on updated perception and energy harvesting activities.

VII. Conclusion and Outlook

Smart energy distribution in self-powered micro-scale networks like sensor networks is a challenge with the goal to satisfy a safe and reliable operational state on system and node level. Under the assumption that nodes are arranged in mesh-like networks with links posing the capability to transfer energy and data between nodes a self-organizing MAS was deployed in this work successfully to distribute energy without a system/world level model and knowledge of the single nodes about the system state. Different agent behaviour were investigated and evaluated. The exploratory help strategy with deliver child agents showed the best and efficient overall behaviour.

The agents were programmed in *JavaScript* using the *JavaScript* Agent Machine Platform (*JAM*) that can be deployed in strong heterogeneous environments on a wide range of devices.

Among the agent behaviour already presented in this work, the issue of rising very bad (non operable) node clusters observed in the current MAS framework must be prevented. One possible solution is directed diffusion propagation around nodes giving energy away, i.e., an agent consuming and transferring energy from a node should trigger energy transfer in the opposite delivery direction (away from the energy valley up to energy hills). Furthermore, distributed supervised learning can be used to improve the emergence of the entire network and MAS on system level and on local region level. The used *JAM* platform already supports agents with an extensive set of learning algorithms posing mobile models that can migrate with agents.

Agent Behaviour

The following algorithms describe parts of the agent behaviour in *AAPL* short notation (details [15]) of node and energy agents and their interaction using the tuple space. The stationary node agent controls energy storage, harvesting, and transfer on network nodes (with direct access to energy devices). The mobile energy agent performs energy negotiation and transport.

Notation: Ψ: Agent class, φ: Subclass, Σ: Agent body variables, α: Agent activity, Θ: Agent creation/destruction (+:create, $\times$:destroy, $\rightarrow$:fork), ∇: Tuple space access (+:out, -:inp, %:rd, $\pm$:listen, $\mp$:evaluate), $\Leftrightarrow$: Agent migration, π: activity transitions. Tuple listener receive tuples (with actual and formal parameters) from a corresponing evaluate operation and pass modifieded tuples to the evaluation request.

Ψnode : *options* $\rightarrow$ {
Σ = { *energy*, $energy_{thres*}$, $energy_{Deposit}$, .. }
α*init* : {
• *Agent asks for energy demand* (+) *or grant* (−)
$\nabla^{\pm}(ENERGY?, ?) \rightarrow (*, ask)$ {
$energy < energy_{Thres_0} + energy_{Deposit}$?
• *energy demand*
$ask \leftarrow energy_{Thres_1} - energy$:
• *energy grant*
$ask \leftarrow -(energy - energy_{Thres_0} - energy_{Deposit})$
}
• *Agent requests energy token*
$\nabla^{\pm}(ENERGY-, ?) \rightarrow (*, con)$ {
$energy > con - energy_{Deposit}$?
$energy \leftarrow energy - con$,
$consumed \leftarrow consumend + con$,
• *conversion loss*
$con \leftarrow con * energy_K$:
$con \leftarrow 0$
}
• *Agent delivers energy token*
$\nabla^{\pm}(ENERGY+, ?) \rightarrow (*, del)$ {
• *conversion loss*
$del \leftarrow del * energy_K$
$energy \leftarrow energy + del$
}
• *Agent delivers energy token after migration*
$\nabla^{\pm}(ENERGYC+, ?) \rightarrow (*, del)$ {
• *conversion loss*
$del \leftarrow del * energy_{CommK}$
$energy \leftarrow energy + del$
}
• *Generic energy request*
$\nabla^{\pm}(REQUEST, ?) \rightarrow (*, req)$ {
• *Is this node good, very good, or bad?*
$energy < energy_{Thres_0}$?
• *bad node, needs energy*
$req \leftarrow 0$:
$energy < energy_{Thres_1}$?
• *goog node : grant only half energy request!*
$req \leftarrow req / 2$:
• *very good node : grant full request*
}
}
}

Energy negotiation is peformed by different tuples (energy tokens): *ENERGY?*, *ENERGY-*, *ENERGY+*, *ENERGYC+*, *REQUEST*. Energy agents can replicate based on behaviour.

***Abstract*—Future smart grid control demands delegation of liabilities to distributed, rather small energy resources in contrast to today's traditional large control power units. Distributed energy scheduling constitutes a complex task for optimization algorithms regarding the underlying high-dimensional, multimodal and non-linear problem structure. For predictive scheduling with high penetration of renewable energy resources, agent-based approaches using classifier-based decoders for modeling individual flexibilities have shown good performance. On the other hand, such decoder-based methods are currently designed for single entities and not able to cope with ensembles of energy resources. Aggregating training sets sampled from individually modeled energy units results in folded distributions with unfavorable properties for training a decoder. Nevertheless, this happens to be a quite frequent use case, e. g. when a hotel, a small business, a school or similar with an ensemble of co-generation, heat pump, solar power, and controllable consumers wants to take part in decentralized predictive scheduling. Recently, an extension to an established agent approach for scheduling individual single energy units has been proposed that is based on second level optimization. The agents' decision routine may be enhanced by a covariance matrix adaption evolution strategy that is hybridized with decoders. In this way, locally managed ensembles of energy units can be included. The applicability has already been demonstrated, but the effects of ensemble composition are so far unknown. Here, we give an widened view on the underlying power level distribution problem and extend the results by conducting a sensitivity analysis on the impact of ensemble size and penetration on communication overhead and residual error.**

I. Introduction

In Germany where a financial security of guaranteed feed-in prices has meanwhile been granted since the early 90th – but also in other countries of the European union and world wide, the share of distributed energy resources (DER) within the electricity grid is constantly and rapidly rising. According to the goal defined by the European Commission [1], concepts for integration into electricity markets will quickly become indispensable to reduce subsidy dependence for both: active power provision and for providing ancillary services like frequency or voltage control [2], [3].

Consequently, combining smart measurement technologies for decentralized information gathering on current operational grid state, new tele-control techniques, communication standards and scalable, decentralized self-organized control schemes will lead to a so called smart grid with decentralized power conditioning and control of the production and distribution of electricity managed without central control; as in the vision of [4] or similar for Europe [5].

As the smart grid will have to delegate many control tasks to small and distributed energy units, new control algorithms are required that are able to cope with large problem sizes and distributed and only locally available information. Virtual power plants (VPP) are a well-known instrument for aggregating and controlling DER [6]. Concepts for several purposes (commercial as well as technical) have been developed. A usual use case commonly emerging within VPP control is the need for scheduling the operation of participating DER. Predictive scheduling [7] describes the optimization problem for day-ahead planning of energy generation in VPPs, where the goal is to select a schedule for each energy unit – from an individual search space of feasible schedules with respect to a future planning horizon – such that a global objective function (e. g. resembling a target power profile for the VPP as close as possible) is optimized.

Recently, distributed approaches gained more and more importance for VPP control. Different works proposed hierarchical and decentralized architectures based on multi-agent systems and market-based computing [8], [9]. Newer approaches try to establish self-organization between actors within the grid [10]–[12]. In contrast, today's commercial VPP are often operated by a single authority that at the same time is the owner of (and responsible for) all distributed energy resources in this rather static unit ensemble. Independently from a concrete implementation for predictive scheduling, the dispatch algorithm has to choose a schedule for each DER in the VPP such that all objectives are met.

In order to choose an appropriate schedule for each participating DER, the algorithm must know from each DER, which schedules are actually operable and which are not. Depending on the type of DER, different constraints restrict possible operations. The information about individual local feasibility of schedules has to be modeled appropriately in (distributed) optimization scenarios, in order to allow unit independent algorithm development. For this purpose, meta-models of constrained spaces of operable schedules have been shown indispensable as a means for independently modeling constraints and feasible regions of flexibility. Each energy unit has its own individual flexibility – i. e. the set of schedules that might be operated without violating any technical operational constraint – based on the capabilities of the unit,

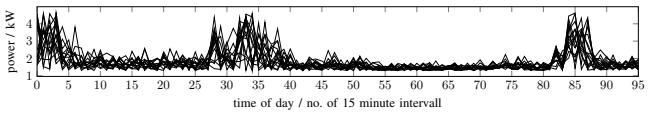

Fig. 1. Example for a training set of schedules for a co-generation plant. A state-of-charge of 50% at night and an increased thermal demand for showering in the morning and dish washing in the evening result in higher flexibilities during these periods.

operation conditions (weather, etc.), cost restrictions and so forth. Integrating these constraints to possible operations of an arbitrary energy unit demands a means for meta-modeling that allows model independent access to feasibility information. [13] introduced a support vector based model that captures individual feasible regions from training sets of operable example schedules. Figures 1 and 2 show example training sets for a co-generation plant and a heat pump respectively.

With an appropriate extension – so called decoders [14] – , these models can also be used for repairing infeasible solution or for systematically generating feasible solutions [15]. Agent-based approaches can derive a so called support vector decoder automatically from the surrogate model and use it as a means for generating feasible solutions without domain knowledge on the (possible, situational) operations of the controlled energy resource [14].

Examples for using decoders in optimization within the smart grid can be found in [16]–[19]. In general, the idea works in two successive stages – a decoder training phase and the actual algorithm/ negotiation execution phase where the decoder is used [7]. During the training phase a decoder is calculated for each unit. These calculations can be done fully parallel. During the succeeding load planning phase, these decoders may be used by an optimization algorithm that determines the optimal partition of a given active power target schedule into schedules for each single unit. The decoder automatically repairs infeasible solutions and thus the solver does not need any domain knowledge about the energy units, their individual constraints, or possible operation.

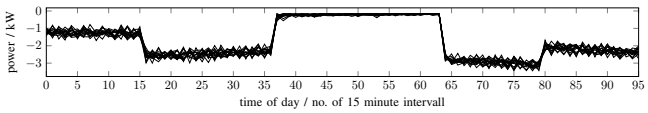

Fig. 2. Example for a training set of schedules for a heat pump with a maximum deviation of 500 Wh from the integral of set thermal demand.

An example for a recently developed agent approach for fully decentralized predictive scheduling is given by the **co**mbinatorial **h**euristics for **d**istributed **a**gents (COHDA). In COHDA [20] each agent is responsible for exactly one energy unit and uses a decoder to locally decide on feasible schedules for the represented unit. The algorithm has shown excellent performance [17], [20], [21]. But, as soon as an agent has to represent a local ensemble of energy units instead of a single device, a problem arises because usually only flexibility models of single units are available. Generating a single decoder for handling all constraints and feasible operations of the whole ensemble is hardly possible due to statistical problems when combining training sets from individually sampled flexibility models. Due to the folded densities only a very small portion from the interior of the feasible region (the dense region) is captured by the machine learning process. But, a combined training set is needed if one wants to train a single decoder for each agent.

For this reason, in [22] a substitute for the single decoder part that generates suitable and feasible schedules for the negotiating agents has been proposed. To achieve this, an evolution strategy is harnessed to do the job of solving the problem using individual decoders (one for each unit in the ensemble). In this way, an optimization problem has to be solved instead of a single mapping with a decoder for each agent decision during the negotiation, but with harnessing the full flexibility of the ensemble. Hence, a new decision method is introduced to the agent approach based on a covariance matrix adaption evolution strategy that widens the applicability to including multiple local ensembles of DER into the VPP without changing the underlying negotiation between the agents.

In [22] the general approach had been scrutinized on basis of gained optimization results regarding effect and performance of the CMA-ES part. A closer look on underlying mechanisms of the agent negotiation and parameter impact is missing so far. Moreover, the influence of ensemble size and composition is unknown. Here, we extend the former work with a study on the impact of folded distributions on different energy units' aggregated flexibility – constituted by the agents' entities – and conduct a sensitivity analysis regarding the impact of group size, composition or group number on the agent approach as well as on the CMA-ES intermediate results.

The rest of the paper is organized as follows. First, an outline on predictive scheduling and related work regarding the decoder approach as well as decentralized, agent-based methods for solving is presented. A strong focus is on the combinatorial heuristics for distributed agents. After scrutinizing the problem of folded power level distributions in aggregated training sets for different types of energy unit ensembles, the necessity of integrating a heuristic approach into the agent method for ensembles is derived. We recap the hybridization of covariance matrix adaption evolutions strategies with support vector decoders and the bi-level approach from [22] for circumventing the problem of folded distributions. The sensitivity of different group traits is analyzed. We conclude with results from several simulation studies showing beyond the effectiveness of the hybrid approach the scalability regarding ensemble size, penetration and communication expenses. Moreover, it is shown that the overall efficiency of the underlying agent approach is not seriously effected by integrating a sub-optimization process into the decision phase.

II. Related Work

A. Predictive scheduling

As related work, solutions to predictive scheduling with decoders have to be discussed in the context of agent-based approaches prior to deriving the root cause that raises the problem when extending scheduling to participants that locally have to control more than one single energy unit. We start with a definition of the general predictive scheduling problem.

As opposed to the usual time series model, we regard a schedule as real valued vector $\boldsymbol{p} = (p_1, \ldots, p_d) \in \mathbb{R}^d$ with each element p_j denoting mean active power generated (positive values) or consumed (negative values) during the j-th of d time intervals. Starting time and width of each time interval are assumed to be known from context information. The feasibility of a schedule $\boldsymbol{p}$ is defined by sets of unit specific technical and economic constraints.

One of the crucial challenges in operating a VPP arises from the complexity of the scheduling task due to the large amount of (small) energy units in the distribution grid [23]. In the following, we consider predictive scheduling, where the goal is to select exactly one schedule $\boldsymbol{p}_i$ for each energy unit U_i from a search space $\mathcal{F}^{(U)}$ of feasible schedules specific to the possible operations and technical constraints of unit U and with respect to a future planning horizon, such that a global objective function (e. g. resembling a target power profile) is optimized by the sum of individual contributions [24]. A basic formulation of the scheduling problem is given by

$$\delta\left(\sum_{i=1}^{m} \boldsymbol{p}_i, \boldsymbol{\zeta}\right) \rightarrow \min;\ \text{s.t.}\quad \boldsymbol{p}_i \in \mathcal{F}^{(U_i)}\ \forall U_i \in \mathcal{U}. \tag{1}$$

In equation (1) δ denotes an (in general) arbitrary distance measure for evaluating the difference between the aggregated schedule of the group and the desired target schedule $\boldsymbol{\zeta}$. W. l. o. g. we assume the Euclidean distance is used.

To each energy unit U_i exactly one schedule $\boldsymbol{p}_i$ has to be assigned. The desired target schedule is given by $\boldsymbol{\zeta}$. $\mathcal{F}^{(U_i)}$ denotes the individual set of feasible schedules that are operable for unit U_i without violating any (technical) constraint. Solving this problem without unit independent constraint handling leads to specific implementations that are not suitable for handling changes in VPP composition or unit setup without having changes in the implementation of the scheduling algorithm [17].

Flexibility modelling can be understood as the task of modelling constraints for energy units. For optimization approaches in smart grid scenarios, black-box models capable of abstracting from the intrinsic model have proved useful [25], [26]. They do not need to be known at compile time. A powerful, yet flexible way of constraint-handling is the use of a decoder that gives a search algorithm hints on where in the search space to look for schedules satisfying local hard constraints (*feasible schedules*) [26], [27].

For our experiments, we used a decoder as described in [15]. Here, a decoder γ is given as mapping function

$$\gamma : \mathbb{R}^d \rightarrow \mathbb{R}^d;\ \gamma(\boldsymbol{p}) \mapsto \boldsymbol{p}^*. \tag{2}$$

With $\boldsymbol{p}^*$ having the following properties:

- $\boldsymbol{p}^*$ can be operated by the respective energy unit without violating any constraint,
- the distance $\|\boldsymbol{p} - \boldsymbol{p}^*\|$ is small; where the term small depends on the problem at hand and often denotes the smallest distance of $\boldsymbol{p}$ to the feasible region.

With such decoder concept for constraint handling one can now reformulate the optimization problem as

$$\delta\left(\sum_{i=1}^{m} \gamma_i(\boldsymbol{p}_i), \boldsymbol{\zeta}\right) \rightarrow \min, \tag{3}$$

where γ_i is the decoder function of unit i that produces feasible, schedules from $\boldsymbol{p} \in [0, p_{max}]^d$ resulting in schedules that are operable by that unit. Please note, that this is a constraint free formulation. With this problem formulation, many standard algorithms for optimization can be easily adapted as there are no constraints (apart from a simple box constraint $\boldsymbol{p} \in [0, p_{max}]^d$) to be handled and no domain specific implementation (regarding the energy units and their operation schedules) has to be integrated. Equation (3) is used as a surrogate objective to find the solution to the constrained optimization problem equation (1).

B. COHDA

The Combinatorial Optimization Heuristics for Distributed Agents (COHDA) was originally introduced in [28], [29]. Since then it has been applied to a variety of smart grid applications [17], [24], [30], [31]. With our explanations we follow [29].

Originally, COHDA has been designed as a fully distributed solution to the predictive scheduling problem (as distributed constraint optimization formulation) in smart grid management [28]. In this scenario, each agent in the multi-agent system is in charge of controlling exactly one distributed energy resource (generator or controllable consumer) with procuration for negotiating the energy. All energy resources are drawn together to a virtual power plant and the controlling agents form a coalition that has to control the VPP in a distributed way. It is the goal for the predictive scheduling problem to find exactly one schedule for each energy unit such that

1) each assigned schedule can be operated by the respective energy unit without violating any hard technical constraint, and
2) the difference between the sum of all targets and a desired given target schedule is minimized.

The target schedule usually comprises 96 time intervals of 15 minutes each with a given amount of energy (or equivalently mean active power) for each time interval, but might also be constituted for a shorter time frame by a given energy product that the coalition has to deliver.

An agent in COHDA does not represent a complete solution as it is the case for instance in population-based approaches [32], [33]. Each agent represents a class within a multiple choice knapsack combinatorial problem [34]. Applied to predictive scheduling each class refers to the feasible region in

the solution space of the respective energy unit. Each agent chooses schedules as solution candidate only from the set of feasible schedules that belongs to the DER controlled by this agent. Each agent is connected with a rather small subset of other agents from the multi-agent system and may only communicate with agents from this limited neighborhood. The neighborhood (communication network) is defined by a small world graph [35]. As long as this graph is at least simply connected, each agent collects information from the direct neighborhood and as each received message also contains (not necessarily up-to-date) information from the transitive neighborhood, each agent may accumulate information about the choices of other agents and thus gains his own local belief of the aggregated schedule that the other agents are going to operate. With this belief, each agent may choose a schedule for the own controlled energy unit in a way that the coalition is put forward best while at the same time own constraints are obeyed and own interests are pursued.

All choices for own schedules are rooted in incomplete knowledge and beliefs in what other agents are probably going to do; gathered from received messages. The taken own choice (together with the basis for decision-making) is communicated to all neighbors and in this way knowledge is successively spread throughout the coalition without any central memory. This process is repeated. Because all spread information about schedule choices is labeled with an age, each agent may decide easily whether the own knowledge repository has to be updated. Any update results in recalculating of the own best schedule contribution and spreading it to the direct neighbors. By and by all agents accumulate complete information and as soon as no agent is capable of offering a schedule that results in a better solution, the algorithm converges and terminates. Convergence has been proven in [20].

More formally, each time an agent receives a message, three successive steps are conducted. First, during the perceive phase an agent a_j updates its own working memory κ_j with the received working memory κ_i from agent a_i. From the foreign working memory the objective of the optimization (i. e. the target schedule) is imported (if not already known) as well as the configuration that constitutes the calculation base of a neighboring agent a_i. An update is conducted if the received configuration is larger or has achieved a better objective value. In this way, schedules that reflect the so far best choices of other agents and that are not already known in the own working memory are imported from the received memory.

During the following decision phase agent a_j has to decide on the best choice for his own schedule based on the updated belief about the system state Γ_k. Index k indicates the age of the system state information. The agent knows which schedules of a subset of other agents (or all) are going to operate. Thus, the schedule that fills the gap to the desired target schedule exactly can be easily identified. Due to operational constraints of the controlled DER, this optimal schedule can usually not be operated. Thus, each agent is equipped with a decoder that automatically maps the identified optimal schedule to a nearby feasible schedule that is operable by the DER and thus feasible. In this way, the decision routine of the agent reduces simply to a mapping call of the decoder. Based on a set of feasible schedules sampled from an appropriate simulation model for flexibility prediction [36], the decoder can be built by learning a support vector model after the approach of [15].

If the objective value for the configuration with this new candidate is better, this new solution candidate is kept as selected one. Finally, if a new solution candidate has been found, the working memory with this new configuration is sent to all agents in the local neighborhood. The procedure terminates, as soon as all agents reach the same system state and no new messages are generated. In this case no agent is able to find a better solution. Finally, all agents know the same final result.

As the whole procedure is based exclusively on local decisions, each agent decides privately which schedules are taken. Private interest and preferences can be included and all information on the flexibility of the local DER is kept private. The same must hold true for agents controlling an ensemble of energy units.

III. Ensemble scheduling

A. Problem

Sometimes the technical equipment of a single participant in a virtual power plant consists of more than just a single generator (or prosumer or controllable consumption). Nevertheless, the owner as operator is usually still represented by a single controlling agent when embedded into a decentralized agent-based control scheme inside a virtual power plant. In this case that agent has to handle the ensemble of energy units as a single unit (in a sense as a single sub VPP) and negotiate to the other agents with the aggregated flexibility. Nevertheless, there is usually no joint model of the whole ensemble, and thus the agent has to use an individual model of each unit and thus a set of individual decoders for deciding on an aggregated schedule for the ensemble.

If an agent covers a set of energy units instead of a single unit, a decoder for the joint feasible region of the group of units has to be used. A model of the operation of the ensemble of units is usually not available. Using the training sets of individual energy units and randomly combining them (adding up exactly one from each training set) to joint schedules in order to gain a training set for the joint behavior is not targeted. The problem is that all source trainings sets are independent random samples and thus the resulting training set exhibits a density (of operable power levels) that results from folding the source distributions.

Figure 3(a) shows a first example. Rather uniformly – except for the gap between zero and minimum engine velocity and a slightly degrading likelihood of higher power levels – distributed values for levels of power as in the case of an co-generation plant with sufficient buffer capacity fold up to an multi-modal Irvin-Hall-distribution [37]. This distribution has some similarities to a sharp normal distribution and the more

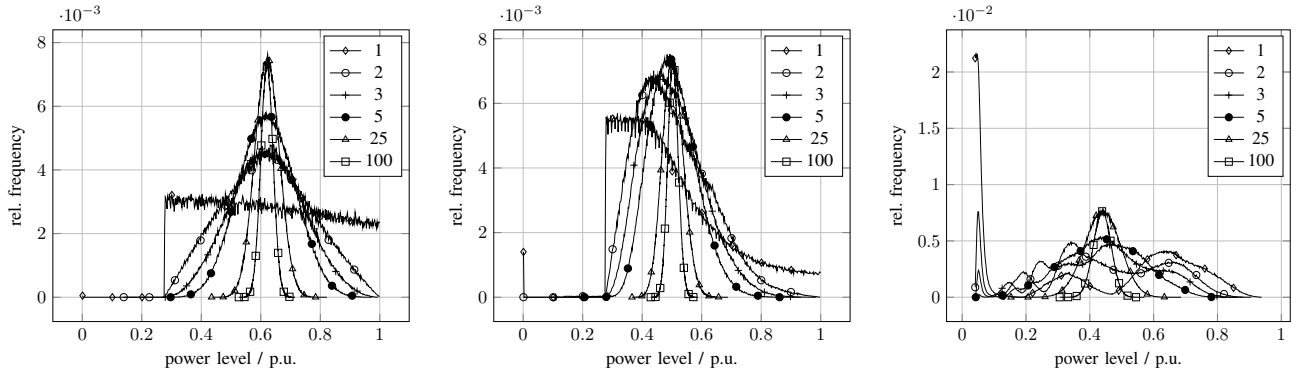

Fig. 3. Probability density of different numbers of folded distributions of operable power levels for co-generation plants for a very cold winters day.

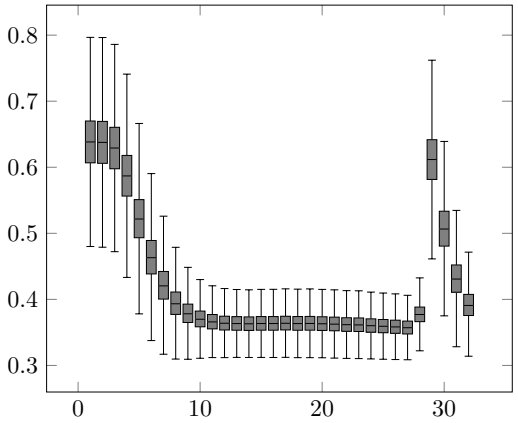

Fig. 4. Probability distribution of power levels at different time intervals of an ensemble of 10 micro CHP units. The training set exhibits a concentration in the inner part of the whole flexibility (grey boxes denoting 3/4 of the samples) making it highly imbalanced.

samples (number of energy units in the ensemble) are folded the more leptokurtic the pdf gets.

Whereas Figure 3(a) considers the distribution of power levels at a certain point in time (7:00 a.m.), shows Figure 3(b) the situation averaged over all time periods of a sample winters day. Due to the integration of the warmer daylight periods, the likelihood of high power levels degrades. Nevertheless, in the case of ensembles of co-generation plants the distributions fold up to a similar aggregated distribution that generates training sets unsuitable for machine learning. If a model is based on an estimation of probability distributions, then it is highly susceptible to the spatial distribution of the samples in feasible space [38] because merely regions of high density are learned. Figure 3(c) shows as a third example the folded distributions in the case of a heat pump.

This folding leads to a sample with a very high density in the middle of the feasible region. At the outskirts the sample is extremely sparse. Thus, almost all instances from the outer parts are neglected as outliers from the support vector approach that generates the surrogate model and the decoder.

For this reason, a decoder trained from such a training sample reproduces only a very small, inner portion of the feasible region. In this way, most of the flexibility that an ensemble could bring in into virtual power plant control is neglected. This can also be seen in Figure 4. The rather small grey boxes represent the data (power levels for different time intervals) that actually should spread over the area denoted by the outer whiskers. Only the small inner part is going to be learned by a model.

B. CMAES with decoder

The covariance matrix adaption evolution strategy [39], [40] (CMA-ES) is a well known evolution strategy for solving multi modal black box problems.

CMA-ES improves its operations by harnessing lessons learned from previously successful evolution steps for future search directions. A new population of solution candidates is sampled from a multi variate normal distribution $\mathcal{N}(0, \boldsymbol{C})$ with covariance matrix $\boldsymbol{C}$ which is adapted such that it that it maximizes the occurrence of improving steps according to previously seen distributions for good steps. Sampling offspring is weighted by a selection of solutions of the parent generation. In a way, the method learns a second order model of the objective function and exploits it for structure information and for reducing calls of objective evaluations. An a priori parametrization with structure knowledge of the problem by the user is not necessary as the method is capable of adapting unsupervised. A good introduction can for example be found in [41]. Especially for non-linear, non-convex black-box problems, the approach has demonstraded excellent performance [41]. CMA-ES is initially not designed for integrated constraint handling in constrained optimization. Nevertheless, some approaches for integrating constraint handling have been developed. In [42] a CMA-ES is introduced that learns constraint function models and rotates mutation distributions accordingly. In [43] an approximation of the directions of the local normal vectors of the constraint boundaries is built by accumulating steps that violate the respective constraints. Then, the variances of these directions are reduced for mutation.

CMA-ES is used for solving the internal optimization problem that arises when an agent has to decide on the best

possible joint schedule to offer during the decision phase of the COHDA negotiation for virtual power plants. With our explanations we follow [22].

We consider an agent negotiation with a stage where each agent has to search the individual flexibility and thus the individual feasible region of operable schedules for the best option (according to given objectives). In case the agent has to control an ensemble with more the one local unit, a decoder that models the feasible region cannot be used as in the case of a single unit. For this reason, a local optimization problem has to be solved in order to decide on a schedule: find the closest aggregated schedule that the local ensemble can operate. This is basically the same problem as for predictive scheduling Eq. 1. As this smaller sub-problem happens to be a local one seen from the agent's perspective, there is no need to harness a distributed solving strategy. Additionally, the problem size is expected to stay rather small with a limited number of devices e. g. inside a household.

Because the operation of several decoders that model the different feasible regions of the local ensemble has to be involved, a heuristic that uses only a small number of objective evaluations is advantageous. CMA-ES is well known for this characteristic [41]. For handling the constraints, the readily available decoders can be used. Thus, the decoder technique also adapted to and employed to the CMA-ES part (cf. . [22]).

In each iteration g of CMA-ES a multivariate distribution is sampled in order to generate a new offspring solution population in the vicinity of good parent solutions:

$$\boldsymbol{x}_k^{(g+1)} \sim \boldsymbol{m}^{(g)} + \sigma^{(g)} \mathcal{N}(0, \boldsymbol{C}^{(g)}),\ k = 1, \ldots, \lambda. \quad (4)$$

$\boldsymbol{C}^{(g)} \in \mathbb{R}^{n \times n}$ constitutes the covariance matrix of the search distribution at generation (iteration) g with overall standard deviation $\sigma^{(g)}$ which can also be interpreted in terms of an adaptive (multivariate) step size. The step size is adapted individually for each dimension to support and favor direction where fast improvement can be expected according to formerly seen results. The mean of the multivariate distribution is denoted by $\boldsymbol{m}^{(g)}$, $\lambda \geq 2$ denotes the population size.

The new mean $\boldsymbol{m}^{(g+1)}$ for generating the sample of the next generation in CMA-ES is calculated as weighted average

$$\boldsymbol{m}^{(g+1)} = \sum_{i=1}^{\mu} w_i \boldsymbol{x}_{i:\lambda}^{(g+1)},\ \sum w_i = 1,\ w_i > 0, \quad (5)$$

of the best (in terms of objective function evaluation) individuals form the current sample $\boldsymbol{x}_i^{(g)}, \ldots, \boldsymbol{x}_\lambda^{(g)}$. In order to introduce the decoder into CMA-ES, ranking is now done with the help of the decoder mapping γ:

$$f(\gamma(\boldsymbol{x}_{1:\lambda}^{(g)})), \ldots, f(\gamma(\boldsymbol{x}_{\lambda:\lambda}^{(g)})),\ \lambda \geq \mu, \quad (6)$$

to define $\boldsymbol{x}_{i:\lambda}^{(g)}$ as the ith ranked best individual.

For the case of the ensemble scheduling example, a solution candidate $\boldsymbol{x}$ is the concatenation of individual schedules

$$\begin{aligned} \boldsymbol{x} &= \boldsymbol{p}_1 \boldsymbol{p}_2 \ldots \boldsymbol{p}_m \\ &= (p_{11}, p_{12}, \ldots, p_{1d}, p_{21}, \ldots, p_{2d}, \ldots, p_{md}) \end{aligned} \quad (7)$$

with $\boldsymbol{p}_1, \ldots, \boldsymbol{p}_m$ denoting schedules for the respective units in the ensemble.

Finally, the covariance matrix is updated as usual, but also based on the decoder based ranking Eq. 6:

$$\boldsymbol{C}_\mu^{(g+1)} = \sum_{i=1}^{\mu} w_i \left(\boldsymbol{x}_{i:\lambda}^{(g+1)} - m^{(g)} \right) \left(\boldsymbol{x}_{i:\lambda}^{(g+1)} - m^{(g)} \right)^\top. \quad (8)$$

CMA-ES has a set of parameters that can be tweaked to some degree for a problem specific adaption. Nevertheless, default values that are applicable for a wide range of problems are usually available. For our experiments, we used the following default settings for the CMA-ES part. The (external) strategy parameters are $\lambda, \mu, w_{i=1\ldots\mu}$, controlling selection and recombination; c_σ and d_σ for step size control and c_c and μ_{cov} controlling the covariance matrix adaption. We have chosen to set these values after [41]:

$$\lambda = 4 + \lfloor 3 \ln n \rfloor, \quad \mu = \left\lfloor \frac{\lambda}{2} \right\rfloor, \quad (9)$$

$$\boldsymbol{w}_i = \frac{\ln(\frac{\lambda}{2} + 0.5) - \ln i}{\sum_\mu^{j=1} \frac{\lambda}{2} + 0.5) - \ln i},\ i = 1, \ldots, \mu \quad (10)$$

$$C_c = \frac{4}{n+4},\ \mu_{\text{cov}} = \mu_{eff}, \quad (11)$$

$$\begin{aligned} C_{\text{cov}} = &\frac{1}{\mu_{\text{cov}}} \frac{2}{(n+\sqrt{2})^2} \\ &+ \left(1 - \frac{1}{\mu_{\text{cov}}}\right) \min\left(1, \frac{2\mu_{\text{cov}} - 1}{(n+2)^2 + \mu_{\text{cov}}}\right). \end{aligned} \quad (12)$$

An in-depth discussion of these parameters is also given in [44]. These settings are specific to the dimension N of the objective function. In our case is $N = d \cdot m$ related to the number of agents and the dimension of the assigned schedules in the test cases that are discussed in the following section.

IV. Results

Evaluation was again done by simulation with a setup comprising a set of simulated energy resources and a multi-agent system for control [22]. The agent system was implemented after [20]. Each agent is responsible for conducting local decisions and communication with other agents in charge of controlling a small local ensemble of jointly controlled energy resources. Each agent is equipped with the described CMA-ES approach for local decisions on operation.

As a model for distributed energy resources we used a model for co-generation plants that has already served in several studies and projects for evaluation [15], [30], [31], [45], [46]. This model comprises a micro CHP with 4.7 kW of rated electrical power (12.6 kW thermal power) bundled with a thermal buffer store. Constraints restrict power band, buffer charging, gradients, min. on and off times, and satisfaction of thermal demand. Thermal demand is determined by simulating losses of a detached house (including hot water drawing) according to given weather profiles. For each agent the model is individually (randomly) configured with state of charge, weather condition, temperature range, allowed operation gradients, and similar. From these model instances, the respective training sets for building the decoders have been generated with the sampling approach from [36]. In addition, we used models for heat pumps and boilers for hot water provision [47]. A fourth model simulates the flexibilities of a cool storage.

The applicability of the hybridized CMA-ES has already been demonstrated in [22]. The approach is able to achieve optimization results with a residual error less than 1 percent. Often well better results with an absolute error of about 30 W for scenarios with a rated power of 470 kW are achieved. Here, again we used the mean absolute percentage error (MAPE)

$$\delta_{MAPE} = \delta(\boldsymbol{x}, \boldsymbol{\zeta}) = \frac{100}{d} \sum_{i=1}^{d} \left| \frac{\zeta_i - x_i}{\zeta_i} \right|, \qquad (13)$$

in order to be able to compare different scenarios with different number of energy units and different rated power.

We simulated the effect of integrating ensembles instead of single energy units into a VPP on the residual error and on the number of exchanged messages between the agents. As the agent system under research is a gossiping type of agent system [48], each message triggers a local decision that translates into a decoder call in the single unit case but into solving a optimization problem with CMA-ES in the ensemble case. Thus, the number of messages is an important indicator for performance scaling with number of integrated ensembles.

Figure 5 shows a first result. The experiment scrutinized a VPP with 10 participants. One participant is an ensemble. The size of the ensemble has been increased from 1 to 10 (an ensemble of size 1 translates again to a single unit) to evaluate means residual error and number of exchanged messages. The experiment has been conducted for differently large planning horizons. For shorter planning horizons the size of the ensemble has almost no impact. Actually, the residual error decreases a little (due to growing flexibility in the VPP). For longer planning horizons the same effect can be observed up to a size where the error escalates to a higher level. At the same time, the number of exchanged messages decreases (cf. Fig. 6). Obviously, the CMA-ES approach starts suffering from some premature convergence problems when the local problem size (ensemble size time schedule dimension) exceeds a certain size; at least when the standard parametrization is

used. Premature convergence at the second level optimization inside an ensemble leads to similar results in successive optimization attempts with similar schedule configurations in the whole VPP. As no better solution is found, the agent sends no message and the first level optimization at agent level ceases earlier with a sub-optimal solution. Hence, integrating methods to prevent premature convergence in the CMA-ES part could largely improve the whole VPP optimization in case of larger ensemble sizes.

Another experiment scrutinizes the number of ensembles in a VPP. Tables I to III show the result. Now, the share of ensembles (with a fixed size of 3 CHP) in a VPP is varying from 0 to 100 percent and the effect is scrutinized. The result quality increases in most of the cases due to a growing flexibility with a growing number of ensembles. For smaller VPP sizes the communication effort grows with the number of ensembles, for larger VPPs the number of sent messages stays on the same level compared with the case of 100 percent single units.

With these results, one can conclude that the introduction of ensembles does not deteriorate the performance of the agent-based predictive scheduling. Performance shortcomings for larger ensembles seem to be due to premature convergence and should be overcome with future integration of e. g. a better adapted step size control.

V. Conclusion

Using machine learning approaches for flexibility modeling and automatically deriving decoders from these models for efficient and domain knowledge independent implementation of (distributed) optimization methods has proven a useful tool in managing the future smart grid. So far, these models can only be applied to single energy units, because distributions of power levels in the training sets of single units fold up when aggregating them to ensemble training sets. Thus, the training set renders useless for appropriately learning a model for the joint flexibility of a group of energy units.

[22] presented a hybrid approach to overcome the problem of folded densities when training decoders for ensembles of energy resources in predictive scheduling. To achieve this, we embedded a CMA-ES solver in the decision routine of an established agent-based solution.

With this approach also households, hotels, small businesses, schools or similar with an ensemble of co-generation, heat pump, solar power, and controllable consumers can take part in agent-based decentralized predictive scheduling for providing energy services in future smart grid architectures without a need for an (expensive) individual link of each single device in the ensemble. By using a hybrid approach of evolution strategy and support vector based decoder, such ensemble based participants in virtual power plants can easily be represented by a single agent. Moreover, agents with our decision method still implement the same interface as single unit agents and can thus be easily integrated with the standard COHDA protocol. Applicability had already been demonstrated in [22].

Our new simulations showed that CMA-ES is well suitable for being hybridized with a decoder in order to build a system that may operate with arbitrary energy units regardless of individual constraints that restrict feasible operation. CMA-ES performs satisfactorily on reasonable large ensembles. Additional simulations showed that size and number of ensembles within a VPP scale well up to reasonable sizes. Communication does not suffer from an increase in number of exchanged messages. Based on these results the inclusion of secondary, local optimization objectives like cost or preferences are a consequentially next step in future work.

11th International Workshop on Computational Optimization

MANY real world problems arising in engineering, economics, medicine and other domains can be formulated as optimization tasks. These problems are frequently characterized by non-convex, non-differentiable, discontinuous, noisy or dynamic objective functions and constraints which ask for adequate computational methods.

The aim of this workshop is to stimulate the communication between researchers working on different fields of optimization and practitioners who need reliable and efficient computational optimization methods.

TOPICS

The list of topics includes, but is not limited to:

- combinatorial and continuous global optimization
- unconstrained and constrained optimization
- multiobjective and robust optimization
- optimization in dynamic and/or noisy environments
- optimization on graphs
- large-scale optimization, in parallel and distributed computational environments
- meta-heuristics for optimization, nature-inspired approaches and any other derivative-free methods
- exact/heuristic hybrid methods, involving natural computing techniques and other global and local optimization methods

The applications of interest are included in the list below, but are not limited to:

- classical operational research problems (knapsack, traveling salesman, etc)
- computational biology and distance geometry
- data mining and knowledge discovery
- human motion simulations; crowd simulations
- industrial applications
- optimization in statistics, econometrics, finance, physics, chemistry, biology, medicine, and engineering.

BEST PAPER AWARD

The best WCO'18 paper will be awarded during the social dinner of FedCSIS 2018.

The best paper will be selected by WCO'18 co-Chairs by taking into consideration the scores suggested by the reviewers, as well as the quality of the given oral presentation.

EVENT CHAIRS

***Abstract*—Rearranging cars of an incoming train in a hump yard is a widely discussed topic. We focus on the train marshalling problem where the incoming cars of a train are distributed to a certain number of sorting tracks. When pulled out again to build the outgoing train, cars sharing the same destination should appear consecutively. The goal is to minimize the number of sorting tracks. We suggest a graph-theoretic approach for this $\mathcal{NP}$-complete problem. The idea is to partition an associated directed graph into what we call pseudochains of minimum length. We describe a greedy-type heuristic to solve the partitioning problem which, on random instances, performs better than the known heuristics for the train marshalling problem.**

I. Introduction

A HUMP yard usually consists of a hump and a set of classification or sorting tracks and one or more roll-in and pull-out tracks [1]. In hump yards freight cars are arranged or rearranged into a specific sequence of cars. The outgoing trains will deliver goods to new destinations. A practical introduction to hump yards with examples can be found in the work of Hiller [2].

This can be very complex. For example the hump yard in in Zürich-Limmattal (CH) consists of 18 roll-in tracks, 64 sorting tracks with a length of 650-850 meters and 16 roll-out tracks, see [2][3].

Every incoming car arriving at the hump yard will be assigned to a sorting track. At the end of this process all cars of every sorting track will be placed as a block on the roll-out track. For an optimization approach the number and length of sorting tracks, the number of roll-in and pull-out operations can be minimized.

Hansmann provided a general class of *Sorting of rolling Stock Problems* (SRSP) in [4]. We will focus on the *Train Marshalling Problem* (TMP): using a minimum number of tracks, rearrange the cars in a hump yard in such a way that cars sharing the same destinations appear consecutively in the rearranged train.

During the process only two movements are allowed: the sorting of cars to the tracks and one pull-out movement for all cars. The tracks are not limited in length, so we can think of the tracks as stacks. We only allow one roll-in operation per car and one pull-out operation per track. No further shunting is allowed.

Apparently, TMP was first introduced by Zhu and Zhu [5] in 1983 who considered it under additional constraints and gave first results and polynomial algorithms. In 2000, Dahlhaus et al. [6] proved that TMP is $\mathcal{NP}$-complete and introduced new bounds. Brueggeman et al. show in [7] that the problem is fixed parameter tractable. In another work by Dahlhaus, Manne, Miller and Ryan [8] they described similar problems. More bounds and algorithms can be found in the work of Beygang [9] and Beygang et al. [1]. They introduced a graph-theoretic approach by considering the interval graph of a given instance. The problem also occurs in the works of Hansmann [4]. Other approaches can be found in the work of Rinaldi and Rizzi [10] who focused on dynamic programming and Haahr and Lusby [11].

First of all we will give a short formal problem description and all relevant definitions. After introducing pseudochains and discussion splittable destinations we will derive a novel greedy heuristic to solve the TMP. We will evaluate the results on some random instances and finish with a conclusion.

II. Problem description

With every *car* i in the hump yard we associate a natural number $\sigma_i \in \mathbb{N}^+$ representing the destination of the car. A *train* σ of length n then is a sequence

$$\sigma = (\sigma_1, ..., \sigma_n)$$

of cars with $\sigma_i \in \{1, ..., d\}$ for $i \in \{1, ...n\}$.

Example II.1. *Let $\sigma = (1, 2, 1, 3, 2)$. There are three destinations, where the first and third car and, resp., the second and the last have the same destination.*

We want to rearrange the cars in a departing train such that all cars are sorted in blocks according to their destination. For this, only two shunting operations are permitted: the roll-in movement of a car to one of the sorting tracks and the pull-out of all cars on a sorting track. The goal is to minimize the number of sorting tracks, denoted by $K(\sigma)$. Since only one shunting operation per sorting track is allowed the minimization of shunting operations is equivalent to the minimization of sorting tracks.

For a given sequence σ let S_k be the elements of σ with destination k. Then we may describe the incoming sequence by a partition $S = \{S_1, \ldots, S_d\}$ of $\{1, 2, ...n\}$. Dahlhaus et al.

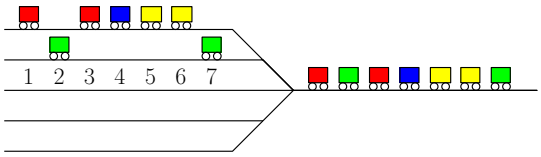

Fig. 1: Illustration for example II.2.

[6] have shown that TMP may be rephrased as follows: find the smallest number $K(S)$ and a permutation π of $1,\ldots,d$ such that the sequence of numbers

$$\underbrace{1,2,...,n,1,2,...,n,1,2,...,n}_{K(S)\text{-times}}$$

contains the elements of $S_{\pi(1)}$ as a subsequence followed by all elements of $S_{\pi(2)}$ and so on.

Example II.2. *Let $n = 7$, $d = 4$ und $S = \{S_1, S_2, S_3, S_4\}$ with $S_1 = \{1,3\}$, $S_2 = \{2,7\}$, $S_3 = \{4\}$ and $S_4 = \{5,6\}$. Then $K(S) = 2$ and $\pi(1,3,4,2)$, see figure 1 for an illustration:*

$$\underbrace{\mathbf{1}\,2\,\mathbf{3}}_{S_1}\ \underbrace{\mathbf{4}}_{S_3}\ \underbrace{\mathbf{5}\,\mathbf{6}}_{S_4}\ 7\ 1\ \underbrace{\mathbf{2}\,3\,4\,5\,6\,\mathbf{7}}_{S_2}$$

We now define some necessary preliminaries following the work of Beygang in [9].

III. Preliminaries

Let $\mathbb{S}^n$ be the set of all problem instances of TMP with n cars. For $S \in \mathbb{S}^n$ let $d = d(S)$ be the number of destinations in this instance. For an instance $S \in \mathbb{S}^n$, a *track assignment* is function $tr : \{1,...,n\} \to \mathbb{N}$ which assigns a track to every car. A track assignment is feasible if it gives a feasible solution for TMP.

For a given sequence σ and a destination k let $first(k)$ denote the position of the first occurrence of k and $last(k)$ be its last occurrence. Let $I_k = [first(k), last(k)]$ be the associated interval. Then the intervals induce a partial order on the set of destinations via $i < j$ if $last(i) < first(j)$. We consider the associated comparability graph and its complement, the interval graph.

Definition III.1. *(Comparability Graph associated with an Input Instance) For a given instance S of TMP, the associated comparability graph graph is given by $D(S) = (V, A)$ such that $V = (I_1, ..., I_d)$ and $(I_k, I_j) \in A$ if $k < j$.*

Definition III.2. *(Interval Graph associated with an Input Instance) For a given instance S of TMP, the associated interval graph is given by $G(S) = (V, E)$ such that $V = (I_1, ..., I_d)$ and $(I_k, I_j) \in E$ if $I_k \cap I_j \neq \emptyset$.*

Beygang already introduced some bounds and two important heuristics for the TMP. The deterministic SPLIT-Algorithm was introduced in [9] and computes a feasible solution by splitting destinations whenever possible in $O(n)$. The GREEDY-Algorithm was also introduced in [9]. It finds a feasible solution by partitioning the interval graph $G(S)$ into a minimum number $\chi(G_S)$ of stable sets, each assigned to one track. Recall that this is equivalent to partitioning $D(S)$ into a minimum number of chains. We will generalize this approach to partition $D(S)$ into pseudochains.

IV. Pseudochains

Let $D = (V, A \cup B)$ be a directed graph with a set B of blue arcs, $A \cap B = \emptyset$. We allow that $B = \emptyset$ or $A = \emptyset$. Recall that a chain in a transitively oriented graph is a subset $v_1, \ldots, v_k$ of vertices such that $(v_i, v_j) \in A$ for all $1 \leq i < j \leq k$.

Definition IV.1. *(Pseudochain) Let $D = (V, A \cup B)$ as above such that the subgraph D_A induced by the arcs in A is transitively orientable. $\mathcal{C} \subseteq V$ is a* pseudochain *of length $\ell(\mathcal{C}) = k \geq 1$ if $\mathcal{C}$ can be written as*

$$\mathcal{C} = C_1, b_2, C_2, b_3, C_3, ..., b_k, C_k,$$

where the C_i's are mutually disjoint chains in D_A with last element a_i and first Element c_i and $(a_{i-1}, b_i), (b_i, c_i) \in B$ for $2 \leq i \leq k$.

Figure 2 illustrates a pseudochain of length three.

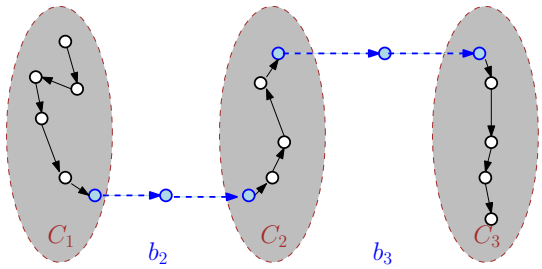

Fig. 2: A pseudostable chain of length 3. Transitive arcs are omitted, dashed arcs correspond to blue arcs.

Now we can define the minimization problem as follows.

Definition IV.2. *(minPC) Given a directed graph $D = (V, A \cup B)$ with a set B of blue edges, $A \cap B = \emptyset$ such that D_A is transitively orientable. Partition V into pseudochains $P = \mathcal{C}_1, \ldots, \mathcal{C}_k$ such that the total length $\ell(P) = \sum_{i=1}^{k} \ell(\mathcal{C}_i)$ of the partition is minimal.*

Lemma IV.3. *Given a directed graph $D = (V, A \cup B)$ with a set B of blue edges such that D_A is transitively orientable and a minimum partition V into pseudochains $P = \mathcal{C}_1, \ldots, \mathcal{C}_k$. Then there is a partition P' with $\ell(P') = \ell(P)$ such that for all centers $c(b_i)$ of all blue paths b_i in P' exist two nodes u in C_{i-1} and v in C_i so that $(c(b_i), v)$, $(u, c(b_i))$ and $(u, v) \notin A$.*

V. Splittable destinations

Observe that we can always produce a feasible track assignment by opening a track for each destination. But we may be able to do better by distributing the cars of one destination to two tracks. For this, we consider three destinations (a, b, c) with $I_a \cap I_b \neq \emptyset$ and $I_b \cap I_c \neq \emptyset$. Thus we need at least two tracks for $S(a) \cup S(b)$ and two tracks for $S(b) \cup S(c)$. We call the destination b *splittable* with predecessor a and successor c

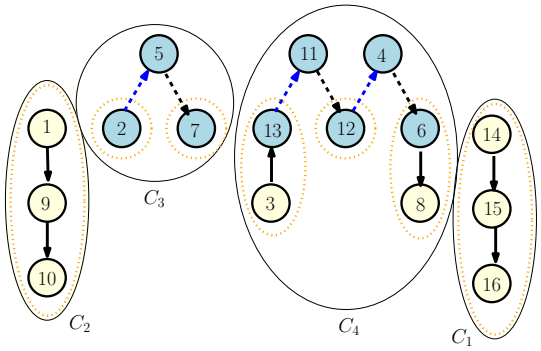

Fig. 3: A pseudochain partition found in example VI.1

if there is a feasible track assignment which assigns b to two different tracks. For short, we say that a triple (a, b, c) with the properties above is splittable.

In order to be feasible, some cars of $S(b)$ must then form a block at the end of one track containing the cars of $S(a)$ and a block at the beginning of some other track containig the cars of $S(c)$. It is easy to show the following Theorem:

Theorem V.1. *(Splittable Destinations) Given an instance $S \in \mathbb{S}^n$ of TMP. Let (a, b, c) be a triple of destinations with $I_a \cap I_b \neq \emptyset$ and $I_b \cap I_c \neq \emptyset$. Then the triple (a, b, c) is splittable if and only if there is no car of destination b between $first(c)$ and $last(a)$.*

Proof. Given a feasible track assignment and a destination b which is assigned to two tracks. We may assume that both tracks contain cars of other destinations. Let a be the destination preceding cars of b on the first track and c the destination following the cars on the other track. Then it is easy to see, that in the incoming train either $last(a) < first(c)$ or no car of destination b occurred between $first(c)$ and $last(a)$.

Conversely, let (a, b, c) a triple of destinations (a, b, c) as above. We start by assigning $S(a)$ to an open track, track 1 say, and cars of $S(c)$ to track 2. Cars of destination b will also be assigned to track 2 if they occur before $last(a)$, and to track one track 1 otherwise. All other cars are assigned to a destination-specific track. By assumption, either $last(a) < first(c)$, and the assignment is feasible. In the other case, after the first car of $S(c)$ is assigned to track 2, all remaining cars of $S(b)$ are assigned to the end of track 1. So in both cases the assignment is feasible. □

Observe that splittable triples cannot be read off from the comparability graph D itself. So in the next section we will enhance D to capture this extra information.

VI. MINPC AND TMP ARE EQUIVALENT

Let D be the comparability graph of the intervals given by an instance $S \in \mathbb{S}^n$ and (a, b, c), a splittable triple. Observe that by definition I_b overlaps both I_a and I_c. So $(a, b), (b, c) \notin A$. Let $B = \{(a, b), (b, c) \mid (a, b, c)$ is a splittable triple$\}$ and $D^* = D^*(S) = (V, A \cup B)$ be the *extended comparability graph* of S.

Example VI.1. *Given an instance $S \in \mathbb{S}^{50}$ with 16 destinations and*

$$\sigma = (1, 1, 2, 1, 2, 3, 3, 3, 4, 2, 2, 1, 5, 3, 3, 4, 2, 1, 1, 6, 6, 2, 5, 7, 8, 1, 9, 10, 8, 11, 12, 13, 2, 5, 8, 10, 14, 14, 15, 16, 16, 12, 7, 4, 10, 5, 7, 8, 13, 11)$$

A partition P of the extended comparability graph $D^*(S)$ in pseudochains is given by

- $\mathcal{C}_1 = \{14, 15, 16\}$ *with* $\ell(\mathcal{C}_4) = 1$.
- $\mathcal{C}_2 = \{1, 9, 10\}$ *with* $\ell(\mathcal{C}_2) = 1$.
- $\mathcal{C}_3 = \{2, 5, 7\}$ *with* $C_1 = \{2\}$, $b_2 = 5$, $C_2 = \{7\}$ *and* $\ell(P_1) = 2$.
- $\mathcal{C}_4 = \{3, 4, 6, 8, 11, 12, 13\}$ *with* $C_1 = \{3, 13\}$, $b_2 = 11$, $C_2 = \{12\}$, $b_3 = 4$, $C_3 = \{6, 8\}$ *and* $\ell(P_3) = 3$.

See Figure 3. The weight is $\ell(P) = 7$.

Lemma VI.2. *Let $S \in \mathbb{S}^n$ and P, a pseudochain partition of the extended comparability graph $D^*(S)$. Then P induces a feasible track assignment using $\ell(P)$ tracks.*

Proof. It suffices to show that we can assign a pseudochain $\mathcal{C} = C_1, b_2, C_2, b_3, C_3, ..., b_k, C_k$ of length k to k tracks. Let chain C_i begin with c_i and end with a_i. Let $B'_i = \{c \in b_i : c < last(c_{i-1})\}$ and $B''_i = \{c \in b_i : c > last(c_{i-1})\}$. We claim that, for $1 \leq i \leq k-1$, we can schedule the pseudochain such that track i contains B'_{i-1} followed by C_i again followed by B''_i. Suppose this is true for some $1 \leq j < k$. Since, by definition, the triple (a_j, b_{j+1}, c_{j+1}) is splittable, we may fill track j with B''_{j+1}, open track $j+1$ with B'_j and fill it with C_{j+1}. □

Lemma VI.3. *Let $S \in \mathbb{S}^n$ and tr, a feasible track assignment using k trains. Then tr induces a pseudochain partition P of the extended comparability graph with $\ell(P) = k$.*

Proof. Since tr is feasible, the cars of a destination d are assigned to at most two tracks and form a consecutive subsequence on their tracks. If they are assigned to two tracks they must be placed at the end of one track and at the beginning of some other track. Define a directed graph H on the set of destinations. Two destinations i, j are linked by an edge (i, j) if cars of i are placed immediately before cars of j on the same track. Then each connected component of H induces a pseudochain C of $D(S)$. Since $\ell(C)$ corresponds to the number of tracks used by the component, the claim follows. □

Example VI.4. *Consider the instance of example VI.1. The pseudochain partition P induces the following track assignment:*

Track 1 :	$2_3, 2_{33}\ 5_{34}, 5_{51}$
Track 2 :	$5_1, 5_{23}\ 7_{24}, 7_{47}$
Track 3 :	$1_1, 1_{26}\ 9_{27}\ 10_{28}, 10_{45}$
Track 4 :	$3_6, 3_{15}\ 13_{32}, 13_{49}\ 11_{50}, 11_{51}$
Track 5 :	$11_1, 11_{30}\ 12_{31}, 12_{42}\ 4_{44}, 4_{51}$
Track 6 :	$4_9, 4_{16}\ 6_{20}, 6_{21}\ 8_{25}, 8_{48}$
Track 7 :	$14_{37}, 14_{38}\ 15_{39}\ 16_{40}, 16_{41}$

Here, the lower indices represent the position of the car in the input sequence. It is a feasible track assignment using $\ell(P) = 7$ tracks.

Theorem VI.5. *Let $S \in \mathbb{S}^n$ and $D^*(S)$, the extended comparability graph. Then minPC on $D^*(S)$ is equivalent to TMP.*

Proof. Follows from Lemma VI.2 and VI.3. □

Thus for every optimal solution of an instance $S \in \mathbb{S}^n$ of the TMP using $K(S)$ tracks, there exists a corresponding partition of the extended comparability graph $D(S)$ into pseudochains.

VII. A new Greedy-Approach: Greedy-PC

This greedy approach is based on the above observations on pseudochain partitions. Let $S \in \mathbb{S}^n$ be an instance of TMP and $T = (t_1, ..., t_{t_S})$ be the list of all splittable destination in $\mathcal{S}$ sorted increasingly by their left boundary. Our approach will return a partition of $D^*(S)$ into pseudochains.

Given a splittable destination $(a, b, c) \in T$, the function add applied to a pseudochain P returns `true` if the triple can be added to P and `false` otherwise. We follow the idea to have the best solution within this chain P and try to add every possible splittable triple in T to a pseudochain. We will redo this as long as nodes remain in $\mathcal{S}$.

The worst-case runtime of this heuristic is $f(n) = (\frac{1}{2}n^3 + n^2) = O(n^3)$. See algorithm 1 for an implementation in pseudocode.

VIII. Experimental Results

We used Python 3.4 with NetworkX for creating random instances and implement the greedy heuristic as well as the Linear Programming relaxation introduced by Beygang [9]. Four 2.4 GHz processors and 8 GB RAM were available running Linux Kernel 3.10. We used GLPK (GNU Linear Programming Kit) 4.52 to solve the linear program. To get comparable results, we followed [9] to create random instances. This function takes the number n of cars and computes uniform and independent problem instances.

The greedy heuristic introduced by Beygang et al. ([9] and [1]) leads to the upper bound denoted by *Coloring*. It is equivalent to a graph coloring approach for the interval graph $G(S)$. The runtime is $O(n^2)$. Algorithm 1 has also polynomial runtime in $O(n^3)$.

We approximate the optimal solution according to the bounds u_{lp} and l_{lp}, the upper and lower bound given by the solution of the linear program introduced by [9]. It was observed in [12] that the lower bound very often coincides with the value of the optimal solution.

Figures 4 and 5 summarize the output of the heuristics on 50 random instances with a fixed number of cars. For a small number of cars the distance between *Coloring* and u_{greedy} is small, but notable, see figure 4. We notice the greedy approach can lead to solutions using more tracks than the *Coloring* approach. The situation changes significantly for instances with more cars. Figure 5 shows that Greedy-PC performs better than *Coloring* on instances with 300 cars.

Algorithm 1 Greedy-PC

Require: Extended comparability graph $D^*(S)$ with its maximal stable set $\mathcal{S}$ in $D(S)$ and a list $T = (t_1, ..., t_{t_S})$ of splittable destinations in $\mathcal{S}$.
Ensure: Partition of $D^*(S)$ in pseudochains

```
visited = ∅
count = 0
while |T| > 0 do
    count++
    P.add(pseudochain P_count)
    for every (a, b, c) = t_i ∈ T do
        if P_count.add(a, b, c) = true then
            visited.add a, b, c
        end if
    end for
    for every v ∈ visited do
        delete every t_i containing v from T
    end for
end while
for every node v ∈ V(G) do
    if v ∉ visited then
        for i = 1, ..., count do
            if P_i.add(v) = true then
                visited.add v
                exit
            end if
        end for
        count++
        P.add(pseudochain P_count)
        P_count.add(v)
    end if
end for
return P
```

IX. Conclusions

We have introduced and discussed pseudochain partitions and their relation to the Train Marshalling Problem. There is only little discussion about TMP in the literature, but the problem has an intimate relationship to other sorting problems of rolling stock, see [4]. Thus it is an important step to provide a better understanding of the underlying graph structures. Pseudochain partitions directly lead to a new heuristic providing a improved upper bounds for optimal solutions of TMP. We could proof that every optimal solution of TMP is equivalent to a minimal partition of the corresponding extended comparability graph $D^*(S)$ into pseudochains.

The greedy approach has been evaluated for 2 instances with 100 and 300 cars, each consisting of 50 random instances each. The computational results show that the model is useful and the proposed Greedy-approach performs in general significantly better than other state-of-the art approaches.

To sum up, although we achieved encouraging results, there are still questions which are not answered or even discussed in this paper. For example, can the inherent structure of

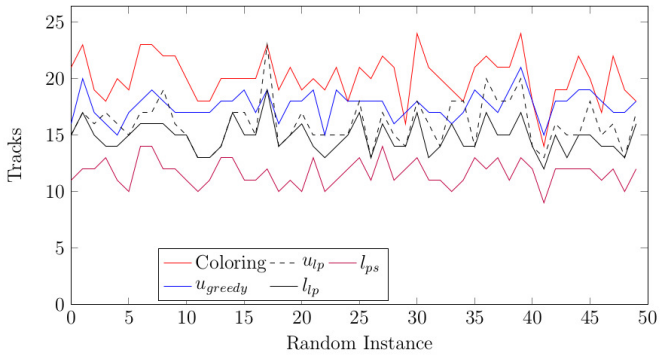

Fig. 4: Results for random instances with $n = 100$ cars. *Colouring* is a Greedy-approach introduced by Beygang, u_{lp} and l_{lp} are upper and lower bounds of the integer linear program approach, see [9]. The lower bound l_{ps} was introduced in [12]. u_{greedy} shows the results of our novel algorithm 1.

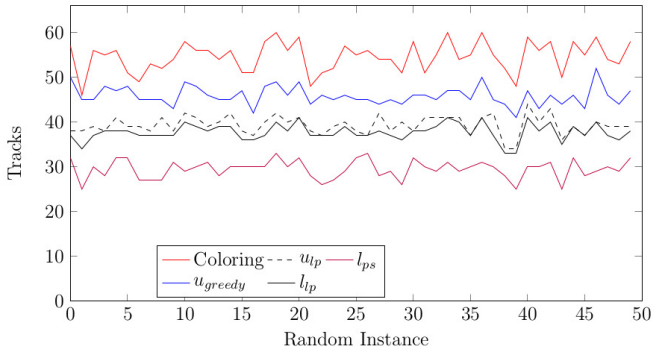

Fig. 5: Results for random instances with $n = 300$ *Colouring* is a Greedy-approach introduced by Beygang, u_{lp} and l_{lp} are upper and lower bounds of the integer linear program approach, see [9]. The lower bound l_{ps} was introduced in [12]. u_{greedy} shows the results of our novel algorithm 1.

pseudoschains be used to find even better heuristics than those discussed in this paper? Are there any instances of the TMP that can be solved in polynomial time?

The results encourages the further improvement on heuristics to solve minPC and the application of this method to other sorting of rolling Stock Problems.

***Abstract*—Every organization and factory optimize their production process with a help of workforce planing. The aim is minimization of the assignment costs of the workers, who will do the jobs. The problem is very complex and needs exponential number of calculations, therefore special algorithms are developed to be solved. The problem is to select employers and to assign them to the jobs to be performed. This problem has very strong constraints and it is difficult to find feasible solutions. The objective is to fulfil the requirements and to minimize the assignment cost. We propose a hybrid Ant Colony Optimization (ACO) algorithm to solve the workforce problem, which is a combination between ACO and an appropriate local search procedure.**

Keywords: Workforce Planning, Ant Colony Optimization, Metaheuristics, Local search

I. Introduction

One of the most important decision making problem, common for all branches of industry, is workforce planning. The workforce planing is a part of the human resource management. It includes multiple level of complexity, therefore it is a hard optimization problem (NP-hard). This problem consists of two decision sets: selection and assignment. The first set shows selected employees from available workers. The assignment set shows which worker which job will perform. The aim is to fulfil the work requirements with minimal assignment cost.

As we mentioned the problem is a hard optimization problem with strong constraints and is impossible to be solved with exact methods or traditional numerical methods for instances with realistic size. These kind of methods can be apply only on some simplified variants of the problem. A deterministic workforce planing problem is studied in [11], [17]. Workforce planing models are reformulated as mixed integer programming in [11]. The authors show that the mixed integer program is much easier to solve than the non-linear program. In [17] the model includes workers differences and the possibility of workers training and upgrading. In [4] and [18] a variant with random demands of the problem is proposed. Two stage program of scheduling and allocating with random demands is considered in [4]. Other variant of the problem is to include uncertainty [12], [14], [16], [23], [24]. Most of the authors simplify the problem by omitting some of the constraints. In [6] a mixed linear programming is applied and in [18] a decomposition method is applied. For the more complex non-linear workforce planning problems, the convex methods are not applicable.

Nowadays, nature-inspired metaheuristic methods receive great attention [2], [15], [19], [21], [22]. In considered here problem some heuristic method including genetic algorithm [1], [13], memetic algorithm [20], scatter search [1] etc., are applied.

So far the Ant Colony Optimization (ACO) algorithm is proved to be very effective solving various complex optimization problems [7], [10]. In our previous work [8] we propose ACO algorithm for workforce planning. We have considered the variant of the workforce planning problem proposed in [1]. Current paper is the continuation of [8]. We propose a hybrid ACO algorithm which is a combination of ACO with a local search procedure. The aim is to improve the algorithm performance.

The rest of the paper is organized as follows. In Section 2 the mathematical description of the problem is presented. In Section 3 hybrid ACO algorithm for workforce planing problem is proposed. Section 4 shows computational results, comparisons and discussion. A conclusion and directions for future work are done in Section 5.

II. Definition of the Workforce Planning Problem

In this paper we solve the workforce planning problem proposed in [1] and [9]. The set of jobs $J = \{1, \ldots, m\}$ must be completed during a fixed period of time. The job j requires d_j hours to be completed. $I = \{1, \ldots, n\}$ is the set of workers, candidates to be assigned. Every worker must perform every of assigned to him job minimum h_{min} hours to can work in efficient way. Availability of the worker i is s_i hours. One worker can be assigned to maximum j_{max} jobs. The set A_i shows the jobs, that worker i is qualified. Maximum t workers can be assigned during the planed period, or at

most t workers may be selected from the set I of workers. The selected workers need to be capable to complete all the jobs. The aim is to find feasible solution, that optimizes the objective function. c_{ij} is the cost of assigning the worker i to the job j. The mathematical model of the workforce planing problem can be described as follows:

The objective function is the minimization of the total assignment cost. The number of hours for each selected worker is limited . The work must be done in full . The number of the jobs, that every worker can perform is limited . There is minimal number of hours that every job must be performed by every assigned worker to can work efficiently . The number of assigned workers is limited.

Same model can be used with different objective functions. Minimization of total assignment cost is the aim of this paper. If $\tilde{c}_{ij}$ is the cost the worker i to performs the job j for one hour, than the objective function can minimize the cost of the hall jobs to be finished.

$$f(x) = \text{Min} \sum_{i \in I} \sum_{j \in A_i} \tilde{c}_{ij}.x_{ij} \tag{1}$$

The workforce planning problem is difficult to be solved because of very restrictive constraints especially the relation between the parameters h_{min} and d_j. When the problem is structured (d_j is a multiple of h_{min}), in this case it is more easier to find feasible solution, than for unstructured problems (d_j and h_{min} are not related).

III. Hybrid Ant Colony Optimization Algorithm

The ACO is a nature inspired method. It is metaheuristics methodology following the behaviour of real ants looking for a food. Real ants use chemical substance, called pheromone, to mark their path ant to can return back. An ant moves in random way and when it detects a previously laid pheromone it decides whether to follow it and reinforce it with a new added pheromone. Thus the more ants follow a given trail, the more attractive that trail becomes. Using their collective intelligent the ants can find a shorter path between the source of the food and the nest.

A lot of problems coming from real life and industry needs exponential number of calculations. Therefore the only option is to be applied some metaheuristics. The goal is to find a good solution for a reasonable time [5].

A. ACO Algorithm for Workforce Planning

In this section we will apply the ACO algorithm for workforce planing from our previous work [8], which is without local search procedure. One of the main points of the ant algorithm is the proper representation of the problem by graph. In our case the graph of the problem is 3 dimensional and the node (i, j, z) corresponds worker with number i to be assigned to the job j for time z. The graph of the problem is asymmetric, because the maximal value of z depends of the value of j, different jobs needs different time to be completed. At the beginning of every iteration every ant starts to construct their solution, from random node of the graph of the problem. For every ant are generated three random numbers. The first random number corresponds to the worker we assign and is in the interval $[0, \ldots, n]$. The second random number corresponds to the job which this worker will perform and is in the interval $[0, \ldots, m]$. We verify if the worker is qualified to perform the job, if not, we chose in a random way another job. The third random number corresponds to the number of hours worker i is assigned to performs the job j and is in the interval $[h_{min}, \ldots, \min\{d_j, s_i\}]$. After, the ant applies the transition probability rule to include next nodes in the partial solution, till the solution is completed, or there is not a possibility to include new node.

We propose the following heuristic information:

$$\eta_{ijl} = \begin{cases} l/c_{ij} & l = z_{ij} \\ 0 & otherwise \end{cases} \tag{2}$$

When there are several candidate nodes with a same probability, the next node is chosen between them in a random way. When some move of the ant do not meets the problem constraints, then the probability of this move is set to be 0. If for all possible nodes the value of the transition probability is 0, it is impossible to include new node in the solution and the solution construction stops. When the constructed solution is feasible the value of the objective function is the sum of the assignment cost of the assigned workers. If the constructed solution is not feasible, the value of the objective function is set to be equal to -1. The ants constructed feasible solutions deposed a new pheromone on the elements of their solutions. The new added pheromone is equal to the reciprocal value of the objective function.

$$\Delta\tau_{i,j} = \frac{\rho - 1}{f(x)} \tag{3}$$

Thus the nodes of the graph belonging to solutions with less value of the objective function, receive more pheromone than others and become more desirable in the next iteration.

The end condition used in our algorithm is the number of iterations.

B. Local Search Procedure

The our main contribution in this paper is the hybridization of the ACO algorithm with a local search procedure. The aim of the local search is to decrease the time to find the best solution and eventually to improve the achieved solutions. We apply local search procedure only on infeasible solutions and only one time disregarding the new solution is feasible or not. Thus, our local search is not time consuming. If the solution is not feasible we remove part of the assigned workers and after that we assign in their place new workers. The workers which will be removed are chosen randomly. On this partial solution we assign new workers applying the rules of ant algorithm. The ACO algorithm is a stochastic algorithm, therefore the new constructed solution is different from previous one with a high probability.

IV. Computational Results

In this section test results are reported and compared with ACO algorithm without local search procedure. We use the artificially generated problem instances considered in [1]. The test instances characteristics are shown in Table I.

The set of test problems consists of 20 used in [1], [8]. In our previous work [8] we show that our ACO algorithm outperforms the genetic and scatter search algorithms from [1]. The number of iterations is fixed to be maximum 100. In Table II the parameter settings of our ACO algorithm are shown. The values are fixed experimentally.

The workforce problem has very restrictive constraints. Therefore only 2-3 of the ants, per iteration, find feasible solution. Sometimes exist iterations without any feasible solution. Its complicates the search process. Our aim is to decrease the number of unfeasible solutions and thus to increase the possibility ants to find good solutions and so to decrease needed number of iterations to find good solution. We observe that after the local search procedure applied on the first iteration, the number of unfeasible solutions in a next iterations decrease. It is another reason the calculation time does not increase significantly. We are dealing with four cases: without local search procedure (ACO); local search procedure when the number of removed workers is quarter from the number of all assigned workers (ACO quarter); local search procedure when the number of removed workers is half from the number of all assigned workers (ACO half); local search procedure when all assigned workers are removed and the solution is constructed from the beginning (ACO restart).

We perform 30 independent runs with every one of the four cases, because the algorithm is stochastic ant to guarantee the robustness of the average results. We apply ANOVA test for statistical analysis to guarantee the significance of the achieved results. We are interested of the number of iterations for finding the best result. It can be very different for different test problems, so we will use ranking of the algorithms. The variant of our hybrid algorithm is on the first place, if it achieves the best solution with less average number of iterations over 30 runs, according other cases and we assign to it 1, we assign 2 to the case on the second place, 3 to the case on the third place and 4 to the case with most number of iterations. On some cases can be assigned same numbers if the number of iterations to find the best solution is the same. We sum the ranking of the cases over all 20 test problems to find final ranking of the different cases of the hybrid algorithm.

TABLE III: Hybrid ACO ranking

	ACO	ACO quarter	ACO half	ACO restart
first place	4 times	4 times	8 times	8 times
second place	4 times	4 times	7 times	6 times
third place	8 times	6 times	4 times	3 times
forth place	4 times	6 times	1 times	3 times
ranking	52	54	38	41

We observe that the local search procedure decreases the number of unfeasible solutions, found by traditional ACO algorithm in the next iterations, thus when the number of iterations increase, the need of local search procedure decreases. On Table III we report the achieved ranking of different cases of our hybrid algorithm. As we mentioned above, with ACO quarter we call the case when quarter of the workers are removed. ACO half is the case when half of the workers are removed. ACO restart is the case when all workers are removed. It is like to restart the solution construction, to construct the solution from the beginning.

We calculate the ranking, regarding the average number of iterations to find best solution over 30 runs of the test. When more than half of the ants find unfeasible solutions, the deviation from the average is larger compared to the tests when the most of the ants achieve feasible solutions. The Table III shows that the local search procedure decreases the number of iterations needed to find the best solution, when more than half of the workers are removed. The traditional ACO algorithm and hybrid ACO with removing quarter of the workers are 4 times on the first place when either, by chance, the algorithm find the best solution on the first iteration, or all ants find feasible solutions. We observe that the both cases are on the third and forth place 12 times. This means that removing less than half of the workers is not enough to construct feasible solution. The ACO algorithm with removed half of the workers 15 times is on the first or second place and only one time is on the fourth place, which means that it performs much better than previous two cases. When all workers are removed the achieved ranking is similar to the case when half of the workers are removed. Let the maximal number of assigned workers is t. Thus the every one of the solutions consists about t workers. If all of the workers are removed, the ant need to add new workers on their place which number is about t. When half of the workers are removed, then the ant will add about $t/2$ new workers. The calculation time to remove and

TABLE IV: Hybrid ACO comparison according calculation time

	ACO	ACO quarter	ACO half	ACO restart
first place	4 times	3 times	10 times	6 times
second place	7 times	5 times	5 times	5 times
third place	8 times	4 times	3 times	4 times
forth place	1 times	8 times	2 times	5 times
average time	82.244 s	93.98 s	79.63 s	103.012 s

add about $t/2$ workers is about two times less than to remove and add about t workers. Thus we can conclude that the local search procedure with removing half of the workers performs better than other cases.

Another way for comparison is the calculation time. For every test problem and every case we calculate the average time to achieve best solution over 30 runs. In Table IV we did similar ranking as in Table III, but taking in to account the calculation time instead number of iterations. Regarding the Table IV the ranking according the time is similar to the ranking according to the number of iterations from the Table III. The best performance is when half of the worker are removed in the local search procedure and the worst performance is when quarter of the workers are removed. The local search procedure with removing half of the worker is on the first place 10 times and on the forth place only 2 times. The local search procedure with removing quarter of the workers is on the first place 3 times and on the forth place 8 times. Regarding the calculation time the local search procedure with removing half of the workers again is the best, but the worst is the local search procedure with removing all workers. Reconstructing a solution from the beginning takes more time than to reconstruct partial solution, therefore ACO algorithm with local search procedure removing all workers performs worst. The results from Table IV show that removing only quarter of the workers from the solution is not enough for construction of good solution and is time consuming comparing with traditional ACO algorithm.

V. Conclusion

In this paper we propose Hybrid ACO algorithm for solving workforce assignment problem. The ACO algorithm is combined with appropriate local search procedure. The local search procedure is applied only on unfeasible solutions. The main idea is to remove part of the workers in the solution in a random way and to include new workers in their place. Three variants of the local search procedure are compared with traditional ACO algorithm, removing quarter of the assigned workers, removing half of the assigned workers and removing all assigned workers. The local search procedure with removing half of the assigned workers performs better than other algorithms.

***Abstract*—Community detection is a widely discussed topic in network science which allows us to discover detailed information about the connections between members of a given group. Communities play a critical role in the spreading of viruses or the diffusion of information. In [1], [8] Kempe et al. proposed the Independent Cascade Model, defining a simple set of rules that describe how information spreads in an arbitrary network. In the same paper the influence maximization problem is defined. In this problem we are looking for the initial vertex set which maximizes the expected number of the infected vertices. The main objective of this paper is to further improve the efficiency of influence maximization by incorporating information on the community structure of the network into the optimization process. We present different community-based improvements for the infection maximization problem, and compare the results by running the greedy maximization method.**

I. Introduction

BUILDING networks between people, companies, or other individuals based on their activities or properties became a common task in the previous decade. These networks describe the connection structure of their members, and show us a bigger and more detailed picture about their behavior. One of the most useful methods applied to networks is the detection of dense subgraphs, known as the detection of *communities*. Community detection is a well researched area of network science and a large variety of methods exists in its literature[2], but validating the results of an arbitrary community detection method, especially in an application-oriented way, remains an open problem.

Strong connections between individuals belonging to the same community make it easy for viruses, information or influence to spread between members. The Independent Cascade [1] model provides a possible scenario of how an actual spreading event can happen. The inputs of this model are: a graph, an assignment of edge infection probabilities to its edges and the set of initially active vertices. The process is iterative and in each iteration, every active vertex tries to activate its neighbors with the probability assigned to the edge connecting them. Each vertex remains active for exactly one iteration, afterwards it is removed from the spreading process. The process stops if there are no more active vertices. In the same paper the influence maximization problem is defined. In this problem we are looking for the initial vertex set which maximizes the expected number of the infected vertices. While the optimization problem is NP-complete, Kempe et al.

proposed a greedy method that gives a guaranteed precision result. A variety of other algorithms and heuristics were proposed to improve the efficiency of influence maximization [3][20][21]. A good overview of the maximization problem can be found in [22].

The greedy method gives us a good and guaranteed solution for infection maximization, but in real-sized networks it is unable to solve the task within a acceptable time. Here we introduce a new method, where the search space of the original greedy method is reduced based on different scores. Another objective is to compare the output of different community detection algorithms. Community detection methods are hard to validate if real life, since information about the members is not available.

In this paper we present new community based infection maximization methods which can improve the basic greedy method and increase the size of the solvable network. The methodology is also suitable to validate and compare different community detection methods.

II. Community detection

The main objective of community detection is to find dense subgraphs. The largest fraction of detection methods in the literature defines communities as disjunct sets of nodes. A significant number of works, however, follow a different approach, allowing overlaps between the groups of nodes. In this paper we take the latter, overlapping approach.

First of all we define different community detection algorithms to extract information for the infection maximization algorithm. For this purpose we chose a directed community detection method, and converted an undirected method from the literature to directed. The first algorithm which is used in this paper, is the directed version [6] of the original Clique percolation method [5]. The second method is the Hub Percolation method (HPM) [4], which was extended to work on directed networks.

A. Directed Hub Percolation

The original hub percolation [4] method is based on cliques and hubs. Maximal cliques are maximal fully connected subgraphs of an arbitrary graph, while hubs are locally important nodes in community detection. We choose the method because during the detection process, the method provides additional information which can be useful for the maximization problem. At first the algorithm finds undirected maximal cliques containing at least 3 nodes in the network. In our case the clique detection algorithm is replaced by a directed clique detection algorithm, and an additional parameter is introduced in the end of the method because providing higher resolution of the results. First of all we define the concept of a directed maximal clique.

Let d_{v_c} be the restricted out-degree of a node v in clique c: the out-degree of a given node inside the clique. The definition of the directed maximal clique is the following:

- The clique contains all directed edges from v_1 to v_2 where $d_{v1_c} > d_{v2_c}$

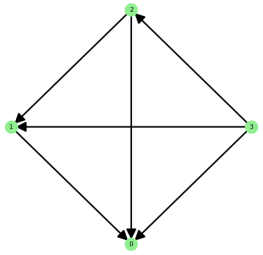

Fig. 1. An example of a directed clique. The restricted out degree of the nodes are 3, 2, 1 and 0.

- The clique contains no directed loops
- Every node in a clique has a different restricted out-degree
- It is maximal so it can not be expanded to a bigger clique

The Figure 1 shows an example of a directed clique. The restricted out degree of the nodes are different from each other. In the literature this structure also called transitive tournament [18][19]. Based on the clique definition, the algorithm of the directed hub percolation method is the following:

1) Find all at least 3 sized maximal cliques in the network. Let C contain these cliques.
2) A HubValue is defined for every node as follows: $\forall v \in V(G)$ let $h_v = |H_v|$ where $H_v = \{h | v \in h, h \in C\}$.
3) Base on h_v and a Hub Selection strategy we decide whether vertices are chosen as hub. Let H be the set of the hubs.
4) Let C_h be the set of the cliques which contains only hubs.
5) Let C_e be the set of extended cliques built in the following way: expand all $c_h \in C_h$ with the cliques containing at least 2 common vertices with c_h, that is with $c \in C$ where $|c_h \cap c| \geq 2$. Let c_e be the subgraph of the expanded vertices.
6) Merge every $c_{e_0}, c_{e_1} \in C_e$ if they have at least x common hubs.
7) The given C_e set contains the communities of the network.

B. Hub Selection

The third step of the algorithm introduces a Hub Selection strategy, which defines how vertices are chosen as a hubs. The hub selection strategies are the following:

- **Median of 1 neighborhood:** A vertex v is hub, if the value of h_v is greater than the median of the h_v values of its neighbors.
- **Mean of 1 neighborhood with parameter**: A vertex v is hub, if the value of h_v is greater than the average of the h_v values of the neighbors, multiplied by a $q > 0$ parameter.
- **Weighted mean of 1 neighborhood:** The value of the h_v is multiplied by the weights on the out-edges. A vertex

v is hub, if the value of the computed h_v is bigger than the average of the h_v values in one neighborhood.

The third strategy was changed compared to the original, emphasizing the direction of the edges, because a hub is better if it has more out edges. In our experience, it improves the quality of the output, if the hub selection strategy contains information about the edge weights.

III. Independent Cascade Model

There are numerous models of infection spreading in the literature, and these models were adopted to many different scientific fields including epidemics, sociology and economics. The two models most relevant to this paper were proposed in [8] by Domingos and Richardson and [7] by Granovetter. The former was used to improve the efficiency of virus marketing, the latter was the first method used to model the spreading of behavior. These models were later adopted to networks in [1], [9] by Kleinberg and Kempe. The infection model discussed in this paper is the Independent Cascade Model. The rest of this section describes this model in detail.

Let $G = (V, E)$ be a directed network, where $\forall(v, u) \in E$ edge has a $p(v, u)$ probability where $0 < p(v, u) \leq 1$. We assign states to the nodes: they are either susceptible, infected or removed. Let A_0 be the initial infected set of nodes $A_0 \subset V(G)$, all other nodes are susceptible at the beginning. The infection process takes place in discrete time steps or iterations. Through the iterations let A_i denote the set of the nodes which become infected in the i-th iteration. Each node stays infected for exactly one iteration, afterwards it is removed from the process. The process terminates in finite steps, and let A denote the set of removed nodes at the end of the process. In each iteration each infected node may make one attempt to infect its susceptible neighbors according to the value $p(v, u)$ on the edge connecting them. Algorithm 1 summarizes the Independent Cascade Model.

Algorithm 1 Independent Cascade

```
Let A_0 denote the set of initially infected nodes
While A_i ≠ ∅
    A_i ← newly infected nodes
    ∀v ∈ A_i tries to infect their neighbors with p(v, u)
    If the infection is successful
        A_{i+1} = A_{i+1} ∪ u
    End If
End While
```

If the A_i set is empty the infection process stops. Let $\sigma(A_0)$ denote the expected number of infected nodes with A_0 as the initial set. Let $w_f(v)$ be the final infection probability of a given node. The value of the $\sigma(A_0)$ formally is the following:

$$\sigma(A_0) = \sum_{v \ in \ G(V)} w_f(v) \tag{1}$$

There are numerous examples in the literature to compute the $\sigma(A_0)$ [3], [11]. The exact computation of $\sigma(A_0)$ is a #P-Complete problem [21].

A. Complete Simulation

In this paper the complete simulation algorithm proposed in [3], [1] is used to compute the expected number of infected vertices. A generalized version of the model can be found in [3]. In Complete Simulation algorithm sample size is an important parameter because it sets the number of independent simulations, as such the precision of the result. The Complete Simulation algorithm for the Independent Cascade Model is shown on Algorithm 2.

Algorithm 2 Complete Simulation

```
Input: Graph G, sample size s
A_0 ← initially infected nodes
j ← 0
∀v ∈ G(V) : f_v = 0
While j < s
    ∀e ∈ G(E) let the edge active or passive based on p(e)
    Modified DFS from ∀v ∈ A_0
    If n ∈ G(V) node is accessible from v ∈ A_0
        n : f_v ← f_v + 1
    End If
j ← j + 1
End While
∀v ∈ G(V) : fv ← fv / s
```

The simulation generates s different networks, each having different, randomized edge infection probabilities, and in every independent simulation every edge is either in an active or a passive state. The modified Depth First Search uses only active edges to visit the nodes, and increases the f_v values of the nodes if they are visited in the simulation instance. Finally, the f_v values are divided by the number of the independent simulations, which gives us an expected value for every node. In this paper complete simulation is used to get the $\sigma(A_0)$ value for a given initially infected set.

B. Infection maximization

The infection maximization problem is an optimization problem where the main objective is to maximize the spread of infection in the network. The problem is to find the set of k initial infectors which give the maximal expected infection, so in other words we are looking for an A_0 vertex set for any $|A_0| = k$ which maximizes the value of $\sigma(A_0)$.

To try different varieties of these sets, several repeated computations of the simulation is needed. If we want to try all possible initially infected sets for $k = 2$ of the example on Figure 2 we need 56 different simulations for this small network, but in a real-sized network it is not computable in acceptable time. The original infection maximization problem was published by Kempe et. al [1]. In the same paper they have proven the NP-hardness of the problem, and gave a greedy optimization method which can give at least 63% of the optimum for any case.

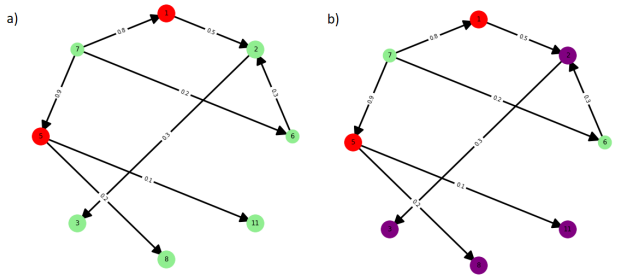

Fig. 2. On figure a) the $A_0 = \{1, 5\}$ so nodes 1 and 5 are infected initially and $k = 2$. The figure b) shows the result of the simulation with samplesize of 100 000. The red nodes are the initially infected nodes, the purple nodes have greater infection than zero, and the green nodes are uninfected. In this example $\sigma(A_0) = 2.94546$.

C. Greedy method

The greedy method starts from an empty set and increases the number of the initially infected nodes until it reaches the given k. In every iteration the algorithm chooses the node that currently seems to be the best choice. The algorithm does not give the optimal solution but it has a guaranteed precision of 63% of the optimum, but in most real-life cases it gives much better solution. At first the algorithm chooses the most infectious node from the network which can maximize the spread alone in the most efficient way. After that in every iteration one node is added to A_0 which gives the greatest improvement of the spread of infection with the other selected nodes. In the end, the algorithm gives an infected node set which maximizes the expected value of the infection. Algorithm 3 shows the greedy method.

Algorithm 3 Greedy method

1: **Input:** Graph G, size of the infected set k
2: **Output:** A_0 infected set
3: $A_0 \leftarrow \emptyset$
4: **While** $|A_0| \leq k$
5: $\quad A_0 = A_0 \cup \ arg\ max_{v \in G(V) \setminus A_0)} \sigma(A_0 \cup \{v\})$

In every iteration of the algorithm the next node is chosen from a $\{G(V) \setminus A_0\}$ set. The idea of the paper is to reduce the size of the set of the possible nodes so we will minimize the search space in every iteration based on some computed value which comes from a community detection algorithm.

IV. Reduction methods

The original greedy method gives us a quite good solution, but in real-sized networks the running time of the method can be too high. If the search space of the greedy method is reduced, it cannot guarantee the 63% precision of the optimal solution, but with a well chosen heuristic it can give a better solution. The main advantage of our methodology is the running time. In this section different reduction methods are demonstrated based on a computed value assigned to every node describing the quality of a node as an infector. We aim to improve the performance of the method by incorporating community-based information taken from one of the detection methods discussed above. Let $V*$ be the reduced selection set, and in every iteration the reduced greedy algorithm chooses from $\{G(V*) \setminus A_0\}$ resulting in decreased runtime. We give two different values based on the directed hub percolation method and the directed clique percolation methods. We introduce two different $f(v)$ functions which scores the nodes based on a different community or clique based statistic.

A. Hub Value

Cliques indicate the strongest connection between groups of nodes because in a clique every node is connected with each other. Let $f(v)$ $f : v \rightarrow Z$ be a function which assigns a number to every node. Let $f_{hv}(v)$ be a function that assigns the hub value h_v introduced in section 2 to the nodes of the network indicating how many directed cliques contain the node. The score is based on the idea, that a node can be a good infector if multiple cliques contain it, because in this way the node can spread the infection between cliques.

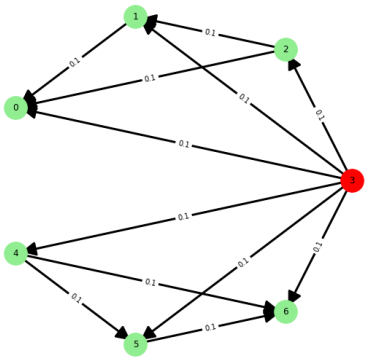

Fig. 3. Example of hub value calculation. The hub value of node 3 is $f_{hv}(3) = 2$ because two directed cliques contain the red node. All of the green nodes have one as a h_v. In this case the node 3 is a very good infector because it can spread the infection in both directed cliques.

After every nodes get the score, the $G(V)$ set is sorted according to h_v. The reduced $V*$ set contains the top nodes of the ordered $G(V)$ set. Since the hub value doesn't contain information on the edges of the graph, we introduce two different approaches.

- *unweighted hub value:* The nodes are sorted based only on h_v values.
- *mean weighted hub value:* The h_v is multiplied by the mean of the probabilities on every out-edge of the actual node.

Since the second technique contains information on the edge weights and the out degree of the node, it gives a higher score if a node is in many cliques, has many out edges, and the out probabilities are high. If the network is undirected, the method can be more efficient because an undirected clique indicates a stronger connection than a directed.

B. Community Value

The second technique can be based on the results of different community detection methods, providing the ability to compare these methods. In this case the score for a given node is how many communities contain the actual node. Every overlapping community detection method can be compared using this methodology providing a comprehensive community comparing technique.

The basic idea is the same in the previous section, the difference is in the $f(v)$ function. Let c_v be the community value and let the $f_{cv}(v)$ $f : v \to Z$ be a function which scores the nodes based on their community values. The reduced set works in the same way as in the case of hub values. The communities in real life have additional meanings: they can group the nodes into different sets, but if the main objective is infection maximization, a node can be a good infector if it is a member of many communities. The nodes with large community values can work as an infection bridges between different communities, since in real life a person or a company can be a good infector if it appears in many different areas of life.

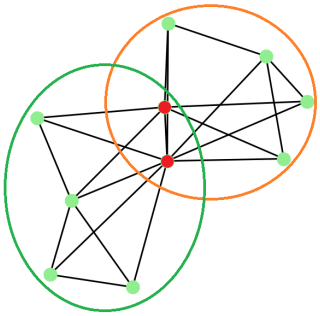

Fig. 4. Community values in overlapping communities. Since two different communities contain the red nodes, the community value of the red nodes is 2. The community value of the green node is 1.

Figure 4 shows an example of the community value. Considering only the individual communities, the red nodes and the green nodes are the same because they are just simple members of the group. From a global viewpoint however, the green nodes can be less effective in disease spreading because they are only connected to nodes inside their communities. The red nodes have access to both communities. The community value can also be used in two ways based on the computation of the value.

- *unweighted community value:* The c_v values denote how many communities contain the node.
- *mean weighted community value:* The c_v values are multiplied by the mean of the probabilities on every out-edge from v.

The nodes with zero or low out degrees are also eliminated from the reduced set. In the results section, the above techniques were compared to the results of the original greedy method.

V. Results

In this section we present the results of our modified infection maximization method, and test our methodology which provides a way to compare different overlapping community detection techniques. We ran the algorithm on a PC with I7 4790 CPU (3.6 Ghz) and 16GB of RAM. The Complete Simulation and the optimization framework is implemented in Java. We tested our methodology on six different randomly generated and seven real-life networks. For the random networks we used the igraph package of the R language and for the figures we used a Python version of our framework. With the greedy method the sample size was set high to get the best precision.

A. Precision of the results

All test were run with $s = 1000$ in every iteration because in the greedy method the algorithm has to compute the expected value for all possible nodes which is very time-consuming. Higher s values do not give more precise results as presented in this section, but their computation takes much longer. At the end of the testing process the final solution was rerun with $s = 100000$. Results show that complete simulation has lower precision compared to the greedy method by 1.14% measured on the final set of infected nodes. Let $\sigma(A_0)_{greedy}$ be the expected value of the given infected set in the greedy method, and $\sigma(A_0)_{final}$ be the expected value of the infected set with a high precision complete simulation. Table I shows the precision loss of complete simulation compared to the greedy method on the final infection values ordered according to the density of the network.

TABLE I
PRECISION OF INFECTION MAXIMIZATION

Diff	Precision	Density
0.70245	1.148%	1.774
0.8183	1.082%	1.802
0.87047	0.403%	1.833
0.86507	0.905%	1.834
0.77251	0.545%	1.838
0.06035	0.161%	3.104
0.81857	0.654%	3.473
0.05284	0.252%	3.492
0.03828	0.038%	3.708
0.69613	0.562%	3.872
0.51405	0.550%	4.602
2.53454	0.270%	6.393
1.05984	0.158%	25.44

The column diff shows the difference between $\sigma(A_0)_{greedy}$ and $\sigma(A_0)_{final}$. The precision column denotes the percentage of loss compared to the expected value of the final infections. Results were computed on the random networks below.

B. Random networks

The random graphs were generated in 6 different sizes with the forest fire model [12]. The properties of the random networks are the following:

- Number of nodes from 250 to 1500
- Number of edges from 873 to 5205

- Forward burning probability was 0.34
- Edge probabilities were randomly drawn from an uniform distribution between 0 and 0.2

The test results of the original greedy algorithm, and the size of the networks are shown on Table II.

TABLE II
RESULTS OF THE ORIGINAL GREEDY ALGORITHM ON RANDOM NETWORKS

Graph	nodes	edges	k	Greedy	Time
rand_1	250	873	3	20.922	15.81s
rand_2	500	1552	5	37.338	84.31s
rand_3	750	3452	8	93.321	438.52s
rand_4	1000	3708	10	99.462	796.65s
rand_5	1250	4841	13	123.756	1704.85s
rand_6	1500	5205	15	125.044	2534.69s

During testing the size of the initial infected set was 1% of the number of nodes in every scenario. The randomly generated networks are not too big, just enough to show our concept works. Furthermore, a real-sized network has millions of nodes and edges or more and it is not possible to test the greedy algorithm on it due to its time complexity. The size of the reduced set $V*$ was 10% of the number of nodes. Table III shows the result of the greedy algorithm with the reduced $V*$ based on hub and community based methods. As the size of the networks increases, the running times follow the size of the reduced set. The time column shows that the running times are approximately 10% of the original.

TABLE III
RESULTS FOR THE HUB AND COMMUNITY BASED REDUCED SET ALGORITHM ON RANDOM NETWORKS. (**HV:** HUB VALUE, **DHP:** COMMUNITY VALUE BASED ON DIRECTED HUB PERCOLATION, **DCP**: COMMUNITY VALUE BASED ON DIRECTED CLIQUE PERCOLATION, **DIFF:** PERCENTAGE OF THE SOLUTION COMPARED TO THE GREEDY ALGORITHM, **TIME:** TIME OF THE SOLUTIONS COMPARED TO THE TIME OF THE GREEDY METHOD)

Graph	HV	Diff	DHP	Diff	DCP	Diff	Time
rand_1	20.87	99.7%	21.03	100.5%	4.65	22%	18%
rand_2	37.35	**100%**	37.67	**100.8%**	9.45	25%	13%
rand_3	93.07	99.7%	93.35	**100.1%**	26.45	28%	11%
rand_4	99.46	**100%**	100.25	**100.5%**	22.63	22%	11%
rand_5	124.06	**100%**	123.1	99.5%	31.15	25%	10%
rand_6	124.9	99.9%	121.4	97%	34.55	28%	10%

In four cases the hub or community value based reduced set method gives a similar or better solution than the original greedy algorithm. However in the rest of the cases it cannot reach the reference solution but it still gives acceptable results with a much better running time than the simple greedy method. If we compare our two community detection methods, the table shows that the directed hub percolation method gives much better solution than the directed clique percolation. The DHPM detects the overlapping nodes, and the strongly connected dense subgraphs better than the DCPM in these networks. Besides random networks we also tested our methodology on real-life networks.

C. Real networks

The first five real-life networks considered in this paper are word association graphs based on a survey connected to the website "Agykapocs.hu" created by László Kovács[17]. The nodes of these graphs are words and the edges are associations between the words based on the user answers. The different networks come from the different versions of the word-association network. The rest of the real-life networks are from a well known data set from Stanford University [13]. The first network from this data set is an email network which describes email connections of a large European research institution [14][15]. The second is the bitcoin alpha trust network which describes trust connections between bitcoin traders [16]. The edge weights of the network were generated in the same way as with the random networks: they were drawn from an uniform distribution between 0 and 0.2.

TABLE IV
RESULTS OF THE ORIGINAL GREEDY ALGORITHM ON REAL NETWORKS

Graph	nodes	edges	k	Greedy	Time
real_1	2751	5043	28	215.955	8969.39s
real_2	2088	3839	21	141.533	3868.12s
real_3	1680	3082	17	95.563	2005.33s
real_4	1460	2632	15	75.568	1298.91s
real_5	1305	2315	13	61.137	889.64s
email	1005	25571	10	670.187	5742.73s
bitcoin	3783	24186	38	936.535	83303,53s

We can find a lot of real-life networks larger than these, but according to Table IV even on these quite small networks the running times can be very high, indicating that the normal greedy algorithm may not be able to find a good solution especially with a high k parameter. The results of the reduced set algorithm are shown in Table V.

TABLE V
RESULTS FOR THE HUB AND COMMUNITY BASED REDUCED SET ALGORITHM ON REAL-LIFE NETWORKS.(**HV:** HUB VALUE, **DHP:** COMMUNITY VALUE BASED ON DIRECTED HUB PERCOLATION, **DCP**: COMMUNITY VALUE BASED ON DIRECTED CLIQUE PERCOLATION, **DIFF:** PERCENTAGE OF THE SOLUTION COMPARED TO THE GREEDY ALGORITHM, **TIME:** TIME OF THE SOLUTIONS COMPARED TO THE TIME OF THE GREEDY METHOD)

Graph	HV	Diff	DHP	Diff	DCP	Diff	Time
real_1	215.05	99%	215.8	**100%**	189.6	87%	10%
real_2	139.92	99%	138.6	98%	122.8	87%	10%
real_3	99.46	**104%**	97.78	**102%**	87.69	91%	10%
real_4	74.87	99%	74.34	98%	71.64	94%	10%
real_5	61.18	**100%**	59.54	97%	58.54	95%	11%
email	662.5	99%	662.4	99%	663.4	99%	10%
bitcoin	924.7	98%	916.4	98%	928.1	99%	11%

On real-life networks the results are not as pronounced as with the random networks. In three cases our method reaches very good solutions with a satisfactory running time, but the other solutions are still satisfactory. If we compare the two reduced set methods, we can say that the DCPM works much better on real-life networks. In the general case however, the DHPM still works better.

VI. CONCLUSION AND FUTURE WORK

In this paper we proposed a new community based infection maximization algorithm to reduce the running time of the

greedy algorithm of Kempe et al, allowing the application of the algorithm to real-life networks. The methodology also allows us to measure the quality of any overlapping community detection method. Our approach is based on a community or hub based $f(v)$ function that scores the nodes according to their ability to infect other nodes, and builds a reduced candidate set for the greedy method.

The main result of this paper is based on the hypothesis, that in real-life infections spread easier inside communities. Apart from the main result, the improved infection maximization method, we present a comparing methodology which can support the development of different high resolution community detection algorithms. In the future we want to improve the presented community-based approaches and try out different $f(v)$ functions to score the nodes. While our current methodology is based on and supports the greedy algorithm, we want to develop a clearly community based infection maximization method using the results of this paper.

***Abstract*—The selection of relevant features in large databases is one of the most important and challenging problems in data mining. Samples forming a given database are generally described by a predefined set of features, and the situation where not all such features can be used for classification purposes needs very often to be faced in real applications. This situation is very typical when the database is related to a phenomenon whose characteristics are not well known. In this context, the extraction of relevant features can therefore also provide additional information on the studied phenomena. We tackle the feature selection problem from an optimization point of view, by reducing it to the problem of finding a maximal consistent "clustering" grouping together the samples and the features of the database. In this work, we extend this approach to dynamical databases, where features are not represented by only one real value, but they are rather given as sequences of a predefined number of real values. Our main contribution consists in proposing an alternative representation of the database so that it fits with a tridimensional matrix with no missing entries, from which a consistent triclustering can be obtained.**

I. Introduction

More and more attention is given nowadays to techniques for mining data, because of the growing amount of information that can be obtained from different resources and that needs to be analyzed [11]. The main aim of such techniques is to identify suitable partitions of a given set of data, where *similar* data can be grouped together. Such partitions can in fact help in finding important relationships in the original data. In some applications, a subset exists for which a classification of the data is already available; the classification associated to this subset can therefore be exploited for *learning* how to classify data for which a classification is not yet known. In this context, our work aims at looking for optimal selections of the features of a dataset in order to improve the quality of the performed classifications.

Let $\mathbb{S}$ be a set of n samples, where every $S_i \in \mathbb{S}$ is represented by an ordered set of m time-series Q_j^i. The number m of time-series per sample is fixed, whereas the length of every time-series can vary. We suppose that a classification of the samples S_i of $\mathbb{S}$, in a given number of classes, is available.

More formally, we suppose that every time-series Q_j^i is a sequence of ℓ_i real values $q_{j,k}^i$, with k counting from 1 to ℓ_i. The length of every time-series depends on the sample S_i, and, since all features of a sample are generally recorded at the same time, we can suppose, without losing generality, that ℓ_i is a constant for all time-series forming the same sample. In brief, we have:

$$\begin{array}{rl} \mathbb{S} = (S_1, S_2, \ldots, S_n) & \text{a set of samples,} \\ S_i = (Q_1^i, Q_2^i, \ldots, Q_m^i) & \text{ordered set of time-series,} \\ Q_j^i = (q_{j,1}^i, q_{j,2}^i, \ldots, q_{j,\ell_i}^i) & \text{time-series.} \end{array}$$

We consider the problem of selecting the subset of time-series that can better describe the phenomena under study. To this purpose, we propose a three-dimensional matrix representation of the original dataset $\mathbb{S}$ that is independent from the length of the time-series, and look for a consistent clustering in sub-matrices where the maximal number of time-series is preserved. Our approach finds its inspiration and extends some previous works (the reader is referred to [7] for a complete description) where non-dynamical problems were considered (every feature was represented by one real value per sample, and not by a time-series).

This short paper is organized as follows. In Section II, we will briefly recall previous works on static problems where the matrix representation of $\mathbb{S}$ is possible with a two-dimensional full matrix. In Section III, we will introduce our three-dimensional matrix representation for datasets where features are represented by time-series. In Section IV, we will propose an extension of the approach recalled in Section II to the data representation introduced in Section III. Finally, Section V will discuss on how to create datasets of human motions to be analyzed by the presented technique, and Section VI will conclude the paper.

II. Feature Selection by Consistent Biclustering

Feature selection is widely studied in the context of data mining. In case the samples of a given dataset do not have a temporal component, the feature selection problem can be tackled by consistent biclustering [7], [9], [10]. This approach works particularly well for problems where measurements are available for every sample, and where the number of features is generally larger than the number of samples in the dataset. The aim, in fact, is to select only important and relevant features from the dataset, whereas others may not be adequate for describing the samples. This gives two immediate consequences. First, if only pertinent features are used and all others are rejected, the memory space necessary for storing the data is optimized. Secondly, a strict relationship between

samples and features can this way be identified, which may reveal important information about the problem under study.

If a set of data contains n samples which are described by m features, then the dataset can be represented by a $m \times n$ matrix $\mathcal{A}$, where the samples are organized column by column, and the features are organized row by row. In this context, we refer to a *bicluster* of $\mathcal{A}$ as a sub-matrix of $\mathcal{A}$, whose elements are a subset of samples and features. Equivalently, a bicluster can be seen as a pair of subsets (S_r, F_r), where S_r is a class (or cluster) of samples, and F_r is a class (or cluster) of features. A *biclustering* [1] is a partition of $\mathcal{A}$ in p biclusters:

$$\mathbb{B} = \{(S_1, F_1), (S_2, F_2), \ldots, (S_p, F_p)\},$$

such that the following conditions are satisfied:

$$\bigcup_{r=1}^{p} S_r \equiv \mathcal{A}, \qquad S_\zeta \cap S_\xi = \emptyset \quad 1 \leq \zeta \neq \xi \leq p,$$

$$\bigcup_{r=1}^{p} F_r \equiv \mathcal{A}, \qquad F_\zeta \cap F_\xi = \emptyset \quad 1 \leq \zeta \neq \xi \leq p,$$

where $p \leq \min(n, m)$ is the number of biclusters.

If a classification for the samples of $\mathcal{A}$ is available, as well as a classification for its features, a biclustering $\mathbb{B}$ can be trivially constructed. Inversely, classifications of samples and features can be obtained from $\mathbb{B}$.

In some data mining applications, there exist sets of data for which a classification of its samples is already given: we say in this case that a *training set* is available. However, the classification of the features used for describing the samples is generally not known, or, equivalently, there is no biclustering $\mathbb{B}$ associated to this training set. Therefore, no a priori information about possible relationships between samples and features is in general given.

A way to obtain a classification for the features from a training set $\mathcal{A}$ is to assign each feature to the class where it is "mostly expressed" (see [7] for a wider discussion). This idea comes from the study of biclusterings related to gene expression data [4], but it can be applied as well to problems arising in other fields (see for example [8]). Once a classification for the features is obtained, a biclustering $\mathbb{B}$ for $\mathcal{A}$ can be computed by simply applying the definition of biclustering. If the found biclustering is *consistent* (in the sense given in [7] for the bidimensional case, the reader is referred to Section IV for additional details), then the selected features are most likely the ones that better describe the samples. In this work, this approach is extended in Section IV to consistent *tri*clusterings.

The feature selection problem can subsequently be formulated as a 0–1 linear fractional optimization problem, which was proved to be NP-hard [5]. We consider a bilevel reformulation of this optimization problem, whose inner problem is linear. For its solution, we employ a heuristic that is based on the meta-heuristic Variable Neighborhood Search (VNS) [3] where, at each iteration, the inner problem is solved exactly.

III. Constructing 3D comparison matrices

As stated in the Introduction, our focus in this work is on datasets whose samples S_i are described by a predefined number of time-series Q^i_j. As in the previous works on consistent biclustering, it is supposed that, for every sample S_i, the same number of time-series Q^i_j are available. Moreover, every pair of time-series Q^A_j and Q^B_j, sharing the same index j but belonging to two different samples, must be related to the same kind of information (e.g. we cannot compare angle variations with the concentration level of a chemical compound). These requirements, which basically ensure that the matrix representation of the biclustering has no missing entries in dimension 2, does not imply a similar property when working with time-series and clustering in 3D. In fact, while the number of samples and the number of features are two constants of the problem (the first two dimensions), the number of elements ℓ_i forming a time-series depends on the sample S_i. Therefore, the corresponding three-dimensional matrix may, in general, have missing entries. Moreover, elements $q^i_{j,k}$ sharing the same index k may have no relationship (whereas common index i means "same sample", and common index j means "same time-series", or equivalently "same feature").

Consider two samples A and B, and two homologous time-series Q^A_j and Q^B_j:

$$(q^A_{j,1}, q^A_{j,2}, \ldots, q^A_{j,\ell_A}), \qquad (q^B_{j,1}, q^B_{j,2}, \ldots, q^B_{j,\ell_B}).$$

In order to obtain a coherent three-dimensional matrix representation, we construct a new matrix where the entries represent comparison scores between pairs of time-series Q^i_j. We consider Dynamic Time Warping (DTW) for a global and temporal alignment of every pair of time-series (see for example [12]). Together with DTW, we also consider the more recent Correlation DTW (CoDTW) [2], which is able to perform better quality alignments in more difficult situations. From the original dataset $\mathbb{S}$, we can therefore compute a full three-dimensional matrix consisting of DTW scores between pairs of samples A and B, for a given feature j:

$$\mathrm{DTW}(A, B; j).$$

A graphical representation of this three-dimensional matrix is given in Fig. 1.

The rows of such a matrix (as well as its columns) contain all (Co)DTW values of one sample S_i in comparison with all the others, for a fixed set of homologous time-series. For this reason, it is reasonable to represent a sample S_i with either a row or a column of such a matrix. This three-dimensional matrix is the result of extending this sample representation to all sets of homologous time-series.

IV. Consistent triclustering

The matrix representation of the original dataset $\mathbb{S}$ that we propose consists of all scores obtained from the time-series comparisons (see previous section). Let DTW be the $n \times n \times m$ matrix containing all such scores. Once the binary vector x is

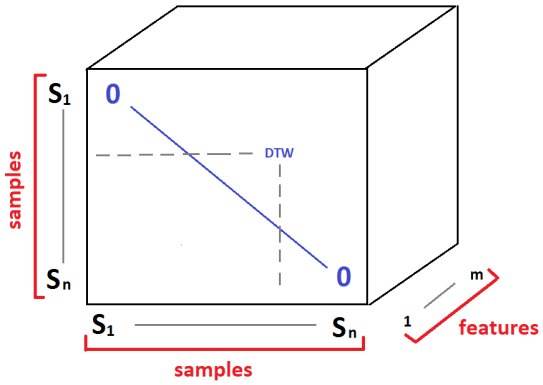

Fig. 1. Score comparison matrix obtained from the original dataset $\mathbb{S}$.

defined over the index set $\{1,2,\ldots,m\}$ so that

$$x_j = \begin{cases} 1 & \text{if the feature } j \text{ is selected} \\ 0 & \text{otherwise,} \end{cases}$$

we can define the sub-matrix DTW[x] obtained by removing from the matrix DTW all features j such that $x_j = 0$.

We suppose that a classification C_S for the samples of $\mathbb{S}$ in p classes is already available. Let $C_S(r)$, with $r \in \{1,2,\ldots,p\}$, indicate the subset of samples belonging to r^{th} class, and let s_{Ar} be a binary parameter indicating whether the sample S_A belongs to the class of samples r. A classification C_F for the homologous sets of time-series can be identified by applying the following rule. For a fixed $\hat{r} \in \{1,2,\ldots,p\}$, the homologous set indexed by $j \in \{1,2,\ldots,m\}$ is assigned to the $\hat{r}^{th}$ class if, and only if, by definition:

$$\forall \xi \in \{1,2,\ldots,p\} \,|\, \xi \neq \hat{r},$$
$$\sum_{A,B \in C_S(\hat{r}) \,|\, A \neq B} \frac{\mathrm{DTW}(A,B;j)}{|C_S(\hat{r})|} < \sum_{A,B \in C_S(\xi) \,|\, A \neq B} \frac{\mathrm{DTW}(A,B;j)}{|C_S(\xi)|}.$$

We suppose working on datasets for which the equation above cannot be satisfied with the equality, otherwise the classification of the features would not be unique.

Let f_{jr} be a binary parameter indicating whether the time-series with index j belongs to the class of features r. A *triclustering* of DTW[x] is *consistent* if

$$\forall \hat{r}, \xi \in \{1,\ldots,p\}, \hat{r} \neq \xi, \forall A,B \in C_S(\hat{r}), A \neq B$$
$$\frac{\sum_{j=1}^{m} DTW(A,B,j) f_{j\hat{r}} x_j}{\sum_{j=1}^{m} f_{j\hat{r}} x_j} < \frac{\sum_{j=1}^{m} DTW(A,B,j) f_{j\xi} x_j}{\sum_{j=1}^{m} f_{j\xi} x_j}. \quad (1)$$

It is important to remark that the matrix DTW does not admit, in general, a consistent triclustering if all features are considered. Notice that, differently from the previous works, we are interested here in the *less expressed* scores, because they correspond to time-series showing higher similarities.

The problem of selecting the relevant features by consistent triclustering can be stated as follows:

$$\max_x \left(f(x) = \sum_{j=1}^{m} x_j \right)$$
$$\text{subject to} \quad \forall \hat{r}, \xi \in \{1,\ldots,p\}, \hat{r} \neq \xi, \forall A,B \in C_S(\hat{r}), A \neq B$$
$$\frac{\sum_{j=1}^{m} DTW(A,B,j) f_{j\hat{r}} x_j}{\sum_{j=1}^{m} f_{j\hat{r}} x_j} < \frac{\sum_{j=1}^{m} DTW(A,B,j) f_{j\xi} x_j}{\sum_{j=1}^{m} f_{j\xi} x_j}. \quad (2)$$

As already pointed out, we consider the bilevel reformulation proposed in [7], and we solve the problem by employing a VNS-based heuristic. To perform such a reformulation, we transform the denominators of the optimization problem constraints (see equ.(2)) into continuous variables $y_r, r = 1,\ldots,p$, where y_r represents the number of selected features in the feature class $C_F(r)$:

$$\forall r \in \{1,\ldots,p\}, \; y_r = \sum_{j=1}^{m} f_{jr} x_j.$$

Using the newly introduced variables, the constraint in the original optimization problem can be rewritten by replacing $\sum_{j=1}^{m} f_{j\hat{r}} x_j$ and $\sum_{j=1}^{m} f_{j\xi} x_j$ by $y_{\hat{r}}$ and y_ξ, respectively. We normalize the values:

$$\overline{y}_r = \frac{\sum_{j=1}^{m} f_{jr} x_j}{m},$$

so that the following constraint is satisfied:

$$\sum_{r=1}^{p} \overline{y}_r \leq 1.$$

Our bilevel program is therefore:

$$\textbf{outer pb} \begin{cases} \min_{\overline{y}} \left(g(x,\overline{y}) = \sum_{r=1}^{p} \left[(1 - \overline{y}_r) + \sum_{\xi=1:\xi\neq r}^{p} c(x,r,\xi) \right] \right) \\ \text{subject to} \\ \textbf{inner pb} \begin{cases} x = \arg\max_x \left(f(x) = \sum_{j=1}^{m} x_j \right) \\ \text{subject to consistency constraint (1)} \end{cases} \\ \sum_{r=1}^{p} \overline{y}_r \leq 1, \end{cases}$$

where $c(x,\hat{r},\xi)$ is

$$\sum_{j \in C_S(\hat{r})} \left| \frac{\sum_{j=1}^{m} DTW(A,B,j) f_{j\hat{r}} x_j}{\sum_{j=1}^{m} f_{j\hat{r}} x_j} - \frac{\sum_{j=1}^{m} DTW(A,B,j) f_{j\xi} x_j}{\sum_{j=1}^{m} f_{j\xi} x_j} \right|_+,$$

with $|\cdot|_+$ denoting the function that returns its argument if positive, and 0 otherwise. Hence, $c(x,\hat{r},\xi)$ is strictly positive if and only if at least one constraint is not satisfied.

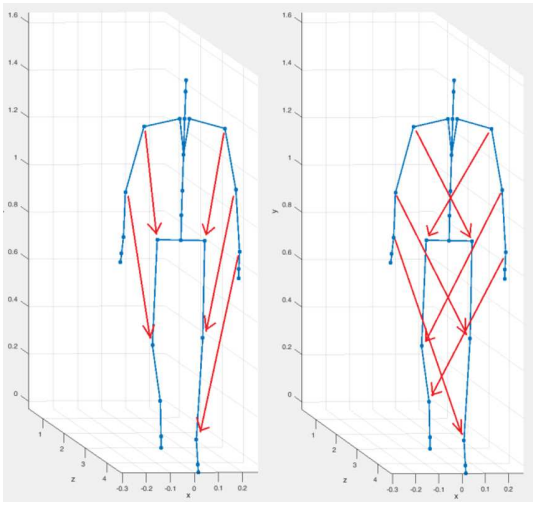

Fig. 2. A graphical representation of some newly introduced features aiming at measuring the symmetries in the movements (see distance sets represented by the red arrows).

V. Creating a Dataset of Human Motions

Motion capture makes it possible to track human movements over time. Markers are generally placed on the body surface of an actor, from which main bones and joint positions of the corresponding skeletal structure, over time, are derived. In general, absolute positions, together with bone rotation angles, are given for every frame of the motion capture (see skeletal representation in Fig. 2, in blue). The data are often stored in a specific format named BVH (BioVision Hierarchy), where joints and bones representing the actor are organized in a hierarchical way.

By collecting a certain number of captured human motions in BVH format, we can define a dataset of motions having particular properties (e.g. all motions are related to a certain human movement, but performed by different classes of humans, such as experts and novices, or male and female). This dataset can serve as a basis for our analyses, but it needs to be manipulated before its effective use.

In fact, the position of each skeleton joint in space may not give very useful information about the movements. Therefore, we propose to enrich the dataset with additional information as follows. For every motion, together with some information related to rotation angles between body parts (which can be easily extracted from BVH files), we also consider relative distances between joint pairs. Some recent studies, in fact, have shown that relative distances can play an important role in the representation of human motions [6]. As Fig. 2 shows, subset of distances can provide information about the symmetry of the movements. All these additional features are represented by time-series.

We have performed some very preliminary experiments where some relevant features were extracted from a so-constructed dataset of human motions (walking motions, with male and female actors) by using our optimization-based approach for feature selection by consistent triclustering. For lack of space, we cannot include any of them in this short paper. As for a future work, we will create a larger collection of motion datasets, having various properties, and we will use them to validate the theory presented in this paper.

VI. Conclusions

We extended an optimization-based approach to feature selection to datasets containing dynamical data. To do so, we proposed an alternative matrix representation of the data, where the original time-series are replaced by similarity scores. This made it possible to extend a previous approach for consistent biclustering to our new three-dimensional matrix representation.

Future works will be aimed at performing supervised classifications by exploiting the information that can be derived from obtained consistent triclusterings. Moreover, we plan to extend this approach to fuzzy sets, so that samples and features can actually belong to more than one class. It is our opinion that this would help better describing real phenomena, such as human motions.

***Abstract*—A *rooted labeled caterpillar* is a rooted labeled tree transformed to a path after removing all the leaves in it. In this paper, we design the algorithm to compute the edit distance between rooted labeled caterpillars in $O(\lambda^2 h^2)$ time, where λ and h are the maximum number of leaves and the maximum height in two caterpillars, respectively.**

I. Introduction

COMPARING tree-structured data such as HTML and XML data for web mining or RNA and glycan data for bioinformatics is one of the important tasks for data mining. The most famous distance measure [2] between *rooted labeled unordered trees* (*trees*, for short) is the *edit distance* [9]. The edit distance is formulated as the minimum cost of *edit operations*, consisting of a *substitution*, a *deletion* and an *insertion*, applied to transform a tree to another tree. It is known that the edit distance is always a metric and coincides with the minimum cost of *Tai mappings* [9].

Unfortunately, the problem of computing the edit distance between trees is MAX SNP-hard [13]. This statement also holds even if trees are binary or the maximum height of trees is at most 3 [1], [4].

Many variations of the edit distance have developed as more structurally sensitive distances, by introducing the restriction of Tai mappings (*cf.*, [7], [11]). All the variations except those of an alignment distance [5] are metrics and the problem of computing them is tractable [10], [11], [12], [14]. In particular, the *isolated-subtree distance* (or *constrained distance*) [12], which is defined as the minimum cost of isolated-subtree mappings, is the most general tractable variation of the edit distance [11].

On the other hand, a *caterpillar* (*cf.* [3]) is a tree transformed to a path after removing all the leaves in it. Whereas the caterpillars are very restricted and simple, there are some cases containing many caterpillars in real dataset, see Table II in Appendix.

As a method to compare two caterpillars, we can adopt a *complete subtree histogram distance*, which is an L_1-distance between histograms consisting of complete subtrees in two trees [1]. The complete subtree histogram is computable in linear time and always a metric but it is greater than the edit distance in general [1]. In particular, as an extreme case, there exists two caterpillars such that the edit distance between them is one but the complete subtree histogram distance is the number of nodes in two caterpillars, consider two paths with the same length such that the labels of leaves are different.

As another method, we can also adopt a *path histogram distance*, which is an L_1-distance between histograms consisting of paths from the root to leaves in two trees [6]. The path histogram distance is computable in linear time and always a metric for caterpillars, which is not a metric for trees, but it is incomparable with the edit distance [6].

Since a caterpillar is an unordered tree, it remains open whether or not the problem of computing the edit distance between caterpillars is tractable. Hence, we discuss this problem.

First, we point out that there exists a Tai mapping between two caterpillars that is not an isolated-subtree mapping. Then, we cannot apply the algorithm to compute the isolated-subtree distance or its variations [10], [11], [12], [14] that are tractable variations of the edit distance, to compute the edit distance between caterpillars.

On the other hand, a caterpillar has the structural property that the children of a non-leaf node in a caterpillar consist of at most one caterpillar and leaves (possibly empty). Then, by deleting a non-leaf node in a caterpillar, we obtain at most one caterpillar and the set of leaves as a forest. Furthermore, once such leaves are obtained, then we can add them to the previous set of leaves.

Based on this property, in this paper, we design the algorithm to compute the edit distance between caterpillars in $O(\lambda^2 h^2)$ time, where λ and h are the maximum number of leaves and the maximum height in two caterpillars, respectively. Furthermore, we point out that the structural restriction of caterpillars provides the limitation of tractable computing of the edit distance for unordered trees.

II. Caterpillars and Edit Distance

A *tree* T is a connected graph (V, E) without cycles, where V is the set of vertices and E is the set of edges. We denote V and E by $V(T)$ and $E(T)$. The *size* of T is $|V|$ and denoted by $|T|$. We sometime denote $v \in V(T)$ by $v \in T$. We denote an empty tree $(\emptyset, \emptyset)$ by $\emptyset$. A *rooted tree* is a tree with one

node r chosen as its *root*. We denote the root of a rooted tree T by $r(T)$.

Let T be a rooted tree such that $r = r(T)$ and $u, v, w \in T$. We denote the unique path from r to v, that is, the tree (V', E') such that $V' = \{v_1, \ldots, v_k\}$, $v_1 = r$, $v_k = v$ and $(v_i, v_{i+1}) \in E'$ for every i $(1 \leq i \leq k-1)$, by $UP_r(v)$. The *parent* of $v(\neq r)$, which we denote by $par(v)$, is its adjacent node on $UP_r(v)$ and the *ancestors* of $v(\neq r)$ are the nodes on $UP_r(v) - \{v\}$. We say that u is a *child* of v if v is the parent of u and u is a *descendant* of v if v is an ancestor of u. We call a node with no children a *leaf* and denote the set of all the leaves in T by $lv(T)$.

The *degree* of v, denoted by $d(v)$, is the number of children of v, and the *degree* of T, denoted by $d(T)$, is $\max\{d(v) \mid v \in T\}$. The *height* of v, denoted by $h(v)$, is $\max\{|UP_v(w)| \mid w \in lv(T[v])\}$, and the *height* of T, denoted by $h(T)$, is $\max\{h(v) \mid v \in T\}$.

We use the ancestor orders $<$ and $\leq$, that is, $u < v$ if v is an ancestor of u and $u \leq v$ if $u < v$ or $u = v$. We say that w is the *least common ancestor* of u and v, denoted by $u \sqcup v$, if $u \leq w$, $v \leq w$ and there exists no node $w' \in T$ such that $w' \leq w$, $u \leq w'$ and $v \leq w'$.

Let T be a rooted tree (V, E) and v a node in T. A *complete subtree of T at v*, denoted by $T[v]$, is a rooted tree $T' = (V', E')$ such that $r(T') = v$, $V' = \{u \in V \mid u \leq v\}$ and $E' = \{(u, w) \in E \mid u, w \in V'\}$.

We say that u is *to the left of* v in T if $pre(u) \leq pre(v)$ for the preorder number *pre* in T and $post(u) \leq post(v)$ for the postorder number *post* in T. We say that a rooted tree is *ordered* if a left-to-right order among siblings is given; *unordered* otherwise. We say that a rooted tree is *labeled* if each node is assigned a symbol from a fixed finite alphabet Σ. For a node v, we denote the label of v by $l(v)$, and sometimes identify v with $l(v)$. In this paper, we call a rooted labeled unordered tree a *tree* simply. Furthermore, we call a set of trees a *forest*.

As the restricted form of trees, we introduce a *rooted labeled caterpillar* (*caterpillar*, for short) as follows, which this paper mainly deals with.

Definition 1 (Caterpillar (cf., [3])): We say that a tree is a *caterpillar* if it is transformed to a path after removing all the leaves in it. For a caterpillar C, we call the remained path a *backbone* of C and denote it by $bb(C)$.

Next, we introduce an *edit distance* and a *Tai mapping*.

Definition 2 (Edit operations [9]): The *edit operations* of a tree T are defined as follows, see Figure 1.

1) *Substitution*: Change the label of the node v in T.
2) *Deletion*: Delete a node v in T with parent v', making the children of v become the children of v'. The children are inserted in the place of v as a subset of the children of v'. In particular, if v is the root in T, then the result applying the deletion is a forest consisting of the children of the root.
3) *Insertion*: The complement of deletion. Insert a node v as a child of v' in T making v the parent of a subset of the children of v'.

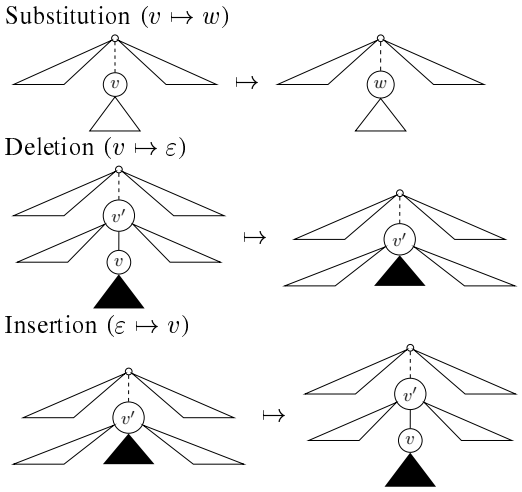

Fig. 1. Edit operations for trees.

Let $\varepsilon \notin \Sigma$ denote a special *blank* symbol and define $\Sigma_\varepsilon = \Sigma \cup \{\varepsilon\}$. Then, we represent each edit operation by $(l_1 \mapsto l_2)$, where $(l_1, l_2) \in (\Sigma_\varepsilon \times \Sigma_\varepsilon - \{(\varepsilon, \varepsilon)\})$. The operation is a substitution if $l_1 \neq \varepsilon$ and $l_2 \neq \varepsilon$, a deletion if $l_2 = \varepsilon$, and an insertion if $l_1 = \varepsilon$. For nodes v and w, we also denote $(l(v) \mapsto l(w))$ by $(v \mapsto w)$. We define a *cost function* $\gamma : (\Sigma_\varepsilon \times \Sigma_\varepsilon \setminus \{(\varepsilon, \varepsilon)\}) \mapsto \mathbf{R}^+$ on pairs of labels. We often constrain a cost function γ to be a *metric*, that is, $\gamma(l_1, l_2) \geq 0$, $\gamma(l_1, l_2) = 0$ iff $l_1 = l_2$, $\gamma(l_1, l_2) = \gamma(l_2, l_1)$ and $\gamma(l_1, l_3) \leq \gamma(l_1, l_2) + \gamma(l_2, l_3)$. In particular, we call the cost function that $\gamma(l_1, l_2) = 1$ if $l_1 \neq l_2$ a *unit cost function*.

Definition 3 (Edit distance [9]): For a cost function γ, the *cost* of an edit operation $e = l_1 \mapsto l_2$ is given by $\gamma(e) = \gamma(l_1, l_2)$. The *cost* of a sequence $E = e_1, \ldots, e_k$ of edit operations is given by $\gamma(E) = \sum_{i=1}^{k} \gamma(e_i)$. Then, an *edit distance* $\tau_{\text{TAI}}(T_1, T_2)$ between trees T_1 and T_2 is defined as follows:

$$\tau_{\text{TAI}}(T_1, T_2) = \min \left\{ \gamma(E) \;\middle|\; \begin{array}{l} E \text{ is a sequence} \\ \text{of edit operations} \\ \text{transforming } T_1 \text{ to } T_2 \end{array} \right\}.$$

Definition 4 (Tai mapping [9]): Let T_1 and T_2 be trees. We say that a triple (M, T_1, T_2) is a *Tai mapping* (a *mapping*, for short) from T_1 to T_2 if $M \subseteq V(T_1) \times V(T_2)$ and every pair (v_1, w_1) and (v_2, w_2) in M satisfies the following conditions.

1) $v_1 = v_2$ iff $w_1 = w_2$ (one-to-one condition).
2) $v_1 \leq v_2$ iff $w_1 \leq w_2$ (ancestor condition).

We will use M instead of (M, T_1, T_2) when there is no confusion denote it by $M \in \mathcal{M}_{\text{TAI}}(T_1, T_2)$.

Let M be a mapping from T_1 to T_2. Let I_M and J_M be the sets of nodes in T_1 and T_2 but not in M, that is, $I_M = \{v \in T_1 \mid (v, w) \notin M\}$ and $J_M = \{w \in T_2 \mid (v, w) \notin M\}$. Then, the *cost* $\gamma(M)$ of M is given as follows.

$$\gamma(M) = \sum_{(v,w) \in M} \gamma(v, w) + \sum_{v \in I_M} \gamma(v, \varepsilon) + \sum_{w \in J_M} \gamma(\varepsilon, w).$$

Trees T_1 and T_2 are *isomorphic*, denoted by $T_1 \equiv T_2$, if there exists a mapping $M \in \mathcal{M}_{\text{TAI}}(T_1, T_2)$ such that $I_M =$

$J_M = \emptyset$ and $\gamma(M) = 0$.

Theorem 1 (Tai [9]): $\tau_{\mathrm{TAI}}(T_1, T_2) = \min\{\gamma(M) \mid M \in \mathcal{M}_{\mathrm{TAI}}(T_1, T_2)\}$.

Unfortunately, the following theorem is known for the problem of computing τ_{TAI}.

Theorem 2 ([1], [4], [13]): Let T_1 and T_2 be trees. Then, the problem of computing $\tau_{\mathrm{TAI}}(T_1, T_2)$ is MAX SNP-hard. This statement also holds even if both T_1 and T_2 are binary or the maximum height of T_1 and T_2 is at most 3.

Finally, we introduce an *isolated-subtree mapping* and an *isolated-subtree distance* as the variations of the Tai mapping and the edit distance.

Definition 5 (Isolated-subtree mapping and distance [12]): Let T_1 and T_2 be trees and $M \in \mathcal{M}_{\mathrm{TAI}}(T_1, T_2)$. We say that M is an *isolated-subtree mapping*, denoted by $M \in \mathcal{M}_{\mathrm{ILST}}(T_1, T_2)$, if M satisfies the following condition for every $(v_1, w_1), (v_2, w_2), (v_3, w_3) \in M$:

$$v_3 < v_1 \sqcup v_2 \iff w_3 < w_1 \sqcup w_2.$$

Furthermore, we define an *isolated-subtree distance* $\tau_{\mathrm{ILST}}(T_1, T_2)$ as follow.

$$\tau_{\mathrm{ILST}}(T_1, T_2) = \min\{\gamma(M) \mid M \in \mathcal{M}_{\mathrm{ILST}}(T_1, T_2)\}.$$

It is obvious that $\mathcal{M}_{\mathrm{ILST}}(T_1, T_2) \subseteq \mathcal{M}_{\mathrm{TAI}}(T_1, T_2)$ and then $\tau_{\mathrm{TAI}}(T_1, T_2) \leq \tau_{\mathrm{ILST}}(T_1, T_2)$. In contrast to Theorem 2, the following theorem also holds.

Theorem 3 (cf., [10]): Let T_1 and T_2 be trees. Then, we can compute $\tau_{\mathrm{ILST}}(T_1, T_2)$ in $O(n^2 d)$ time, where $n = \max\{|T_1|, |T_2|\}$ and $d = \min\{d(T_1), d(T_2)\}$.

It is known that τ_{ILST} is the most general tractable variation of τ_{TAI} [11].

Example 1: Consider two caterpillars C_1 and C_2 illustrated in Figure 2. Then, M illustrated in Figure 2 is the optimum mapping between C_1 and C_2. Here, it holds that $M \notin \mathcal{M}_{\mathrm{ILST}}(C_1, C_2)$ and M is an alignable mapping corresponding to an alignment distance [7], [11]. Note that the problem of computing an alignment distance is MAX SNP-hard in general [5].

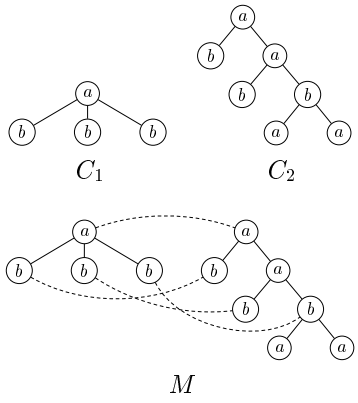

Fig. 2. Two caterpillars C_1 and C_2 and their optimum mapping M in Example 1.

Example 1 shows that there exists the minimum cost mapping between caterpillars which is not an isolated-subtree mapping. On the other hand, it remains open whether or not Theorem 2 holds for caterpillars.

Hence, in the next section, we discuss the problem of computing the edit distance between caterpillars and will solve this problem affirmatively.

III. Computing Edit Distance between Caterpillars

Example 1 also shows that we cannot apply the algorithm to compute τ_{ILST} and its variations [10], [11], [12], [14], which is based on the maximum cost maximum flow algorithm or the maximum weighted bipartite matching algorithm. On the other hand, by using the structural property of caterpillars, in this section, we design the algorithm to compute the edit distance between caterpillars.

Since every forest occurring in a caterpillar C is either obtained by deleting the path from the root to some internal node in $bb(C)$ or the complete subtree of $bb(C)$, a caterpillar C is one of the forms of $\{C\}$, $\{l_1, \ldots, l_k\}$ and $\{l_1, \ldots, l_k, C\}$, where l_i $(1 \leq i \leq k)$ is a leaf and C is a non-leaf caterpillar. By letting $L = \{l_1, \ldots, l_k\}$ and using a list representation of Prolog (*cf.*, [8]). we denote the above forests by $\langle \emptyset \,|\, C \rangle$, $\langle L \,|\, \emptyset \rangle$ and $\langle L \,|\, C \rangle$, respectively. In particular, we denote an empty forest $\langle \emptyset \,|\, \emptyset \rangle$ by Φ simply.

Let $C[v]$ be a caterpillar with the root v, where $L(v)$ denotes a (possibly empty) set of leaves as the children of v and $B(v)$ denotes at most one caterpillar of the child v. Then, $C[v]$ is one of the forms in Figure 3. Furthermore, by deleting v from $C[v]$, we obtain one of the forests of $\langle \emptyset \,|\, B(v) \rangle$, $\langle L(v) \,|\, \emptyset \rangle$ and $\langle L(v) \,|\, B(v) \rangle$, respectively.

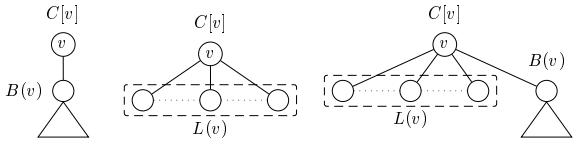

Fig. 3. The representation of a caterpillar $C[v]$.

Figure 4 illustrates the recurrences of computing the edit distance $\tau_{\mathrm{TAI}}(C_1[v], C_2[w])$ between two caterpillars $C_1[v]$ and $C_2[w]$, as $\delta_{\mathrm{TAI}}(\langle \emptyset \mid C_1[v] \rangle, \langle \emptyset \mid C_2[w] \rangle)$. Here, we denote the string representation of the set L of leaves under the alphabetical order on Σ by $s(L)$ and the string edit distance between two strings s_1 and s_2 [2] by $\sigma(s_1, s_2)$.

Theorem 4: The recurrences in Figure 4 are correct to compute the edit distance $\tau_{\mathrm{TAI}}(C_1[v], C_2[w])$ between $C_1[v]$ and $C_2[w]$ as $\delta_{\mathrm{TAI}}(\langle \emptyset \,|\, C_1[v] \rangle, \langle \emptyset \,|\, C_2[w] \rangle)$.

Proof: It is obvious that the recurrences in (A) compute the edit distance when at least one forest is empty and the recurrence in (B) computes the edit distance between two forests such that both of them consist of just leaves.

For the recurrence (C), let M be the minimum cost mapping between $\langle L_1 \mid \emptyset \rangle$ and $\langle L_2 \mid C_2[w] \rangle$. By focusing on w, M contains a pair of either (ε, w) or (v, w) for some $v \in L_1$. See Figure 5.

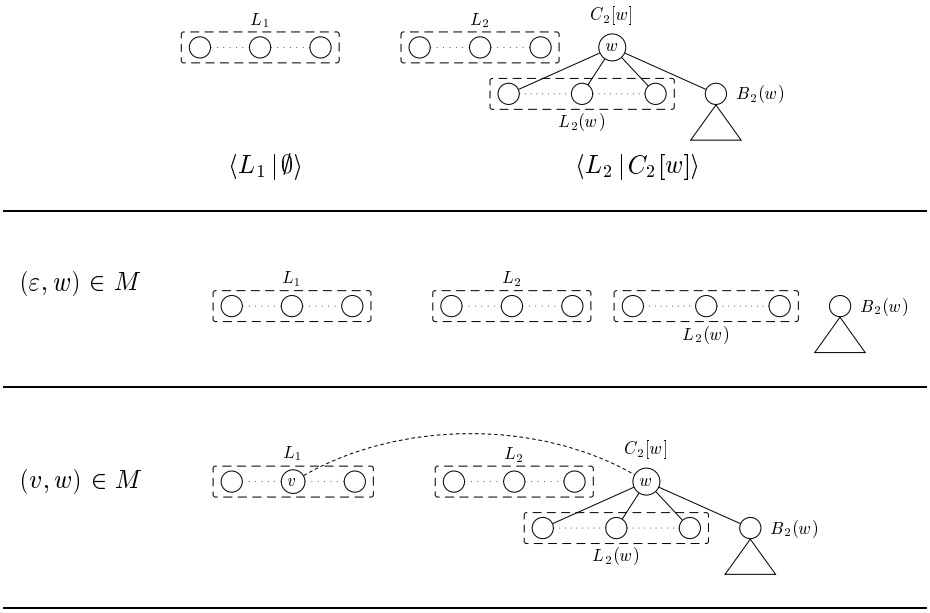

Fig. 5. $\langle L_1 \,|\, \emptyset \rangle$, $\langle L_2 \,|\, C_2[w] \rangle$ and the cases that $(\varepsilon, w) \in M$ and $(v, w) \in M$.

(A) $\delta_{\text{TAI}}(\langle L_1 \,|\, C_1 \rangle, \Phi) = \sum_{v \in L_1} \gamma(v, \varepsilon) + \sum_{v \in C_1} \gamma(v, \varepsilon)$.

$\delta_{\text{TAI}}(\Phi, \langle L_2 \,|\, C_2 \rangle) = \sum_{w \in L_2} \gamma(\varepsilon, w) + \sum_{w \in C_2} \gamma(\varepsilon, w)$.

(B) $\delta_{\text{TAI}}(\langle L_1 \,|\, \emptyset \rangle, \langle L_2 \,|\, \emptyset \rangle) = \sigma(s(L_1), s(L_2))$.

(C) $\delta_{\text{TAI}}(\langle L_1 \,|\, \emptyset \rangle, \langle L_2 \,|\, C_2[w] \rangle)$

$$= \min \left\{ \begin{array}{ll} \gamma(\varepsilon, w) & \\ \quad + \delta_{\text{TAI}}(\langle L_1 \,|\, \emptyset \rangle, \langle L_2 \cup L_2(w) \,|\, B_2(w) \rangle), & (1) \\ \min\limits_{v \in L_1} \{ \gamma(v, w) + \delta_{\text{TAI}}(\langle L_1 \setminus \{v\} \,|\, \emptyset \rangle, \langle L_2 \,|\, \emptyset \rangle) \} & \\ \quad + \delta_{\text{TAI}}(\Phi, \langle L_2(w) \,|\, B_2(w) \rangle) & (2) \end{array} \right\}.$$

(D) $\delta_{\text{TAI}}(\langle L_1 \,|\, C_1[v] \rangle, \langle L_2 \,|\, \emptyset \rangle)$

$$= \min \left\{ \begin{array}{ll} \gamma(v, \varepsilon) & \\ \quad + \delta_{\text{TAI}}(\langle L_1 \cup L_1(v) \,|\, B_1(v) \rangle, \langle L_2 \,|\, \emptyset \rangle), & (3) \\ \min\limits_{w \in L_2} \{ \gamma(v, w) + \delta_{\text{TAI}}(\langle L_1 \,|\, \emptyset \rangle, \langle L_2 \setminus \{w\} \,|\, \emptyset \rangle) \} & \\ \quad + \delta_{\text{TAI}}(\langle L_1(v) \,|\, B_1(v) \rangle, \Phi) & (4) \end{array} \right\}.$$

(E) $\delta_{\text{TAI}}(\langle L_1 \,|\, C_1[v] \rangle, \langle L_2 \,|\, C_2[w] \rangle)$

$$= \min \left\{ \begin{array}{ll} \gamma(v, w) + \delta_{\text{TAI}}(\langle L_1 \,|\, \emptyset \rangle, \langle L_2 \,|\, \emptyset \rangle) & \\ \quad + \delta_{\text{TAI}}(\langle L_1(v) \,|\, B_1(v) \rangle, \langle L_2(w) \,|\, B_2(w) \rangle), & (5) \\ \gamma(v, \varepsilon) & \\ \quad + \delta_{\text{TAI}}(\langle L_1 \cup L_1(v) \,|\, B_1(v) \rangle, \langle L_2 \,|\, C_2[w] \rangle), & (6) \\ \gamma(\varepsilon, w) & \\ \quad + \delta_{\text{TAI}}(\langle L_1 \,|\, C_1[v] \rangle, \langle L_2 \cup L_2(w) \,|\, B_2(w) \rangle) & (7) \end{array} \right\}.$$

Fig. 4. The recurrences of computing the edit distance $\tau_{\text{TAI}}(C_1[v], C_2[w])$ between $C_1[v]$ and $C_2[w]$ as $\delta_{\text{TAI}}(\langle \emptyset \,|\, C_1[v] \rangle, \langle \emptyset \,|\, C_2[w] \rangle)$.

If $(\varepsilon, w) \in M$, then M maps nodes in $\langle L_1 \mid \emptyset \rangle$ to those in $\langle L_2 \cup L_2(w) \mid B_2(w) \rangle$, which is computed by $\delta_{\text{TAI}}(\langle L_1 \mid \emptyset \rangle, \langle L_2 \cup L_2(w) \mid B_2(w) \rangle)$. Hence, the formula (1) computes the cost of M.

If $(v, w) \in M$ for some $v \in L_1$, then M maps nodes in $\langle L_1 \setminus \{v\} \mid \emptyset \rangle$ to those in $\langle L_2 \mid \emptyset \rangle$, which is computed by $\delta_{\text{TAI}}(\langle L_1 \setminus \{v\} \,|\, \emptyset \rangle, \langle L_2 \,|\, \emptyset \rangle)$. Since M is the minimum cost, it is necessary to minimize the value of $\gamma(v, \varepsilon) + \delta_{\text{TAI}}(\langle L_1 \setminus \{v\} \,|\, \emptyset \rangle, \langle L_2 \,|\, \emptyset \rangle)$ for $v \in L_1$. Furthermore, once M contains (v, w) for some $v \in L_1$, M touches no descendants of w, that is, no nodes in $\langle L_2(w) \mid B_2(w) \rangle$, which is computed by $\delta_{\text{TAI}}(\Phi, \langle L_2(w) \mid B_2(w) \rangle)$. Hence, the formula (2) computes the cost of M.

The recurrence (D) is correct as same as the recurrence (C).

For the recurrence (E), let M be the minimum cost mapping between $\langle L_1 \,|\, C_1[v] \rangle$ and $\langle L_2 \,|\, C_2[w] \rangle$. By focusing on v and w, M contains one of the pairs of (v, w), (v, ε) and (ε, w). See Figure 6.

If $(v, w) \in M$, then M maps no nodes in $\langle L_1 \,|\, \emptyset \rangle$ to nodes in $\langle L_1(v) \,|\, B_1(v) \rangle$ and no nodes in $\langle L_2 \,|\, \emptyset \rangle$ to nodes in $\langle L_2(w) \,|\, B_2(w) \rangle$. Then, M maps nodes in $\langle L_1 \,|\, \emptyset \rangle$ to those in $\langle L_2 \,|\, \emptyset \rangle$, which is computed by $\delta_{\text{TAI}}(\langle L_1 \,|\, \emptyset \rangle, \langle L_2 \,|\, \emptyset \rangle)$. Also M maps nodes in $\langle L_1(v) \,|\, B_1(v) \rangle$ to those in $\langle L_2(w) \,|\, B_2(w) \rangle$, which is computed by $\delta_{\text{TAI}}(\langle L_1(v) \mid B_1(v) \rangle, \langle L_2(w) \mid B_2(w) \rangle)$. Hence, the formula (5) computes the cost of M.

If $(v, \varepsilon) \in M$, then M maps nodes in $\langle L_1 \cup L_1(v) \,|\, B_1(v) \rangle$ to those in $\langle L_2 \,|\, C_2[w] \rangle$, which is computed by $\delta_{\text{TAI}}(\langle L_1 \cup L_1(v) \,|\, B_1(v) \rangle, \langle L_2 \mid C_2[w] \rangle)$. Hence, the formula (6) computes the cost of M.

If $(\varepsilon, w) \in M$, then M maps nodes in $\langle L_1 \mid C_1[v] \rangle$ to those in $\langle L_2 \cup L_2(w) \mid B_2(w) \rangle$, which is computed by $\delta_{\text{TAI}}(\langle L_1 \,|\, C_1[v] \rangle, \langle L_2 \cup L_2(w) \,|\, B_2(w) \rangle)$. Hence, the formula (7) computes the cost of M. ■

Example 2: Consider two caterpillars C_1 and C_2 in Figure 2 in Example 1. By applying the recurrences in Figure 4, we obtain that the edit distance $\tau_{\text{TAI}}(C_1, C_2)$ between C_1 and C_2 is 3 as follows. Here, we represent a caterpillar as a term-like representation, that is, $C_1 = a(b, b, b)$ and

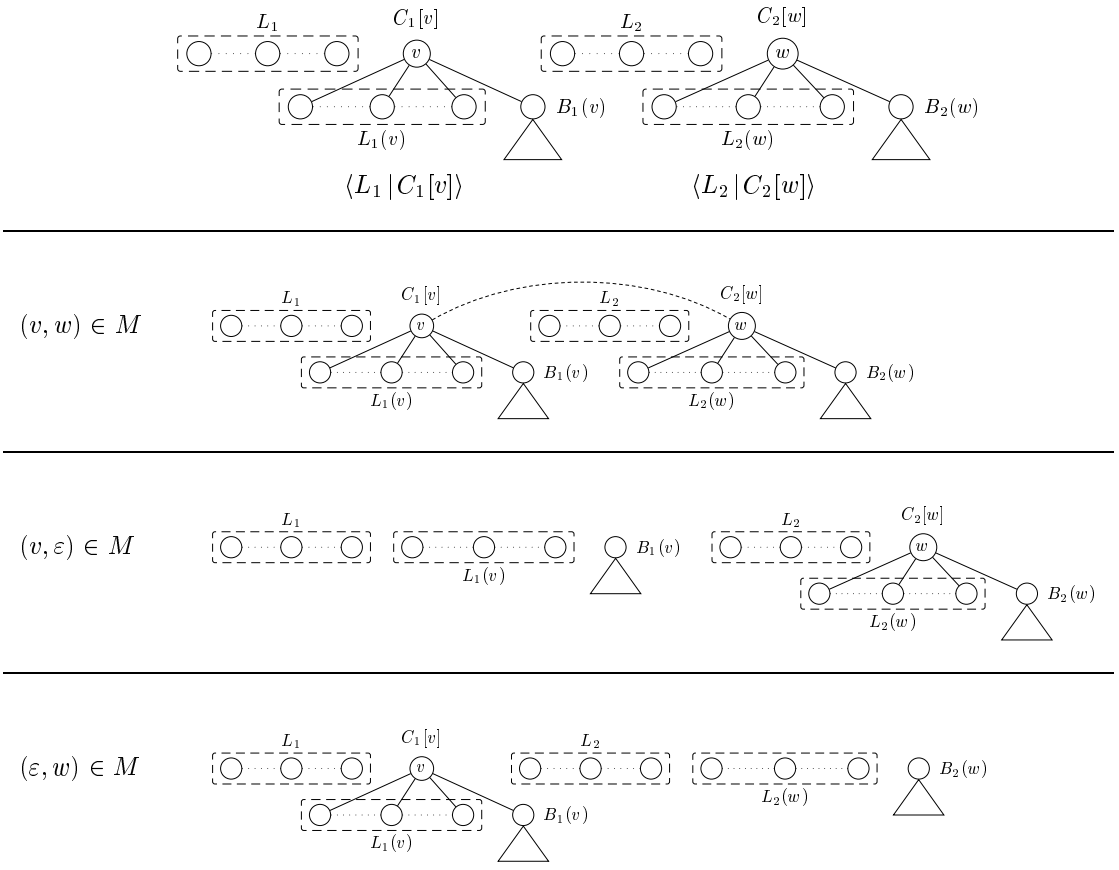

Fig. 6. $\langle L_1 \,|\, C_1[v] \rangle$, $\langle L_2 \,|\, C_2[w] \rangle$ and the cases that $(v, w) \in M$, $(v, \varepsilon) \in M$ and $(\varepsilon, w) \in M$.

$C_2 = a(b, a(b, b(a, a)))$.

$$
\begin{aligned}
& \tau_{\mathrm{TAI}}(C_1, C_2) \\
= \; & \delta_{\mathrm{TAI}}(\langle \emptyset \,|\, a(b,b,b) \rangle, \langle \emptyset \,|\, a(b, a(b, b(a, a))) \rangle) \\
= \; & \underbrace{\gamma(a,a)}_{=0} + \delta_{\mathrm{TAI}}(\langle \{b,b,b\} \,|\, \emptyset \rangle, \langle \{b\} \,|\, a(b, b(a,a)) \rangle) && \text{(E)(7)} \\
= \; & \underbrace{\gamma(\varepsilon,a)}_{=1} + \delta_{\mathrm{TAI}}(\langle \{b,b,b\} \,|\, \emptyset \rangle, \langle \{b,b\} \,|\, b(a,a) \rangle) && \text{(C)(2)} \\
= \; & 1 + \underbrace{\gamma(b,b)}_{=0} + \delta_{\mathrm{TAI}}(\langle \{b,b\} \,|\, \emptyset \rangle, \langle \{b,b\} \,|\, \emptyset \rangle) \\
& + \delta_{\mathrm{TAI}}(\Phi, \langle \{a,a\} \,|\, \emptyset \rangle\}) && \text{(C)(1)} \\
= \; & 1 + \underbrace{\sigma(bb,bb)}_{=0} + \underbrace{\gamma(\varepsilon,a)}_{=1} + \underbrace{\gamma(\varepsilon,a)}_{=1} && \text{(A),(B)} \\
= \; & 3.
\end{aligned}
$$

Hence, we can obtain the optimum mapping M between C_1 and C_2 illustrated in Figure 2, by collecting the pairs $(l_1, l_2) \in C_1 \times C_2$ such that $l_1 \neq \varepsilon$ and $l_2 \neq \varepsilon$ in $\gamma(l_1, l_2)$.

Let $C_1[v]$ and $C_2[w]$ be caterpillars. Then, we denote $bb(C_1[v])$ by a sequence $v_1, \ldots, v_n$ such that $v_n = v$ and $par(v_i) = v_{i+1}$ $(1 \leq i \leq n-1)$ and $bb(C_2[w])$ by a sequence $w_1, \ldots, w_m$ such that $w_m = w$ and $par(w_j) = w_{j+1}$ $(1 \leq j \leq m-1)$. In this case, we denote by $bb(C_1[v]) = [v_1, \ldots, v_n]$ and $bb(C_2[w]) = [w_1, \ldots, w_m]$. Also we use the same notations of $L_1(v_i)$ and $B_1(v_i)$ for $1 \leq i \leq n$ and $L_2(w_j)$ and $B_2(w_j)$ for $1 \leq j \leq m$.

Based on the recurrences in Figure 4, Algorithm 1 illustrates the algorithm to compute the edit distance $\tau_{\mathrm{TAI}}(C_1, C_2)$ between caterpillars C_1 and C_2. Here, the recurrence (A), (B), (C), (D) and (E) are corresponding to the lines 6 and 12, the line 3, the line 9, the line 15 and the line 19, respectively, in Algorithm 1.

Theorem 5: Let C_1 and C_2 be caterpillars. Then, we can compute the edit distance $\tau_{\mathrm{TAI}}(C_1, C_2)$ between C_1 and C_2 in $O(\lambda^2 h^2)$ time, where $\lambda = \max\{|lv(C_1)|, |lv(C_2)|\}$ and $h = \max\{h(C_1), h(C_2)\}$.

Proof: Let $bb(C_1) = [v_1, \ldots, v_n]$ and $bb(C_2) = [w_1, \ldots, w_m]$. Then, it is obvious that $h(C_1) = n + 1$ and $h(C_2) = m + 1$, so it holds that $m \leq h - 1$ and $n \leq h - 1$.

The algorithm $\tau_{\mathrm{TAI}}(C_1, C_2)$ in Algorithm 1 calls every pair $(v_i, w_j) \in bb(C_1) \times bb(C_2)$ just once. When computing $\delta_{\mathrm{TAI}}(\langle L_1(v_{i-1}) \,|\, C_1[v_i] \rangle, \langle L_2(w_{j-1}) \,|\, C_2[w_j] \rangle)$ for $2 \leq i \leq n$ and $2 \leq j \leq m$, it is necessary to construct the string representations $s_1 = s(L_1(v_1) \cup \cdots \cup L_1(v_{i-1}))$ and $s_2 = s(L_2(w_1) \cup \cdots \cup L_2(w_{j-1}))$ and compute the string edit

Algorithm 1: $\tau_{\text{TAI}}(C_1, C_2)$

distance $\sigma(s_1, s_2)$. The running time to construct the string representations is $O(\lambda \log \lambda)$ time (as same as that of sorting) and to compute the string edit distance is $O(\lambda^2)$ time [2].

Hence, the total running time of Algorithm 1 is described as follows:

$$\sum_{i=1}^{n}\sum_{j=1}^{m}(2O(\lambda \log \lambda) + O(\lambda^2)) = O(\lambda^2)mn$$
$$\leq O(\lambda^2)(h-1)^2 = O(\lambda^2 h^2).$$

■

Theorem 5 also claims that the structural restriction of caterpillars provides the limitation of tractable computing the edit distance for unordered trees. We say that a tree is a *generalized caterpillar* if it is transformed to a caterpillar after removing all the leaves in it. Then, the following theorem also holds as corollaries in the proof of [1] or [4].

Theorem 6 (cf., [1], [4]): The problem of computing the edit distance between generalized caterpillars is MAX SNP-hard, even if the maximum height is at most 3.

Proof: It is straightforward from the proof of Corollary 4.3 in [1] or Theorem 1 in [4]. ■

Finally, Table I illustrates the number of pairs (C_1, C_2) of caterpillars such that $\tau_{\text{TAI}}(C_1, C_2) < \tau_{\text{ILST}}(C_1, C_2)$ and $\tau_{\text{TAI}}(C_1, C_2) = \tau_{\text{ILST}}(C_1, C_2)$, respectively, for all the pairs of 514 caterpillars in N-glycans (in Table II,

TABLE I
THE NUMBER OF PAIRS OF CATERPILLARS IN N-GLYCANS SUCH THAT $\tau_{\text{TAI}}(C_1, C_2) < \tau_{\text{ILST}}(C_1, C_2)$ AND $\tau_{\text{TAI}}(C_1, C_2) = \tau_{\text{ILST}}(C_1, C_2)$.

$\tau_{\text{TAI}} < \tau_{\text{ILST}}$		$\tau_{\text{TAI}} = \tau_{\text{ILST}}$	total
$\tau_{\text{ILST}} - \tau_{\text{TAI}} = 2$	$\tau_{\text{ILST}} - \tau_{\text{TAI}} = 1$		
5	1,218	130,618	131,841

Concerned with the 5 pairs in Table I, Figure 7 illustrates the caterpillars C_1 = G04187, C_2 = G00698, C_3 = G00933, C_4 = G01221, C_5 = G01454 and C_6 = G11051 in N-glycans such that $\tau_{\text{ILST}}(C_1, C_i) - \tau_{\text{TAI}}(C_1, C_i) = 2$ for $2 \leq i \leq 6$.

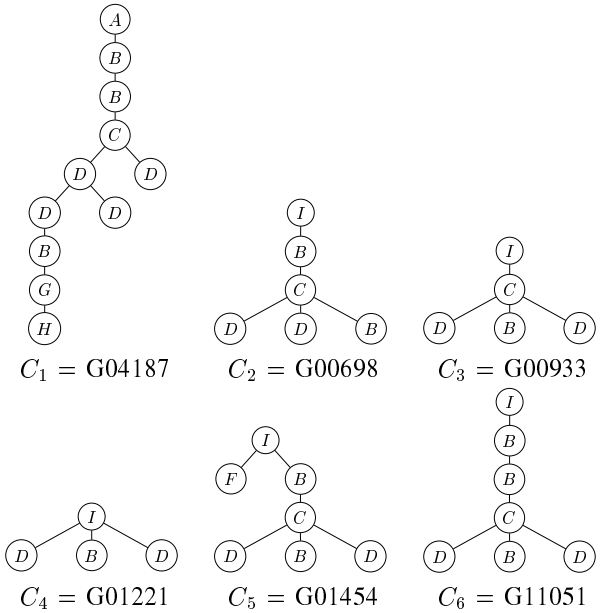

Fig. 7. The caterpillars C_1 = G04187, C_2 = G00698, C_3 = G00933, C_4 = G01221, C_5 = G01454 and C_6 = G11051.

Here, the following statements hold:

$$\tau_{\text{TAI}}(C_1, C_2) = 6,\ \tau_{\text{ILST}}(C_1, C_2) = 8,$$
$$\tau_{\text{TAI}}(C_1, C_3) = 7,\ \tau_{\text{ILST}}(C_1, C_3) = 9,$$
$$\tau_{\text{TAI}}(C_1, C_4) = 8,\ \tau_{\text{ILST}}(C_1, C_4) = 10,$$
$$\tau_{\text{TAI}}(C_1, C_5) = 7,\ \tau_{\text{ILST}}(C_1, C_5) = 9,$$
$$\tau_{\text{TAI}}(C_1, C_6) = 4,\ \tau_{\text{ILST}}(C_1, C_6) = 6.$$

Figure 8 illustrates the optimum mappings $M_1 \in \mathcal{M}_{\text{TAI}}(C_1, C_2)$ and $M_2 \in \mathcal{M}_{\text{ILST}}(C_1, C_2)$ for caterpillars C_1 and C_2 in Figure 7, which is the reason that $\tau_{\text{TAI}}(C_1, C_2) = 6$ (5 deleted nodes and 1 substituted node) and $\tau_{\text{ILST}}(C_1, C_2) = 8$ (6 deleted nodes, 1 inserted node and 1 substituted node).

IV. CONCLUSION AND FUTURE WORKS

In this paper, we have designed the algorithm to compute the edit distance between caterpillars in $O(\lambda^2 h^2)$ time, which

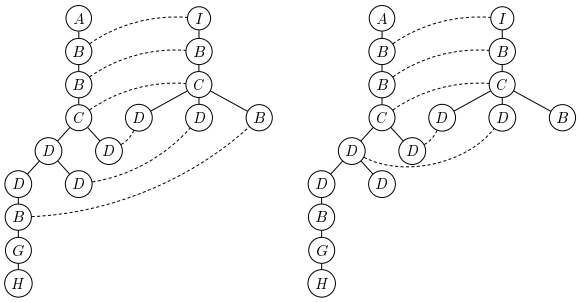

Fig. 8. The optimum mappings $M_1 \in \mathcal{M}_{\mathrm{TAI}}(C_1, C_2)$ and $M_2 \in \mathcal{M}_{\mathrm{ILST}}(C_1, C_2)$ for caterpillars C_1 and C_2 in Figure 7.

is the limitation of tractable computing the edit distance for unordered trees.

Whereas we have given a small experimental result in the last of Section III, it is necessary to implement Algorithm 1 more efficiently. Then, it is a future work to evaluate running time from all the data of caterpillars in Appendix by comparing that of the algorithm of computing τ_{ILST} [10], [11], [12] and to investigate the difference between τ_{TAI} and τ_{ILST}. Also, it is a future work to analyze the correlation for caterpillars in real data between the edit distance and the complete subtree histogram distance [1] or the path histogram distance [6].

Concerned with Theorem 6, it is a future work to give the strict limitation of tractable computing of the edit distance. In other words, it is a future work to investigate whether or not the problem of computing the edit distance between a caterpillar and a generalized caterpillar or a standard tree is tractable. In particular, concerned with D^- for $D \in \{\text{Auction, University, Protein, Nasa}\}$ in Table II in Appendix, it is a future work to investigate whether or not the problem of computing the edit distance between forests of caterpillars is tractable.

As the extension of the edit distance for rooted trees to that for unrooted trees, Zhang *et al.* [14] have extend the degree-2 distance for rooted trees to that for unrooted trees. In their algorithm, first we select a pair of nodes in unrooted trees, compute the degree-2 distance between the rooted trees whose pair of the roots is the selected pair and then select the minimum value of the distances as the degree-2 distance. It is a future work to investigate whether or not we can apply this idea to the problem of computing the edit distance between unrooted caterpillars and, if so, design the algorithm to compute it.

Appendix: Caterpillars in Real Data

In this appendix, we point out how large the number of caterpillars in real data. Table II illustrates the number of caterpillars in N-glycans and all glycans from KEGG[1], CSLOGS[2], dblp[3], and SwissProt, TPC-H, Auction, University, Protein and Nasa from UW XML Repository[4].

TABLE II
The number of caterpillars in N-glycans and all glycans from KEGG, CSLOGS, dblp, SwissProt, TPC-H, Auction, University, Protein and NASA.

dataset	#cat	#data	%
N-glycans	514	2,142	23.996
all glycans	8,005	10,704	74.785
CSLOGS	41,592	59,691	69.679
dblp	5,154,295	5,154,530	99.995
SwissProt	6,804	50,000	13.608
TPC-H	86,805	86,805	100.000
Auction	0	37	0
University	0	6,738	0
Protein	0	262,625	0
Nasa	0	2,430	0
Auction$^-$	259	259	100.000
University$^-$	74,638	79,213	94.224
Protein$^-$	1,874,703	2,204,068	85.057
Nasa$^-$	21,245	27,921	76.089

Here, #cat is the number of caterpillars and #data is the total number of data. Furthermore, for $D \in \{\text{Auction, University, Protein, Nasa}\}$, D^- denotes the trees obtained by deleting the root for every tree in D. Since one tree in D produces some trees in D^-, the total number of trees in D^- is greater than that of D.

***Abstract*—A new Monte Carlo algorithm for solving systems of Linear Algebraic (LA) equations is presented and studied. The algorithm is based on the "Walk on Equations" Monte Carlo method recently developed by Ivan Dimov, Sylvain Maire and Jean Michel Sellier [4]. The algorithm is optimized by choosing the appropriate values for the relaxation parameters which leads to dramatic reduction in time and lower relative errors for a given number of iterations. Numerical tests are performed for examples with matrices of different size and on a system coming from a finite element approximation of a problem describing a beam structure in constructive mechanics.**

I. Introduction

MANY scientific and engineering applications are based on the problems of solving systems of LA equations. For some applications it is also important to compute directly the inner product of a given vector and the solution vector of a LA system. In Monte Carlo numerical algorithms we construct a Markov process and prove that the mathematical expectation of the process is equal to the unknown solution of the problem [3]. Iterative Monte Carlo algorithms can be defined as terminated Markov chains:

$$T = \{\alpha_{t_0} \to \alpha_{t_1} \to \alpha_{t_2} \dots \alpha_{t_k}\}, \tag{1}$$

where α_{t_q}, $q = 1, \dots, i$ is one of the absorbing states. By A and B we denote matrices of size $n \times n$, i.e., $A, B \in I\!R^{n\times n}$. We use the following presentation of matrices:

$$A = \{a_{ij}\}_{i,j=1}^{n} = (a_1, \dots, a_i, \dots, a_n)^t,$$

where $a_i = (a_{i1}, \dots, a_{in})$, $i = 1, \dots, n$ and the symbol t means *transposition*. The following norms of vectors:

$$\| b \| = \| b \|_1 = \sum_{i=1}^{n} |b_i|, \quad \| a_i \| = \| a_i \|_1 = \sum_{j=1}^{n} |a_{ij}|$$

The first author is supported by the Bulgarian National Science Fund under Projects DN 12/5-2017 and DN 12/4-2017 and by the Bulgarian Academy of Sciences through the Program for Career Development of Young Scientists, Grant DFNP-17-88/28.07.2017.

and matrices

$$\| A \|_1 = \max_j \sum_{i=1}^{n} |a_{ij}|, \quad \| A \|_\infty = \max_i \sum_{j=1}^{n} |a_{ij}|$$

are used, where $b \in \mathbb{R}^n$.

We consider a system of LA equations

$$Bx = f, \tag{2}$$

where $B = \{b_{ij}\}_{i,j=1}^{n} \in I\!R^{n\times n}$ is a given matrix; $f = (f_1, \dots, f_n)^t \in I\!R^{n\times 1}$ and $v = (v_1, \dots, v_n) \in I\!R^{1\times n}$ are given vectors.

We deal with the matrix $A = \{a_{ij}\}_{ij=1}^{n}$, such that $A = I - DB$, where D is a diagonal matrix $D = \mathrm{diag}(d_1, \dots, d_n)$ and $d_i = \frac{\gamma}{b_{ii}}$, $i = 1, \dots, n$, and $\gamma \in (0, 1]$ is a parameter that can be used to accelerate the convergence. The system (2) can be presented in the form of equation

$$x = Ax + b, \tag{3}$$

where $b = Df$. Let us suppose that the matrix B is diagonally dominant. It easily follows that if B is a diagonally dominant matrix, then the elements of the matrix A must satisfy the following condition: $\sum_{j=1}^{n} |a_{ij}| \leq 1$, $i = 1, \dots, n$.

A *stationary linear iterative algorithm* [3] can be used:

$$x_k = Ax_{k-1} + b, \quad k = 1, 2, \dots \tag{4}$$

and the solution x can be presented in a form of a Neumann series

$$x = \sum_{k=0}^{\infty} A^k b = b + Ab + A^2 b + A^3 b + \dots \tag{5}$$

The *stationary linear iterative Monte Carlo algorithm* is based on (5). As a result, the convergence of the Monte Carlo algorithm depends on the truncation error of the series (4) [3]. We are interested to evaluate the linear form $W(x)$ of the solution x of the system (3), i.e., $W(x) \equiv (w, x) = \sum_{i=1}^{n} w_i x_i$,

where $w \in I\!R^{n\times 1}$. We shall define a random variable $X[w]$, which expectation is equal to the above defined linear form, i.e., $EX[w] = W(x)$ using a discrete Markov process with a finite set of states. Then the problem is to determine repeated realizations of $X[w]$ and of connecting them into a proper statistical estimator of $W(x)$.

Consider an initial density vector $p = \{p_i\}_{i=1}^n \in I\!R^n$, such that $p_i \geq 0, i = 1, \ldots, n$ and $\sum_{i=1}^n p_i = 1$. Consider also a transition density matrix $P = \{p_{ij}\}_{i,j=1}^n \in I\!R^{n\times n}$, such that $p_{ij} \geq 0,\ i, j = 1, \ldots, n$ and $\sum_{j=1}^n p_{ij} = 1$, for any $i = 1, \ldots, n$.

We will be dealing with *permissible* densities [3] $\mathcal{P}_b$ and $\mathcal{P}_A$. It follows easily that in such a way the random trajectories constructed to solve the problems under consideration never visit zero elements of the matrix. Such an approach decreases the computational complexity of the algorithms [2]. It is also very convenient when large sparse matrices are used.

II. Probabilistic representation of the algorithm

Consider a real linear system of the form $x = Ax + b$ where the matrix A of size n is such that the convergence radius $\varrho(A) < 1$, its coefficients a_{ij} are real numbers and

$$\sum_{j=1}^{n} |a_{ij}| \leq 1, \forall 1 \leq i \leq n.$$

We now define a Markov chain T_k with $n + 1$ states $\alpha_1, \ldots, \alpha_n, \alpha_{n+1}$, such that

$$P(\alpha_{k+1} = j | \alpha_k = i) = |a_{ij}|$$

if $i \neq n + 1$ and

$$P(\alpha_{k+1} = n + 1 | \alpha_k = n + 1) = 1.$$

We also define a vector c such that $c(i) = b(i)$ if $1 \leq i \leq n$ and $c(n + 1) = 0$. Denote by $\tau = (\alpha_0, \alpha_1, \ldots, \alpha_k, \alpha_{n+1})$ a random trajectory that starts at the initial state $\alpha_0 < n + 1$ and passes through $(\alpha_1, \ldots, \alpha_k)$ until the absorbing state $\alpha_{k+1} = n + 1$. The probability to follow the trajectory τ is $P(\tau) = p_{\alpha_0} p_{\alpha_0\alpha_1} \ldots p_{\alpha_{k-1}\alpha_k} p_{\alpha_k}$. We use the MAO algorithm (see [1], [5]) for the initial density vector $p = \{p_\alpha\}_{\alpha=1}^n$ and for the transition density matrix $P = \{p_{\alpha\beta}\}_{\alpha,\beta=1}^n$, as well. The weights Q_α are defined:

$$Q_m = Q_{m-1} \frac{a_{\alpha_{m-1},\alpha_m}}{p_{\alpha_{m-1},\alpha_m}}, \quad m = 1, \ldots, k, \quad Q_0 = \frac{c_{\alpha_0}}{p_{\alpha_0}}. \quad (6)$$

The estimator $X_\alpha(\tau)$ can be presented as $X_\alpha(\tau) = c_\alpha + Q_k \frac{a_{\alpha_k\alpha}}{p_{\alpha_k}}, \quad \alpha = 1, \ldots n$ taken with a probability $P(\tau) = p_{\alpha_0} p_{\alpha_0\alpha_1}, \ldots p_{\alpha_{k-1,k}\alpha_k} p_{\alpha_k}$.

For the convergence of the process we use that the random variable $X_\alpha(\tau)$ is an unbiased estimator of x_α [4], i.e.

$$E\{X_\alpha(\tau)\} = x_\alpha. \quad (7)$$

Consider the variance of the random variable $X_\alpha(\tau)$ for evaluation the linear form for the solution $W(x)$. We use the following notations: $\overline{A} = \{|a_{ij}|\}_{i,j=1}^n$, $\widehat{c} = \{c_i^2\}_{i=1}^{n+1}$. The special choice of the probability densities leads to the Markov chain:

$$c_{\alpha_0} \to a_{\alpha_0\alpha_1} \to \ldots \to a_{\alpha_{k-1}\alpha_k}. \quad (8)$$

For this finite chain we have that

$$A_c^k = c_{\alpha_0} \prod_{s=1}^{k} a_{\alpha_{s-1}\alpha_s}, \quad (9)$$

where $c \in I\!R^{n\times 1}$ and $c(i) = b(i)$ if $1 \leq i \leq n$ and $c(n+1) = 0$. The variance of the random variable $X_\alpha^k(\tau)$ is defined as [4]

$$X_\alpha^k(\tau) = \frac{c_{\alpha_0}}{p_{\alpha_0}} \frac{a_{\alpha_0\alpha_1}}{p_{\alpha_0\alpha_1}} \frac{a_{\alpha_1\alpha_2}}{p_{\alpha_1\alpha_2}} \ldots \frac{a_{\alpha_{k-1}\alpha_k}}{p_{\alpha_{k-1}\alpha_k}} \frac{c_{\alpha_k}}{p_{\alpha_k}} = \frac{A_c^k c_{\alpha_k}}{P^k(\tau)}. \quad (10)$$

The variance of the random variable $X_\alpha^k(\tau)$ is very important for the quality of the algorithm. Smaller variance $Var\{X_\alpha^k(\tau)\}$ leads to better convergence of the stochastic algorithm. It is proven that [4]:

$$Var\{X_\alpha^k(\tau)\} = \frac{c_{\alpha_0}}{p_{\alpha_0} p_\alpha} (\bar{A}_c^k \hat{c})_\alpha - (A_c^k c)_\alpha^2. \quad (11)$$

III. An improved Monte Carlo algorithm for LA systems

We use the Sequential Monte Carlo (SMC) method for linear systems introduced by John Halton [6]. We introduce the new improved Monte Carlo algorithm for the computation a linear functional form $W(x)$ of the solution of a linear system with real coefficients. The matrices B and the right-hand side f are normalized to accelerate the convergence rate of the stochastic process. Special values of the relaxation parameter $\gamma_i = b_{ii},\ i = 1, \ldots, n$, have been chosen, compared to the constant $\gamma \in (0, 1]$ in [4]. Numerical experiments show that it leads to balancing of the iteration matrix A.

The initial equation is picked uniformly at random among the n equations. After that for each state i we define the total score $S(i)$ and the total number of visits $V(i)$ that are modified as soon as state i is visited during a walk.

The following algorithm describes the above:

Now we give a description of the improved Monte Carlo algorithm for computing all the components of the solution. We compute scores for all the states (seen as new starting states) that are visited during a given trajectory. The initialization and preprocessing are the same as in the previous algorithm.

IV. Numerical examples and results

In order to check the accuracy of a computed solution $\hat{x}$, we compute the residual $r := B\hat{x} - f$ and "weighted residual" [8]:

$$\rho := \frac{||r||}{||B||\ ||\hat{x}||}. \quad (12)$$

The number of SMC iteration is N and the computational time t is measured in seconds. In the Tables and Figures below we present the values of the weighted residual. We perform a comparison with the refined iterative Monte Carlo (RIMC) [3] and the original "walk on equations" (WE) method which is completely described in [4]. For our method we use the

Algorithm 1 Computing one component x_{i_0} of the solution $x_i,\ i = 1, \dots n$.

Require: Initialization with initial data: the matrix B, the vector f, the constants $\gamma_i = b_{ii},\ i = 1, \dots, n$, and the number of random trajectories M.

Ensure: Preliminary calculations (preprocessing): compute the matrix A using the parameter $\gamma \in (0, 1]$:

$$\{a_{ij}\}_{i,j=1}^{n} = \begin{cases} 1 - b_{ii} \text{ when} & i = j \\ -b_{ij} \text{ when} & i \neq j \,. \end{cases}$$

Set $S := 0$.
for k=1 **to** M **do**
  set $m := i_0$
  set $S := S + f(m)$
  $test = 0,\ sign = 1$
  update $S := S + sign * f_m$;
end for
return $x_{i_0} = \frac{S}{M}$.

Algorithm 2 Computing all components $x_i,\ i = 1, \dots n$ of the solution.

Require: Initialization.
Ensure: Preprocessing.
Set $S(i) := 0$; $V(i) := 0$.
for $k = 1$ **to** M **do**
  set $m := rand(1 : n)$
  set $test := 0$; $m_1 := 0$
  $V(m) := V(m) + 1$; $m_1 = m_1 + 1$; $l(m_1) = m$
  for $q = 1$ **to** m_1 **do**
    $S(l(q)) := S(l(q)) + f_{l(q)}$
  end for
end for
return
for $j = 1$ **to** n **do**
  $V(j) := \max\{1, V(j)\}$
  $x_j = \frac{S(j)}{V(j)}$
end for

notation improved "walk on equations" algorithm (IWE). We have done numerical experiments with different matrices with dimensions $n = 7, 100, 5000$, where the number of equations in the linear system is n and $B \in \mathbb{R}^{n \times n}$. The number of random trajectories for lower dimensions $n = 7$ is $10n$. The number of random trajectories for $n = 100$ is $5n$ and for $n = 5000$ is n. A few sequential steps for the improved IWE algorithm combined with SMC are necessary.

In the examples below we try to find the solution x defined by the linear systems of algebraic equations $Bx = f$, where the matrix B and the vector b are preliminary given.

Example 4.1: In the first example we deal with two solutions x_1 and x_2 of $Bx = f$, where the matrix B and the vectors b_1 and b_2 are given below. The matrix is:

$$B = \begin{pmatrix} 5 & -1 & -1 & 0 & 0 & -1 & -1 \\ -1 & 5 & -1 & -1 & 0 & 0 & -1 \\ -1 & -1 & 5 & -1 & -1 & 0 & 0 \\ 0 & -1 & -1 & 5 & -1 & -1 & 0 \\ 0 & 0 & -1 & -1 & 5 & -1 & -1 \\ -1 & 0 & 0 & -1 & -1 & 5 & -1 \\ -1 & -1 & 0 & 0 & -1 & -1 & 5 \end{pmatrix}. \quad (13)$$

The vectors f_1 and f_2 are:

$$f_1 = \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \end{pmatrix}, \quad f_2 = \begin{pmatrix} 4 \\ -2 \\ -1 \\ 0 \\ -1 \\ -2 \\ 4 \end{pmatrix}. \quad (14)$$

The solutions are

$$x_1 = \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \end{pmatrix}, \quad x_2 = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}. \quad (15)$$

Example 4.2: Let B is the matrix NOS4 from the Harwell-Boeing Collection [7], and $b \in \mathbb{R}^{100}, b_i = 1,\ i = 1, \dots, 100$. This particular matrix is taken from an application connected to finite element approximation of a problem describing a beam structure in constructive mechanics [7].

Example 4.3: Let B is a dense matrix 5000×5000 with elements in [0,1], and $f \in \mathbb{R}^{5000}, f_i = 1,\ i = 1, \dots, 5000$.

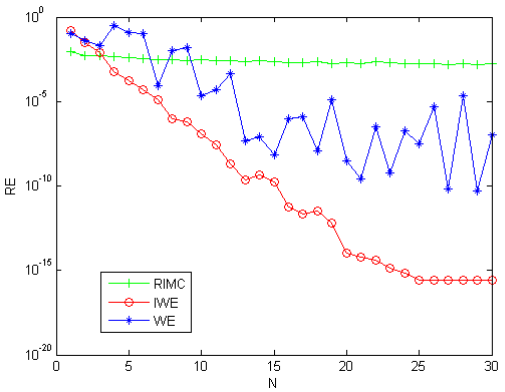

Fig. 2. Weighted residual for the matrix $B \in \mathbb{R}^{5000\times5000}$.

It can be seen that for the 7 dimensional case the difference in the accuracy between the WE and IWE for a given number of iterations is 2-3 order for $N > 15$ – see Table I and Table II. It is worth mentioning that refined iterative Monte Carlo convergence is very slow except for the trivial solution x_1 of Example 1. For the 100 dimensional case of the matrix NOS4 IWE produces much better results than WE and it is nearly 5-6 times faster – see Table III. The prior behavior of the proposed MC algorithm does not depend on the matrix density. The matrix NOS4 has only 5.9 average non-zeros per row and per column. The advantages of the algorithm hold for dense matrices. Also the difference in the accuracy for a fixed number of iterations is 3-5 order – see Figure 1. For larger dimensions the advantage of IWE over WE is even more pronounced. For the last example after 30 iterations WE has accuracy of 10^{-9} while IWE gives accuracy of 10^{-16} – see Figure 2. Also the time for the IWE is 15 times better than WE – see Table IV. The advantages of the proposed MC algorithm can be observed especially for larger matrix size. The special choice of relaxation parameters leads to the balancing of the iteration matrix and the experiments show that for larger dimensions the improvements leads to lower relative errors for small number of SMC iterations for IWE.

V. CONCLUSION

A new improved Monte Carlo algorithm for solving linear algebra problems is presented and studied. It is used for evaluating all the components of the solution of real valued systems. Due to the optimization techniques it gives superior results to the standard "walk on equations" method and it is established as one of the fastest and accurate Monte Carlo algorithm for solving systems of LA equations.

***Abstract*—Patrolling algorithms are coordinating multiple agents with the goal of visiting points of interest in a timely manner. These algorithms play a major role in efficient use of UAVs or other autonomous vehicles for precision agriculture, large area monitoring or security use cases. These algorithms are either centralized and in need of constant connection with the agents or solve NP-hard problems to plan the routes of individual agents on the graph. These requirements become unfeasible when the number of agents or points of interest grow or become dynamic. In this article we further elaborate the performance characteristics of the Partition Based Patrolling Strategy (PBPS) algorithm. The partitioning requires only local interactions between agents, therefore it is scalable to a large number of nodes and agents. On these subgraphs agents patrol independently from each other, therefore the approach eliminates interference between agents.**

I. Introduction

PATROLLING is the task of visiting points of interest in a timely manner. These points of interest can be selected for security purposes (monitoring entry points of an area) or points in space one would like to monitor[1] by making photographs or measurements. Every problem that involves points of interests distributed in space and limited possibilities to move between them (modeled by a graph) is a patrolling problem. When patrolling inside a building, points of interest can be intersections or doors needed to be inspected in a timely manner. When dealing with a large open area, like an agricultural crop, the points of interest are locations where one wants to make measurements, i.e. water level, infections, fruit maturity, etc.

Points of interest are usually modeled as nodes of a graph, where the edges represent the option to travel between them directly and the length of the edges represent the distance or cost of moving between them. Patrolling is usually performed by physical agents, such as Unmanned Autonomous Vehicles (UAVs) or robots[2], either on ground or in the air. In this article we refer to these entities, without loss of generality, as agents. Patrolling with a single agent is a matter of calculating a sequence of points of interest for the agent to visit. Instead, our focus is on multi-agent patrolling, where the task is to efficiently coordinate an arbitrary amount of agents in order to minimize some performance metric associated with the patrolling task.

Coordinating multiple agents to perform patrolling can be reduced to a multiple traveling salesman problem, therefore it is an NP-hard problem[3]. Patrolling algorithms either plan the routes for each agent ahead of time and feed those routes to the agents as a priori information or try to coordinate the agents in real time by allowing them to communicate through some wireless medium and employing various heuristics in the agents to decide on the next graph node to visit.

Patrolling on graphs is either implemented by allowing every agent to visit all nodes in the graph or the graph is partitioned into subgraphs[4], [5] and the agents work only on their own subgraph without interfering with each other. The first case involves interference between the agents that can result in agents blocking each other on the way from one node to another. When agents try to move in the same direction or meet at an intersection, they inhibit each other from carrying out their tasks as fast as possible. These interference events can have a negative impact on the performance and scalability of the patrolling algorithm. Since patrolling is usually a long running task, these interference events will have a continuous, most of the time unpredictable effect on the performance.

To counter this effect, researchers started investigating partition-based patrolling. Currently partitioning is usually done before patrolling starts, on a central entity, and the resulting partitions are assigned to the agents as a priori information. This method is not always feasible as environments can be dynamic: appearing or disappearing graph nodes and failing or newly introduced agents can trigger the recalculation of partitions. Therefore agents need the central entity throughout the patrolling task and need synchronization at times of partition changes. A self-organizing partition based strategy is more desirable, because agents need less synchronization, require only local information and it makes the whole system more robust against agent failures.

II. Related works

Patrolling strategies can be really simple heuristic based approaches or complex learning algorithms that try to find the optimal route for a multi-agent team. It is not always clear whether a complex approach or a simple heuristic can offer better performance. In [6] patrolling is cast into a multi-agent Markov Decision Process and optimization techniques are applied to efficiently find the optimal paths for agents on the graph. However in the same article this solution is compared to a simple reactive algorithm and performance

differences with regards to the instantaneous idleness metric were negligible. This experiment and the conclusion of [7] suggest that computationally complex approaches are not always justified and simple reactive algorithms can match the performance of their more elaborate counterparts.

Agents can be restricted to their own subgraph or partition and perform patrolling alone in that region. An early theoretical study [3] gives some insight into the performance characteristics of the partition-based and cyclic approaches (for example the previously mentioned SingleCycle). Authors of this article claim that the optimal patrolling strategy for a single agent can be obtained by finding a shortest closed walk on the graph. This can be reduced to the Traveling Salesman Problem for which good approximations exist (for example the Christofides algorithm with $O(n^3)$ for a $\frac{3}{2}$ approximation). When multiple agents are considered, one strategy can be to traverse the closed path with evenly distributed agents along the path. The performance of such a strategy is bound by the edge length distribution of the graph [3]. For example on graphs with “long corridors" (edges connecting two distant nodes) a partition-based strategy could be a better fit, because those “long corridors" can be avoided by leaving them out of the partitions assigned to the agents.

So far the solutions enumerated were dealing with the multi-agent patrolling problem based on the assumption that agents cannot interfere with each other. However, interference can occur when two agents are too close to each other and cannot proceed in the direction of their targets. Interference is important when the algorithm is designed to be deployed on physical agents and can render theoretically better algorithms inferior in the real world. Accounting for interference results in a much harder problem, because the theoretically best results are no longer optimal if agents have to stop before colliding with each other or possibly choose different targets. Several new heuristic approaches are taking into account this phenomena, for example in [8] authors implement Greedy Bayesian Strategy (GBS) and State Exchange Bayesian Strategy (SEBS). Both strategies require global communication meaning that agents can communicate with all other agents involved in the patrolling task. They employ reactive agents (so the agents do not form plans ahead of time) and the decision making algorithm that chooses the next graph node to visit is based on Bayes' rule. The latter strategy (State Exchange Bayesian Strategy (SEBS)) aims to minimize the interference between agents while patrolling, by communicating the agent's next node it is intending to visit. SEBS is able to achieve better performance than any other heuristic studied in the article. Interference minimalization and graphs with non uniform edge length distributions contributed to the interest in partition based strategies.

Numerous other approaches have been tried to address the multi-agent patrolling problem, such as spanning tree[9], [10] or graph partitioning based approaches[11], [12]. Others involve task allocation based strategies[13] and evolutionary algorithms[14] or linear programming[15]. Auction based strategies involve agents placing bids on nodes to patrol on the graph. These kind of approaches implement a decentralized task allocation, where the agents decide on the outcome and able to reassign nodes or partitions of poorly performing agents to others[16], [17].

III. The Multi-Agent Patrolling Problem

In this article our goal is to further elaborate the performance characteristics of our proposed PBPS algorithm [18]. In our model the only global knowledge the agents have is the map they are patrolling on. They do not have the capability to communicate globally with each other. Agents' behavior will result in solving the patrolling problem efficiently together, without third party coordination.

In the model, the connected graph $G(V, E)$ consists of nodes $v_1, v_2, ..., v_n \in V$ and undirected edges $e_{i,j} \in E$. Nodes are the points of interest, they are visited by the agents periodically. Each node has a counter that measures time between the last visit to that node and the current time. This counter is usually referred to as the *instantaneous idleness* of the node at time t and is defined as $I_{v_i}(t) = t - I'_{v_i}$, where I'_{v_i} is the time at the last visit to the node and $v_i \in V$. In some use cases patrolling is done to measure some physical quantity at the point of interest periodically and as frequently as possible. Let us suppose that the measurement at each point of interest takes the same amount of time for each agent.

Agents' movement is restricted to the edges between connected nodes. Agents have a priori knowledge of the graph nodes and edges, and are capable of moving between nodes along the edges with constant and uniform speed. Agents are able to communicate with each other, therefore influence each other's decisions by broadcasting messages via a wireless medium.

Patrolling algorithms have very different characteristics with respect to the routes they take, the order in which they visit certain nodes, etc. To be able to compare their performances, we have to define metrics that represent the goodness of an algorithm from a certain point of view. The metric used for this task is usually the *average idleness* or the *worst idleness*. Both of these metrics are based on the *instantaneous idleness* defined before as $I_{v_i}(t)$. This basic metric can be averaged in a window or throughout the simulation to obtain the *average idleness*, defined as:

$$\overline{I_{v_i}}(t) = \frac{\overline{I_{v_i}}(t_{v_i}) \cdot C_i + I_{v_i}(t)}{C_i + 1} \tag{1}$$

where C_i is the number of visits to v_i. The *average graph idleness* is the average of *average idleness* values, such that:

$$\overline{I_G}(t) = \frac{1}{|V|} \sum_{i=1}^{|V|} \overline{I_{v_i}}(t) \tag{2}$$

A problem with the *average graph idleness* metric is that there can be two patrolling algorithms with the same *average graph idleness* but significantly different behaviors. *Average graph idleness* masks important characteristics of patrolling algorithms and as a consequence, its value can be misleading

when comparing different algorithms. The idleness times between visits are samples from an unknown distribution and to reason about that unknown distribution based on the mean of a limited amount of its samples can be misleading. Therefore in this article we use the distribution of the *worst idleness* values to compare performances. The *worst idleness* associated with a node between times t_a and t_b is defined as the maximum *instantaneous idleness* value:

$$WI_{v_i} = max\{I_{v_i}(t_a), ..., I_{v_i}(t_b)\} \quad (3)$$

The worst idleness times are the worst case scenario, therefore by gathering enough samples, one can be reasonably sure of an upper bound of the idleness times that can be observed during patrolling. Patrolling use cases like reading measurements from sensors or taking photographs of certain physical locations usually benefit from a known maximum time between measurements. The *worst idleness* distribution makes it possible to evaluate patrolling algorithms based on this criteria. It also shows the fairness of the algorithm: the difference between the minimum and maximum *worst idleness* values on the graph over time. Moreover the distribution of *worst idleness* can be easily visualized using box plots.

IV. Partition Based Patrolling Strategy (PBPS)

The patrolling strategy we use in this article follows the partition based approach. Based on [3], [19], the performance of such a patrolling algorithm is in theory inferior compared to a cycle-based strategy on graphs without “long corridors". However, if the model accounts for the effects of interference between agents, this may no longer be true. Partitioning the graph between the agents is not a new idea, authors in [8] and [5] improved their patrolling algorithms by limiting the amount of interference between agents. Partition based strategies take this idea to the extreme as there is no interference between agents, they patrol their own partitions independently.

PBPS was published in [18] along with the first results obtained on well-known graphs. Here we give only a short introduction to the algorithm. PBPS has two important assumptions about the environment: agents can localize themselves and they know the structure of the graph a priori. It should be noted, that these assumptions are not typical in self-organized systems, because they require agents with greater knowledge than usual. However the information requirement of PBPS is the same as other patrolling algorithms, such as SEBS or Greedy Bayesian Strategy (GBS). The problem of discovering the environment and forming consensus about it among the agents is not discussed in this article.

The goal of the algorithm is to partition the graph into non-overlapping connected subgraphs and in the process create a global partitioning that enables the efficient patrolling of the graph. All agent’s partitions are empty in the beginning. A partitioning of G is defined as $P = \{P_1...P_k\}$, such that $P_1 \cup ... \cup P_k = V$ and $P_i \cap P_j = \emptyset$. $\{G_1...G_k\}$ refer to subgraphs induced by the partitioning, thus $G_i = (V \cap P_i, E \cap (P_i \times P_i))$. The partition growing process is self-organized, such that there is no global coordination between agents and no global state shared among them. Agents grow their own partitions by claiming nodes from each other’s partitions and broadcasting their new partition after claiming a new node. In the process (see for example Figure 1) of growing partitions, there can be local violations to the strict non-overlapping partitioning introduced above, but these are temporary and will resolve over time. The algorithm always reaches a state, where the partitions are stable, i.e. no more changes made by the agents. When agents arrive at a stable configuration, each partition will belong to one and only one agent and each partition will be a connected subgraph with no overlapping nodes with other partitions. The resulting partitioning assigns a subgraph to each agent to patrol with roughly equal number of nodes.

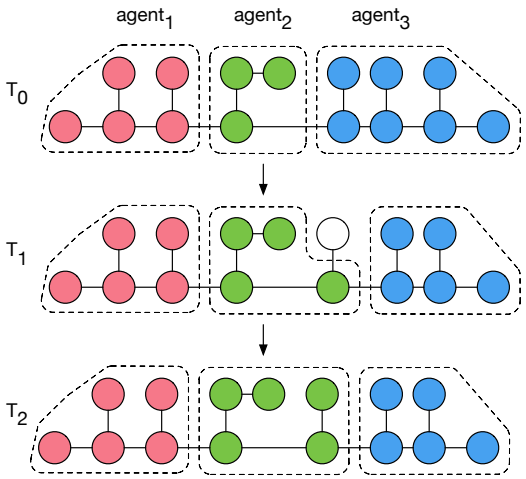

Fig. 1: Claiming of nodes between agents in order to achieve a balanced partitioning.

V. Simulation environment

We have conducted numerous simulations to investigate the performance characteristics of PBPS and compared patrolling on the formed partitions to well-known patrolling algorithms. First we describe the environment in which the experiments were carried out as it was designed to resemble possible real-world usage scenarios. We used the osmnx python library[20] to download maps of two Hungarian cities: Budapest and Komárom. We chose Budapest, since it is the capital of Hungary and like large cities it has a lot of intersections and shorter edges. Komárom on the other hand tends to have differently distributed edge lengths and node degrees (as can be seen on Fig. 2 and 3) as it is a smaller city on the countryside. Node degrees tend to be lower for Komárom but edge lengths are significantly longer than the ones for Budapest. We chose two different real maps to model possible usage scenarios and also to have environments with different characteristics. Our partitioning strategy is based on the assumption that the edge length distribution of the graph is more or less even. The map excerpt from Komárom has a longer tail in its edge length distribution, therefore more variety than the map excerpt from Budapest. The downloaded maps were simplified as the

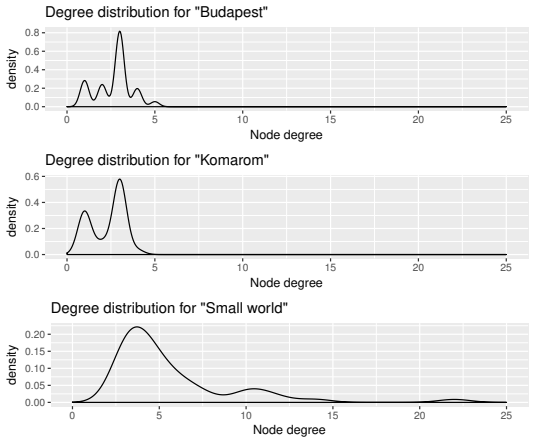

Fig. 2: Degree distributions of the maps used for the experiments.

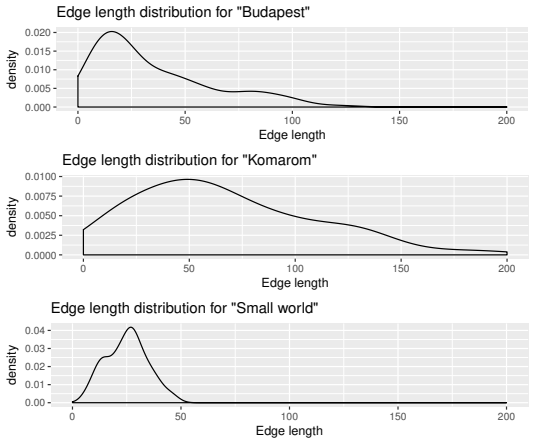

Fig. 3: Edge length distributions of the maps used for the experiments.

original Open Street Map data contains a lot of short edges and unnecessary nodes. The simplification step was done using a built-in functionality in osmnx. A third map was introduced, called Small World, which is a generated small world type graph (Barabási-Albert graph) with a completely different node degree distribution than the other two maps. This graph has 50 nodes and was grown with 3 edges preferentially attached to existing nodes using the networkx python library's built in graph generator. This third environment has some really high degree nodes and claiming those nodes in the partitioning phase can effect other partitions, as these high degree nodes act as access points to the rest of the graph.

We carried out experiments in these graphs with three different patrolling algorithms with parameters given in Table I. First, Conscientious Reactive[21] was used as a baseline as it is a greedy heuristic with no communication requirements among the agents. The second algorithm tested was State Exchange Bayesian Strategy[8], which is based on the idea that agents can perform better if they exchange their intentions and

Parameter	**Value**
Number of agents	$1, 2, 4, \ldots, 32$
Double number of agents every	$200000s$
Number of iterations	10
Agent speed	$1m/s$

TABLE I: Simulation parameters for the local vs. global metric experiment.

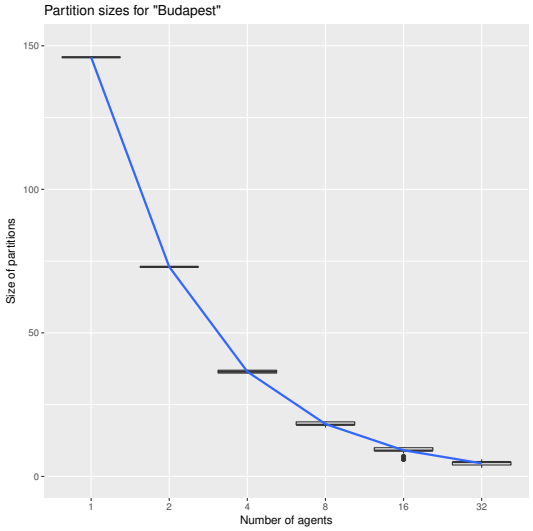

Fig. 4: Partition sizes for Budapest

factor the intentions of other agents in when making a decision which node they visit next. The third was PBPS, which forms partitions on the map in a self-organized manner and agents perform patrolling on their own partition only.

VI. Partitioning algorithm results

The goal of this experiment was to gain insight into the performance characteristics of the partition forming part of the PBPS algorithm. To this end we have disabled the mobility of the agents and tracked the partitioning events throughout the simulation. Partitioning events are either node free or nonfree node claims, or partition resets. In the beginning of every simulation run, only one agent is on the map at a randomly chosen node and it starts forming its partition. After this initial agent claims the whole map as its partition there are no more partitioning events occurring. The simulator waits until there are no more partitioning events for 5000 time steps and then doubles the number of agents on the map. The agents already on the map retain their partitions and the new agents are assigned a random starting node as their initial partition. This mechanism for adding agents sometimes cause overlaps in the partitioning, because the previous generation of agents claimed the whole map together (every node belongs to one and only one agent). However this is not a problem as the first time a new agent broadcasts its initial partition, the overlaps will be resolved by the old agent releasing that node from its partition.

The number of agents simulated on each map are exponentially increasing $(1, 2, \ldots, 16)$. The exponential increment in

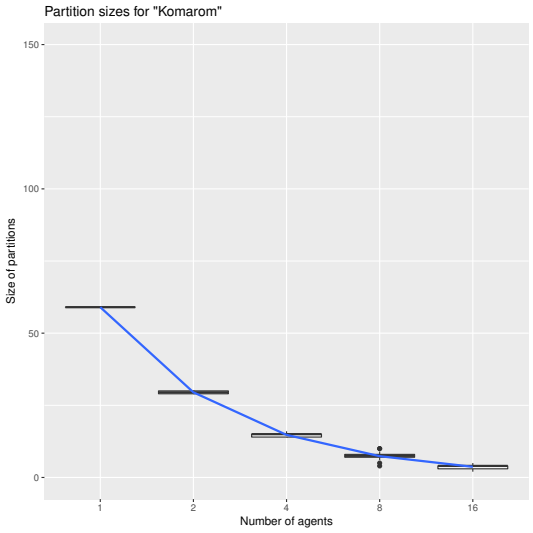

Fig. 5: Partition sizes for Komárom

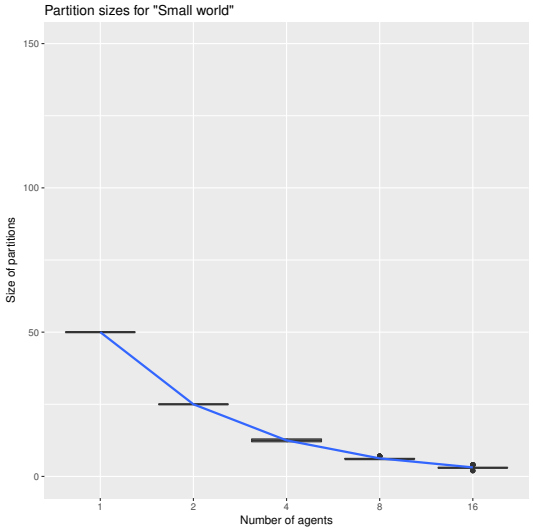

Fig. 6: Partition sizes for Small World

the number of agents can reveal the scalability characteristics of the partition forming part of PBPS with respect to the different maps. As a performance metric, the time to arrive at a stable partitioning was measured for different number of agents $(1, 2, 4, \ldots, 16)$ and at the same time the number of nodes in each partition were tracked.

This was done in order to confirm whether a stable partitioning is also a balanced one. A balanced partitioning in this terminology is where the number of nodes in each agent's partition is close to the $\frac{number\_of\_nodes}{number\_of\_agents}$ number. In other words, a balanced partitioning is where each partition has a roughly equal amount of nodes. Depending on the structure of the map this balanced property might not be achievable, since the tested maps are not full graphs with an edge connecting every node. Figures 4, 5 and 6 report the distribution of

Num. of agents	1	2	4	8	16	32

TABLE II: Mean, variance and index of dispersion values of resulting partition sizes for all three tested maps and different number of agents.

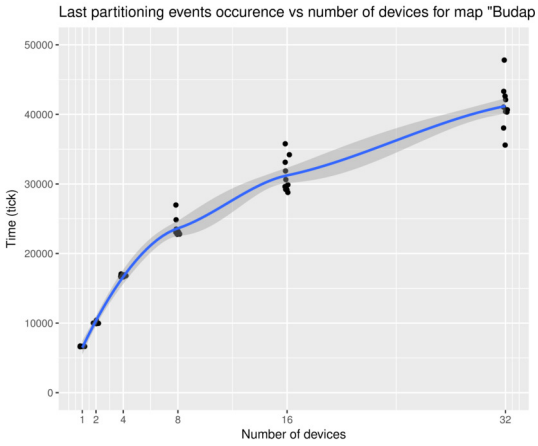

Fig. 7: Times of last partitioning events for versus number of agents for Budapest

partition sizes versus the number of agents. These are box plots[22] where the box contains 75% of the observed values. The blue curve shows the balanced partition sizes for different number of agents, its value is $\frac{number\_of\_nodes}{number\_of\_agents}$, where $number\_of\_nodes$ is constant and a property of the map. The results here show that in all simulated experiments the partitioning algorithm was able to arrive at solutions close to the optimal. Some exceptions show up as outliers on the box plots and indicate that the initial conditions have some influence on the final partitioning. All simulations were done 10 times with different starting positions for the agents, therefore each box represents the distribution of $10 * number\_of\_agents$ different resulting partition sizes.

Additionally the mean, variance and index of dispersion[23] metrics were calculated for the three different maps and for the different agent numbers. These results are summarized in Table II.

The next set of results discuss the time requirements of the partitioning algorithm, paying attention to its scaling properties. The question here is how does adding more agents to a map influence the time needed to arrive at a stable configuration? A stable configuration is one, where no more

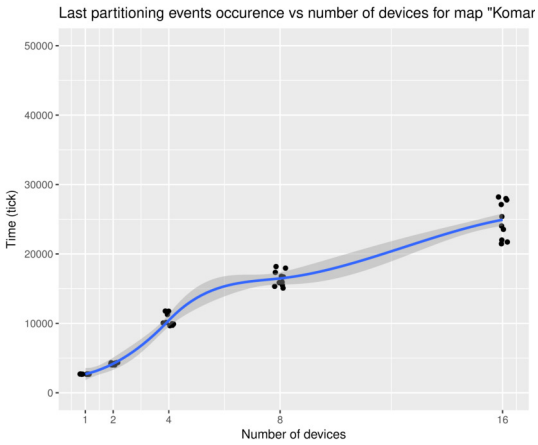

Fig. 8: Times of last partitioning events for versus number of agents for Komárom

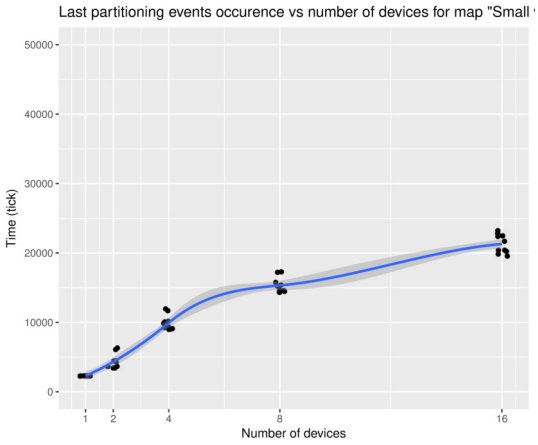

Fig. 9: Times of last partitioning events for versus number of agents for Small World

partitioning events occur. One of the advantages of using a self-organized approach is that in theory it is scalable and can enable multi-agent patrolling on larger graphs for a larger number of agents, than centralized algorithms. Figures 7, 8 and 9 show the distribution of time of the last partitioning event for each different simulated agent population versus the number of agents across all 10 iterations. Each group of values consists of 10 measurements and a curve is fitted to show the observed general trend of the values. It is important to note that the 5000 time step period between agent additions is subtracted from the values on the figures to show an ideal situation where one could determine the exact moment when the partitioning stops. The figures show that although the number of agents increase exponentially, the time needed to partition the graph increases only linearly. This indicates, that for the tested maps, the algorithm behaves well with a large number of agents and might be suitable to handle very large number of agents partitioning the same graph simultaneously. The variance of the values increase for larger number of devices. This indicates that the intermediate resulting partitionings and randomly assigned starting nodes for added agents (initial condition for each addition step) has an increasingly large effect when the number of agents are high. It is possible that by carefully choosing the insertion point for new agents, the observed variance might be decreased. However in this analysis we were interested in the possible outcomes and was aiming of getting a full picture of the dynamic behavior PBPS, rather than optimizing its parameters for ideal performance.

VII. Patrolling results

After investigating the different aspects of the partitioning, we compared the PBPS algorithm with two other algorithms: Conscientious Reactive (CR) and State Exchange Bayesian Strategy (SEBS). Conscientious Reactive (CR) is a simple greedy reactive algorithm, where the agent makes decisions based only on the visits made by itself. Other agents are not taken into account, therefore no communication is needed by this algorithm. Upon arriving to a node it resets the node's idle timer in its own local data structure and evaluates the node's neighbors in the graph. For the next node to visit the agent chooses the one with the largest instantaneous idle time value. CR is a trivial algorithm that requires only an agent with the capability to move and store the graph and timers in its internal memory, therefore the algorithm is an ideal baseline to compare other, more sophisticated algorithms to.

The State Exchange Bayesian Strategy (SEBS) strategy takes into account the interference caused by other agents in the same area. Agents can inhibit each others' movements by standing in the way or forcing other agents to move slower to avoid collision. This effect can cause strategies like CR and GBS to perform poorly in situations, where the number of agents in an area becomes high. GBS and SEBS builds on the idea of Bayesian decisions, where the a priori probability to visit a neighbor node is offset by the instantaneous idleness of the node known to the agent. This way GBS can take into account priorities input by the designer and the actual state of the system (instantaneous idleness of the nodes). SEBS extends GBS by having agents broadcast their intentions (the node they are intend to visit next) for their immediate neighbors. This information is used in all agents when evaluating the agent's next node to visit. If one or more agents intend to visit the same node, it is not beneficial to let another one go in that same direction, even if the instantaneous idleness value of the node is high. SEBS aims to lower the amount of time an agent loses by executing collision avoidance behaviors, causing them to slow down or chose a different target node altogether.

In these simulation runs, each group size (number of agents) ran for 200000 time steps, and after the number of agents were doubled. This process was repeated until there were 16 agents for Komárom and Small World, and 32 agents for Budapest on the map. We ran 10 iterations for each algorithm-map pair with random starting positions for every agent for every iteration. The structure of the graphs and the starting position of the agents can influence their measured performance, therefore in

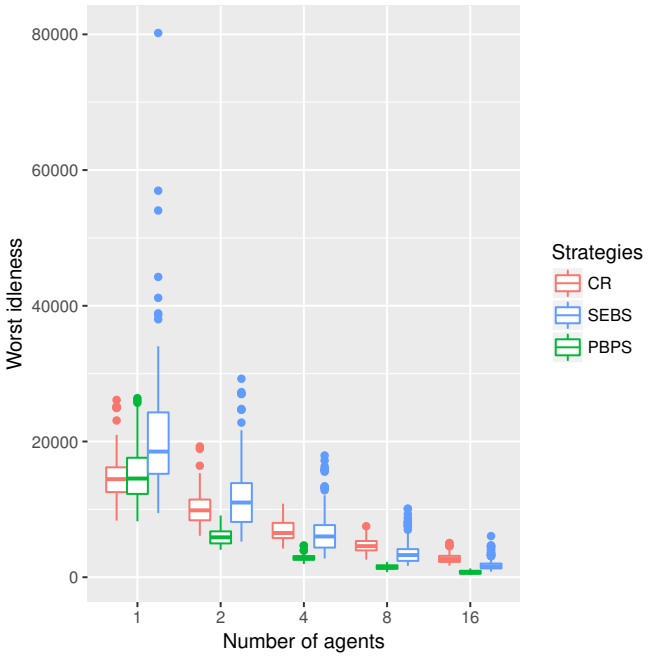

Fig. 10: Worst idleness time distributions for different strategies versus number of agents for Budapest

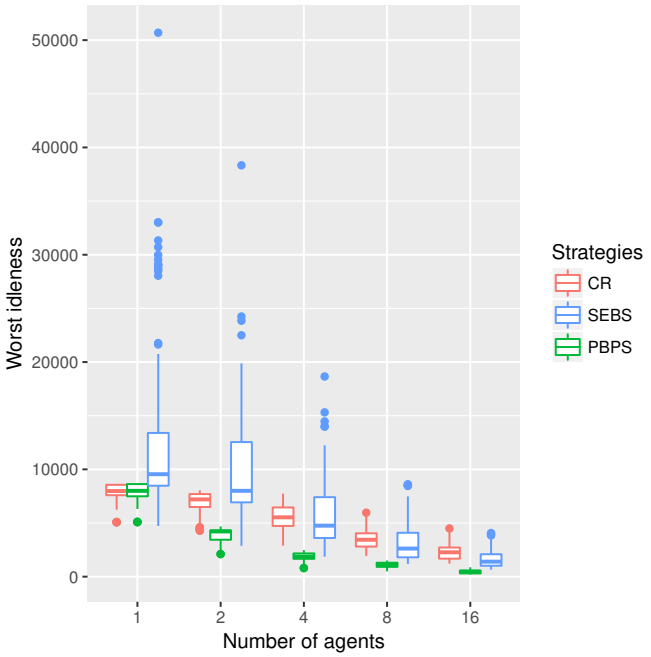

Fig. 11: Worst idleness time distributions for different strategies versus number of agents for Komárom

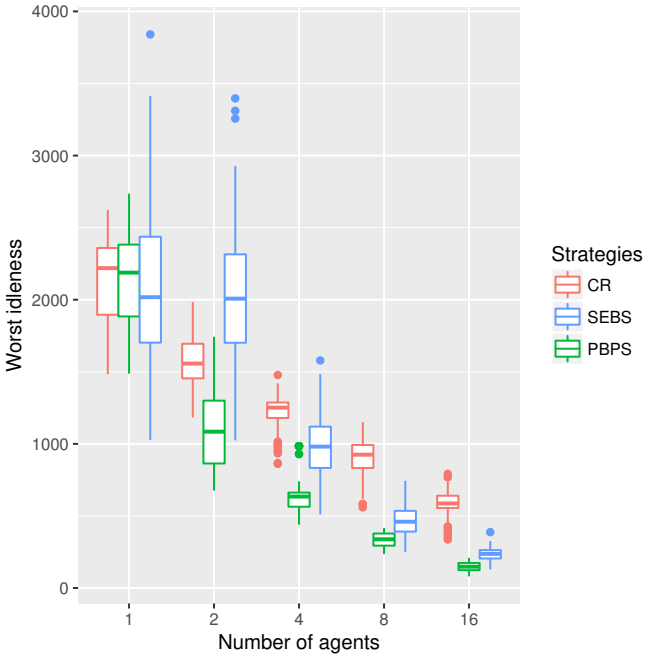

Fig. 12: Worst idleness time distributions for different strategies versus number of agents for Small World

order to gain as much information about the performances of different algorithms as possible, random non-overlapping starting points were chosen for the agents when they were added to the team. In the case of CR and SEBS strategies this means a random node from the graph and in the case of PBPS, this results in a random node from the agent's partition.

Partitioning strategies have a tendency to perform worse when they start on a graph, because they base their decisions on idleness times (and other agents' intentions in the case of SEBS), but in the beginning this data is not available for them. Therefore the first 100000 time steps for each different configuration were dropped in order to let the agents "warm up" and the worst idleness times for each node were collected for the last 100000 of each configuration. Figures 10, 11 and 12 report the worst idleness time distribution measured on the whole map for different strategies and different number of agents.

For one agent, CR and PBPS are almost identical, this is caused by the fact that PBPS employs CR as the patrolling strategy in the agents' partitions. In all tested configurations the performance of PBPS were better than the other tested algorithms. Comparing worst idleness distributions between SEBS and PBPS reveals that PBPS requires on average half the amount of agents to achieve the same performance as SEBS. In the case of map Komárom this effect is even more pronounced as the required number of agents for PBPS is one fourth of that for SEBS.

Another interesting facet is that SEBS tends to have a distribution with a longer tail than CR and PBPS. This means that the majority of values are larger than the mean for maps

Budapest and Komárom (see in Figures 10 and 11), which indicates that judging the performance of SEBS by the mean of its worst idleness times can be misleading, by indicating that the average time between visits to nodes in the map is smaller than what can be interpreted from the distribution of the values. This property means that performance metrics reported in articles like [8] can be only part of the whole picture as one cannot judge every aspect of the performance of the algorithms accurately from the average idleness values.

VIII. Conclusion

We have elaborated on the performance characteristics of the PBPS algorithm first published in [18]. The result of the partitioning algorithm is a set of subgraphs formed by the individual agents cooperating with each other that is used by patrolling agents as their patrolling tasks. These subgraphs are formed cooperatively by the agents on the graph without any central help or control. Using subgraphs of the original graph allows to completely avoid interference between agents, therefore have them performing in a parallel and deterministic manner. The cost function used in this article was the difference in number of nodes between partitions, but changing this cost function opens up possibilities for designers of patrolling systems to tailor the resulting partitions to their use case.

Simulations were performed on three different maps, representing different environments: the inner city of Budapest with shorter edges and more neighbors, part of the small city Komárom with longer edges and fewer neighbors and a random graph, which is a generated small world type graph (Barabási Albert graph). PBPS arrived at a balanced partitioning in every simulation run with low variance in the number of nodes assigned to an individual agent. Moreover PBPS scales well with the number of agents, meaning that the time needed to finish partitioning increased sublinearly with the number of agents tested. This property is in contrast with planning approaches, that usually have worse scaling properties, making it viable to employ this strategy on larger graphs and with a larger amount of agents.

We compared the performance of agents using different patrolling strategies, such as CR, SEBS and PBPS. Patrolling performance was judged by the distribution of worse idleness times for all nodes in the graph, represented as box plots. In every tested case PBPS came out ahead, and on two maps the necessary number of agents for PBPS were half of what was required by CR and SEBS for the same performance. This results in a tradeoff decided by the designer or implementor later: either employ the same amount of agents and get lower worst idleness times throughout the graph, or in a resource constrained scenario, change the patrolling strategy and get the same performance level with only half the agents required by other strategies.

Computer Science & Systems

CSS is a FedCSIS conference area aiming at integrating and creating synergy between FedCSIS events that thematically subscribe to more technical aspects of computer science and related disciplines. The CSNS area spans themes ranging from hardware issues close to the discipline of computer engineering via software issues tackled by the theory and applications of computer science and to communications issues of interest to distributed and network systems. Events that constitute CSNS are:

- BEDA'18—1st International Workshop on Biomedical & Health Engineering and Data Analysis
- CANA'18—11th Computer Aspects of Numerical Algorithms
- C&SS'18 - 5th International Conference on Cryptography and Security Systems
- CPORA'18—3rd Workshop on Constraint Programming and Operation Research Applications
- LTA'18—3rd International Workshop on Language Technologies and Applications
- MMAP'18—11th International Symposium on Multimedia Applications and Processing

Area Supervisory Committee

1st International Workshop on Biomedical & Health Engineering and Data Analysis

IN the recent years, technology has had an accelerating impact on the field of medicine and healthcare. We could observe, in particular, a proliferation of personal health monitoring devices and wearables, such as activity bracelets. These technologies supported by newest developments in data analysis, such as big data and deep learning, have a substantial impact on daily life of many people. They increase awareness of daily activities, help improve sport performance, and can lead to early detection of certain diseases.

The workshop on Biomedical & Health Engineering and Data Analysis—BEDA'2018—provides an open forum for researchers in domains of Biomedical Engineering, Health Technologies, Personal Monitoring Devices, and Data Analysis to communicate high-quality and timely research results. The primary focus is on practical applications, but highly relevant theoretical papers are also of interest.

TOPICS

- Biomedical signal processing;
- Biomedical imaging and image processing;
- Biosensors and bioinstrumentation;
- Neural engineering, neuromuscular systems and rehabilitation engineering;
- Wearable biomedical sensors and systems;
- Health informatics and technology, e-health and telemedicine;
- Biomedical systems management;
- Personal health monitoring devices and wearables;
- Application studies of biomedical and health technologies.

***Abstract*—A diagnostic procedure to predict the probability of diagnosing a patient with Alzheimer's Disease (AD) was developed using features of pupil light reflex (PLR) waveforms. 15 features of PLRs for three colours of light pulses at two levels of brightness were measured. Participants were 12 AD patients and 7 control group subjects. A logistic regression analysis was introduced to identify AD patients using two factor scores of features of PLR. The prediction performance of combinations of factor scores for features of PLRs were then evaluated using a test of fitness. An MCMC technique was introduced to estimate the parameters of the regression functions. The model provides a distribution of the probability of diagnosis of AD patients and control group subjects.**

I. Introduction

The pupil light reflex (PLR), which produces changes in pupil diameter in response to a light pulse of white or red, has been introduced to diagnose Alzheimer's Disease (AD) [1], [2]. In addition to this, the recent discovery of intrinsically photosensitive retinal ganglion cells (ipRGCs) [3] reveals the possibility of using various diagnostic procedures that involve a shorter light wavelength, such as blue light [4]. For example, PLRs related to ipRGCs can be used to detect symptoms of Age-Related Macular Degeneration (AMD) [5]. Some critical studies have suggested that common sources may be the origin of both AD and AMD diseases [6], [7], [8], [9]. Also, because most AD patients are elderly, the influence of aging on PLRs should be evaluated carefully.

The authors have been studying a diagnostic procedure for detecting AD symptoms using PLRs of various types of light pulses and observing the conditions the light pulses produce [10]. Though these results show the possibility of aiding the diagnosis of the disease, a more flexible procedure is required. In particular, the number of AD patients used in the experimental survey was restricted, and the assessment of the prediction of accuracy was insufficient. Therefore, significant features of PLRs, which can be used in the diagnostic procedure, should be extracted as necessary. If the distribution of features can be estimated, the possibility of diagnosing AD patients may be predicted using the Bayesian process.

In this paper, features of PLRs are extracted and the differences between AD patients and control group subjects are discussed. Some procedures for predicting the probability of diagnosing AD patients are compared. The following topics are addressed:

1) Features of PLRs are analysed and their factors are extracted. The differences in features and factor scores between AD patients and control group subjects are compared. Also, the influence of aging is evaluated.
2) Logistic regression is introduced to calculate the probability of diagnosing the disease in AD patients and control group subjects. The models of fitness of the groups are then compared.
3) The MCMC technique is introduced to estimate the parameters of the models, and the performance of the models is discussed.

II. Method

A. Participants

A conventional PLR experiment was performed on 19 participants (42∼89 years old, mean age:70.6), 12 of which were healthy individuals with normal vision (Control group: 62∼89 years old, mean age:72.1) and 7 of which were patients with Alzheimer's Disease (AD Patients: 42∼84 years old, mean age:68.1) who had already been diagnosed by medical doctors. It was not easy to invite volunteers who were aged over 80. The age levels are summarised in Table I.

Informed consent was obtained from all participants prior to the experiment.

B. PLR measurement

The stimuli consisted of three chromatic lights, red (635nm), blue (470nm) and white (CIE x:0.28, y:0.31), at two levels of

TABLE I
Number of subjects by age

Label	Age	Control	Patient
L	≤ 70	5	3
M	71∼80	5	3
H	$81\leq$	2	1

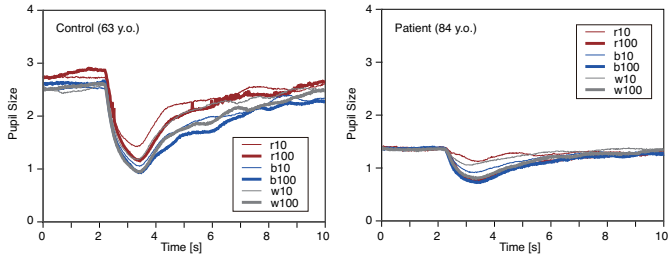

Fig. 1. An example of PLRs for a control group subject and an AD patient

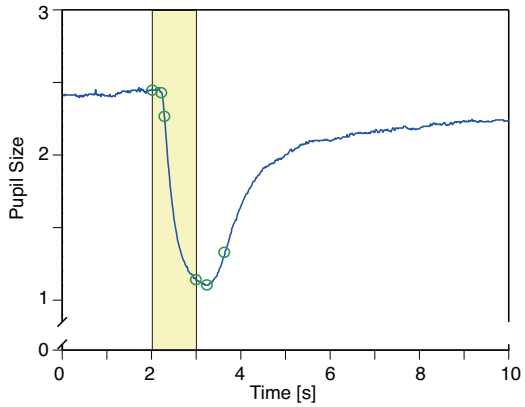

Fig. 2. Feature extraction from PLR responses

brightness (10 and 100 cd/m^2). These stimuli were labelled as r10, r100, b10, b100, w10 and w100.

The duration of observations was 10 seconds, with the first 2s being a pre-stimulus phase as a rest period, followed by a 1s light pulse and 7s as a restoration phase. Pupil diameters were measured in mm at 60Hz using a system developed by some of the authors [11]. PLRs for each stimuli were observed in single trials using a repeated-measure design.

Examples of measurements for a healthy individual and for an AD patient are shown in Figure 1. In these figures, PLRs are illustrated in response to 6 stimuli, namely the 3 colours and two levels of brightness.

III. Results

1) Feature definitions: A typical PLR waveform shape is illustrated in Figure 2. In the figure, the light pulse overlaps for a period of 2∼3 seconds. As the figure illustrates, there are pupillary response delays due to the shrinking of pupil and its restoration to normal size.

Some features are extracted to specify the PLR response, and these variable features are summarised in Table II. They are pupil size, velocity of pupillary change, duration of change, and integration of the waveform. These features are calculated for each PLR response.

A. Comparison of features

The extracted features for each stimulus were compared between two groups. The results are summarised in Table III.

TABLE II
Definitions of PLR features

Variable	Definition & notes
ps_base	Mean of the pupil size for time before light pulse
ps_lon	Pupil size where light pulse on
ps_loff	Pupil size where light pulse off
ps_min	Minimum pupil size
RA	Range of pupil size (ps_lon - ps_min)
v_con	Max amplitude of pupil construction velocity
v_rest	Max amplitude of pupil re-constriction velocity
ac_max	Min amplitude of pupil acceleration
t_delay	Pupil response delay
t_min	Time when “ps_min” appears
t_v_con	Time when “v_con” appears
t_v_rest	Time when “v_rest” appears
int_con	Integration of constriction phase
int_rest	Integration of restoration phase
int	Overall integration (int_con + int_rest)

When there is a significant difference between pairs of values, the values are displayed in bold face. As the table shows, there are many significant pairs for the b100 and r10 conditions, but few pairs for the white stimulus. In regards to the significant differences for the b100 condition, such as pupil size, velocity and acceleration of pupillary change, the pupil size for AD patients is relatively small, and responds slowly.

All participants are elderly, and in addition to being AD patients, their ages may affect pupil responses. Therefore, the effect of two factors (participant group and age level) on pupillary changes is examined using two-way ANOVA. The variables with deviations which contribute most significantly are selected and summarised in Table IV using means across age levels. These means change along with age levels. Most variables selected are related to velocity and time delay. Since there are few significant interactions between the two factors, they may be independent of each other in regards to PLR features. Additionally, most significant differences between age levels appeared for white stimulus and most differences between two groups occurred when w100 light was used. These results may be related to the mechanism of the PLR, and thus a detailed analysis of this will be a topic of our further study.

B. Factor analysis

There are significant differences in some of the PLR features of the AD and control groups. Though their variables exhibit the qualitative tendencies of a change, their sources could not be determined, as the physical variables and measurement units are completely different; some are expressed using sizes and others are expressed as velocities or accelerations.

Factor analysis was used to extract latent sources of the variables which were measured repeatedly. Since overall integration (int) is a summation of two parts such as int_con and int_rest, it has been omitted during the analysis, thus 14 variables were measured. A two factor structure was estimated using a principal component solution and a screw plot. A factor loading matrix using Promax rotation was produced, as shown in Table V.

Contribution ratio(2)	0.52	0.32
Correlation between factors		r=0.38

(1): Each factor with other factors eliminated
(2): Each factor with other factors ignored

The fundamental variables of each participant, such as pupil sizes commonly contribute to both factors. The second factor contains variables which are concerned with features of the progress of restoration of the pupil after a pulse of light, and the first factor contains the remaining variables of the features of PLR. As mentioned above, both factors contain two variables, and there is a significant correlation between these two factors ($r = 0.38$). Since even the contribution ratio of each factor when the other factors are eliminated is over 60%, the two factors can account for the deviation.

The factor scores ($factor1$,$factor2$) were calculated using the factor loading matrix, and their means for each stimuli are summarised in Figure 3 according to group. The horizontal axis indicates the first factor, and the vertical axis indicates the second factor. The error bars show standard errors. The two groups are indicated using suffixes, such as "p" for patients, or "c" for the control group.

When means between the two groups are compared for red (r10 and r100) or white (w10 and w100) stimulus lights, they are located in proximity to each other, but the means of the two groups are relatively far apart from each other for blue stimulus lights (b10 and b100). Pupil reactions in response to light colours are represented in Figure 3. In the results of applying t-tests to pairs of the means for the two subject groups, there are significant differences in the first factor scores for b100 ($t(15) = 2.64$, $p < 0.05$), in the second factor scores for b100($t(15) = 2.88$, $p < 0.05$) and for w100($t(17) = 2.15$, $p < 0.05$). Also, differences without much significance were observed for the second factor scores for b10($t(17) = 2.07$, $p < 0.10$) and for r10($t(17) = 1.77$, $p < 0.10$).

The results show that between the two subject groups there are significant differences in both factor scores for the b100 condition. As Table III shows many significant differences, the factor scores also represent these differences. Also, the second factor seems to reflect the difference in features of PLR between the two groups.

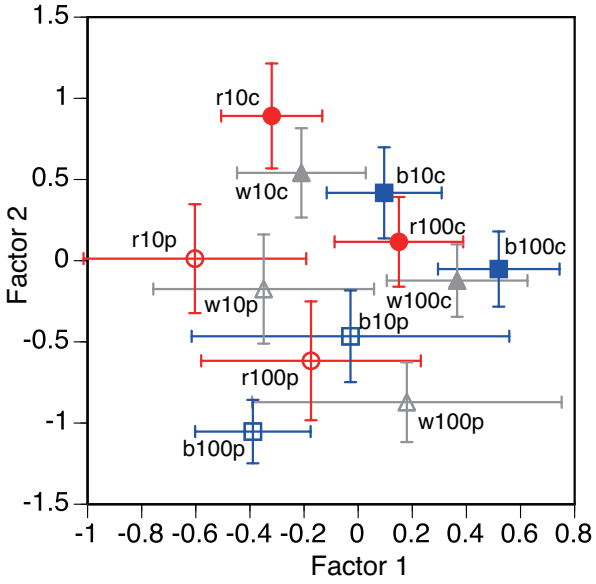

Fig. 3. Distributions of factor scores with error bars showing standard errors

TABLE VI
PERFORMANCE OF MODELS

Stimulus	AIC	R^2	Accuracy	AUC
b10	25.16	0.26	82.1	0.82
b100	17.24	0.47	89.4	0.89
r10	27.33	0.17	73.8	0.74
r100	28.05	0.14	72.6	0.73
w10	27.35	0.18	69.0	0.69
w100	24.70	0.28	79.8	0.80
b(10+100)	21.07	0.48	89.4	0.89
r(10+100)	30.26	0.22	71.4	0.71
w(10+100)	22.94	0.47	90.5	0.91
b+r	18.50	0.73	100	1.00
r+w	29.70	0.50	95.2	0.95
b+w	18.00	0.73	100	1.00
b+r+w	26.00	0.73	100	1.00

Though the influence of age level on factor scores was analysed, it did not affect either factor.

C. Introducing logistic regression

As mentioned in the introduction, this paper introduces logistic regression analysis to estimate the probability of diagnosing AD patients using a binary response variable (p) and PLR features. Here, $p = 1$ for the control subject and $p = 0$ for the AD patient, then p is given by the following equation with logit function.

$$\hat{y}_i = a + b_1 factor1_{i,j} + b_2 factor2_{i,j}$$
$$p_i = \text{logit}^{-1}(\hat{y}_i) = \frac{1}{1 + \exp(-\hat{y}_i)}$$

Suffix i represents the subject, and suffix j represents the stimulus light condition.

Logistic regression analysis was applied to the above factor scores for several conditions, such as the two factor scores for a specific stimulus light condition (light intensity: 10 or 100),

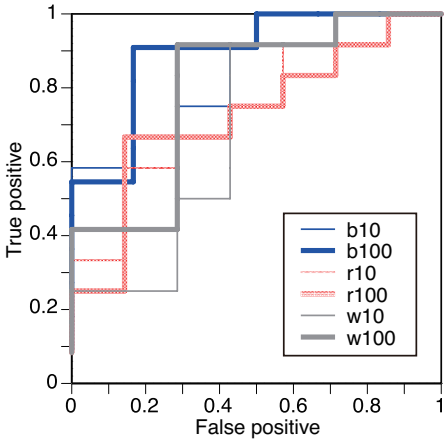

Fig. 4. Comparison of ROC curves

four factor scores for a colour condition (blue, red and white including light intensity 10 and 100) and further combinations such as two colours or all conditions (6 conditions and 2 factor scores). Every model was evaluated for fitness of model using AIC (Akaike Information Criteria), and prediction accuracy using R^2. The accuracy was measured using an appropriate threshold, and performance was summarised using two dimensional metrics such as true positive and false positive. The relationships are then illustrated as ROC (Receiver Operating Characteristics) curves. Figure 4 shows ROC curves of every stimulus condition. The surface area of the curve is also a measure of the AUC (the area under the ROC curve). Their indices are summarised in Table VI.

Results of analyses suggest that discriminant performance is higher for blue light stimuli, in particular for the b100 condition. The ROC curves show step-wise changes, since the number of participants influenced the results. However, the performance of AUC for b100 produced the highest reaction of any single stimulus condition.

D. Model parameter estimation

As Table III shows the possibility of discriminating between AD patients and control group subjects using a logistic regression function. However, the parameters of these functions can not be estimated sufficiently because the amount of data is too limited. Here, the Markov chain Monte Carlo (MCMC) method was introduced for more accurate estimation of the parameters. In regards to the data generation procedure using the MCMC technique, the burn-in period was 2000 and the number of samples was 10000 [12]. Using this procedure for the b100 condition, the parameters are estimated as follows.

$$\hat{y}_i = 5.4229 + 0.4722 * factor1_i + 7.3801 * factor2_i$$

The magnitude of coefficient for the second factor ($factor2$) is 15 times that of the coefficient for the first factor ($factor1$).

As an additional example, the parameters for blue light stimuli were estimated as follows:

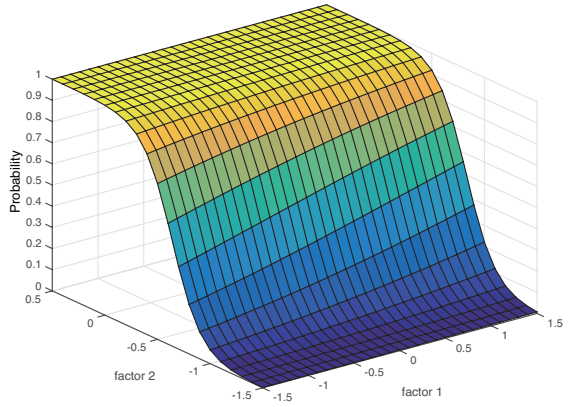

Fig. 5. Probability distribution for b100

$$\hat{y}_i = 9.1664 + 2.5320 * factor1_{i,b10} - 1.1366 * factor2_{i,b10} \\ -1.4011 * factor1_{i,b100} + 12.0891 * factor2_{i,b100}$$

The magnitude of these parameters suggests that the coefficient for the second factor at a high level of brightness (b100) is relatively larger than for others (b10 and the first factor at a low level of brightness). As the patterns of coefficients depend on the light stimulus, the wavelengths of the stimuli may affect these reactions.

In regards to the discussion in the previous section, the probability of control group subjects (1) or AD patients (0) may be illustrated using two dimensional information ($factor1$ and $factor2$), as shown in Figure 5. Figure 5 shows that the probability distribution against patients with AD depends mainly on the scores of the second factor. Also, the score of the first factor helps to more finely adjust the probability during the period where the curve is steep.

In regards to the experimental procedure, the features of PLR can be measured best during a one second high brightness level pulse of blue light (b100). Also, factor scores were calculated using the factor loading matrix shown in Table V. Finally, the probability of diagnosing AD patients can be predicted using the function above.

However, the possibility of developing a more flexible procedure for use in future experiments involving additional new participants will be a subject of our further study.

IV. Summary

This paper presents a procedure for predicting the probability of diagnosing AD patients using features of PLR, which respond to the activities of ipRGCs.

Three colour lights at two levels of brightness were illuminated for 1 second, and pupil light responses were observed. 15 features were extracted from each PLR, and two factor scores were calculated using a factor loading matrix. The following results were produced.

1) There are significant differences in some features between AD patients and control group subjects, in particular for the b100 condition. Also, for a few features for white light there are significant differences between age levels.
2) Logistic regression analysis was introduced to discriminate AD patients from the control group using two factor scores in response to chromatic stimuli. The performance was evaluated using the indices of the fitness of equations. As a result, the performance for b100 was the highest.
3) The MCMC technique was introduced to estimate the parameters of the regression functions. The model provides a distribution of probability for AD patients and the control group.

The validity of the probability estimations should be confirmed using the PLR data of patients. This will be a subject of our further study.

***Abstract*—This paper presents an approach towards aiding the rehabilitation exercises in amblyopia care using mixed reality technology. The Lazy Eye Syndrome is tackled here through an interactive holographic application implemented on Microsoft HoloLens device. It provides an entertaining way for the handicapped eye workout as it is based on a simple game of skill. The game is designed in a way that the majority of aware-requiring objects and events are displayed for the cured eye only, remaining the other eye responsible for background and additional information perception. Such disproportion forces an increased activity of the lazy eye, which is to perform more movements and impose the brain to process the sight more extensively. The proposed prototype is an extension of a novel approach towards treating amblyopia, employing software-based stimulation techniques, which could be easily adapted to various age and ability correlated needs of the user, with minimal requirements regarding the exercise setting and preparation.**

I. Introduction

THE amblyopia, often referred as the lazy eye syndrome is one of the most frequently diagnosed vision disorders among children. The cause of this affliction lays in disrupted cooperation between the eye and the brain. The brain tends to prefer the other eye for visual perception, therefore one of the eyes performs significantly less movements and activity, which causes further decrease of vision in the handicapped eye [1].

The lazy eye syndrome, if not properly treated during childhood, is likely to maintain an issue during adulthood. Such disease prevents an individual from obtaining professional driving licenses, which significantly limits the job opportunities. Moreover, the improper balance of eye activity might increase the risk of other eye injuries and diseases for the healthy eye [2].

The traditional approach of treating amblyopia is to address children only, as the therapy provides best efficiency during the so-called window of visual cortex development. The most common method prescribes putting a patch over the properly working eye and performing high eye-awareness requiring activities, forcing the brain to perform with the disabled eye more intensely. Such approach brings satisfactory results when applied to children in the age between 5 and 8 years old. However, the method is being widely discussed, as it employs highly artificial conditions of eye operation, with no regard of the stereoscopic vision.

Furthermore, noncompliance to wearing the patch (full-time or part-time, accordingly to the diagnosis) drives the treatment to failure. Therefore, the commitment required from the children, as well as their parents - as the proper supervision is necessary for that method, is significantly affecting daily life. Moreover, wearing a patch may cause social anxiety in the peer group and pose a huge challenge in performing some of school and educational tasks.

Thompson et. al. concerned about adult treatment, where the main problem seemed to be the lack of brain plasticity. Experiment with repetitive Transcranial Magnetic Stimulation proved that contrast sensitivity may be improved in the amblyopic eye by regular 10 minutes sessions with rTMS. This is the evidence that neuronal plasticity is not fully attenuated in adulthood. [3]. Further, it is suggested that amblyopia has a binocular nature, being a disrupt of analysing the signals perceived by both eyes. Having provided extended time of viewing and different contrast for each eye, the improvement of vision is noticed [4]. Therefore, the binocular manner of exercising may be perceived as most favorable and beneficial.

In this paper, we would like to propose low-commitment approach towards exercising the amblyopic eye, suitable for both children and adults (yet dedicated mainly to youngster users) concerning workout sessions in home setting.

II. Related Work

Multiple attempts have been made towards alleviating the constraints of traditional amblyopia treatment. One of the most promising approaches is to employ video games for stimulating the amblyopic eye through display design, with no constraint of losing the stereoscopic vision. Li et al. [5] prove that playing video games utilizing the lazy eye significantly develop the fundamental vision functions of the patient [5]. The improvements to a different extent were found for both visual and positional acuity, spatial attention, and the most significant for stereopsis. Cross-over study shown that occlusion approach cannot provide improvements in all those areas.

Those conclusions inspired further development of a tool which could serve as the exercise equipment for game-based treatment. Eastgate et. al. [6] proposed an integrated system, employing VR technology, enabling to practise through

playing various 2D and 3D games, stimulating the vision in different manners, as well as implemented a control view for the clinician. The binocular system provided an extensive setup for game-based lazy-eye treatment, while its high-complexity and ambient requirements made it available only for clinical use, through organised sessions. One of recent reports related to use of Oculus VR technology for adult patients is [7]. Such manner of operation does not solve the high-commitment constraint, as forcing daily visits to the clinic pose additional challenge to the patient's everyday routine.

Bringing the therapy to patient's home seemed to be an ultimate goal in a way to reducing the commitment and obstacles present in the process. Birch et. al.[8] tried to answer this need by proposing a binocular system based on Apple iPad applications. This approach enabled users to exercise in home setting, while being constrained with limited support of optic equipment available for iPad. The study has shown that playing the games using binoculars brought favorable results while being combined with traditional patch-based treatment. Gargantini et al. [9] took another endeavour towards providing affordable solution of home-exercising of the lazy eye syndrome, using Google Cardboard and the smartphone application. This solution differs the level of details displayed in each eye, forcing the amblyopic one to process more information than the healthy eye. The application also supported additional features for doctors. The main advantage of this solution is low-cost implementation for commonly used devices.

A commercial approach to bringing the VR treatment experience to patient's home has been made by Vivid Vision [10]. This solution employed commercially accessible technologies such as Oculus Rift, HTC Vive, Samsung Gear VR. However, even the end-user VR solutions pose high requirements towards the setting of playing, as well as disabling the awareness of any outer factors. In terms of children usage, the setup requires parental supervision, as the risk of undesired action is decent (eg. walking into furniture); see Fig 1. Therefore, we can establish the need for a solution which possess the advantages of VR projection while remaining ambient awareness of the performed activity. Mezad-Koursh et. al. [11] prove the necessity of daily exercising in successful treatment through pilot study of home use of a similar system, based on watching animated television using binoculars. The regular training enables improvements of the amblyopic eye activity even for children older than the assumed visual cortex development window.

Our attempt aims to bring the convenience of mobile solution [8], supported with high eye-involvement and immersive experience of the [6].

III. HoloLens Implementation

The proposed solution employs the Microsoft HoloLens, which is the leading commercial equipment for augmented reality projections. Due to AR approach, the displayed projection can be easily adapted to the ambient conditions, both in terms of visuals and their color contrasts, but also through real-object recognition and automated space-aware algorithm, so the artifacts will not be displayed on the physical obstacles, which becomes a major issue concerning the solution might be used by children.

Unlike the traditional, full-covering VR technology, the HoloLens offers undisturbed perception of the surrounding. As a consequence, the risk of undesired physiological reactions is significantly lower than for full-covering VR [12]. What is more, the experience of full immersion into VR activities is an additional challenge to the brain, which is naturally opposing the perception through display-equipped eyes and other senses. This effect is especially not recommended to the children [13]. Such effects are not observed for augmented reality displays, as the frame of reference is not altered. Therefore, it is more advantageous not to distract the brain with the senses' counteractions and maintain focus on extended activity of the amblyopic eye. The lack of harmful side effects of using the system is especially important due to the specific of the amblyopia curing procedure - the eye shall be forced to operate with enhanced activity for longer periods of time.

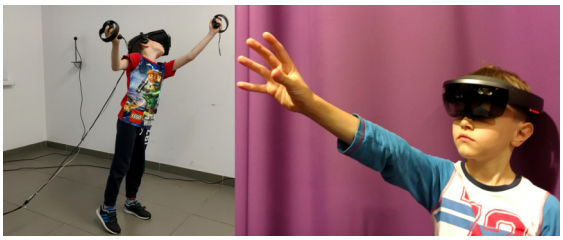

Fig. 1. 8yo user operating VR app (left) and the HoloLens app (right). The AR game is being displayed while maintaining the user fully space-aware.

Another advantage of HoloLens implementation is lack of problems with calibrating the display for children. Fully-covering VR setups are likely to present improper behavior when calibrated for children [14]. The device may lose the focus point, so the sight does not precisely follow the movements of user's head. Another advantageous feature of the HoloLens approach is the independent control of the contents displayed to each eye. Therefore, full control on the balance of the object projected for each eye is maintained and may be adjusted accordingly to the clinical diagnosis, to stimulate the lazy eye with different difficulty/intensity, while supporting the skill of stereo-vision.

Microsoft HoloLens supports streaming of the video displayed for user to any web browser. Thereby other persons may see the real-time cast of the holographic projection. This feature might be advantageous in supervision of the treatment process, as the doctor can dynamically monitor the patients activity. Patient can be therefore guided on specific actions performed within the solution, which is supportive for more complex exercise. Moreover, the clinician is able to assess the performance of the user in completion of the holographic tasks. Therefore the level of difficulty can be easily adapted to skills and abilities of the particular user.

Furthermore, the ability of the HoloLens to record the displays throughout the holographic session might be an asset for improving the exercise scenarios for future patents and enable extensive and precise analysis of users' performance and the results of the therapy applied.

IV. The exercise application

A simple game has been implemented, in which the user moves a spacecraft trying to omit falling asteroids. The space ship reacts to the movements of user's head. Asteroids are falling down one set after another with constant speed. One can adjust number of asteroids in a single set and the time interval between them. The artifacts displayed have been divided accordingly to the importance and awareness requirements to the user.

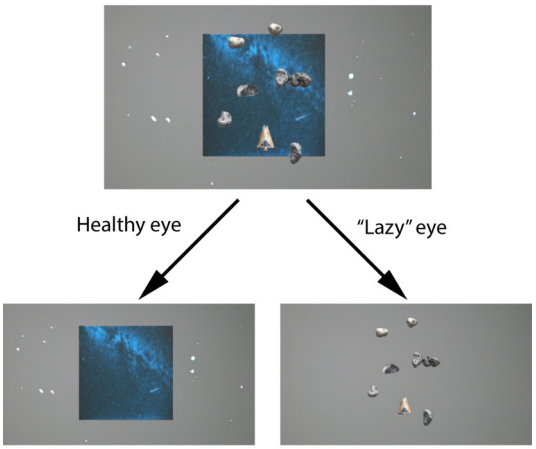

Fig. 2. Exemplary image displayed in the app. Left: the healthy eye part, containing the bacground. Right: the lazy eye part, containing roaming objects in the display.

All the important objects, such as spacecraft controlled and falling asteroids are displayed by single eye projection only - the one set to operate for the amblyopic eye, whereas supplementary objects, such as background and navigation panel are displayed in the healthy-eye part. Therefore, the user's brain is forced to operate the lazy eye to participate in the game. The character of the game imposes high activity of the eye treated. Simultaneously, the healthy eye is not excluded from the perception, unlike in the traditional treatment approach. Therefore, the game acts as an exercise for restoring the proper stereo vision.

Moreover, the exercise is presented as a form of entertainment, which makes the treatment process more pleasant, encouraging to greater compliance to the prescribed training routine. Regarding that the lazy-eye syndrome therapy concerns mostly children, it is even more desirable to provide an enjoyable manner of exercising. Working version of the system was tested on 4 adults (38yo on average) and 4 children (6.5yo on average), including two patients with amblyopia; one in each group. All of the participants were rather new to mixed reality technology. After initial training (c.a. 5 min for adults and c.a. 2 min for children) participants were able to play the game successfully. Children reported more initial problems with starting as well as during the normal operation in the game, yet did not reported problems within the game itself. Adult users reported less problems with starting the game but assessed the play as difficult or requiring too quick reactions for them to follow. Amblyopia child assessed game to be more demanding in terms of both effort as well as initial training in comparison to his experience (very limited, yet wider) with VR Ocullus Rift version of Vivid Vision app. All of the adults as well as all of the children reported more comfort when using HoloLens comparing to VR experience. However, we cannot present any structured nor longitudinal study results so far neither in terms of app assessment nor in terms of therapeutic matters.

V. Discussion

The proposed solution employs recent findings in the lazy-eye syndrome treatment in terms of using modern visual interfaces towards stimulating the disabled vision apparatus. Similar solutions have been offered before, while being aimed mostly for clinical or supervised use. Our system enables the participant to reach more self-reliance during the treatment and make the exercise procedure highly more convenient. The supervised mode is optional and requires additional device to which the sight from HoloLens could be casted.

The efficiency of the exercise is expected to be comparable to that obtained using traditional, full-covering VR approach. However, reduced number and intensity of possible side effects, like digestive discomforts, vertigo and labyrinth disorders is expected [15]. Due to limited projection range and the holographic technology applied, there is less risk of high eye-exhaustion or eye strain syndromes to occur [16]. The proposed solution is the next step towards providing the accessible and convenient tool for home-based amblyopia treatment-supporting procedures. The systems offers an entertaining manner of exercising the disabled eye, with additional activity monitoring features for enhanced supervision. The suggested approach lacks of common disadvantages of the arrangements used so far - those are the undesired side effects, inability to use the system for a long time, complex operation and/or difficult setting requirements.

VI. Future Work

This paper presents a prototype software for the lazy-eye stimulation. Further improvements of the game interface; i.e. more entertainment/gamification features are planned in order to maintain interest of the user for long-period treatments. Additional context-aware sensing may be advisable, for precise assessment of the physical objects in sight and the distance between them and the player, so to obtain the system which could revise itself in order to provide as safety playing conditions as possible, which is a crucial issue concerning the children being a decent group within the target users. Furthermore, the device might be supplied with the gaze tracking system and help in controlling user interfaces [17] [18]. Regarding the efficiency

of using the system in terms of clinical improvements in eye operation, it is necessary to provide a long-term study with a satisfactorily large sample and the control group to assess system's efficiency as a treatment tool. Its' operation is expected to be similarly effective as the VR-based solutions, with the extended support for stereo-vision development. Yet it is expected to overperform VR versions since AR technology is superior in terms of environment awareness and therefore lack of nausea effect and better suitability to young brains development. It would be interesting to employ this technology and similar app design to other settings such as the industrial environments, where similar features (distinct eye display mode) could be utilized for more efficient data analysis and flow instalations control parameters visualisation [19] [20] [21] [22]. The approach may also become useful considering modern visualisation systems for control purposes [23]. [24]. Perhaps most interesting and challenging would be to use the AR technology to implement in hybrid systems such as context-aware data processing or crowdsourcing applications [25] [26] [27].

VII. Conclusions

This work shows a new approach to using computer vision technology for amblyopia therapy. Namely, mixed reality paradigm is applied in order to overcome disadvantages of virtual reality displays that already proven their potential for lazy eye treatment. Therefore, the proposed approach using Hololens device enables to exercise the weaker eye without full immersing into the virtual world. This is of a key advantage over the VR technology especially for children under 14 due to immature nervous system, middle ear bone labyrinth and eye fundus development.

***Abstract*—This work covers deployment of contextual processing of measurement data in application to temporal modeling of pneumatic conveying industrial process. Electrical capacitance tomography (ECT) used as a non-invasive process monitoring tool is supported by data mining for regularization of non-linear inverse problem solution. Processing of a larger number of archived experimental datasets enables extracting additional constraints for inference. Contextual data processing model (CDPM) extracts demanded information from the data in order to incorporate it as an expert knowledge about the process temporal behavior. Then it is incorporated into the Bayesian inference framework. Comparative analysis with previous work and domain expert prepared baseline to the proposed approach is demonstrated. Additionally, simplified parameterization is tested and verified by the quantitative experimental analysis.**

I. Introduction and related work

A. Pneumatic conveying and ECT

Bulk solids, powders and particulates cover about 2/3 of all solid materials used in industry at various stages of manufacturing. However, proper monitoring of processes that involve bulk solids is difficult because of their volumetric and opaque nature. The most promising techniques involve non-invasive and non-intrusive tools such process tomography methods, while electric capacitance tomography is one of the most popular modalities [1] [2]. However, there are some issues related to nonlinear nature of electrical field associated with extracting required process-related information from ECT data [3] [4] [5]. Therefore some methods aiming at improving the inverse problem conditions were developed over last 20 years [6] [7] [8] [9] [10] [11] [12] [13] [14]. Here a contextual tomography-based measurement data processing approach is proposed. It is based on the same contextual data processing model (CDPM) as described in [15] that was valided for big data driven aspects there. In contrast, current work validates CDPM within the scope of inverse problem regularization support. The main contribution of this work is therefore the proposed theoretical model for contextual data processing applied to temporal inference about the process behaviour. It is validated here with binary classification technique comparing to the baseline Bayesian inference framework.

B. Contextual Model for Measurement Data Processing

Contextual methods are derived from a concept of context-aware services or context-awareness in general. These concepts are extensively used in human computer interaction (HCI) discipline. Here it is postulated to outspread these notions to the field of measurement data processing for industrial processes monitoring [16] [17] [18]. Though some modification is required but the core of the concept remains to be based on a simple idea of using the additionally available information describing the object of interest in order to broaden the set of data to be incorporated as the input to the system.

I propose to expand this typical understanding of context

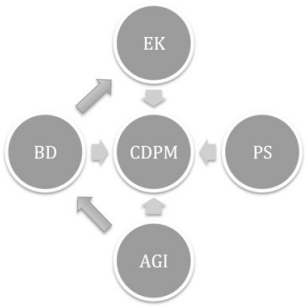

Fig. 1: General diagram of contextual data processing model (CDPM). EK, BD AGI, PS refer to as Expert Knowledge, Big Data, Artificially Generated Input, Peripheral Sensors accordingly.

related to the information coming from peripheral sensors (PS) to the four inter-related categories that form the CDPM model as shown on Fig.1. While PS still stays as substantial pillar of the model, the extension goes towards incorporating the following factors: Expert knowledge (EK), Big Data analysis (BD) and Artificially generated inputs (AGI) into the model. EK refers to any prior knowledge that can be defined independently to the current situation (experiment). BD stands for a broader base of previously conducted experiments or measurement datasets that can be analyzed in order to search for similarities, patterns or knowledge that can be extracted

out of it. AGI works as a complementary tool to supplement knowledge base, especially in case of sporadic phenomena for events that are rarely captured. While AGI can be either a distinct pillar of the CDPM it can also contribute to BD component. While exploring the BD analysis for CDPM is postulated in [15] [19] [20], this paper focuses at showing the method for incorporating EK into the process of inverse problem solving for ECT application to the monitoring of pneumatic conveying flow of bulk solids.

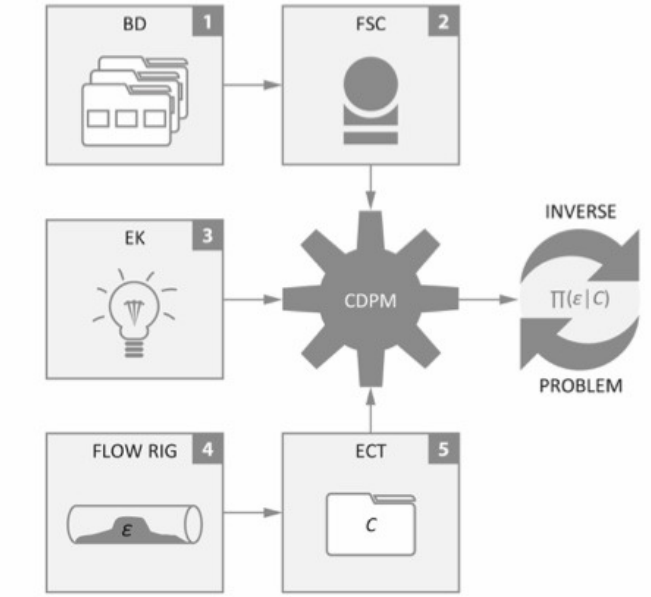

Fig. 2: CDPM for temporal modeling of pneumatic conveying. EK, BD, PS, FSC, ECT, C refer to as Expert Knowledge, Big Data, Artificially Generated Input, Peripheral Sensors, Flow State Classifiers, Electrical Capacitance Tomography, Capacitance data accordingly.

C. Pneumatic Conveying Experimental Setup

Experimental part of this research was conducted at the Tom Dyakowski Process Tomography Laboratory at the Lodz University of Technology. The ECT dual plane, 8-electrode sensors were fixed on a 65mm horizontal section of pneumatic conveying test rig as shown on Fig. 2. More details about the equipment can be found here [18]. Measurement campaign spanned over a range of settings preserving regular slug flow for different combinations of material feed rate, and air pressure (10.0 - 16 Hz inverter, 60 - 100 Hz of the rotary valve) for approx. 3 cubic mm polyamide pellets.

II. Investigation procedure

A. Baseline requirements

This work aims at proving that using available previous experimental data one can derive information useful for current measurement-related computational problem [10]. Spatio-temporal modeling of pneumatic conveying based on Bayesian inference and statistical methods demonstrated possibility of

Fig. 3: Experimental setup: ECT sensor equipped measurement section at horizontal pneumatic conveying rig and a corresponding ECT data acquisition device.

omitting the image reconstruction stage on the way to estimate characteristic flow parameters [8]. Current step is to simplify parametric modeling within the temporal modeling concurrently preserving or increasing the accuracy with the aid of CDPM. Computational environment with use of Hadoop is similar to desribed in [21]. The investigation is based upon the following postulations:

1) Mean concentration of bulk solid is taken as a main parameter describing flow state at any time point. ECT is the main measurement tool to supply estimated electric permittivity distribution (related to bulk concentration) based on capacitance measurement vectors.
2) There is additional information available in form of archived experimental datasets coupled with supplementary information such as estimated flow rate and weighed quantity of total material being transported, material geometry, properties, valves states, other metadata. Fig. 2 illustrates the basic workflow for the inverse problem using CPDM support.
3) Fragments of archive datasets are taken especially for slug rise (ECT recorded slug build up) and fall (ECT recorded slug tail) in order to regularize inverse problem for temporal analysis. Previously geometrical modeling was proposed for temporal smoothing varied in time that resulted in high uncertainty [22].
4) CPDM takes fragments, full-lenght experimental datasets and optional classifiers built on top of BD employment as well as any other general knowledge in order to incorporate it into the EK inverse problem solution as described in [8].
5) Correspondence to baseline, expert-annotated datasets in terms of mean electrical permittivity change in time was proposed as a principal measure to assess the proposed approach accuracy.
6) Calculated total transported material weight (relevant to flow rate) was chosen as an extra measure to verify if the simplification relying on substitution of geometrical modeling with mean concentration change is reasonable.

B. Inference Framework

Eq. (1) shows the approximation of the posterior probability density function related to the unknown distribution of the electric permittivity of the transported bulk solids mixture within the ECT sensor space. The critical factor from the CDPM is the kE which stands for the prior knowledge with relation to the expected constraints on the electric permittivity ϵ distribution in relation to obtained electric capacitance records C and in fact kE(ϵ) is EK equivalent.

$$p(\varepsilon \mid C) \propto p(C \mid \varepsilon) * k_E(\varepsilon) \tag{1}$$

where p(ϵ) is the inverse problem for ECT and bulk solids flow and the p(C—ϵ) is the forward problem that can be numerically approximated using FEM method. Hence the EK can be defined here as the regularization prior, and for an electric permittivity case can be denoted as kE(ϵ) Eq (2):

$$k_E(\varepsilon) \propto \exp\left\{-\beta_s \|\varepsilon\|_l^l\right\}; \beta_s > 0, 0 \le l \le 2. \tag{2}$$

Such stated kE(ϵ) leads to Laplacian distribution with a 1 (l=1) norm and leads to Gaussian distribution for norm 2 (l=2). Now extending this approach to a temporal dependence analysis the following relation expresses how consecutive frames dependence can be described (Eq. 3):

$$\Pi\left(\kappa^t \mid \kappa^{t+1}, \kappa^{t-1}\right) \propto \exp\left\{-\beta_t \left(\kappa^t - \bar{\kappa}^t\right)^2\right\} \tag{3}$$

where Kt is a set of estimated parameters at a given time point t, and βt decides on the level of correlation between these values in consecutive time points (in contrast to βs in a spatial distribution case in Eq. 2). The procedure of tackling the is shown on right hand-side of Fig. 1. There are several possible options for solving the Bayesian-based approach for ECT inverse problem solving. Related work referred to here is based on highly iterative MCMC scheme that is both computationally and time demanding [8] [10]. Current work was decided to use the same option yet thanks to GPU computing and reduced number of parameters the calculations are far less demanding and time consuming as shown in [11].

III. Results

A. Comparative Analysis

The results are given for the modeling of the pneumatic conveying slug flow for several different flow configurations as discussed in experimental setup section. Results are divided into 3 classes with respect to flow rate, i.e. average transported medium rate over time. Table 1 provides the comparison between the compliance of estimated mean concentration of solids (corresponding to amount of medium transported) on the basis of comparison between the raw data, reconstructed images analysis, previous approach [18] and the CDPM model. The datasets are cut to the 100 frames series that always include both the slug and stationary layer portion (i.e. consecutive periods of frames with lower or higher mean concentration values). Each of the 3 categories: low flow rate (Table 1, row 1), medium flow rate (Table 1, row 2) and high flow rate (Table 1, row 3) are arbitrarily divided into 3 consecutively rising classes based on the results and parameters of the performed experiments. Results in rows 1-3 indicate percentage compliance averaged over 10 different calculations and standard deviation both rounded to first decimal digit. Percentage is calculated based on binary classification of a consecutive measurement frame as either belonging or not belonging to a slug as shown in [9]. Row 4 reveals average error. Row 5 shows supplementary measure of total material transported weight comparing to the scale-recorded values for whole experimental datasets.

TABLE I: Pneumatic conveying CDPM results

	Slug flow rates averaged over time	**Results: average classification compliance (accuracy) comparing to the expert ground truth baseline**							
		Raw data		*Reconstructed images*		*Previous approach*		*CDPM*	
		[%]	SD	[%]	SD	[%]	SD	[%]	SD
1	*Low flow rate*	78.6	15.8	91.3	6.9	89.6	7.1	90.4	6.3
2	*Medium flow rate*	81.4	13.6	78.4	16.2	86.9	8.0	92.3	3.8
3	*High flow rate*	92.3	6.1	86.5	11.6	88.8	5.5	94.6	2.3
4	*Average error*	15.9		14.6		11.6		7.6	
5	*Total weight*	89.2	7.7	83.7	10.3	88.6	4.1	91.5	3.2

B. Discussion and directions for future work

The proposed CDPM model using temporal information as an input for expert knowledge (EK) extension to the normal prior knowledge applied in Bayesian inference framework performs well comparing to the baseline, i.e. to the expert provided ground truth in form of marked test datasets. CDPM results for all three classes reached 90%+ accuracy. CDPM performs better than other methods especially for medium and high flow rates for which both reconstructed images post-processing as well as previous work based on geometrical parameterization for temporal modeling obtained the weakest scores. Interesting feature is that the reconstructed images based analysis outperform both compared methods for low flow rates while is giving worse results for more dynamic flow regimes while the other two gain more accuracy for higher flow rates. It will be interesting to verify performance of the proposed model for a truly large data sample, especially of mixed origins of different experimental installations [23] [24]. On the other hand, it is noticeable that CDPM beats direct estimation based on raw data records by a small difference yet with much lower variance as well.

Total weight of material transported by the pneumatic conveying flow rig shown in row 5 of Tab. 1 showed superior

performance of CDPM model over the others however accuracy on 91.2% is not yet sufficient to treat ECT-based systems as a reliable, stand-alone, online monitoring tool for pneumatic conveying process. Nevertheless as stated in the beginning this measure proved that simplification of modeling process meant by the reducing the parameters number is feasible. Model that assumed mean material concentration value related to mean electric permittivity performed better than geometrical modeling of assumed cross-sectional areas of homogeneous material distribution.

More extensive computational study is required to derive more definitive conclusion about the performance of the CDPM model. Especially, further research work on the larger number of datasets in order to verify the range of applicability of this method to more general classes of applications for ECT monitoring of powder flows in vertical and inclined sections is needed. Next step is to construct a distributed computational environment for big experimental measurement data employing map-reduced paradigm in order to cope and test CDPM performance extensively. It would be interesting to see the AR-based study and track users what and how these professionals perceive the industrial environments to obtain a baseline for further development [15][25][26].

IV. Summary

This work illustrates experimental verification of the proposed CDPM model for temporal modeling of industrial pneumatic conveying process. The method is based on the incorporation of the extra expert knowledge as the regularization factor into the inverse problem solving for electrical capacitance tomography. As the initial results show, the methodology is suitable for temporal modeling of ECT-based monitored pneumatic conveying of bulk solids flow since it helps to identify the flow states (regimes) with similar or better accuracy than the state of the art methods. Calculated total quantity of material transported based on the proposed approach is of approximately 5-10% more accurate than the previous research shown. Hence the proposed simplified model based on mean material concentration value seems to be sufficient and in at least some aspects superior over previously reported geometrical parameterization for temporal bulk solid flow modeling.

***Abstract*—This paper presents a new approach to computer supported esophageal pH-metry measurement analysis performed in order to diagnose gastroesophageal reflux disease. In this approach wavelet analysis was used to analyse the esophageal pH-metry course. The research was performed on three groups of pH-metry courses: whole 24-hour pH-metry course, sleep only pH-metry course and 20 minutes after the end of a meal pH-metry course. After performing a 128 level decomposition of the pH-metry course, the W_x was defined as a parameter of extreme differential. This parameter was used to distinguish patients esophageal pH-metry results and on that basis classify patients as healthy or sick. Using this method the sensitivity of 77% was achieved.**

I. Introduction

GASTROESOPHAGEAL reflux disease (GERD) is one of the most commonly diagnosed diseases of the upper gastrointestinal tract, especially among the inhabitants of developed countries [1], [2], [3], [4]. It is estimated that the symptoms occur at least once a month in 44% of American adults, about 20% of Europeans, 6.6% of Japanese and Singaporeans or 3.5% of Koreans. However, among people in Africa and some Asian countries the disease is diagnosed very rarely [2]. The impact on the occurrence and development of the disease is largely influenced by the lifestyle of inhabitants of developed countries including the type of diet, the use of stimulants (alcohol, coffee, smoking cigarettes) or stress. In addition, the symptoms of GERD may increase as a result of misalignment during sleep or during increased physical effort (eg. during exercise in the gym) [5]. Studies suggest that many people are not fully aware of having the disease, though being effected by it's developing symptoms, and reporting to the doctor only when the disease has developed [5].

Among the numerous methods of diagnosing GERD 24hour esophageal pH-metry and 24-hour pH-metry with impedance measurements are the most popular invasive diagnostic techniques. These methods are characterized by a very high percentage of correctly diagnosed patients, but their main drawback is the time needed by a specialist gastroenterologist to evaluate the results of the measurement. Analysis of 24-hour format pH and impedance is a tedious and time-consuming task, that reduces the time the physician can spend on treating other patients or performing studies [6], [7], [8], [9].

Due to the impact of GERD on the condition of the upper gastrointestinal tract, which reflects on the health and lifestyle of patients, special attention should be paid to the process of early GERD diagnosis. This is particularly important in the context of the increase in the amount of positively diagnosed inhabitants of developed countries. In view of the increasing trend in the incidence of patients affected by GERD, taking into account the time-consuming diagnostic test, it is advisable to take steps to automate the assessment process of pH and pH with impedance measurements. Automating the process of pH-impedance courses evaluation will shorten the laborious analysis allowing the physician to quickly assess the results using their knowledge and experience. In order to implement the automation assessment process of pH courses discrete wavelet analysis was used.

II. Upper gastrointestinal tract reflux diseases

The mechanism of regurgitation of the stomach to the esophagus is a physiological process that occurs naturally in the human circadian cycle [2], [10]. Excessive exposure of tissues of the esophagus to the material alleged to reflux - mainly of hydrochloric acid and pepsin is prevented by the antireflux barrier, consisting of four components: the gastro-esophageal connection (lower esophageal sphincter), a mechanism for cleaning the esophagus of hydrochloric acid - the so called acid clearance, the upper esophageal sphincter and the resistance of esophageal mucosa [9]. These mechanisms help to protect esophagus tissue against chemical reactions destroying the tissues, since the esophagus is not adapted, as is the case of the stomach or duodenum, to longer exposure to the harmful effects of gastric acid.

The pathological situation will occur when, for various reasons, the physiological mechanisms protecting the esophagus from the gastric acid fail. Given that the hydrochloric acid and pepsin are the most harmful secretions of the upper gastrointestinal tract, often such a situation leads to occurrence and development of upper gastrointestinal tract reflux

TABLE I
PARAMETERS USED TO CALCULATE THE *Total DeMeester Parameter*

Lp.	Required parameter
1	Number of reflux episodes
2	Number of long reflux episodes (longer than 5 minutes)
3	Time of the longest reflux episode
4	Time during pH < 4 in horizontal position [%]
5	Time during pH < 4 in suspine position [%]
6	Total time during which pH < 4

diseases, mainly gastroesophageal reflux disease - GERD and reflux laryngo-pharyngeal - LPR. If left untreated, pathological changes result in deterioration of the patients quality of life, and in the extreme case lead to tumour lesions that are more complicated to treat and can lead to death [2], [5], [11], [12].

III. GERD DIAGNOSTICS

GERD diagnosis is possible with the use of a number of invasive and non-invasive tests. Apart from 24-hour pH-metry and 24-hour pH-metry impedance other methods are used, such as: gastrointestinal endoscopy, radiography with a double contrast or esophageal manometry [2], [12]. Each of these methods has a number of advantages, however, their limitations result in a lower GERD detection efficiency in comparison with pH-metry with impedance measurements. Therefore esophageal pH-impedance measurement is considered to be the best and the most common invasive GERD diagnostic method. Multichannel intraluminal Impedance-pH metry (MII-pH) is now the "gold standard" in reflux disease diagnostics [2], [5], [12], [13], [14], [15], [16], [17], [18], [19].

Esophageal pH-metry can determine the pH of the contents in the esophagus. It is accepted that the exposure of the esophagus to content which pH is less than 4 is harmful. Analysis of pH courses involves determining and defining certain parameters, characteristic to GERD, based on the method described by *DeMeester* [8]. These characteristic parameters are shown in Table I.

After characteristic parameters are calculated, the Total DeMeester Count can be calculated and compared with a reference value of 14.71 [8]. If the value of the Total DeMeester Count is higher than the reference value the patient is diagnosed as sick. Unfortunately, pH-metry alone has some limitations, as it allows track only pH changes in the esophagus, but it does not allow to determine the physical state of content passing from the stomach into the esophagus. This is especially problematic, since non-acid reflux episodes cannot be detected [12]. An extensions of diagnostic capabilities can be provided by studying esophageal impedance. Esophageal impedance measurement was first described in 1991 [12] and has since gained considerable popularity in the diagnosis of diseases of the upper gastrointestinal tract. This method, however, was not the subject of this research work.

IV. WAVELET ANALYSIS

Wavelet transform is currently one of the most used signal processing technique [20]. It allows for the use of other than the sine basis function (Fourier analysis can decompose a signal into components of a sinusoidal). As a result, it is possible to decompose the analysed signal components based other shapes, which often is highly useful in the identification of the signal's characteristics. In addition, the Fourier transform allows to obtain the data only in the frequency domain, while wavelet transform can give information in both time and frequency domains. Wavelet transform of a signal is calculated according to the formula (1)

$$S_\psi(a,b) = \frac{1}{\sqrt{a}} \int_{inf}^{\inf} s(t)\psi(\frac{t-b}{a})dt \qquad (1)$$

where: a: scale parameter, b: ptranslation parameter, $s(t)$: examined signal, ψ: chosen wavelet, $S_\psi(a,b)$: wavelet coefficient and $\psi(\frac{t-b}{a})$: kernel [20].

The coefficient a in the formula (1) is responsible for the scale representation of the selected wavelets. Values between 0 and 1 cause the wavelet to be shortened, and for a value above 1 is extended. The b in the formula (1) is responsible for moving the wavelet in the time domain (for b greater than 0 the wavelet is moved to the right on the timeline). This transformation should be viewed in the context of the five most popular families of wavelets, containing the ranks of their representatives: orthogonal (*Haar, Daubechies, Symlets*, etc.), the biorthogonal (*BiorSplines, ReversBiors*, etc.), function scaling (eg. *Meyer*) without scaling function (*Morlet, Mexican hat, Gaussian*, etc.) and the type Complex (*Shanon, Gaussian Complex, Complex Morlet*, etc.). The most common representatives of each of these families usually include wavelet type *Daubechies, Taking, Meyr, Morlet, Shannon*. The set of wavelet functions used to transform the signal consists of a basic waveform and the features that are scaled and time-shifted copies of the output signal.

A. pH-metry wavelet analysis

The study aimed to develop new mechanisms to accelerate the evaluation of esophageal pH measurements by the gastroenterologist. Currently used methods of pH-metry analysis are based on strictly defined coefficients *DeMeester*. In this paper an attempt to develop an alternative evaluation method is shown, which is based on wavelet digital signal processing.

To determine the effectiveness of diagnostic method the sensitivity parameter is used. Sensitivity is one of the most commonly used parameters to assess diagnostic tests [21]. The sensitivity of the test means the number of detected ill patients compared to the total number of patients in the study group of patients.

The esophageal pH courses were subjected to wavelet analysis. The aim of the decomposition was to find and determine clear criteria to distinguish and classify different pH courses into two groups: healty and sick. Three different approaches were adopted in relation to the types of analysed pH data:

- 21-hour test results (total registration period) divided into 4-hour intervals,
- courses of 20 minutes measured from the end of meals,

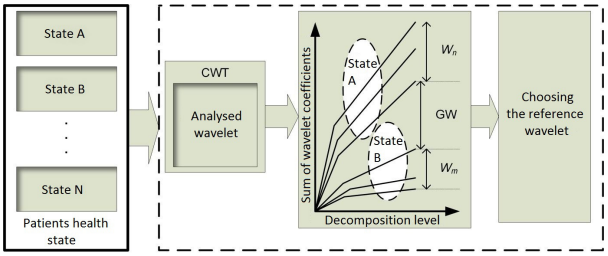

Fig. 1. The idea of wavelet decomposition of pH-metry courses.

- waveforms representing the 6 hour and 25 minute periods of sleep.

Wavelet decomposition was carried out using the five most common representatives of wavelet families *Daubechies, Taking, Meyer, Morlet, Shannon*.

B. Wavelet selection

The method of selecting wavelets for the analysis of non-stationary signals (biomedical signals) was preceded by a comprehensive analysis of the literature [22], [23], [24], [25], [26]. This analysis shows that different states of patients health (registered on pH courses) can be presented in the form of graphs, representing the sum of wavelet coefficients as a function of the level of the signals decomposition. The resulting graph shows the sum of wavelet coefficients in the form of ribbons. It was suspected that different health states will cause those ribbons to be located close to each other in a specific part of the coordinate system. In another approach it was suspected that health states could be distinguished when calculating and comparing the length between value of extreme wavelet sum coefficient, distinguished in the coordinate system. Such parameters were named W_m and W_n. Also a GW coefficient was defined as width of the gap between W_m and W_n regions. This approach is illustrated in Fig. 1, where the defined health states are: A - sick, and B - healthy.

In each case of the carried out analysis a 128 level, continuous decomposition was performed. For each level of decomposition, a series of wavelet coefficients were obtained, which then were summed. As a result a vector of dimension 1 x 128 containing sums of wavelet coefficients was obtained. This approach was used directly in the analysis of 20-minute pH courses after the end of a meal or sleep time. In the case of 21 hours pH courses, the whole course was divided into seven 4-hour episodes and subjected to decomposition separately. Eventually vectors were combined formed in one graph.

In the next step, W_x was defined and named - parameter of extreme differential, calculated using the (2) equation, that is related to maximal differential between extreme wavelet ribbons coefficients values.

$$W_x = L_{max128} - L_{min128} \tag{2}$$

where: L_{max128}: maximal value for the 128 level of decomposition and L_{min128}: minimal maximal value for the 128 level of decomposition.

To determine which of the wavelets from selected wavelet families is the best, an experiment was conducted, using a model pH course of a healthy person. In this experiment a 128 level continuous wavelet decomposition was carried out, followed by an examination - for which of the checked wavelets the difference between the extreme values W_n will be the lowest. The results of the experiment are shown in Table II. The analysis showed that in two cases - for wavelets type *Shannon Haar*, the result of the decomposition virtually precludes their further use in these studies. Very good, as expected, results were obtained for wavelets *db3, Bior* and *Morlet*. However, in the case of wavelet type *Meyer* when plotting the ribbons representing the sum of the wavelet coefficients, it turned out that the value of the designated indicators W_1, W_2 and GW are highly unsatisfactory. This issue is caused by an overlap in some of the waveforms representing health states: A and B (which in practice means the inability to distinguish them). To sum up, taking into account the previously made assumptions about the selection process, it has been shown that the most effective wavelet to decompose pH waveforms is *Morlet* wavelet type.

V. 21-HOUR PH-METRY COURSE ANALYSIS

Conducting research in the relevant field, wavelet decomposition of each registered 21-hour pH course was performed. For this purpose, each 24-hour pH course was divided into seven 4-hour intervals, and then - after the process of their decomposition - the wavelet coefficients were summed and plotted on a single graph, representing a patient exam results.

Patients results were divided into two groups: a test and a validation group. The test group consisted of patients whose Total DeMeester Count was below 50, and therefore diagnosed as healthy and/or mildly sick. The validation group included patients whose Total DeMeester Count was above 50.

In the first place the W_x coefficient was calculated for patients of the test group. The calculated values, as well as the *DeMeester* coefficients are shown in the Table III.

As a result, it was observed that in the case of healthy individuals the extreme differential coefficient W_x is equal to 336 (first case) and 557 (in second) units. The above observation can be justified by analyzing the pH courses of healthy patients, in whose case - because of the a small or marginal amount of reflux episodes - there is no frequent changes of pH during 24 hours. Therefore, the amount of wavelet components in the pH courses remain relatively low, which in turn leads to low sum of wavelet coefficients values.

For sick patients the extreme differential coefficient W_x vary from 789 to 2.327 units. High W_x values are associated with a large dynamics in pH signal changes, resulting from various kinds of components, causing significant variations in pH over a short of period of time. High values of W_x however are not directly proportional to the *DeMeester* count, which can be seen by comparing patients with D and G. The *DeMeester* count for the G patient is lower than that of patient D, while the value of the extreme differential takes a value equal to 2371, which is 250% higher than for the patient D. High *DeMeester*

TABLE II
VALUES OF MAXIMUM WIDTH OF WAVELET COEFFICIENTS W_n

Wavelet decomposition level	32			64			96			128		
Wavelet type	W1	GW	W2	W1	GW	W2	W1	GW	W2	W1	GW	W2

Haar	solutions ambiguous											

TABLE III
VALUES OF W_x PARAMETER FOR PATIENTS FROM THE TEST GROUP: WHOLE 21 HOUR PH COURSES

Patients ID	W_x parameter	Pateints diagnosis	*DeMeester* count
C	789	sick	68,0
D	924	sick	94,0
E	1417	sick	107,8
F	1477	sick	102,0
G	2327	sick	80,4
A	336	healthy	1,0
B	557	healthy	11,7

TABLE IV
VALUES OF W_x PARAMETER FOR PATIENTS FROM THE VALIDATION GROUP: WHOLE 21 HOUR PH COURSES

Patients ID	W_x parameter	Pateints diagnosis	*DeMeester* count
H	382	sick	42,0
I	973	sick	19,5
J	987	sick	43,1
K	624	sick	18,7
L	1608	sick	41,8
M	1434	sick	15,9
N	601	sick	19,4
O	1198	sick	29,5
P	647	sick	21,5

count is due to the presence of components dependent not only on pH value but also on time. Hence, in some patients high *DeMeester* count results from the presence of only one dominant pathological symptom, which determines the high value, while in other patients all or most of the symptoms are present, but manifest less frequently.

In the next stage of research, the extreme differential coefficient W_x was compared between a wider group of patients - the validation group, in order to verify the results of the analysis performed on the test group. The test results are shown in Table IV.

As can be seen in Table IV except the case of patient H, the value of W_x for all patients is above 600. Therefore, on the basis of both the above observations and the results from the test group patients, to distinguish the sick from the healthy patients, the value of W_x coefficient was set to 600 units. This allowed to achieve a 77% sensitivity. It should also be noted that the value of extreme differential of more than 1000 units always points to the case of a sick person.

TABLE V
DATA CONCERNING INDIVIDUAL PATIENTS FROM THE TEST GROUP: PH COURSES DURING SLEEP

Patients ID	Pateints diagnosis	*DeMeester* count
1	12,4	healthy
2	11,3	healthy
3	68,0	sick
4	42,0	sick
5	94,0	sick
6	19,5	sick
7	18,7	sick
8	41,8	sick
9	15,9	sick
10	19,4	sick
11	19,6	sick
12	29,5	sick
13	107,8	sick
14	102,0	sick

A. Wavelet analysis of pH-metry courses during sleep

The next stage of the research was wavelet decomposition referred to the pH courses registered during patients sleep. The purpose of this approach was to check if the plotted sum of wavelet coefficients (as a function of the decomposition level) concerning healthy and sick patients differ from each other in such a way that they can be helpful from a diagnostic point of view. As previously, a continuous 128 lv wavelet decomposition was performed after which the sum of wavelet coefficients was plotted. In contrast to earlier studies - relating to the entire pH course - this analysis was carried out for the entire time during the patients sleep, without dividing it into pieces. Therefore, in this case the W_x coefficient was not calculated, and only a single ribbon curve was plotted for each patient. As previously the patient were divided into two groups: test and validation groups. The results for the test group is shown in Table V.

Analysis of these results, shown in Fig. 2 (for the patients listed in Table V) indicates that distinguishing a clear criterion for patient assessment using wavelet analysis based on pH courses of sleep is not possible. Charts of healthy and sick patients in many cases overlap, and therefore there is no direct way to observe a border of a clear division of the plane between the healthy and the sick. Regarding these observations and the medical *DeMeestera* criteria it can be stated, that a comparison of healthy and sick patients (relating to the sleep phase), is pointless in relation to cases in which the *DeMeester* coefficient does not exceed 25.

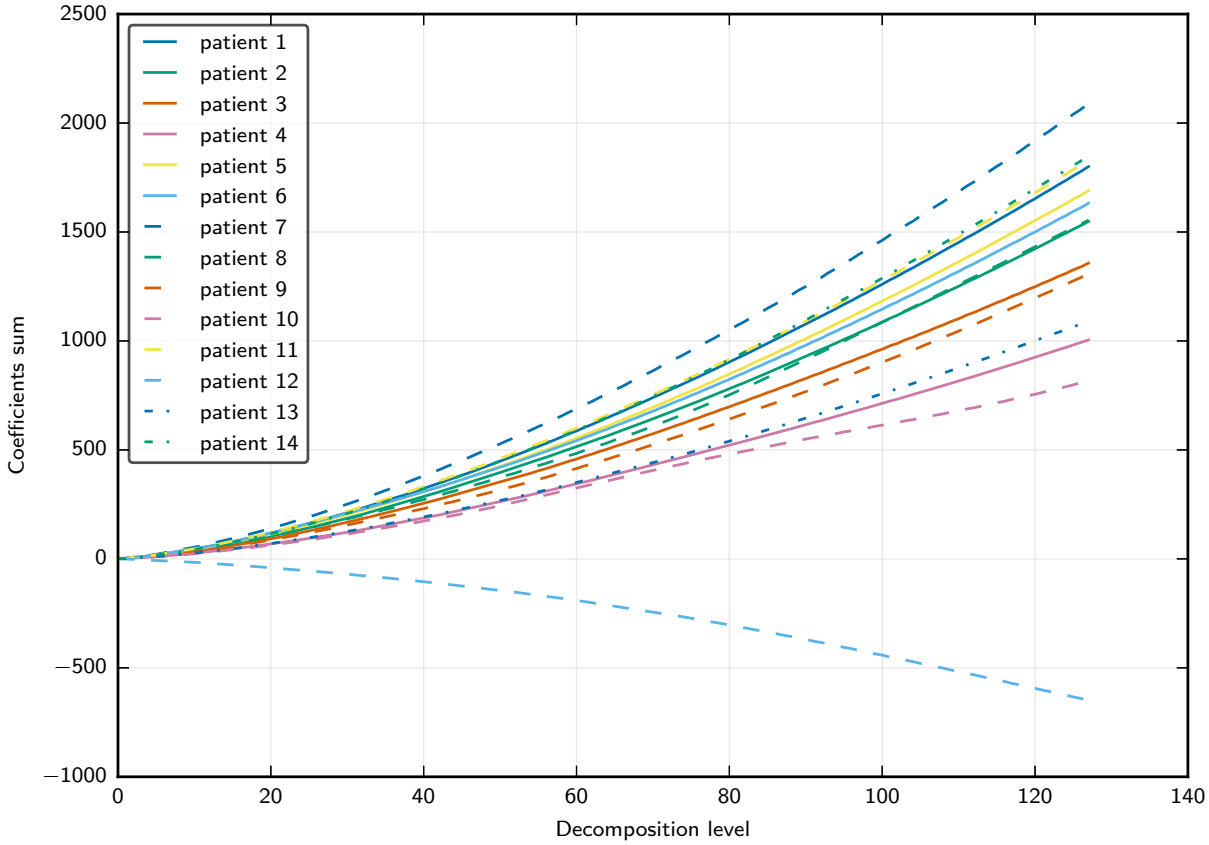

Fig. 2. Results of wavelet analysis of pH-courses during sleep

TABLE VI
VALUES OF W_x PARAMETER FOR PATIENTS FROM THE TEST GROUP: PH COURSES AFTER MEALS

Patients ID	W_x parameter	Pateints diagnosis	*DeMeester* count
A	821	sick	68,0
B	713	sick	94,5
C	1246	sick	107,8
D	887	sick	102,0
E	1303	sick	80,4
F	230	healthy	11,7
G	196	healthy	1,0

B. Wavelet analysis of pH-metry courses after meals

The basis for this approach were 20 minute fragments of pH recordings, that represented the changes in the pH after the patient stopped eating a meal. An example analysis is shown in Fig. 3. During that 20 minutes, the patients couldn't eat another meal. As previously the patients were divided into 2 groups: test and validation groups.

When analysing the results presented in Table VI it can be concluded that in the case of healthy patients extreme differential coefficient W_x achieves the lowest value in the group, whereas in the group of sick patients, the value of the coefficient is greater than 500 units. The conducted experiments did not confirm that the ribbons of wavelet coefficients sums are grouped in certain areas of the coordinate system separately for healthy and sick patients. Therefore the only clear difference between the ribbons describing healthy and sick patients is the W_x coefficient. On this basis - in order to verify the observed phenomenon, that in healthy patients the extreme differential is lower that sick patients - a threshold has been set, to discriminate those two groups of medical conditions. The threshold was set to 250 units. To verify the primary results, the threshold was applied to results obtained from the validation group. The results of these studies, together with *DeMeester* coefficients are shown in Table VII.

The results shown in Table VII lead to state that adopting a threshold of 250 units for W_x coefficient, to distinguish healthy from sick patients, is not fully satisfactory. This is due to the fact that for one of the healthy patient W_x is equal 405, although in can be noted that for this patient the *DeMeester* coefficient is 12.4, so very close to the borderline od 14.7. Moreover it can be seen that the lowest W_x was calculated for a patient whose *DeMeester* coefficient was equal 17. Therefore in the relevant group of 6 sick patients (whose *DeMeester* coefficients were higher than 20) only in 3 cases the W_x coefficient is above 400. For all sick patients, whose *DeMeester* coefficient were higher than 30 the W_x coefficient was significantly higher than 400. On this basis it can be stated that, as with the analysis of 21-hour pH courses, the

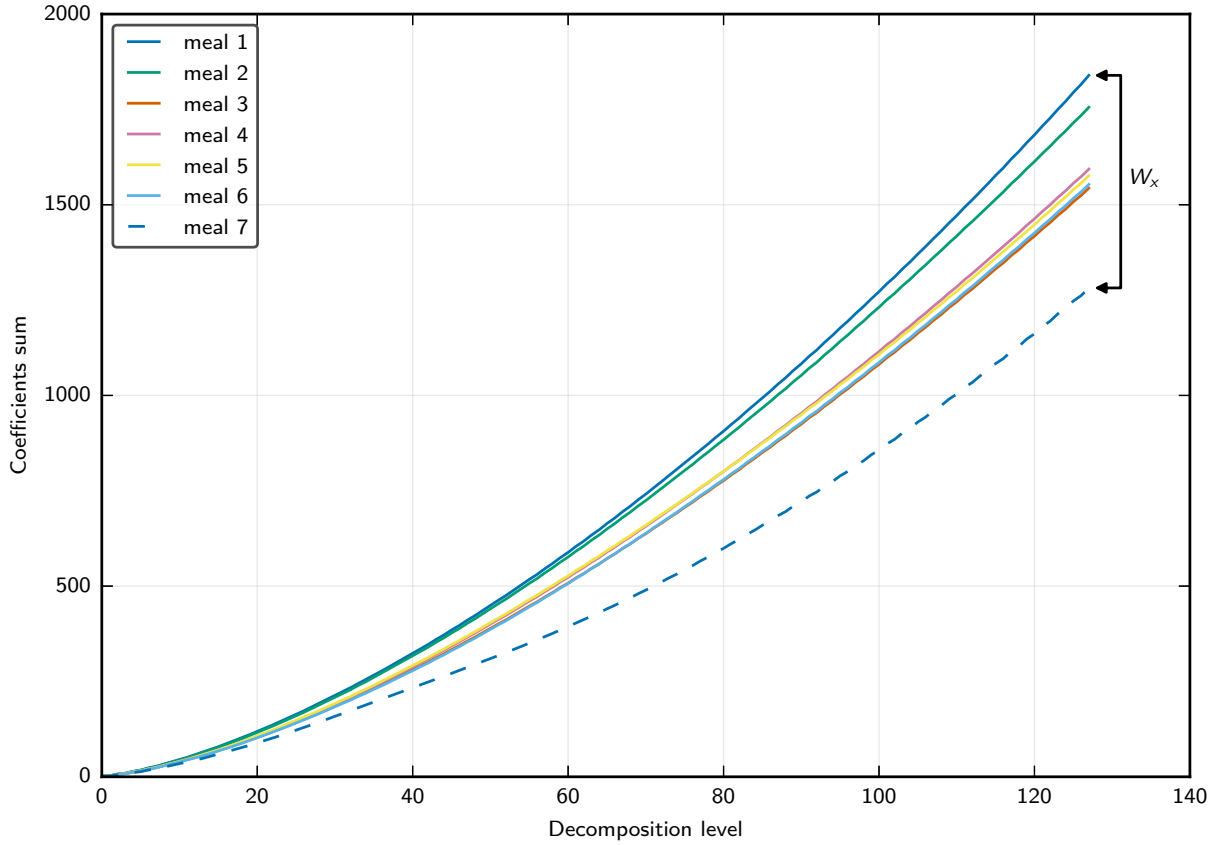

Fig. 3. An example wavelet analysis of 20 minute pH-metry courses taken after meals

TABLE VII
VALUES OF W_x PARAMETER FOR PATIENTS FROM THE VALIDATION GROUP: PH COURSES AFTER MEALS

Patients ID	W_x parameter	Pateints diagnosis	*DeMeester* count
H	405	healthy	12,4
I	821	sick	68,0
J	592	sick	42,0
K	713	sick	94,0
L	486	sick	19,5
M	266	sick	18,7
N	757	sick	41,8
O	543	sick	15,9
P	730	sick	19,4
R	385	sick	19,6
S	1988	sick	29,5
T	603	sick	107,8
U	887	sick	102,0
Q	206	sick	17,0

values of wavelet coefficients depend directly on the nature of changes in the pH course. Thus, both courses that in a short amount of time change their values quickly and courses with a small amount of fluctuation, but constant low pH value may eventually affect the resulting high value of the calculated *DeMeester* coefficient. The sensitivity in this case was 71%.

VI. CONCLUSION

Summing up the results of the research, it can be stated that: A) the method of wavelet analysis of esophageal pH courses registered during the patients sleep can not be used as a tool supporting the diagnosis of reflux diseases, B) both the method of 21-hour pH courses wavelet analysis and the 20-minute pH courses registered after meals wavelet analysis do not give fully satisfactory results, and therefore can not be used as the only method of diagnosing reflux diseases, but they can be used as an additional source of information, support the decision.

The proposed methods can be used as a preliminary assessment procedure when analysing esophageal pH courses, which would be subject to verification by a medical specialist in the course of further analysis. A particular advantage of the presented methods is that its implementation on a computer is quick, and the extreme differential W_x calculation process takes a small amount of time. This in turn leads to a fast diagnosis suggestion that is computed and available for the gastroenterologist. Significant advantages and disadvantages developed methods are shown in Table. VIII.

The conducted experiments showed that wavelet analysis can be successfully applied to evaluate esophageal pH courses in the means for supporting diagnosis of reflux diseases of the gastrointestinal tract. Further research on the methods pro-

TABLE VIII
ADVANTAGES AND DISADVANTAGES OF USING WAVELET DECOMPOSITION TO ANALYSE ESOPHAGEAL PH COURSES

W_x advantage	W_x disadvantage
use only pH courses	sensitivity level around 71% to 77%
easy to implement as a computer program	no possibility to asses the level of the reflux disease advancement
possibility to apply regardless of the pH recording equipment manufacturer	no possibility to check the number or the time of reflux episodes
possibility to fully automate the process of initial diagnostics/classification	possibility to use only as a additional, aiding tool in the diagnostics process

posed should focus primarily on determining accurate extreme differential coefficients W_x to distinguish between the results of healthy and sick patients. Moreover effort should be put on researching the dependence of the thresholds on other, not mentioned here, factors, eg. age, ancestry or general health of patients, to improve the sensitivity of the test. Research showed that improving the sensitivity of the method could be obtained by: increasing the number of patients (collected data), researching other wavelets, researching the corelation between GERD symptoms and pH data for each patient and optimizing the threshold for other specific factors in order to better adjust the threshold value to each patient (like age, sex, general health, etc). Since using wavelet decomposition is a new approach to the topic of GERD diagnostics it is difficult to state which path will lead to better results without commencing more research. Hence, with this state of knowledge, it is difficult to predict the best or optimal course of action. Therefore future work in this topic will present the latest findings in all or in the most promising of the proposed paths.

Further studies should be performed in order to apply classification algorithms to the found wavelet parameters. This can improve the sensitivity of the results as well as allow to find correlations between GERD symptoms and the pH-courses. Such algorithms were successfully applied in other similar research like [27], [28]. Such course can lead in the near future to develop a full medical computers system to aid the diagnostic process of GERD detection, that can be wildly used in the healthcare system. Such system would improve the quality of diagnosis, lower the cost of the diagnostic process and could be wildly used by medical staff. Such systems are being developed in a vast field of medical and healthcare areas: [29], [30].

11th Workshop on Computer Aspects of Numerical Algorithms

NUMERICAL algorithms are widely used by scientists engaged in various areas. There is a special need of highly efficient and easy-to-use scalable tools for solving large scale problems. The workshop is devoted to numerical algorithms with the particular attention to the latest scientific trends in this area and to problems related to implementation of libraries of efficient numerical algorithms. The goal of the workshop is meeting of researchers from various institutes and exchanging of their experience, and integrations of scientific centers.

TOPICS

- Parallel numerical algorithms
- Novel data formats for dense and sparse matrices
- Libraries for numerical computations
- Numerical algorithms testing and benchmarking
- Analysis of rounding errors of numerical algorithms
- Languages, tools and environments for programming numerical algorithms
- Numerical algorithms on coprocesors (GPU, Intel Xeon Phi, etc.)
- Paradigms of programming numerical algorithms
- Contemporary computer architectures
- Heterogeneous numerical algorithms
- Applications of numerical algorithms in science and technology

EVENT CHAIRS

Lodz University of Technology
18/22 Stefanowskiego St., 90-924 Łódź, Poland
Email: dbrzezinski@iis.p.lodz.pl

***Abstract*—In the paper there are presented efficient and accurate methods of Gauss-Jacobi nodes and weights computation. They include an enhancement for standard iteration method for Jacobi polynomials zeros finding, weight function formula transformation for increased accuracy of fractional derivatives computation and arbitrary precision application for mitigation of double precision arithmetic flaws. The results of numerical experiments presented in the paper prove high accuracy and efficiency of developed methods for computation of quadratures' nodes and weights, decreased amount of required iterations for polynomials zeros finding and elimination of truncation errors during weights computation. Accuracy of computations depends on height of precision applied for it, which is limited only by accessible hardware.**

I. Introduction

SPECIAL FUNCTIONS are part of mathematics that covers not only well known logarithmic, exponential and trigonometric functions, but also beta, gamma and zeta functions and orthogonal polynomials.

Special functions have numerous applications, not only in mathematics, but also in applied sciences, astronomy, heat conduction, electrical circuits, quantum mechanics and mathematical statistics. More about this subject can be found in [1].

Classical Jacobi orthogonal polynomials are applied in many important scientific areas that include functions' approximation in collocation points method for solutions of ordinary differential equations known as Sturm-Liouville problem and lately - fractional order derivatives and integrals computations by applying Gauss-Jacobi Quadrature [2], [3].

Methods of mathematical formulas implementations in computer programs are crucial part of numerical methods research due to their influence on general accuracy and efficiency of scientific computing. Especially in the case of a basic research as for example computation of polynomials values, their derivatives or their zeros, that can become a part of another computational methods.

Available research on these subjects focus on achieving the highest order of calculated polynomial [4], highest computational speed [5] and lowest computational complexity [6].

Besides of an interesting implementation of algorithms around orthogonal polynomials by applying Julia programming language [4], the majority of results published in scientific papers are obtained by applying computer implementations in Matlab, C++ or Python programming languages and the use of the double precision arithmetic.

The double precision arithmetic is optimized for speed and has many flaws influencing negatively accuracy of computations, e.g. limitations of number values which double precision variables can hold or no programmer influence on mathematical operations rounding.

In the meantime, computational capabilities of computers has been steadily increased and they presently enable using numerous enhancements for the uniform programming languages on the everyday basis. They include *infinite precision computing* for increasing accuracy and correctness of numerical calculations and Nvidia CUDA parallelization technology for their effectiveness, are the best examples in this context.

The term *Infinite Precision Computing* is just a metaphor suggesting, that precision of computation is only limited by an amount of accessible hardware. The more appropriate description of this aspect of computation would be *Arbitrary Precision Computing*.

Arbitrary precision computing has numerous advantages over standard double precision one, e.g. it makes possible for the user to choose a precision for each calculation and for each variable storing a value; it is also not depended on machine or IEEE standard types of data. Therefore, it opens brand new possibilities in terms of accuracy and correctness of scientific computing.

Having that in mind, the primary aim of the following paper is to present high-accuracy computing methods of Jacobi polynomial and its derivative, nodes (zeros of Jacobi polynomials) and weights of Gauss-Jacobi Quadrature.

The secondary aim is to present application usefulness of high-accurate computed Gauss-Jacobi Quadrature for fractional order derivatives and integrals computation.

Presented results of the experiments enable investigating in the future the possibility of their application in spectral methods for solutions of fractional order differential equations and the research of the high-accuracy computation on mitigation of Runge Phenomenon.

The paper is organized as follows: In section II, there are presented mathematical formulas for Jacobi polynomials and their derivatives computation. Section III and IV provides mathematical preliminaries about Gauss-Jacobi Quadrature together with detailed guidance how to adapt it for high-accuracy

fractional derivatives and integrals computation. Section VI describes standard methods for zeros of Jacobi polynomials finding (nodes of quadrature) and their enhancements for increasing computational accuracy and efficiency. Next section VII expands the information on methods of Gauss-Jacobi Quadrature weights computation with details on their enhancements. Both sections include numerous test plots and some preliminary results. Last section VIII presents practical testbed for developed methods in terms of accuracy and efficiency for fractional derivatives of two example functions computation. The paper ends with usual conclusions and future research.

II. Jacobi Polynomial and Its Derivative Computation

Jacobi orthogonal polynomials have two parameters usually denoted as α and β [7] and can be computed by applying Rodrigues' formula [8]

$$P_n^{(\alpha,\beta)}(x) = \frac{(-1)^n}{2n\cdot n!}(1-x)^{-\alpha}(1+x)^{-\beta}\frac{d^n}{dx^n}\left[(1-x)^{n+\alpha}(1+x)^{n+\beta}\right]. \tag{1}$$

Jacobi polynomials are orthogonal with respect to the weight function

$$w(x) = (1-x)^{\alpha}(1+x)^{\beta} \tag{2}$$

only for

$$\alpha,\beta > -1,\ -1 < x < 1$$

and particularly

1) For $\alpha = \beta = 0$ we obtain ultraspherical Jacobi polynomials - Legendre polynomials,
2) For $\alpha = \beta = \frac{1}{2}$ we obtain ultraspherical Jacobi polynomials - Chebyshev polynomials of second kind,
3) For $\alpha = \beta = -\frac{1}{2}$ we obtain ultraspherical Jacobi polynomials - Chebyshev polynomials of first kind,
4) For $\alpha = \beta$ we obtain Gegenbauer polynomial.

Jacobi polynomials $P^{(\alpha,\beta)}(x)$ of order n $P_n^{(\alpha,\beta)}(x)$ can be calculated by applying explicit form of the Rodriguez formula [9]

$$P_n^{(\alpha,\beta)}(x) = 2^{-n}\sum_{k=0}^{n}\binom{n+\alpha}{k}\binom{n+\beta}{n-k}(x-1)^{n-k}(x+1)^k, \tag{3}$$

wherein

$$P_0^{(\alpha,\beta)}(x) = 1,\ P_1^{(\alpha,\beta)}(x) = \frac{1}{2}(\alpha+\beta+2)\,x\frac{1}{2}(\alpha-\beta).$$

The derivative of Jacobi polynomial $P_n'^{(\alpha,\beta)}(x)$ of order n $P_n'^{(\alpha,\beta)}(x)$ can be calculated by applying the following formula

$$\frac{d}{dx}\left[P_n^{(\alpha,\beta)}(x)\right] = \frac{1}{2}(n+\alpha+\beta+1)\,P_{n-1}^{(\alpha+1,\beta+1)}. \tag{4}$$

However, application of formula (3) for computations is impractical. We can replace it by three-term recurrent formula (6) for this purpose resulting from theorem 1.1.1 published in [9].

According to it, more practical formula for Jacobi polynomial computation $P_n^{(\alpha,\beta)}(x)$, $n = 0,1,2,3,\ldots$ is

$$P_n^{(\alpha,\beta)}(x) = \sum_{i=0}^{n}\frac{(-1)^{n-i}(1+\beta)_i(1+\alpha+\beta)_{n+i}}{m!\,(n-i)!\,(1+\beta)_i(1+\beta+\alpha)_n}\left(\frac{x+1}{2}\right)^i, \tag{5}$$

where $(\alpha)_i = \alpha(\alpha+1)\cdots(\alpha+i-1)$, $\alpha_0 = 1$.

From (5) the following computational three-term recurrence formula can be then derived

$$\begin{aligned} P_0^{(\alpha,\beta)}(x) &= 1, \\ P_1^{(\alpha,\beta)}(x) &= \frac{1}{2}\left[(\alpha-\beta)+(\alpha+\beta+2)\,x\right], \\ P_{n+1}^{(\alpha,\beta)}(x) &= (\alpha_n x+\beta_n)P_n^{(\alpha,\beta)}(x) - \gamma_n P_{n-1}^{(\alpha,\beta)}(x), \\ & n = 1,2,\cdots, \end{aligned} \tag{6}$$

where

$$\begin{aligned} \alpha_n &= \frac{(2n+\alpha+\beta+1)(2n+\alpha+\beta+2)}{2(n+1)(n+\alpha+\beta+1)}, \\ \beta_n &= \frac{(2n+\alpha+\beta+1)(\alpha^2-\beta^2)}{2(n+1)(n+\alpha+\beta+1)(2n+\alpha+\beta)}, \\ \gamma_n &= \frac{(n+\alpha)(n+\beta)(2n+\alpha+\beta+2)}{(n+1)(n+\alpha+\beta+1)(2n+\alpha+\beta)}. \end{aligned}$$

Two example plots for Jacobi polynomial $P_n^{(1.5,-0.5)}(x)$ and its derivative $P_n'^{(1.5,-0.5)}(x)$, $x \in \langle -1,1\rangle$ of order $n = 1,2,\ldots 5$ are presented in Figures 1 and 2.

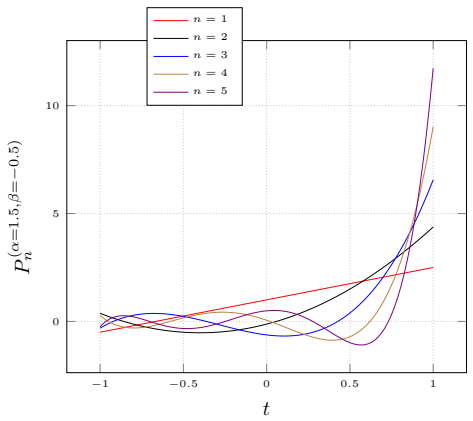

Fig. 1. Graph of Jacobi polynomial $P_n^{(1.5,-0.5)}(x)$, $x \in \langle -1,1\rangle$ of order $n = 1,2,\ldots 5$

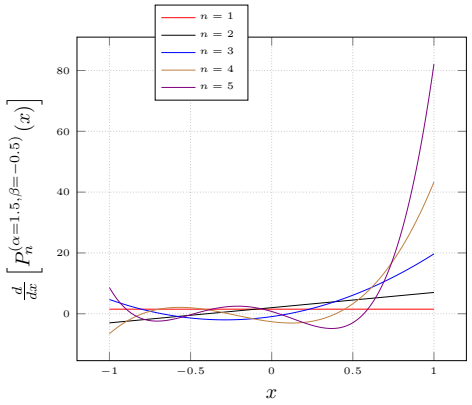

Fig. 2. Graph of Jacobi polynomial 1^{st} derivative $\frac{d}{dx}\left[P_n^{(1.5,-0.5)}(x)\right]$, $x \in \langle -1, 1\rangle$ of order $n = 1, 2, \ldots 5$.

III. Gauss-Jacobi Quadrature

A weight function enabling elimination of problems with integration of functions with singularities at both ends of integration interval is so called *Jacobi weight* (2).

By using some of its properties, there can be increased the accuracy of numerical integration, e.g. for computation of derivatives and integrals of fractional orders. Detailed description will be presented in subsection of section IV.

Jacobi polynomials are orthogonal in respect to weight function (2).

By applying Gauss-Jacobi Quadrature definition, formula for finite integral approximation assumes the following form

$$\int_{-1}^{1} (1-x)^{\alpha} (1+x)^{\beta} \cdot f(x)\, dx \approx \sum_{k=1}^{n} w_k f(x_k), \quad (7)$$

where the nodes of the quadrature x_k are the zeros of Jacobi polynomial $P_n^{(\alpha,\beta)}(x_k)$ of order n.

The weights w_k can be computed by applying the following formula

$$w_k = 2^{\alpha+\beta+1} \frac{\Gamma(\alpha+n+1)\Gamma(\beta+n+1)}{n!\Gamma(\alpha+\beta+n+1)(1-x_k^2)\left[P_n^{(\alpha,\beta)'} x_k\right]^2}, \quad (8)$$

where $P_n'(x_k)$ is 1^{st} derivative $P_n^{(\alpha,\beta)'}(x_k)$ of Jacobi polynomial of order n and $\Gamma(.)$ is Euler Gamma function.

IV. Formulas for Fractional Order Derivatives and Integrals Approximation

Fractional order derivatives and integrals can be approximated by applying numerous formulas representing various approaches to this problem [10]. The most popular are as follows.

Riemann-Liouville integral of fractional order $\nu > 0$

$${}_0^{RL}\mathrm{I}_t^{(\nu)} f(t) = \frac{1}{\Gamma(\nu)} \int_0^t \frac{f(\tau)}{(t-\tau)^{1-\nu}} d\tau, \quad (9)$$

Riemann-Liouville derivative of fractional order $\nu > 0$

$${}_0^{RL}\mathrm{D}_t^{(\nu)} f(t) = \frac{d^n}{dt^n}\left[\frac{1}{\Gamma(n-\nu)} \int_0^t \frac{f(\tau)}{(t-\tau)^{\nu-n+1}} d\tau\right], \quad (10)$$

Caputo derivative of fractional order $\nu > 0$

$${}_0^{C}\mathrm{D}_t^{(\nu)} f(t) = \frac{1}{\Gamma(n-\nu)} \int_0^t \frac{f^{(n)}(\tau)}{(t-\tau)^{\nu-n+1}} d\tau \quad (11)$$

with the following conditions: $f(t) = 0$ for $t \le 0$, $f(0) = 0, f^{(1)} = f^{(2)} \ldots f^{(n)} = 0$.

The following formula presents the relationship between formula (10) and (11)

$${}_0^{RL}\mathrm{D}_t^{(\nu)} f(t) = {}_0^{C} D_t^{(\nu)} f(t) + \sum_{k=0}^{n-1} \frac{t^{k-\nu}}{\Gamma(k-\nu+1)} f^{(k)}(0). \quad (12)$$

Inserting formula (11) to the right side of equation (12) enables derivation of an equivalent to (10) formula for Riemanna-Liouville'a derivative of fractional order

$${}_0^{RL}\mathrm{D}_t^{(\nu)} f(t) = \sum_{k=0}^{n-1} \frac{t^{k-\nu} f^{(k)}(0)}{\Gamma(k-\nu+1)} + \frac{1}{\Gamma(n-\nu)} \int_0^t \frac{f^{(n)}(\tau)}{(t-\tau)^{\nu-n+1}} d\tau. \quad (13)$$

In formulas (9)-(13) ν is a real number such as $n-1 < \nu < n$, n denotes an integer number $n = \lceil \nu \rceil$.

The practical application advantage of Caputo fractional derivative (11) over Riemann-Liouville fractional derivative (10) is, that the first one enable defining initial conditions in terms of classical, integer order derivatives [11]. Therefore, the Riemann-Liouville derivative definition is used more often in theoretical consideration, in which initial conditions must be defined in terms of fractional order integrals [12].

V. Approximation of Fractional Order Derivatives and Integrals by Applying Gauss-Jacobi Quadrature

Using the weight function (2) and integration formula (7), we can "remove" the kernel of the integrand from the formula (9)

$${}_0^{RL}\mathrm{I}_t^{(\nu)} f(t) = \frac{1}{\Gamma(\nu)} \int_0^t \underbrace{(t-\tau)^{\nu-1}}_{\text{kernel}} f(\tau)\, d\tau,$$

substituting $\lambda = \nu - 1, \beta = 0$, we obtain

$$\int_{-1}^{1} (1-t)^{\lambda} f(t)\, dt \approx \sum_{k=1}^{n} w_k f(t_k) = \sum_{k=1}^{n} \frac{2^{\nu}}{(1-t_k^2)\left[P_n^{(\lambda,0)'} t_k\right]^2} f(t_k), \quad (14)$$

where w_k are the weights (8).

Transforming integration interval $[0,t]$ into $\langle -1,1\rangle$

$$\left(\frac{t-t_0}{2}\right)^{\nu}\int_{-1}^{1}\frac{f(u)}{(1-u)^{\lambda}}du$$

where

$$f(u)=f\left(\left(\frac{t-t_0}{2}\right)u+\left(\frac{t+t_0}{2}\right)\right),$$

we obtain formula (15), which can be applied for computing Riemann-Liouville and Caputo fractional derivatives with high accuracy. A formula for fractional integrals computation can be derived in a similar way.

In the formula (15) the difficult part of the integrand - the kernel - equipped with singularity and high increases of function values, is computed using different, much more accurate method - by applying formula for the weights w_k [2].

$$\begin{aligned}{}_{t_0}^{RL}\mathrm{D}_t^{(\nu)}f(t)&=\sum_{k=0}^{n-1}\frac{(t-t_0)^{k-\nu}f^{(k)}(t_0)}{\Gamma(k-\nu+1)}+\frac{1}{\Gamma(n-\nu)}\left(\frac{t-t_0}{2}\right)^{n-\nu}\int_{-1}^{1}\frac{f^{(n)}(u)}{(1-u)^{\nu-n+1}}du\\&=\sum_{k=0}^{n-1}\frac{(t-t_0)^{k-\nu}f^{(k)}(t_0)}{\Gamma(k-\nu+1)}+\frac{1}{\Gamma(n-\nu)}\left(\frac{t-t_0}{2}\right)^{n-\nu}\underbrace{\sum_{k=1}^{n}\frac{2^{\nu}}{(1-u_k^2)\left[P_n^{(\nu-n+1,0)'}u_k\right]^2}}_{w_k}f^{(n)}(u_k),\ n=\lceil\nu\rceil.\end{aligned}\tag{15}$$

VI. Methods of Finding Zeros of Jacobi Polynomials

Formula (7) suggests that the construction of Gauss-Jacobi Quadrature is limited to finding zeros x_k of Jacobi polynomial $P_n^{(\alpha,\beta)}(x_k)$ of order n and determining its derivative $P_n^{(\alpha,\beta)'}(x_k)$.

Polynomial of order n has n distinct zeros [13]. This rule extends for systems of orthogonal polynomials, including Jacobi polynomials. Proof of this theorem can be found in [14].

Chebyshev polynomials of I, II, III and IV kind are special cases of Jacobi polynomial for α and β with values $-0.5,-0.5,\ 0.5,0.5,-0.5,0.5$ and $0.5,-0.5$ respectively.

Zeros of Chebyshev polynomials called Chebyshev points are given by the following formulas [15]:

$$\begin{aligned}x_k&=\cos\frac{(k-0.5)\pi}{n},\\x_k&=\cos\frac{k\pi}{n+1},\\x_k&=\cos\frac{(k-0.5)\pi}{n+0.5},\\x_k&=\cos\frac{k\pi}{n+0.5},\ k=1,2,\dots n.\end{aligned}\tag{16}$$

Finding zeros of Jacobi polynomial with other values α and β is not easy.

However, a standard method for finding zeros of polynomials is an iteration algorithm called Newton-Raphson algorithm [16].

Iteration algorithms usually require first raw approximation for finding a zero. In case of Jacobi polynomial, it can be for example a zero of Chebyshev polynomial of 1^{st} kind (16).

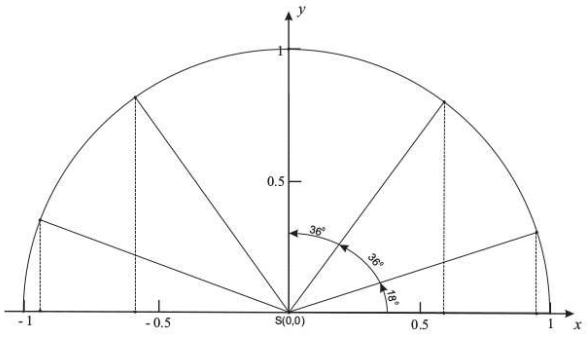

Fig. 3. Chebyshev points,$n=5$ of Chebyshev polynomial of the I kind.

Then, the Newton-Raphson method is used for finding highly accurate location of that zero.

This method is usually fast-convergent, especially for orthogonal polynomials.

Let s denote consecutive iteration. Each iteration of standard Newton-Raphson method requires computation of polynomial value and its derivative. Both values can be used for approximating k^{th} zero in the following way

$$x_k^{s+1}=x_k^s-P_n(s_k^s)/P_n'(x_k^s),\tag{17}$$

where $P_n^{(\alpha,\beta)}(x)$ is Jacobi polynomial computed using recurrent relationship (6).

Its derivative $P_n'^{(\alpha,\beta)}(x)$ can be computed by another recurrence relation

$$P_{n+1}'=P_n+(x-\alpha)P_n'-\beta_nP_{n-1}'.\tag{18}$$

A. Accuracy of the Standard Iteration Method

For the purpose of assessing accuracy of finding zeros of Jacobi polynomial P_n for arbitrary selected values of n by

applying standard iteration method, relative error measure e_r and norm $\|e_r\|_{L_\infty}$

$$\|e_r\|_{L_\infty} = max_i \frac{\|x_i - \hat{x}_i\|}{\|x_i\|}. \tag{19}$$

are used.

The norm (19) assess similarity of two vectors, e.g. with zeros values by applying standard iteration method $\hat{x}_i$ and their exact values. In both cases, there are applied standard double precision for computations and first raw approximations of zeros by applying formulas (16) proposed in [17].

TABLE I
Relative error $\|e_r\|_{L_\infty}$ for selected order n of Jacobi polynomial.

n	Chebyshev I	Chebyshev IV
50	2.89e-15	5.66e-15
100	9.55e-15	1.04e-14
200	1.37e-14	1.10e-14
300	3.18e-14	2.02e-14
400	2.19e-14	4.11e-14
500	2.00e-14	1.19e-14
1000	5.36e-14	7.39e-14

Application of first raw approximation of zeros by applying formulas (16) in Newton-Raphson method enabled finding n distinct zeros with double precision exactness of each zero after 8-10 iterations.

B. Enhancements of the Standard Iteration Method

1) More accurate first raw approximations of zeros: Application of more accurate first raw approximations of zeros can reduce an amount of required iterations for finding an exact location of a zero in Newton-Raphson method.

As it is to see in figure 4 with plots of Jacobi polynomials of order 5 and 6, in the middle part, the polynomials are similar to sine and cosine functions. Near boundary, at $x = 1$ they become compressed. Therefore, we can draw a conclusion that an amount of zeros of Jacobi polynomial increases towards end of the interval $[-1, 1]$. This conclusion suggests that we should use different formulas for first raw approximations for zeros in Newton-Raphson method for middle and boundary parts of Jacobi polynomial.

According to [18] an universal formula for the middle part of the Jacobi polynomials, zeros $4, n-2$ for $k = 1, 2, 3, \ldots, n$ is (20).

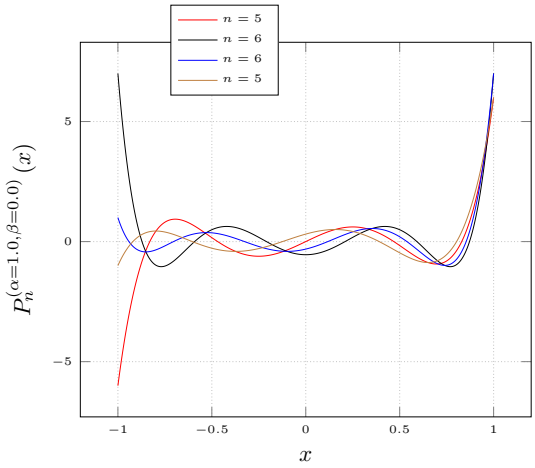

Fig. 4. Jacobi polynomials $n = 5$ and $n = 6$.

$$x_k = -\cos(\theta_k + \delta\theta_k) + O\left(n^{-4}\right) \tag{20}$$

where

$$\theta_k = \pi(2k + \beta - 0.5)/\sigma,$$
$$\delta\theta_k = \left[\left(0.25 - \beta^2\right)\cot\left(\frac{\theta_k}{2}\right) - \left(0.4 - \alpha^2\right)\tan\left(\frac{\theta_k}{2}\right)\right]/\sigma^2,$$
$$\sigma = 2n + \alpha + \beta + 1.$$

For approximating zeros for nodes $[1, 2, n-1, n]$ i.e. for both ends of the interval we can use formula by [18] that uses zeros of Bessel functions of order 5 $J^5_{\alpha,k}$, e.g. [19]

$$x_k = \cos(\theta_k + \delta\theta_k) + O\left(J^5_{\alpha,k} n^{-7}\right) \tag{21}$$

where

$$\theta_k = \frac{J^5_{\alpha,k}}{\nu},$$
$$\delta\theta_k = -\theta_k\left[\frac{4 - \alpha^2 - 15\beta^2}{720\nu^4}\left(\frac{J^2_{\alpha,k}}{2}\right) + \alpha^2 - 1\right],$$
$$\nu = 0.5\sqrt{\sigma^2 + (1 - \alpha^2 - 3\beta^2)/3}.$$

2) Application of reflection formula: For finding zeros of Jacobi polynomial for $\alpha \neq \beta$, there can be applied reflection formula

$$P_n^{(\alpha,\beta)}(-x) = (-1)^n P_n^{(\beta,\alpha)}(x),$$
$$\frac{d}{dx}\left[P_n^{(\alpha,\beta)}(-x)\right] = (-1)^{n-1}\frac{d}{dx}\left[P_n^{(\beta,\alpha)}(x)\right], \tag{22}$$

which results from formula for Jacobi polynomial of order n (1).

It enables reducing computational effort of polynomial values to the right part of the interval, i.e. $x \in [0, 1]$. It means that we only require to compute zeros from the right part of the interval and copy them to the second one $x \in [-1, 0]$.

3) Application of arbitrary precision: enables increasing overall accuracy of computations.

To be able to solve a difficult numerical problem according to a set goal, we have to make some crucial decisions regarding applied hardware, programming tools and techniques for that purpose. This includes a selection of an appropriate computer programming language, mathematical libraries and hardware.

The selection of uniform C++ equipped with the standard mathematical library as a main programming tool is not enough nowadays to take full advantage of available hardware. And it is the main task for a computer scientist, because the newest hardware gives the opportunity to solve many problems, which appeared "unsolvable" not long time ago. The application of *infinite precision computing* for increasing the accuracy and the correctness of numerical calculations and Nvidia CUDA parallelization technology for their effectiveness, are the best examples in this context.

In this paper there is presented application of arbitrary precision for increasing accuracy of computations.

The standard double precision computer arithmetic was replaced by arbitrary precision for most parts. This move made possible unlocking full potential of developed algorithms by using available hardware.

Double precision arithmetic commonly applied in scientific numerical calculations is optimized for speed and has many flaws which influence negatively the accuracy of computations, e.g. limitations of number values which double precision variables can hold or no programmer influence on mathematical operations rounding.

However, it is the lack of clarity in handling of intermediate results which troubles the most, i.e. the floating-point standard only defines that the results must be rounded correctly to the destination's precision and not defines the precision of destination variable. This choice is commonly made by a system or a programming language. The user can not influence it in any way. Therefore, the same program returns significantly different results depending on the implementation of the IEEE standard.

Arbitrary precision makes possible for the user to choose a precision for calculation and for each variable storing a value and it is nor machine or IEEE standard types depended. It is only limited by accessible hardware.

Arbitrary precision can be applied for calculating important constants like π or increase general accuracy of the mathematical computations. Its application purpose is above all to increase accuracy of numerical calculations, e.g. by eliminating under- and overflows, increasing accuracy of a polynomial zeros finding and derivatives and integrals calculating.

Still, application of arbitrary precision has drawbacks:

Arbitrary precision is simulated and therefore, depending on chosen precision, calculations with the help of it require more time to complete than by applying standard data types optimized to run on standard processors - even with the use of FPGAs (field programmable gate arrays), which can be fully programmed by the user.

Another challenge is a requirement of special computational algorithms which can handle different data structures.

Nevertheless, arbitrary precision application already became a part of standard computations without the consent of the user. The process named *constant folding with arbitrary precision* is used in preprocessing phase to increase the accuracy of constants before they can be handled with standard precision data types. This procedure [20] involves replacing constant expressions with their final value in order to reduce the need of recomputing the same result every time the program executes the code line containing the constant. When the compiler flag -01 is inserted GCC complier uses the GNU MPFR library with version 4.3 to handle constant folding and evaluate mathematical applied to constants at compile time at arbitrary precision.

The GNU MPFR library is an arbitrary precision package for C/C++ [21] and is based on the GNU Multiple-Precision Library (GMP) [22]. MPFR supports arbitrary precision floating-point variables and provides exact rounding of all implemented mathematical functions [23]. The code is portable, i.e. it will produce the same result independently from the hardware.

The GNU MPFR library is written in C and thus it can not use operator overloading. Even the most basic arithmetic operations have to be conducted using function calls. Therefore MPFR includes multiple functions for each operation and for each supported data type.

C. Results

Table II presents accuracy of computed zeros of Jacobi polynomial in form of relative error (19) calculated in respect to the exact values obtained by applying Czebyshev points (16) for 50, 100, 500 and 1000 digits precision.

It is worth noting, that the proposed enhancements of the standard iteration method enables finding zeros with arbitrary precision. The level of exactness depends on how high precision is selected applied for computations.

Additionally, application of more accurate first raw approximations of zeros (20) and (21) before Newton-Rapshon method starts, decreases an amount of required iterations until exact zero position is found.

Computation time complexity of running program is presented in figure 5. The time depends directly on the hight of precision selected for computations: for polynomial order $n < 500$ and up to 100 digits precision, the time is similar to double precision computations, for $n > 500$ and more than 100 digits precision, the complexity is 2^n, and $n!$ is for 1000 and more digits precision.

VII. Methods of Jacobi Weights Computation

A. Standard Approach

A standard approach to the problem of Jacobi weights computation is the direct use of formula (8).

In this formula proposed in [24], weight is computed by using value of derivative of Jacobi polynomial of order n and a value of Jacobi polynomial of order $n-1$.

TABLE II
RELATIVE ERROR $\|e_r\|_{L_\infty}$ OF FOUND ZEROS OF $P_n(x)$ FOR SELECTED n IN RESPECT TO (16).

	Czebyszew I			Czebyszew II			Czebyszew III			Czebyszew IV		
n	50	time(s)	iter	100	time(s)	iter	500	time(s)	iter	1000	time(s)	iter
50	1.50e-49	0.047	6	3.77e-99	0.053	7	6.24e-499	0.102	7	8.31e-647	0.150	6
100	6.84e-49	0.0168	6	6.74e-99	0.195	7	1.40e-498	0.392	7	5.24e-641	0.562	7
200	9.52e-49	0.588	7	7.43e-99	0.765	6	1.35e-498	1.323	7	1.89e-641	2.073	7
300	1.66e-48	1.236	6	2.22e-99	1.673	6	1.31e-498	3.012	7	3.64e-640	4.514	7
500	1.49e-48	3.089	6	1.59e-99	4.349	6	9.05e-498	8.034	7	1.58e-648	12.598	7
1000	5.61e-48	11.867	6	2.60e-98	15.913	6	7.96e-498	34.37	7	8.99e-709	49.015	7
2000	7.00e-48	47.353	6	5.45e-98	63.445	6	3.78e-497	126.664	7	8.99e-709	49.173	7

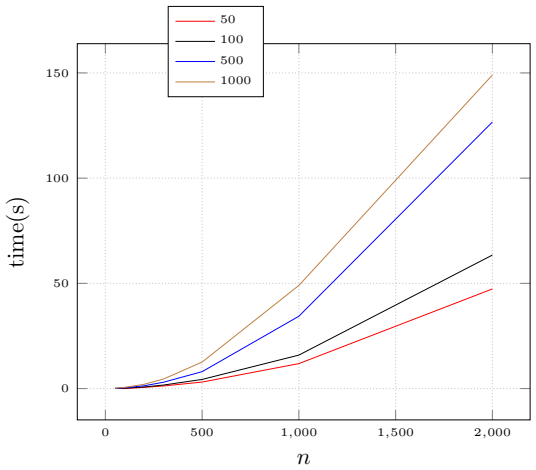

Fig. 5. Computation time complexity of finding zeros of Jacobi polynomials of selected order n with 50, 100, 500 and 100 digits precision.

However, due to $1-x_k^2$ expression occurrence in the denominator of (8), high truncation error is expected if standard double precision is applied.

Additionally, deducing from 4, an amount of zeros in Jacobi polynomials increases quadratically with increasing n (hence the distance between then decreases) towards bounds of integration interval $[-1,1]$. It causes the following problem: if standard double precision is applied, for enough large n, zeros become indistinguishable.

B. Enhancement of Standard Approach

Instead of formula (8), an equivalent formula is suggested to apply

$$w_k = 2^{\alpha+\beta+1}\frac{\Gamma(\alpha+n+1)\,\Gamma(\beta+n+1)}{n!\Gamma(\alpha+\beta+n+1)}\frac{1}{\left[\frac{d}{d\theta}P_n(\cos\theta_k)\right]^2}, \tag{23}$$

in which $\frac{d}{d\theta}P^{(\alpha,\beta)}$ is derivative of Jacobi polynomial of order n and $\theta_k = \cos^{-1}x_k$, x_k are zeros of Jacobi polynomial of order n.

The conversion into trigonometric functions space has been proposed by [25]. It enables omitting the expression $1-x_k^2$ and hence reduce truncation error at the same time.

C. Results

Table III presents accuracy of Jacobi weights computation in form of relative error (19) calculated in respect to the exact values obtained by applying Czebyshev weights [15] for 50, 100, 500 and 1000 digits precision. Application arbitrary precision enables computing Jacobi weights with high-accuracy. However, computational accuracy is not so straightforward depended on an amount of digits of precision applied for computations. It is caused by the fact that computational complexity is increased by zeros of finding of the polynomial of a given order.

General time complexity of Jacobi weights w_k computation presented in figure 6 depends directly on precision applied for computations: for $n<500$ and up to 100 digits precision it is similar to double precision, $n>500$ and more than 100 digits precision it is 2^n, and $n!$ for more than 1000 digits precision.

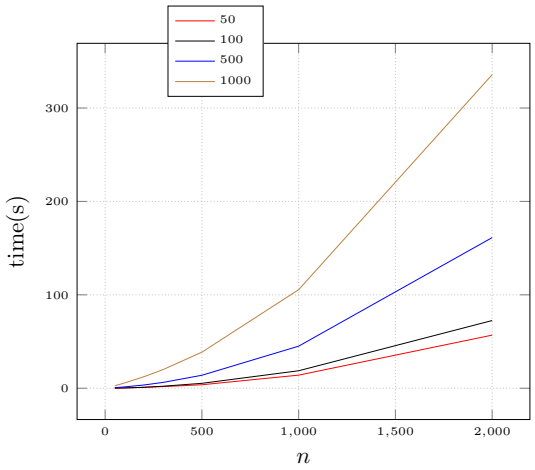

Fig. 6. Computation time complexity of Jacobi weights for selected order n with 50, 100, 500 and 100 digits precision.

VIII. FRACTIONAL ORDER DERIVATIVES AND INTEGRALS COMPUTATION

The most useful method of presenting practical capabilities of algorithms proposed in the following paper is computation of values of integrals and derivatives of fractional order of two exponential functions by applying formulas (9) and (13) with the help of Gauss-Jacobi Quadrature (15).

TABLE III
RELATIVE ERROR $\|e_r\|_{L_\infty}$ OF COMPUTED WEIGHTS w_k FOR SELECTED n IN RESPECT TO (16).

To assess accuracy of computations of fractional derivatives and integrals, it is required to computed exact values with high-accuracy for relative error computation. In case of fractional order derivative and integral computations, the effective accuracy assessment is difficult, sometimes not possible due to general lack of formulas for exact values.

Despite the availability of a handful of analytical formulas for fractional order $\nu = \frac{1}{2}$ and some computational formulas, they are accessible for selected types of functions only. Some other formulas are in form of series expansion only. As it is in case of exponential functions.

For the error (19) computation Mittag-Leffler function is used.

A. Mittag-Leffler Function Computation

The Mittag-Leffler function [26] is a direct generalization of the exponential function e^{at} and it plays a major role in fractional calculus. The one, two and three-parameter representations of the Mittag-Leffler function can be defined in terms of a power series as

$$E_\alpha(at) := \sum_{k=0}^{\infty} \frac{at^k}{\Gamma(\alpha k + 1)},\ \alpha > 0, \tag{24}$$

$$E_{\alpha,\beta}(at) := \sum_{k=0}^{\infty} \frac{at^k}{\Gamma(\alpha k + \beta)},\ \alpha, \beta > 0. \tag{25}$$

When $\beta = 1$, $E_{\alpha,1}(at) = E_\alpha(at)$.

$$E^\gamma_{\alpha,\beta}(at) := \sum_{k=0}^{\infty} \frac{(\gamma)_k}{\Gamma(\alpha k + \beta)} \frac{at^k}{k!},\ \alpha, \beta > 0, \tag{26}$$

in which $(\gamma)_k$ is Pochhammer symbol [27]

$$(\gamma)_k := \frac{\Gamma(\gamma + k)}{\Gamma(k)}.$$

When $\gamma = 1$, $E^1_{\alpha,\beta}(at) = E^\gamma_{\alpha,\beta}(at)$, and when $\gamma = \beta = 1$, $E^1_{\alpha,1}(at) = E_\alpha(at)$. Some particular cases of the Mittag-Leffler function are: $E_0(at) = \frac{1}{1-at}$, $E_1(at) = e^{at}$ $E_2(at) = cosh\sqrt{at}$, $E_{1,2}(at) = \frac{e^{at}-1}{t}$, $E_{2,2}(at) = \frac{sinh\left(at^{1/2}\right)}{at^{\frac{1}{2}}}$, $E_{\frac{1}{2},2}(at) = e^{at^2}\, erfc(-at)$. Papers [28] and [29] present comprehensive knowledge of computing the Mittag-Leffler function and its first derivative.

To calculate the Mittag-Leffler fractional order derivative/integral we combine the Riemann-Liouville fractional derivative of the power function $(t - t_0)^p$, $p \in \mathbf{R}$ and the Mittag-Leffler function (24) or (25)

$${}_{t_0}D_t^{(\nu)} E_{\alpha,\beta}(at) = t^{-\nu} \sum_{k=0}^{\infty} \frac{\Gamma(k+1)\, at^k}{\Gamma(k+1-\nu)\,\Gamma(\alpha k + \beta)} \tag{27}$$

and for calculations of fractional order integral of the Mittag-Leffler function, we apply the following formula

$${}_{t_0}D_t^{(-\nu)} E_{\alpha,\beta}(at) = at^\nu \sum_{k=0}^{\infty} \frac{(at^\nu)^k}{\Gamma(\alpha k + \beta + \nu)}. \tag{28}$$

B. Computing Environment Configuration

All computations described in the paper were conducted using PC computer with Intel i7 2600K Processor, 8 GB of RAM armed with full open-source operating system and compiler: Ubuntu 16.04 LTS 64-bit Linux OS and gcc 5.4.0 compiler.

The computer system can be described as high-performance, because its computational power is enormous. However, it dates from 2011. Therefore it also can be described as commonly used.

To complete the picture that is important for time complexity assessment, calculations were also conducted on an older notebook with Intel Core 2 Duo Processor 2.4 GHz with 4 GB of memory from 2008 with exactly the same software configuration.

C. Results

Figures 7 and 9 present plots of fractional integral and derivative of two exponential functions. Figures 8 and 10 present plots of relative error (19) for $n = 8, 16, 32$ computed with 100 digits precision.

As it is to see, steady 100 digits accuracy can be obtained by applying Jacobi polynomial of order $n = 32$ for computations.

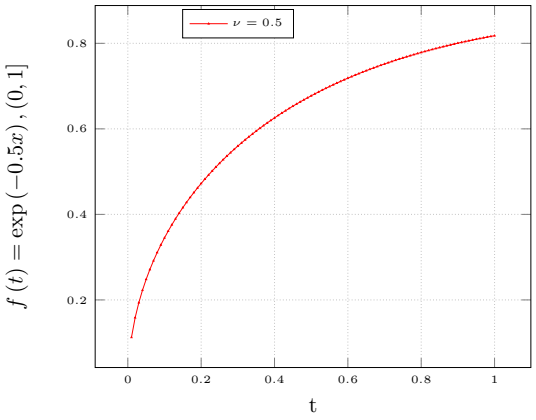

Fig. 7. Plot of fractional integral of order $\nu = 0.5$ of function $f(t) = \exp^{-0.5x}$ in interval $(0, 1]$.

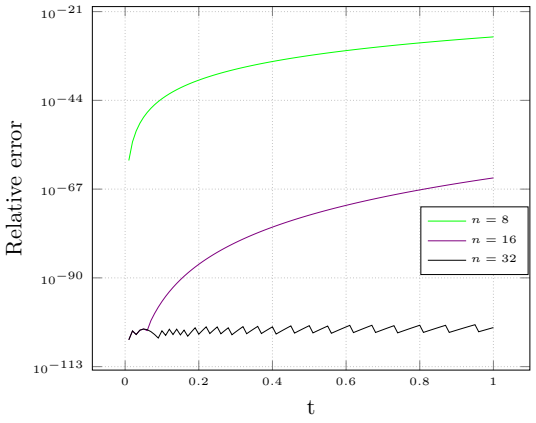

Fig. 8. Plot of relative error of fractional integral of order $\nu = 0.5$ of function $f(t) = \exp^{-0.5x}$ in interval $(0, 1]$.

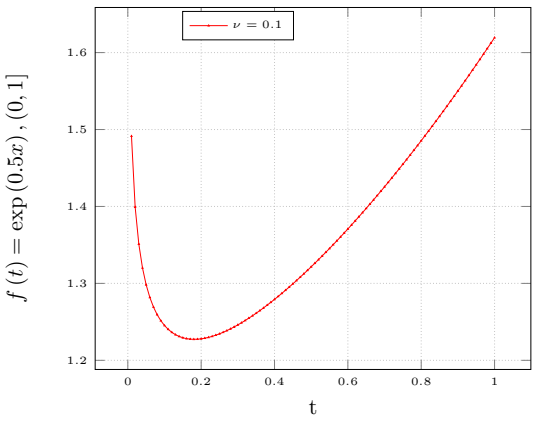

Fig. 9. Plot of fractional integral of order $\nu = 0.5$ of function $f(t) = \exp^{0.5x}$ in interval $(0, 1]$.

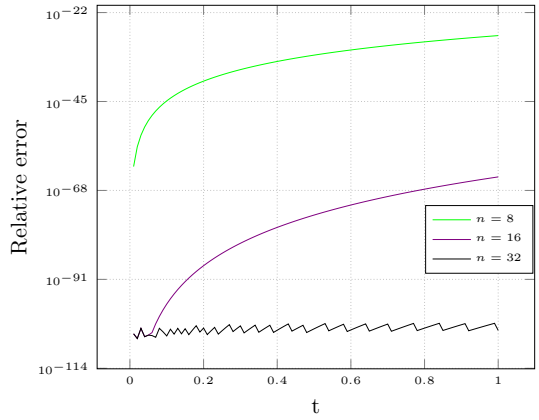

Fig. 10. Plot of relative error of fractional integral of order $\nu = 0.5$ of function $f(t) = \exp^{0.5x}$ in interval $(0, 1]$.

IX. Conclusions

The aim of the following research was to develop the most efficient and accurate numerical algorithms for Gauss-Jacobi Quadrature nodes and weights computation. In the paper, we discuss efficient mathematical formulas for nodes and wights computations and accurate methods of their computer implementations.

Results of numerical experiments presented in the paper prove that application of more accurate raw first approximations of zeros in the standard iteration method of polynomial zeros finding leads to significant decrease of an mount of iterations required for finding high-accurate zero location.

The proposed enhancements for the standard iteration method of determining zeros of Jacobi polynomial enables decreasing an amount of iterations required for finding each zero and increasing their accuracy many hundred times; changes to the weight function formula and its computation by applying cosine function enables massive reduction of truncation errors and increasing overall accuracy of computations.

The enhanced methods programmed by applying excellent arbitrary precision libraries GNU GMP and GNU MPFR together with C++ programming language enable computation of Gauss-Jacobi Quadratures and nodes and wights with arbitrary precision, i.e. with precision limited only by accessible hardware (computer memory).

Results of computations of fractional order derivatives and integrals of example exponential functions prove that modified Gauss-Jacobi Quadrature that uses high-accurately computed nodes and weight enables their computation with steady 100-digits precision with only 32 sampling points at most. It is worth nothing that standard numerical integration methods', e.g. Newton-Cotes quadratures' accuracy is limited to a few digits at best for the same computations [30], [31].

High accurately computed nodes of Jacobi polynomial are an excellent starting point for research on mitigation of Runge phenomenon. High-accurate methods of fractional order derivatives and integrals computation can be useful for constructing more efficient and accurate spectral methods

for solutions of fractional differential equations. This in turn enables more accurate simulations of physical processes and systems.

ACKNOWLEDGEMENT

The work was created as a result of the research project no. DEC-2016/23/D/ST6/01709 financed from the funds of the National Science Center, Poland.

***Abstract*—The authors developed a GPU approach to the uniformization method for the computing transient solution of Markov models. The authors use two techniques to reduce the memory size of storing matrices. One of them is a modification of a storage sparse matrix format HYB; second is to utilize two GPU cards and the multicore CPU. The modified HYB format is suitable for sparse Markovian transition rate matrices and oversized matrices on single GPU, also improving computation performance at the same time. The use of two GPUs enables processing matrices of even bigger sizes.**

I. Introduction

A POWERFUL tool used widely for modeling a lot of processes and systems (natural and artificial ones) are Markov chains.

In [2], we provided details of a heterogeneous (CPU-GPU) implementation of the uniformization method [6], [11], [12] for solving Markov chains. Markov chains transition rate matrices (which are very sparse) were stored with the use of the HYB format which is a hybrid of other well-known sparse formats (ELL and COO). The HYB format was chosen because it gave the best results in experiments described in [1].

However, matrices in question are usually very large and do not fit into one GPU memory. Thus, in [3], we presented an implementation of uniformization for many GPU. Notwithstanding, the communication between GPUs was slow and the results were not satisfactory. Hence, in [4] we described an effective storage scheme for Markov chains transition rate matrices, namely HYBIV, which reduced the memory requirements and the number of miss caches and thereby improved the overall performance. That format was not studied for uniformization though.

This work shows numerical experiments where that format (HYBIV) is used for uniformization and tested for four groups of transition rate matrices (from PRISM). It also compares the HYB format with HYBIV (on 1 and 2 GPUs) and with CSR (on CPU).

The structure of the article is following. Section II describes the conducted numerical experiments. Section III presents the memory usage for formats used in experiments. In Section IV, the performance time of the experiments is analyzed. Section V concludes the experiments and the paper.

II. Methodology of Numerical Experiments

The memory requirements were tested and compared in this section, as well as the time of the uniformization algorithm, with the use of three storage schemes:

- HYB — the original format from the CUSP library;
- HYBIV — the modified format;
- the well-known CSR format (as the most common and often the most efficient format for CPUs), on CPU, with the use of the MKL library [13].

We were interested in studying and comparing memory required by the original HYB format and for our modified HYBIV format — on one GPU and on two GPUs. Also, the times elapsed by the uniformization method with the use of these formats for one and two GPUs were compared. The comparison between times of these formats on GPUs with the use of the CUSP library and the CSR format on CPU with the use of the MKL library was done.

All the codes are written in C++. We tested the uniformization on CPU and GPU under Linux with `gcc` and NVIDIA `nvcc` compilers with optimization flag `-O3`. The experiments were run on an Intel system with 12 cores. The Intel system has two sockets with six-core Intel Xeon X5650 clocked at 2.67 GHz and 48 GB memory. In the performance evaluation were used NVIDIA GPUs (2× Tesla M2050 with 3 GB memory) and libraries: CUDA Toolkit 4.0, CUSP 0.2, MKL 10.3.

We tested the implementations on four widely used benchmark models: mutex [7], a Kanban system [5], a cyclic server Polling system [9], tandem queueing network [10].

These protocols were chosen due to their scalability and the possibility to verify their properties by numerical solving. The first model (MUTEX) is generated by the authors, which allowed scaling up this model. The remaining three models were generated using PRISM [8] (unfortunately, we were unable to generate matrices of bigger size), a probabilistic model checker developed at the University of Birmingham.

Tables I and II present details of test matrices, where:

- *name* is the name of the matrix with parameters describing the model
- n is the number of rows,
- nz is the number of non-zero elements,
- nz/n represents the matrix density,
- uv is the number of unique values of matrix' elements,
- x is the size of the ELL part,
- c is the size of the COO part.

TABLE I
PROPERTIES OF THE MATRICES FOR THE 'MUTEX' MODELS

#	name	n	nz	nz/n	uv	x	c

TABLE II
PROPERTIES OF THE MATRICES FOR THE 'KANBAN', 'POLL' AND 'TANDEM' MODELS

#	name	n	nz	nz/n	uv	x	c
17	kanban_sm-1	160	776	4.85	73	0	776
18	kanban_sm-2	4600	32720	7.11	142	5	9845
19	kanban_sm-3	58400	504800	8.64	191	9	25910
20	kanban_sm-4	454475	4434325	9.76	200	10	245084
21	kanban_sm-5	2546432	27006448	10.61	200	11	1268920
22	poll17_sm	3342336	34537472	10.33	51	11	1730158
23	poll18_sm	7077888	76677120	10.83	45	12	2653722
24	tandem_sm-2047	8386560	37724163	4.50	14	5	0

We divide matrices into the COO and ELL parts with the HYB format using CUSP. With very small matrices format COO is faster, therefore the ELL part remains empty. In Table I, there are matrix properties describing MUTEX model; the matrices differ in size and also in the proportion of COO and ELL. Six matrices with empty ELL part were chosen, three matrices with not empty COO and ELL parts and seven matrices with empty COO part.

In Table II we describe properties of the matrices from three remaining models: 'kanban', 'poll' and 'tandem'. Among the describe matrices only one has an empty COO part, and only one an empty ELL part. The other have not empty COO and ELL parts.

III. GPU MEMORY REQUIREMENTS

Memory usage was checked by the function `cudaMemGetInfo`. This function returns the total GPU memory and free GPU card memory which gives us information about memory occupation by the application. The method of the measurement is not precise enough to enable comparison of such small matrices. It prints total GPU memory usage, not only of matrices but also all additional values. The 'basic' value of 63 MB consists of not only explicitly allocated data but also the inner CUDA variables. It is visible that minimal, constant size is about 63 MB (for $n = 13$). The memory usage depends directly on nz. With small differences in nz it may happen that the memory use will be smaller for a bigger matrix. It is difficult to find dependencies of n because the matrices have different sparsity patterns.

Tables III and IV show the memory usage in MB on one and two GPUs (respectively) for the 'kanban', 'poll' and 'tandem' models. This memory was counted by function `cudaMemGetInfo` and therefore we call this memory experimental. Basing on Tables III and IV we can say that:

- The HYBIV format on larger matrices required almost twice less memory than HYB which results from experimental data.
- Memory usage per GPU was smaller in HYB2 and HYBIV2 than in HYB and HYBIV but it was higher by half because some variables were stored on each GPU.
- The number of non-zeros (nz) and the number of unique elements (uv) had the biggest influence on the memory occupation.

TABLE III
EXPERIMENTAL MEMORY USAGE (IN MB) ON ONE GPU FOR THE 'KANBAN', 'POLL' AND 'TANDEM' MODELS ($M_{exp} = \frac{\mathbf{HYB}}{\mathbf{HYBIV}}$)

#	name	**HYB**	**HYBIV**	M_{exp}

23	poll18_sm	757.91	+	703.91	507.37	+	453.37
24	tandem_sm-2047	526.49	+	462.49	406.48	+	342.48

IV. TIME

All the processing times are reported in seconds. The time is measured with an MKL function `dsecnd`. Computations were made in double precision. Let us assume that $pt = \pi(0) = [1, 0, \ldots, 0]^T$. The choice of e_1 as the starting vector may seem too special, but it reflects the fact that we order the state space by reachability and that the Markov chain starts in the first state before evolving into other states.

Tables V and VI show run-time on CPU (CSR format, SpMV operation from MKL library), on one GPU (HYB and HYBIV formats, SpMV operation from CUSP library), on two GPUs (HYB2 and HYBIV2 formats, modified SpMV operation from CUSP library) respectively for $t = 1$, $t = 100$ and $\varepsilon = 10^{-10}$ (t and ε are parameters of the uniformization method), for matrices from 'MUTEX' model with numbers: 13, 14, 15 and 16. The bold values denote the fastest computation times and '—' denotes that the matrices could not be stored in the device memory.

Figures 1–6 show SpMV run-time (in seconds) on CPU, on one GPU, on two GPUs for the 'MUTEX' model.

On the basis of the charts of run-time it can be concluded that computation on CPU on CSR format takes the longest

TABLE V
RUN-TIME (IN SECONDS) ON CPU (CSR, SPMV FROM MKL); ON ONE GPU (HYB AND HYBIV, CUSP); ON TWO GPUS (HYB2 AND HYBIV2, CUSP) — THE 'MUTEX' MODELS FOR $t = 10$ AND $\varepsilon = 10^{-10}$

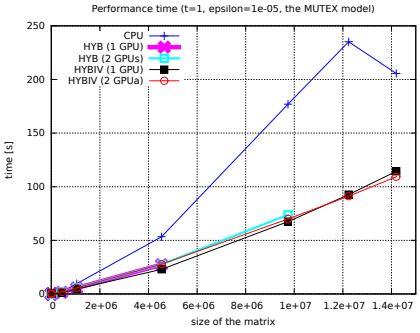

Fig. 1. Run-time (in seconds) on CPU (CSR, SpMV from MKL); on one GPU (HYB and HYBIV, CUSP); on two GPUs (HYB2 and HYBIV2, modified CUSP) — the 'MUTEX' model ($t = 1$, $\varepsilon = 10^{-5}$)

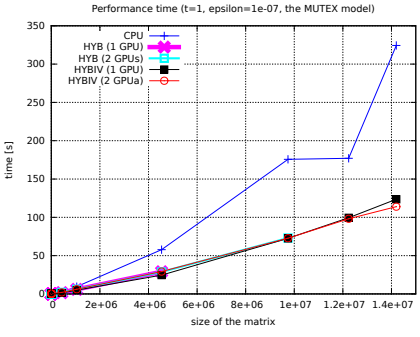

Fig. 2. Run-time (in seconds) on CPU (CSR, SpMV from MKL); on one GPU (HYB and HYBIV, CUSP); on two GPUs (HYB2 and HYBIV2, modified CUSP) — the 'MUTEX' model ($t = 1$, $\varepsilon = 10^{-7}$)

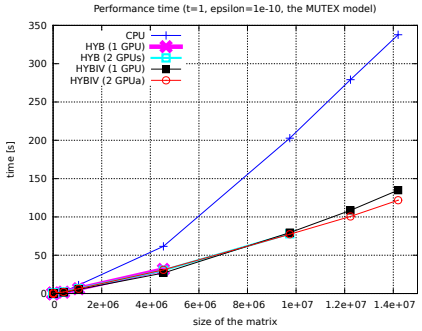

Fig. 3. Run-time (in seconds) on CPU (CSR, SpMV from MKL); on one GPU (HYB and HYBIV, CUSP); on two GPUs (HYB2 and HYBIV2, modified CUSP) — the 'MUTEX' model ($t = 1$, $\varepsilon = 10^{-10}$)

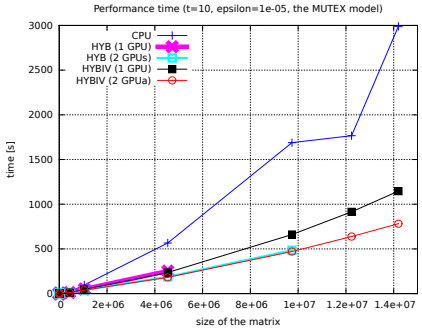

Fig. 4. Run-time (in seconds) on CPU (CSR, SpMV from MKL); on one GPU (HYB and HYBIV, CUSP); on two GPUs (HYB2 and HYBIV2, modified CUSP) — the 'MUTEX' model ($t = 10$, $\varepsilon = 10^{-5}$)

time, while GPU application speedup the run-time considerably.

The value of the variable l depends on t variable value. For 'MUTEX' model it is worth using two GPUs. Clearly, computations were done faster for proposed HYBIV format than for HYB format.

Tables VII and VIII show the time in seconds for the double precision uniformization method using the HYB and HYBIV storage formats on one GPU and two GPUs and the CSR

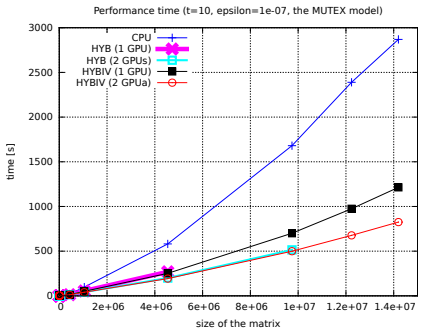

Fig. 5. Run-time (in seconds) on CPU (CSR, SpMV from MKL); on one GPU (HYB and HYBIV, CUSP); on two GPUs (HYB2 and HYBIV2, modified CUSP) — the 'MUTEX' model ($t = 10$, $\varepsilon = 10^{-7}$)

poll18_sm	35.70	8.37	26.26	**4.59**	24.59
tandem_sm-2047	1410.19	121.03	482.84	**88.31**	466.98

storage format from the MKL library on CPU for $\varepsilon = 10^{-10}$, $t = 1$ and $t = 10$ for the other three models - 'kanban', 'poll' and 'tandem'. The bold values denote the fastest computation times.

Run-times on two GPUs are slower than on one GPU for matrices which $\frac{nz}{n} < 16$ (for all matrices 'kanban', 'poll' and 'tandem' models and matrices number from 1 to 10 for 'MUTEX' model). There are too few computations to sensibly use two GPUs. For 'poll' and 'tandem' models we achieve considerable computation speedup on one GPU.

The best storage scheme — that is, the fastest and the most compact — for bigger transition rate matrices is HYBIV2 (HYBIV on 2 GPUs). The HYB storage format performs not quite efficiently in many cases. It is because the granularity (one thread per row) of the sparse matrix-vector multiplication is not fine enough for them, so the bigger the matrix, the better the utilization of the GPU. The performance of HYBIV was a little better than HYB, because in HYBIV less data is stored in slow global memory. Using two GPUs we almost doubled the performance in comparison to single GPU. For smaller matrices, HYBIV and splitting data across two GPUs were not useful.

TABLE VIII
SPMV RUN-TIME (IN SECONDS) ON CPU (CSR, SPMV FROM MKL); ON ONE GPU (HYB AND HYBIV); ON TWO GPUS (HYB2 AND HYBIV2) — THE 'KANBAN', 'POLL' AND 'TANDEM' MODELS, $t = 10$, $\varepsilon = 10^{-10}$)

name	CPU	HYB	HYB2	HYBIV	HYBIV2

V. CONCLUSION

In this article, we investigated the use of a modified sparse memory format on the GPU in a practical problem, namely calculating probabilities from Markov transition matrices. Our results showed that in the case of small size matrices, we did not achieve high performance in the HYBIV format or significant memory savings. However, the proposed method reduces the memory size for storing larger matrices. In addition, the use of HYBIV does not degrade performance and the use of two GPUs allows the processing of larger matrices than one GPU. In our future work, we try to transfer codes to the CUDA version beyond 4 and use streams to optimize overall performance.

***Abstract*—The parallelization of the leading procedures of the finite element method applied to solving physically nonlinear problems of structural mechanics is considered.**

I. Introduction

THE SOLUTION of physically nonlinear problems of structural mechanics by the finite element method requires a large number of calculations. The vast majority of such problems are solved on multi-core shared memory computers - desktops, laptops and multiprocessor workstations with SMP (Symmetric Multiprocessing) architecture. When using the finite element method, the most time-consuming procedures are the assembling of a tangent stiffness matrix, the evaluation of an internal force vector, and the solution of a system of linear algebraic equations with a sparse symmetric matrix. Solver PARDISO [1] from the Intel Math Kernel Library (MKL) [2] or PARFES [3], [4] is used to solve systems of linear algebraic equations with a symmetric sparse tangent stiffness matrix. These solvers have successfully proven themselves on multi-core computers of SMP architecture and demonstrate stable acceleration with an increase in the number of cores during the factorization stage. In addition, forward and backward substitutions are also parallelized. Therefore, this paper considers parallel algorithms for the assembling of a tangent stiffness matrix and the calculation of an internal force vector.

A. Assembling of the stiffness matrix

1) Related works: In [13] is presented a parallel node-by-node assembling approach, when each block of the global stiffness matrix, corresponding to given node, is processed on the same processor. The blocks of an element matrices related to given node are evaluated on this processor. There are no overlapping of blocks in the global stiffness matrix and no communication between processors are needed.

In [14] is considered only banded matrices. The set of consecutive rows are taken as a synchronization region. Such a partitioning the matrix into a sufficient number of synchronization regions allows to avoid simultaneous modification of the same elements by the different threads.

The algorithm [15] assembles the stiffness matrix by groups of rows related to each node of the finite element mesh. Each processor will only assemble the rows related to a specific group of nodes. Therefore, no synchronization is required because each processor updates only their addresses of the memory.

The method [16] creates for each element the list of the processors onto which the associated columns in global stiffness matrix composing this element have been mapped. If this list consists in only one processor, the finite element is totally local to this processor, and non totally local otherwise. The totally local elements are mapped to each processor. The remaining finite elements are processed on several processors and need a synchronization.

In [17] before assembling is precomputed a coloring of the finite elements such that no two elements of the same color share any given degree of freedom. The appropriate heuristic coloring algorithm is presented. The several algorithms realising assembling on GPU, are presented.

We present the procedure of the stiffness matrix assembling (section II.B) which require no synchronization between threads and demonstrates an almost perfect load balance even for different types of finite elements – triangular and quadrilateral shell elements, spatial bar elements and so on. It is the typical situation in structural analysis when design model consists of different types of finite elements, and evaluation of their stiffness matrices requires the quite different computational efforts.

2) Assembling procedure: The procedure for a tangent stiffness matrix assembling is as follows:

$$\mathbf{K}_t = \sum_{e=1}^{Ne} \mathbf{P}_e^T \mathbf{K}_{e,t} \mathbf{P}_e, \tag{1}$$

where $\mathbf{K}_{e,t}$ is a tangent stiffness matrix of the e-th finite element, $\mathbf{P}_e$ is a permutation matrix and N_e is a number of finite elements in the design model. In the case of physically

This work was supported by IT company SCAD Soft

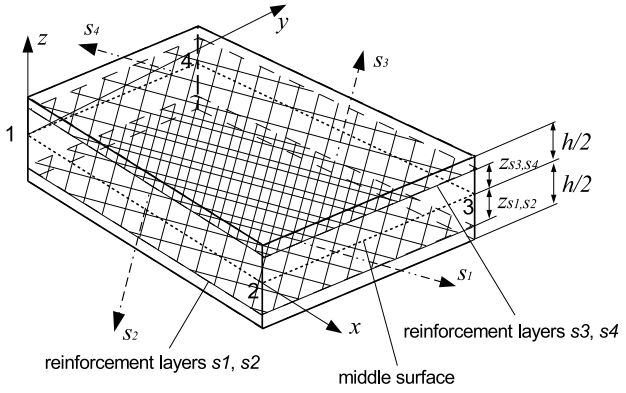

Fig. 1. The flat shell finite element

nonlinear problems, the calculation of the tangent stiffness matrix for the thin plane shell finite element (Fig. 1) is represented as a sum of the following type integrals:

$$\mathbf{K}_e = \int\limits_{\Omega} \mathbf{B}^T(\Omega) \left[\int\limits_{-h/2}^{h/2} f(\Omega, z)\, dz \right] \mathbf{B}(\Omega)\, d\Omega, \qquad (2)$$

where Ω is an in-plane domain ($d\Omega = dxdy$), h is the shell thickness, $\mathbf{B}(\Omega)$ is a deformation matrix [5], $s_1, s_2, ...$ are the axes of the reinforcement layers, $z_{s1}, z_{s2}, ...$ are the distances between reinforcement layers $s_1, s_2, ...$ and middle surface.

The trapezoid method is applied to calculate the integral over the shell thickness. In this case, the shell is divided into 10 - 40 layers through thickness. In addition, reinforcing rods of the same direction form a layer of reinforcement. Usually, the number of reinforcement layers is 4, although it may be arbitrary. The integral over the domain of the finite element Ω is computed by the Gauss method using the 2×2 integration scheme. The components of the stress and strain tensors are calculated at each Gaussian point. The number of such points for a given type of finite element is $2 \times 2 \times$ (the number of layers plus the number of reinforcement layers). The tangent stiffness matrix for other types of finite elements is defined similarly.

Thus, the procedure for the tangent stiffness matrix assembling requires significant computational effort. The tangent stiffness matrix assembling time is of the same order as the factorization time of this matrix.

B. Internal force vector evaluation

The internal force vector is calculated as follows:

$$\mathbf{f}^{int} = \sum_{e=1}^{Ne} \mathbf{P}_e^T \mathbf{r}_e \mathbf{P}_e, \qquad (3)$$

where

$$\mathbf{r}_e = \mathbf{K}_e \mathbf{q}_e, \qquad (4)$$

$\mathbf{q}_e$ is a nodal displacement vector and $\mathbf{r}_e$ is a nodal reaction vector for the e-th finite element. The stiffness matrix $\mathbf{K}_e$ has to be calculated for each finite element in the expression (3). It is not a tangent stiffness matrix, but it is a full stiffness matrix [6], [7], [9].

This paper is devoted to the technique of multithreaded parallelization of problems (1) and (3).

II. Multithreaded Parallelization

A. Internal force vector evaluation

First of all, we consider parallelization of the problem (3), the corresponding Algorithm 1 is presented below.

Algorithm 1 Internal force vector evaluation

1: Initialization.
   $\mathbf{rr}_{ip} \leftarrow 0$, $ip \in [0,\ np-1]$, $\mathbf{f}^{int} \leftarrow 0$

2: **for parallel** $e = 1$ **to** N_e **schedule(dynamic) do**
3: ip = $omp\_get\_thread\_num()$
4: *Compute a transformation matrix* $\mathbf{T}_e$
   $\mathbf{u}_e^{glob} \leftarrow \mathbf{u}$
   $\mathbf{u}_e^{loc} = \mathbf{T}_e \mathbf{u}_e^{glob}$
5: *Compute a nodal reaction vector* $\mathbf{r}_e^{loc}$, *using the constitutive relations.*
   $\mathbf{r}_e^{glob} = \mathbf{T}_e \mathbf{r}_e^{loc}$
   $\mathbf{rr}_{ip} \leftarrow + \mathbf{r}_e^{glob}$
6: **end for**

7: **for** $ip = 0$ **to** $np - 1$ **do**
8: **for parallel** $eqn = 1$ **to** Neq **schedule(dynamic, chunk) do**
9: $\mathbf{f}_{eqn}^{int} += \mathbf{rr}_{ip,eqn}$
10: **end for**
11: **end for**

At the initialization stage (point 1), we dynamically allocate memory for vectors $\mathbf{rr}_{ip}$, where ip is the thread number and np is the number of threads. After Algorithm 1 is finished, vector $\mathbf{f}^{int}$ will store internal forces. Vectors $\mathbf{rr}_{ip}, ip \in [0, np-1]$, and $\mathbf{f}^{int}$ have the dimension Neq - the number of equations in the finite element model. All these vectors are zeroed.

At the second stage (points 2 – 6) we run a parallel loop **for** over the number of finite elements N_e, where e is a number of the current finite element. We obtain the thread number ip (point 3) end evaluate the coordinate transformation matrix $\mathbf{T}_e$ (point 4). Then we put elements of the displacement vector $\mathbf{u}$, corresponding to the degrees of freedom of the finite element e, to vector $\mathbf{u}_e^{glob}$. Vector $\mathbf{u}$ of dimension Neq (number of equation) contains the nodal displacements and rotations in the global coordinate system (CS) for the entire finite element model. Vector $\mathbf{u}_e^{glob}$ of dimension $nstAct$ contains the nodal displacements and rotations of the finite element e. The displacements and rotations in the global CS are transformed into the displacements and rotations in the local CS of the e-th finite element with the help of the coordinate transformation matrix $\mathbf{T}_e$.

The evaluation of the nodal reaction vector $\mathbf{r}_e^{loc}$ in the local CS is performed according to (4) (point 5). The constitutive relations, reflecting the mechanical rules, are applied to evaluate the full stiffnes matrix $\mathbf{K}_e$. Then, the transformation of the reaction vector, given in the local CS, to the global CS is performed ($\mathbf{r}_e^{glob} = \mathbf{T}_e \mathbf{r}_e^{loc}$). After this, the elements of the reaction vector $\mathbf{r}_e^{glob}$ are added ($\leftarrow +$) to the corresponding elements of the vector $\mathbf{rr}_{ip}$.

At the third stage (points 7 – 11), partially prepared reaction vectors $\mathbf{rr}_{ip}, \quad ip \in [0, np-1]$ are combined in the vector $\mathbf{f}^{int}$ of internal forces. We parallelize an inner loop (points 8 – 9) covering the equations of the entire model. To avoid incoherence in the processor caches when writing data to vector $\mathbf{f}^{int}$ at multithreading, the chunk size **chunk** is assumed to be sixteen. In doing so, we assume that the size of the cache line is 64 or 128 bytes, that is, eight or sixteen double words respectively. It is important to do it to avoid a degradation of performance at multithreading on processors, which are not protected against such incoherence at the hardware level.

B. Stiffness matrix assembling

Unlike the internal forces evaluation algorithm discussed in the previous subsection, the tangent stiffness matrix assembling algorithm stores a large array to memory - a nonzero structure of sparse matrix that comprises only nonzero elements. The symmetric sparse matrix in compressed column format (CCS) is represented in the form of three arrays: $Space[pos], ind[pos]$ and $Pos[j]$. Array $Space[pos]$ comprises nonzero elements located column-by-column from the diagonal element to the last nonzero element of the column. Array $ind[pos]$ stores the i subscript for the corresponding element k_{ij} of matrix $\mathbf{K}_t$ located in $Space[pos]$. Array $Pos[j]$ points to the position pos of the diagonal element k_{jj} of the column j in the arrays $Space$, ind. Here $j \in [1,\ Neq], \quad i \geq j$. For instance, the CCS format for the matrix (5) is presented in (6).

$$\begin{pmatrix} k_{11} & & & & & \\ 0 & k_{22} & & & & \\ 0 & 0 & k_{33} & & & \\ k_{41} & 0 & 0 & k_{44} & & \\ 0 & k_{42} & 0 & 0 & k_{55} \end{pmatrix} \tag{5}$$

pos	0	1	2	3	4	5	6
$Space$	k_{11}	k_{41}	k_{22}	k_{42}	k_{33}	k_{44}	k_{55}
ind	1	4	2	4	3	4	5
Pos	0	2	4	5	6	7	
j	1	2	3	4	5	–	

(6)

Subscript j is a column number. The last element in Pos is required to properly obtain the number of nonzero elements in the last column using the following expression $nonzero_j = Pos[j+1] - Pos[j]$, where $nonzero_j$ – the number of nonzero entries in the column j counting from the diagonal element to the lowest one. The nonzero structure of a symmetric sparse matrix is presented by the undirected adjacency graph, where vertexes correspond to columns of matrices or to diagonal elements and the edges – to nonzero off-diagonal elements [10].

The reordering of the adjacency graph reduces the number of fill-in in the factorized matrix. The symbolic factorization procedure [10] enables to create a nonzero structure of the factorized sparse matrix without numerical factorization. It is a very fast procedure, which operates only on the adjacency graph of the initial matrix $\mathbf{K}_t$ and obtains a factor-graph. As a result, the arrays Pos and ind are filled. Therefore, the assembling procedure fills the array $Space$. Algorithm 2 demonstrates a trivial solution of a such problem.

Algorithm 2 Assembling of the tangent stiffness matrix with using of critical sections (trivial solution)

```
1:  for parallel e = 1 to N_e schedule(dynamic) do
2:    ip = omp_get_thread_num()
3:    evaluate a finite element matrix K_{e,t} and the list of
      global equation numbers list_glob_eqns
4:    for jeqn = 1 to nstAct do
5:      jglobeqn = list_glob_eqns(jeqn)
6:      prepare the inverse data structure to avoid a search
        procedure
7:      for pos = Pos[jglobeqn] to Pos[jglobeqn+1] - 1
        do
8:        iglobeqn = ind[pos]
          Col[ip][iglobeqn] = pos
9:      end for
        fill Space:
10:     for ieqn = jeqn to nstAct do
11:       iglobeqn = list_glob_eqns(ieqn)
          pos = Col[ip][iglobeqn]
12:       begin_critical_section
13:         Space[pos] += K_{e,t}[ieqn, jeqn]
14:       end_critical_section
15:     end for
16:   end for
17: end for
```

The parallel loop **for** is performed over the number of finite elements (point 1). The thread number ip is defined (point 2) and the finite element tangent stiffness matrix $\mathbf{K}_{e,t}$ with the list of global equation numbers $list\_glob\_eqns$ are obtained (point 3).

The loop **for** is performed over the local equation number $jeqn$ (point 4 – 15). A column number $jglobeqn$ of the global tangent stiffness matrix $\mathbf{K}_t$ (point 5) is defined for each column number $jeqn$ of the matrix $\mathbf{K}_{e,t}$. Then, the inverse data structure $Col[ip][iglobeqn]$ is prepared to avoid a time-consuming search of the position pos in the array $Space$ (points 7 – 9).

Loop **for** (points 10 – 15) runs along the column $jeqn$ of the matrix $\mathbf{K}_{e,t}$. The position number pos is extracted from $Col[ip][iglobeqn]$, where $ieqn$ is a row number of the matrix $\mathbf{K}_{e,t}$ and $iglobeqn$ is a row number of the global tangent stiffness matrix $\mathbf{K}_t$ (point 11 and a line below). To avoid the situation, when several threads simultaneously modify the

same element of the array $Space[pos]$, a critical section is used (points 12 – 14).

Using a critical section in such a situation is not a good idea, because the speedup with the increasing number of threads begins to degrade very fast. The application of interlocked functions [11] instead of a critical section does not improve the speedup much.

Therefore, we do not use Algorithm 2. The following approach is proposed instead. We divide the finite elements into groups so that each group is simultaneously processed by different threads and writes only in its positions pos of the array $Space$. In other words, a situation, when different threads simultaneously write data to the same addresses of the array $Space$, should be eliminated.

To create such groups, we prepare an adjacency graph for the finite elements of the design model (Fig. 2). The vertices of the graph present the finite elements and the edges – the nodes in which the adjacent finite elements are coupled.

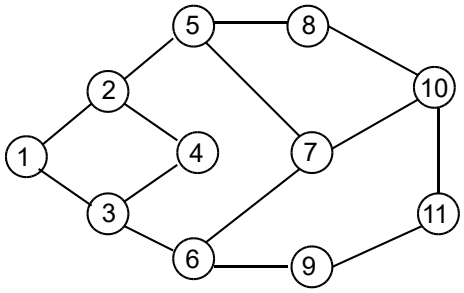

Fig. 2. The finite element adjacency graph. The vertices present the finite elements and edges – the nodes of the design model.

Then, we search for a pseudo peripherical vertex and create a structure of levels with a root in such a vertex [10] (Fig. 3).

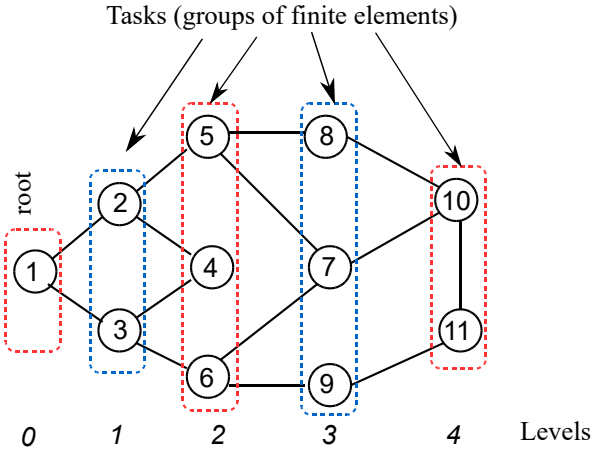

Fig. 3. The structure of levels for the finite element adjacency graph with a root in a (pseudo) peripherical vertex

The root of the level structure is placed in the pseudo peripheral vertex in order for the structure to be maximally elongated (containing as many levels as possible) and to minimize the number of vertices on each level. We call the vertices belonging to a given level a computational task or just a task. If we choose tasks of only even levels, then the vertices of each task are not connected in any way with the vertices of the remaining selected tasks. In other words, the finite elements belonging to each even-level task do not have any common nodes with finite elements belonging to tasks of other even levels. Thus, we guarantee that the finite elements belonging to different even levels make contributions to different degrees of freedom of the design model, that is, the modification of different elements of the $Space$ array is performed. Therefore, each even-level task can be performed simultaneously at multithreaded data processing. In the same way, as in the case of even levels, each task belonging to odd level can be solved independently from the other tasks of odd levels.

To achieve an acceptable load balance between threads, the Algorithm 3 is applied.

Algorithm 3 Mapping tasks onto threads

1: *Prepare finite element adjacency graph*
2: *Find a (pseudo) peripherical vertex*
3: *Create a structure of levels for the finite element adjacency graph with the root in a (pseudo) peripherical vertex*

Prepare the weights for even levels:
4: **for** *lev=0;* **to** *NoLevels-1, lev += 2* **do**
5: $levelWeight_{lev} = \sum_{e \in lev} nstAct_e^2$
6: **end for**

7: *Sort the even levels in descending order of their weights. Map tasks of even levels onto threads:*
$sumWeigh\,[ip] \leftarrow 0, \quad ip \in [0, np-1]$
8: **for** *lev=0;* **to** *NoLevels-1, lev += 2* **do**
9: *Find the thread number* min_ip *having a minimum sum of already mapped weights,* $min\_ip \in [0, np-1]$
10: $queue\,[min\_ip] \leftarrow \forall e \in lev$
$sumWeigh\,[min\_ip] += levelWeight_{lev}$
11: **end for**

Prepare the weights for odd levels:
12: **for** *lev=1;* **to** *NoLevels-1, lev += 2* **do**
13: $levelWeight_{lev} = \sum_{e \in lev} nstAct_e^2$
14: **end for**

15: *Sort the odd levels in descending order of their weights. Map tasks of odd levels onto threads:*
$sumWeigh\,[ip] \leftarrow 0, \quad ip \in [0, np-1]$
16: **for** *lev=1;* **to** *NoLevels-1, lev += 2* **do**
17: *Find the thread number* min_ip *having a minimum sum of already mapped weights,* $min\_ip \in [0, np-1]$
18: $queue1\,[min\_ip] \leftarrow \forall e \in lev$
$sumWeigh\,[min\_ip] += levelWeight_{lev}$
19: **end for**

The points 1 – 3 of the presented algorithm have been discussed above. After creating the level structure with a root

at a (pseudo) peripherical vertex, we obtain the weight of each even level (points 4 – 6). Here, the $NoLevels$ is the number of levels of a level structure and $levelWeight_{lev}$ is defined as a sum of weights for all vertices (finite elements) belonging to the level lev. The dimension of the finite element tangent stiffness matrix $\mathbf{K}_{e,t}$ is denoted as $nstAct_e$ and the weight of the vertex is accepted as a number of elements $nstAct_e^2$ in $\mathbf{K}_{e,t}$.

Then, we sort all vertices belonging to the even levels, in descending order of their weights, and zero the sum of weights $sumWeight\,[ip]$ mapped onto thread ip, $\quad ip \in [0, np-1]$ (point 7). For each even level we find a thread min_ip which has a minimum sum of already mapped weights (point 9), put all vertices of the given level to the $queue\,[min\_ip]$ and correct $sumWeight\,[min\_ip]$ (point 10).

Finally, we apply the same approach to all the odd levels and obtain $queue1\,[ip]\,, ip \in [0, np-1]$ (points 12 – 19).

Therefore, all even levels are mapped onto np threads and are presented by $queue\,[ip]\,, \quad ip \in [0, np-1]$ queues. Similarly, all odd levels are presented by $queue1\,[ip]\,, \quad ip \in [0, np-1]$ queues.

Sorting in descending order improves a load balance between threads. A similar approach has been used in [3], [4] to achieve a load balance between threads in solver PARFES and in block incomplete Cholesky factorization solver [8].

The Algorithm 4 demonstrates a tangent stiffness matrix assembling using multithreading without any synchronization allowing a high speedup with the increasing thread number.

In the first parallel region (points 1 – 18) the **while** loop runs for each thread ip until the $queue\,[ip]\,, \quad ip \in [0, np-1]$ is empty. These queues contain parallel tasks for even levels of level structure. In each **while** loop, the nearest finite element number e is retrieved (point 4) and the tangent stiffness matrix $\mathbf{K}_{e,t}$ with the list of global equation numbers are evaluated (point 5). The loop **for** is executed over the columns of the matrix $\mathbf{K}_{e,t}$ (points 6 – 16), where *nstAct* is a dimension of $\mathbf{K}_{e,t}$. The $Col\,[ip]$ array stores a position number *pos* of the nonzero entry $Space\,[pos]$ with the global equation number *iglobeqn* (points 9 – 11). It allows us to avoid a time-consuming search of pos, corresponding to the global equation number $iglobeqn$. The loop **for** (points 12 – 15) fills the $Space\,[pos]$ with elements of the matrix $\mathbf{K}_{e,t}$.

The second parallel region (points 19 – 35) does the same as the previous parallel region, but operates with queues $queue1\,[ip]$, containing parallel tasks for odd levels of a level structure. In contrast to Algorithm 2, Algorithm 4 does not contain any synchronization objects due to the approach presented above. This allows us to hope a high speedup with the increasing thread number, even when the number of threads is large. This approach formed the basis for the master's degree thesis in computer science [12], in which one of the authors, S. Fialko, was a scientific leader.

Algorithm 4 Assembling of the tangent stiffness matrix using the proposed approach

1: **parallel region**
2: $ip = omp\_get\_thread\_num()$
3: **while** $queue\,[ip]\,is \quad not \quad empty$ **do**
4: $e \leftarrow queue\,[ip]$ *retrieve element number* e
5: *evaluate a finite element matrix* $\mathbf{K}_{e,t}$ *and the list of global equation numbers* $list\_glob\_eqns$
6: **for** $jeqn = 1$ **to** $nstAct$ **do**
7: $jglobeqn = list\_glob\_eqns\,[jeqn]$
8: *prepare the inverse data structure to avoid a search procedure*
9: **for** $pos = Pos[jglobeqn]$ **to** $Pos[jglobeqn+1]-1$ **do**
10: $iglobeqn = ind[ieqn]$
$Col\,[ip]\,[iglobeqn] = pos$
11: **end for**
fill Space:
12: **for** $ieqn = jeqn$ **to** $nstAct$ **do**
13: $iglobeqn = list\_glob\_eqns\,[ieqn]$
$pos = Col\,[ip]\,[iglobeqn]$
14: $Space\,[pos] += \mathbf{K}_{e,t}\,[ieqn, jeqn]$
15: **end for**
16: **end for**
17: **end while**
18: **end of a parallel region**

19: **parallel region**
20: $ip = omp\_get\_thread\_num()$
21: **while** $queue1\,[ip]\,is \quad not \quad empty$ **do**
22: $e \leftarrow queue1\,[ip]$ *retrieve element number* e
23: *evaluate a finite element matrix* $\mathbf{K}_{e,t}$ *and the list of global equation numbers* $list\_glob\_eqns$
24: **for** $jeqn = 1$ **to** $nstAct$ **do**
25: $jglobeqn = list\_glob\_eqns\,[jeqn]$
prepare the inverse data structure to avoid a search procedure
26: **for** $pos = Pos[jglobeqn]$ **to** $Pos[jglobeqn+1]-1$ **do**
27: $iglobeqn = ind\,[ieqn]$
$Col\,[ip]\,[iglobeqn] = pos$
28: **end for**
fill Space:
29: **for** $ieqn = jeqn$ **to** $nstAct$ **do**
30: $iglobeqn = list\_glob\_eqns\,[ieqn]$
$pos = Col\,[ip]\,[iglobeqn]$
31: $Space\,[pos] += \mathbf{K}_{e,t}\,[ieqn, jeqn]$
32: **end for**
33: **end for**
34: **end while**
35: **end of a parallel region**

III. Numerical Results

We consider a design model of a reinforced concrete floor slab, comprising 65 117 equations (Fig. 4). The triangular and

quadrilateral finite elements, taking into account the physical nonlinearity, are used. The supports, modeling the walls, are shown in blue color. The uniform normal pressure simulates the dead and operational loads.

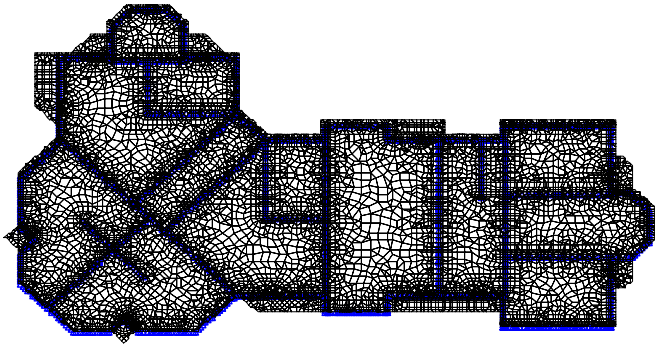

Fig. 4. The design model of a reinforced concrete floor slab

The computer with sixteen-core AMD Opteron 6276 processor, 2.3/3.2 GHz, 64 GB DDR3 RAM, OS Windows Server 2008 R2 Enterprise SP1, 64-bit, is used. Table I depicts a tangent stiffness matrix assembling time (s) during the solution of the entire nonlinear problem for the different number of threads np in the case with no optimization, optimization using a (pseudo) peripherical vertex and optimization using a (pseudo) peripherical vertex and weights of levels.

The "no optimization" case means that a root for the level structure is taken in the vertex 1. The pseudo peripherical vertex is not found. The weights of levels are not used. The queues $queue\,[ip]$ and $queue1\,[ip]\,,\quad ip \in [0, np-1]$ are prepared using a cyclic mapping of levels onto threads.

In the "use a peripherical vertex" case the pseudo peripherical vertex is found, but the weights of levels are not used. The cyclic mapping of levels onto threads is applied. Taking the pseudo peripherical vertex as a root of the level structure results in an increase of the levels from 110 to 114 for the given problem. It should be pointed out that for other problems the choice of a root in a pseudo peripherical vertex has a considerably larger impact on the increase of the level number. Therefore, for the considered problem of the "use a peripherical vertex" option on the reduction of the computing time is not observed.

Algorithm 3 is applied in the "plus the use of the weights of levels" case. The red color means that the load imbalance between threads exceeds 15%. The shortest computing time on a large number of threads is achieved when all optimizations are applied.

Table II shows the distribution of sum of weights among threads for the "no optimization" and "use peripherical vertexes and weights of levels" cases. Here, ip is a thread number, a red color indicates a thread with a maximum computational effort and a green color indicates a thread with a minimum computational effort. The difference between the maximum sum of weights and the minimum one is a measure of imbalance between threads. These results demonstrate that at a maximum number of threads the proposed approach, corresponding to Algorithm 3 and Algorithm 4, has a imbalancee between threads of about 11%. The "no optimization" approach has a imbalance of about 36%. We estimate a imbalance as (maximum sum of weights – minimum sum of weights)/maximum sum of weights in percent. Therefore, the above optimizations play an important role in improving a load balance between threads.

The Fig. 5 demonstrates a speedup with the increasing thread number in the range of the physical core number for the given processor: $S_{np} = T_1/T_{np}$, where T_1 is a time when using one thread and T_{np} is a time on np threads. The "ideal" curve corresponds to an ideal speedup, passing through the points (0, 0), (1, 1), (2, 2), ... However the given processor has a turbo core mode. When a small number of cores are loaded, the clock frequency is 3.2 GHz. When the number of loaded cores is a maximum, the clock frequency reduces to 2.3 GHz. Therefore, an ideal speedup is unreachable.

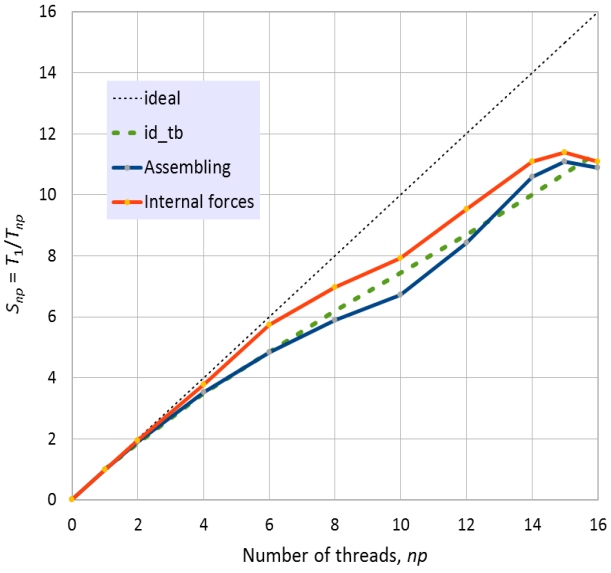

Fig. 5. The speedup with the increasing thread number for the evaluation of the internal forces and the tangent stiffness matrix assembling

The curve "id_tb" approximates an ideal speedup caused by the turbo core mode using a square parabola. The points (0, 0), (1, 1) and (16, x) are used to define such a parabola. The ordinate x is obtained as follows. A processor with sixteen cores without a turbo core mode should work with a clock frequency 3.2 GHz and should achieve a speedup of 16 times. A processor in the turbo core mode works with a clock frequency 2.3 GHz and has a speedup of x times. So, from the proportion, we obtain x = 2.3/3.2*16 = 11.5 times.

The "Internal forces" curve demonstrates a speedup of the internal force vector evaluation with the increasing thread number (Algorithm 1). The "Assembling" curve depicts a speedup of the tangent stiffness matrix assembling procedure with the above optimizations, presented by Algorithms 3

and 4. We obtain an acceptable correlation between "Internal forces" and "Assembling" curves with the "id_tb" curve. A steady increase in the speedup, with the exception of the last point (np = 16), confirms the effectiveness of the proposed approaches.

It should be noted that if we define speedup as $\frac{T_1 \cdot \Delta t_{np}}{T_{np} \cdot \Delta t_1}$, where Δt_1 and Δt_{np} are the time of a single processor's tick when using a single thread and when using the np threads correspondingly, then this ratio is not dependent on the processor clock speed, and the curve describing an algorithm's acceleration can be compared with the ideal speedup (curve "ideal"). However, for users, the definition of speedup as $S_{np} = T_1/T_{np}$, based on real-time execution of the tasks, is more understandable, therefore we use such a definition and above approach.

IV. CONCLUSION

Two different approaches for multithreaded parallelization of similar procedures – internal force vector evaluation and tangent stiffness matrix assembling have been considered.

The first approach requires the allocation of an additional vector of dimension Neq (number of equations) for each thread. Therefore, the amount of additional core memory is $Neq \times np$ words of double. On the other hand, such an approach is relatively simple and fully eliminates incoherences in caches of different processor cores.

The second approach, based on creating a finite element adjacency graph and preparing a level structure, ensures the independence of computational tasks, belonging to only even levels or only odd levels of a level structure, allows us to reject any type of synchronization and obtain a stable speedup with an acceptable correlation in comparison with an ideal speedup, taking into account the turbo core mode. Taking a pseudo peripherical vertex of the adjacency graph as a root of the level structure results in an increase of the levels number, so, the number of computational tasks increases too and each task becomes shorter. Together with a specific mapping-tasks-onto-threads algorithm, using the weights of computational tasks, this approach significantly improves the load balance between threads (Tables I, II) and helps to achieve a stable speedup.

On the other hand, the second approach does not guarantee the absence of incoherence in the processor caches. Numerous tests, performed on different computers, demonstrate the reliability of this approach. Moreover, the above example as well as other tests, performed on the AMD Opteron processor, which does not have hardware protection against performance degra-

dation due to incoherence in the processor caches, demonstrate stable speedup with the increasing thread number. This approach could be applied to the multithreaded parallelization of the internal force vector evaluation procedure, but we wanted to compare the efficiency of two different approaches to justify the reliability of the more complicated second method.

ACKNOWLEDGMENT

The authors are deeply grateful to IT company SCAD Soft for the financial support of this research and for providing a collection of problems.

***Abstract*—The energy efficiency of program executions is an active research field in recent years and the influence of different programming styles on the energy consumption is part of the research effort. In this article, we concentrate on SIMD programming and study the effect of vectorization on performance as well as on power and energy consumption. Especially, SIMD programs using AVX instructions are considered and the focus is on the AVX load and store instruction set. Several semantically similar but different load and store instructions are selected and are used to build different program versions of for the same algorithm. As example application, the Gaussian elimination has been chosen due to its interesting feature of using arrays of varying length in each factorization step. Five different SIMD program versions of the Gaussian elimination have been implemented, each of which uses different load and store instructions. Performance, power, and energy measurements for all program versions are provided for the Intel Sandy Bridge, Haswell and Skylake architectures and the results are discussed and analyzed.**

***Index Terms*—Energy consumption, power consumption, AVX instruction set, Gaussian elimination.**

I. Introduction

In addition to performance optimization of codes for numerical algorithms, there is a growing need to optimize the power and energy consumption of such programs as well. Reasons are well-known and include aspects, such as budgeting, battery life, cooling capacity, or physical boundaries. A possibility to reduce the power and energy consumption of the execution of a program is the choice of energy-saving architectures and or architecture components, which have been developed by the hardware manufacturers for this purpose. An example for such an architecture components are SIMD or vectorization units supplied by recent processors. A CPU based SIMD execution unit calculates multiple elements in special registers simultaneously with one instruction in contrast to processing them sequentially. For the same computation, a vectorized program activates less transistors than a sequential program and, hence, vectorization provides a potential for performance and, power and energy optimization.

The exploitation of SIMD units for executing numerical algorithms requires to provide a suitable program which contains so-called vector operations that cause the architecture to exploit the vector units. One possibility to do this is to use the Intel AVX instruction set, which can be used on recent Intel architectures, such as the Intel processors Sandy Bridge, Haswell or Skylake. The design of such a vectorized program using AVX instruction includes several decisions when transforming a sequential program or algorithm into a vectorized program version. The decisions include the selection of program parts to be coded as vector operations but also the specific choice of AVX instructions to be used for the coding. Both, the strategy to include SIMD parallelization into a program as well as the choice of instructions, can have an effect on the performance as well as the power and energy consumption. This article concentrates on the AVX load and store instruction set and investigates the effect on the performance when different but semantically similar instructions are chosen.

The investigations of this article concentrate on different load and store instructions provided by the AVX instruction set, such as aligned, unaligned, streaming or masked load and store instructions. Using these alternatives for load and store, different SIMD program versions for the Gaussian elimination are built. The experimental investigation of these program versions exhibits interesting differences in the performance results, such as the different performance of aligned and unaligned load and store instructions. In detail, this article makes the following contributions:

- Several program versions for the Gaussian elimination are implemented with different AVX instructions.
- The performance, power and energy of the the five program versions with different AVX instructions have been investigated on three processor architectures.
- A detailed discussion and comparison of differences in performance, energy and power consumption of the implemented program versions is given.

The rest of this article is structured as follows: In Sec. II, we introduce AVX instructions, the Gaussian elimination, and the vectorized program versions of the Gaussian elimination. Section III introduces the execution environment and hardware architecture. Section IV presents the performance properties of the program versions. In Sec. V, we discuss the influence of different AVX instruction on the energy efficiency of a program. Section VI shows related research and Sec. VII concludes.

II. SIMD IMPLEMENTATION OF THE GAUSSIAN ELIMINATION

The vectorized implementation of the Gaussian elimination leaves room for different choices of load/store AVX instructions. This section introduces the AVX instructions, their expected influence, the Gaussian elimination, and the vectorized program versions.

A. Programming with AVX

Many of today's CPUs have vector or SIMD instruction sets, which support parallel executions by applying the same operation simultaneously to two, four, or more pieces of data. Two popular SIMD instruction sets are the *Streaming SIMD Extensions* (SSE) and the *Advanced Vector Extensions* (AVX), both implemented into various AMD® and Intel® processors. SSE and AVX provide instructions to load, modify, and store 128-bit (SSE) or 256-bit (AVX) vectors containing multiple elements, where the number of elements is specified by their particular size. In principle, program executions can reach a speedup equal to the number of data elements per vector, in practice several factors limit the optimal speedup. The performance properties and limitations for vectorization have been demonstrated for multiple examples, e.g. in [2]. Only few articles cover vectorization in the context of energy efficiency. Examples from Cebrián et. al. [3] or Lorenz et. al. [4] demonstrate a potential to increase the energy efficiency by the application of vectorization.

The SSE and AVX instructions can be used either as assembler instructions or embedded into C-style intrinsic functions. It is recommended to use intrinsic functions instead of assembler instructions, since it enables the compiler to apply further optimizations, such as dead code analysis. The intrinsic functions have the following format:

```
                <type>
_mm<size>_<operation>_<type_suffix>(
          <type> param1,..)
```

- `<type>` can either be a standard C-type (e.g. `float`) or a special vector type (e.g. `__m256` for 8 single-precision floating-point values) depending on the actual function purpose and definition.
- `<size>` denotes the number of bits used for the instruction, e.g. `256` for AVX.
- `<operation>` expresses the implemented operation, e.g. `add` for an addition.
- `<type_suffix>` denotes the type of data to operate on, e.g. `ps` for packed single precision.
- The number and type of parameters varies dependent on the instruction.

Table 1 lists the specific intrinsic functions used in this article with their semantic, and the values for latency and throughput on different processor architectures given in [1].

B. Alternative load/store instructions

The different semantic of the intrinsic functions can be investigated with regard to the energy efficiency. For this purpose the intrinsic functions in Tab. 1 are evaluated in the context of expected differences in measurement results. Such differences can arise from their difference in latency and throughput, and due to their requirement on memory alignment, i.e. the memory address being divisible by 32 byte. The following instructions are amenable to demonstrate such differences:

- **Unaligned** load/store: Load and store operations accessing unaligned memory are applicable for any memory position to load/store any consecutively stored elements. The cache line size is a multiple of the AVX register size of 256 bit, and thus the access of unaligned memory positions may contain a cache line border, resulting in a possible performance loss [5].
- **Aligned** load/store: Vectors aligned at 256 bit reside in the same cache line. Thus, the access is expected to lead to a higher performance of the program, compared to unaligned instructions. However, an aligned memory access has to be ensured by the programmer using methods such as loop peeling, special allocators, and/or alternative strategies.
- **Streaming** store: Streaming stores are special, aligned store instructions that bypass the caches when storing data. In detail, they are implemented using a "non-temporal hint" to indicate that no intermediate copy should be created in cache. Thus, streaming stores provide the possibility to issue a Write Through operation at the programming level.
- **Masked** load/store: Vector instructions usually use all elements for their calculations leading to a strict SIMD implementation and execution. A possibility to use only parts of a vector register is provided by masked instructions. Masked load/store instructions have an additional mask parameter which specifies the elements to be loaded/stored. The elements to be omitted, i.e. not to be loaded/stored, are specified by 0-bits in the mask parameter. Values omitted by loads are assigned zeros in the vector, whereas values omitted by stores are skipped while writing to memory. Values to be loaded/stored are identified by 1-bits in the mask parameter and treated accordingly.

```
1 for k = 0 < N-1; k+=1
2   //exchange rows with pivot element
3   for i = k+1 < N; i+=1
4     L[i*N+k] = A[i*N+k] / A[k*N+k]
5     for j = k+1 < N; j+=1
6       A[i*N+j] = A[i*N+j] - A[k*N+j] * L[i*N+k]
7     b[i] = b[i] - b[k] * L[i*N+k]
8 //Backward substitution
```

Listing 1: Algorithm of a Gaussian elimination adapted from [6] of which the vectorized program versions are derived.

C. The Gaussian elimination

The Gaussian elimination is an important kernel in scientific applications for solving linear equations. For the Gaussian elimination, a set of N linear equations with N

Intrinsic function	Instruction semantic	HSW Lat	HSW Tp	SKL Lat	SKL Tp
`_mm256_load_ps(*mem)`	Loads 8 float values from an aligned memory position `mem` into a vector variable.	1	0.5	1	0.25
`_mm256_loadu_ps(*mem)`	Loads 8 float values from an unaligned memory position `mem` into a vector variable.	1	0.5	1	0.25
`_mm256_maskload_ps( *mem,mask)`	Loads a specified selection (`mask`) of values from a memory position `mem` into a vector variable. Omitted values are 0.	8	2	11	1
`_mm256_broadcast_ss(*mem)`	Loads one float value (`mem`) into all elements of a vector variable.	-	-	-	-
`_mm256_loadu_si256(*mem)`	Loads 256 bits of integer values from an unaligned memory position `mem` into a vector variable.	1	0.25	1	0.25
`_mm256_store_ps(*mem,a)`	Stores the elements of a vector variable (`a`) into an aligned memory position `mem`.	1	0.5	1	0.25

`_mm256_sub_ps(a,b)`	Subtracts the elements of one vector variable (`b`) from another vector variable (`a`).	3	1	4	0.5

Table 1: AVX intrinsic functions used in this article with their respective values for Latency (Lat.) and Throughput (Tp.) for the Haswell (HSW) and Skylake (SKL) architectures from [1].

unknowns x_k and their respective coefficients a_{ik} and right hand side b_i, where $1 \leq i,k \leq N$ is given. The equation and solution for $Ax = b$, with $A \in \mathbb{R}^{N\times N}$ and $x, b \in \mathbb{R}^N$, has to be solved.

The Gaussian elimination can be divided into two phases: A forward elimination and a backward substitution. In the forward elimination the matrix A is transformed into an upper triangular form, such that $Ux = b'$ holds, where U is the matrix in upper triangular from.

The forward elimination is depicted in Listing 1 as pseudocode. The *k-loop* in Line 1 executes the steps of the forward elimination and iterates along the diagonal elements a_{kk} of matrix A. Each step starts with a pivot search in which the maximum value below (a_{ik}) the diagonal element a_{kk} is searched, and a row exchange of the *current* row $a_{k\_}$ with the row of the pivot $a_{piv\_}$ is done. In each step the *i-loop* in Line 3 calculates for each row $a_{i\_}$, with $i > k$, the elimination factor $l_{ik} = \frac{a_{ik}}{a_{kk}}$ (Line 4), which is stored in a separate matrix $L \in \mathbb{R}^{N\times N}$. Using the elimination factor l_{ik} all elements of row $a_{i\_}$ are calculated by $a_{ij} = a_{ij} - a_{kj} \cdot l_{ik}$, where $k+1 \leq j \leq N$ denotes the column that is iterated by the loop in Line 5. Afterwards, for each row the element b_i of the result vector b is calculated by $b_i = b_i - b_k \cdot l_{ik}$. After $N-1$ steps the former matrix A is transformed to upper triangular form U. The resulting matrix U is stored in the same memory location as the former matrix A, in which the lower triangular elements are *assumed* to be zero.

The second phase is the backward substitution in which the values for vector x are calculated. The elements of vector x are calculated in the order of $x_N, x_{N-1}, \ldots x_1$ according to $x_k = \frac{1}{a_{kk}} \left(b_k - \sum_{j=k+1}^{N} a_{kj} \cdot x_j \right)$.

The algorithm of Listing 1 is not optimized to preserve the ratio of memory- and computation-instructions.

```
1  for k = 0 < N; k+=1
2    //exchange rows with pivot element
3    for i = k + 1 < N; i+=1
4      L[k*N+i] = A[i*N+k] / A[k*N+k];
5      __m256 lv = _mm256_broadcast_ss(&L[k*N+i]);
6      for j = k + 1 < N - 8; j+=8
7        __m256 ak = _mm256_loadu_ps(&A[k*N+j]);
8        __m256 ai = _mm256_loadu_ps(&A[i*N+j]);
9        ak = _mm256_mul_ps(ak,lv);
10       ai = _mm256_sub_ps(ai,ak);
11       _mm256_storeu_ps(&A[i*N+j],ai);
12     if(j < N)
13       int loadmask = {0,0,0,0,0,0,0,0,
           -1,-1,-1,-1,-1,-1,-1,-1};
14       __m256i mask = _mm256_loadu_si256(
           (__m256i*)&loadmask[N-j]);
15       j = N - 8;
16       __m256 ak = _mm256_loadu_ps(&A[k*N+j]);
17       __m256 ai = _mm256_loadu_ps(&A[i*N+j]);
18       ak = _mm256_mul_ps(ak,lv);
19       ai = _mm256_sub_ps(ai,ak);
20       _mm256_maskstore_ps(&A[i*N+j],mask,ai);
21   //calculate b similarly
22 //Backward substitution
```

Listing 2: Vectorized implementation of the Gaussian elimination from Listing 1, which is the starting point for the subsequent program versions.

D. SIMD implementation versions of the Gaussian elimination

A vectorized implementation of the Gaussian elimination from Listing 1 is presented in Listing 2. The implementation uses the intrinsic functions introduced in Tab. 1 to calculate multiple elements of the row (of the *j-loop*) simultaneously. Lines 1 to 4 of Listing 1 remain unchanged. For the vectorized calculation the resulting value of l_{ik} is copied into all elements of a vector variable `lv` in Line 4. The *j-loop* in Line 6 is unrolled eight times to calculate

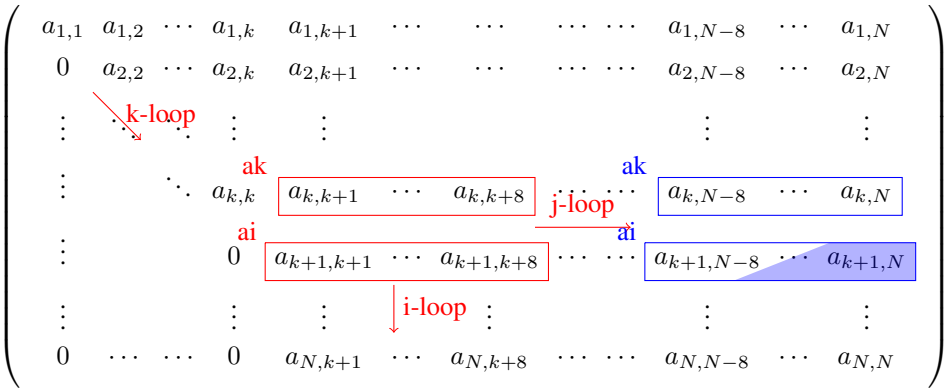

Figure 1: Matrix A in step k, with $i = k + 1$ and $j = k + 1$. The vector variables and the iteration directions according to Listing 2 are depicted in red. The remainder is calculated using the vectors highlighted as blue rectangles for which only the new elements (blue filled) are stored back to the array.

eight single-precision floating-point values simultaneously as demonstrated in Fig. 1. For the use with vector instructions the elements are loaded into vector variables (`ak` and `ai` in Lines 7 and 8, red rectangles in Fig. 1). The vector variables are used to calculate the new values for $a_{i,j}, a_{i,j+1}, \ldots, a_{i,j+7}$ (see red `ai` in Fig. 1) that are written back into the array in Line 11.

Since the number of iterations for the *j-loop* $(N-(k+1))$ is not guaranteed to be divisible by eight a special case has to be implemented. The remaining elements are handled in the block after Line 12 using the masked instructions. Usually, masked instructions are used to load the last elements of the row and values which would not be part of the row are omitted. We choose a different strategy to avoid two costly `maskload` instructions. For this strategy the last eight elements of each row are loaded, regardless of how many are actually needed (see blue rectangle in Fig. 1). After calculation, when storing the results, a mask is applied to write only those elements that are part of the remainder, discarding the twice used elements (blue fill of `ai` in Fig. 1). The mask is created by using an array (`loadmask` in Line 13) of 256 0-bits followed by 256 1-bits and loading the mask in Line 14 which contains the correct amount of 1-bits. The calculation of the $N-(k+1)$ elements of vector b is done similarly.

Different program versions of the Gaussian elimination are built with different load/store instructions. In the following we describe the five program versions:

- The **storeu** program version is the *starting point* implementation using unaligned loads and stores. The *storeu* program version is presented in Listing 2.
- The **store** program version uses aligned loads (`_mm256_load_ps`) and stores (`_mm256_store_ps`). Hence, the *j-loop* in Line 6 does not start at $j = k + 1$ but at the beginning of the aligned block of memory in which $k + 1$ resides. Thus, additional elements are calculated, but a peeling loop is avoided. The aligned load instructions are implemented in Line 8, and the aligned store instructions in Line 11 of Listing 2.
- The **stream** program version uses aligned loads identically to the *store* program version. However, the `store` instruction in Line 11 is replaced with a streaming store (`_mm256_stream_ps`) instruction which bypasses the cache while writing.
- The **maskload** program version replaces all load instructions with masked load (`_mm256_maskload_ps`) instructions. Explicitly, the `maskload` instruction is implemented in Lines 7, 8, 16 and 17 of Listing 2. The masks of these may be either all 1-bits or the correct mask for the remainder. The *maskload* program version illustrates the difference between masked loads and normal loads.
- The **SeqRem** program version replaces the vectorized remainder (Lines 12 to 20 in Listing 2) with a sequential loop that processes each remaining element sequentially as in Listing 1. A sequential remainder loop may be more efficient due to the expected higher cost of masked instructions.

The program versions cover a set of selectable instructions to implement a vectorized Gaussian elimination. The program versions differ only in the modifications shown.

III. Experimental Evaluation

The measurements for this article are conducted in the environment described in this section. Each measurement is conducted ten times and the presented values are averaged. For the measurements we use a matrix A that has $10\,000 \times 10\,000$ elements.

A. Execution Environment

For the measurements of this article we use three Intel® Core i7 processors with a similar specification but different architecture families. The three processors are: A Core i7-2600 of the Sandy Bridge architecture, a Core i7-4770K of the Haswell architecture, and a Core i7-6700 of the

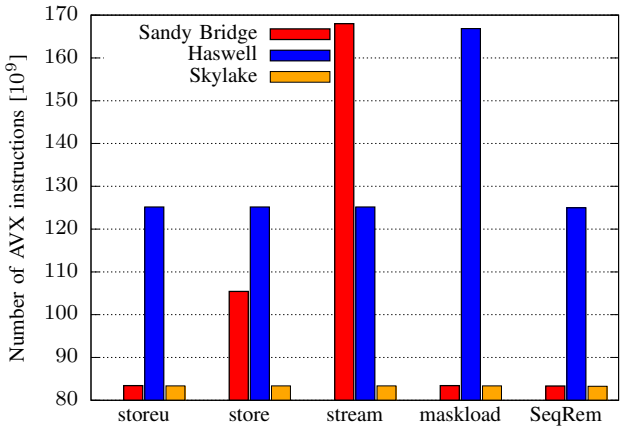

Figure 2: Number of AVX instructions actually executed in the CPU by the execution of the five program versions on the three processors.

Skylake architecture. All three processors allow processor frequency scaling with the `cpu-freq` tool. For the Haswell and Skylake processor scaling is enabled between 0.8GHz and 3.5GHz and for the Sandy Bridge processor the scaling is possible between 1.6GHz and 3.7GHz.

We measure the energy consumption of program executions using a simple interface to read the on chip energy values provided by the Intel® RAPL interface. Additionally, we measure other performance counters using the PAPI library version 5.5. We compiled the program versions using the Intel® C++ Compiler (`icc` version 17.0.0 [gcc version 4.9.0]) with the additional compiler flags `-O3` and `-restrict`. Additionally, we applied the compiler flags `-mavx` for Sandy Bridge architecture and `-march=core-avx2` for the other architectures. The usage of the `-march-avx2` flag implies the usage of FMA instructions rather than `sub` and `mul` by the compiler.

B. Issued AVX instructions

A variation of the number of issued AVX instructions occurs when executing the five program versions on the three processors. The number of issued AVX instructions can be measured during program execution and reflects the number of 256-bit instructions executed.

The number of issued AVX instructions is depicted in Fig. 2 for the different program versions from Sec. II and the three architectures. It is notable that most of the program executions have a nearly identical number of issued instructions. The expected behavior would be all issued instruction counts being nearly identical, since the number of instructions should be predefined by the number of assembler instructions that are generated by the intrinsic functions.

There are multiple exceptions to the expected behavior. For all program versions, the number of instructions issued on the Haswell architecture is about 50% higher, than for the other two architectures. Additionally, some program versions generate an untypical high number of executed

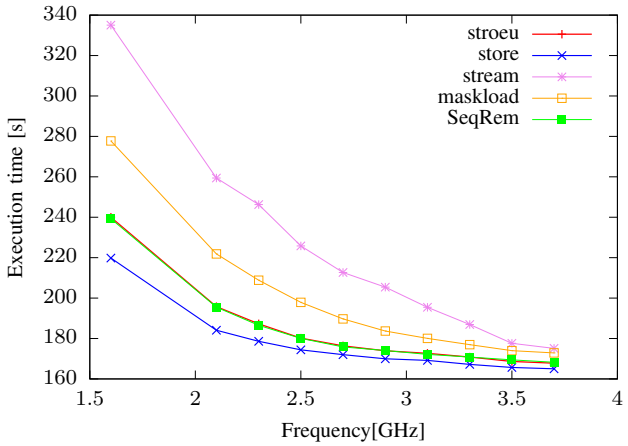

Figure 3: Execution time of the Gaussian elimination versions from Sec. II on Sandy Bridge architecture depending on CPU frequency.

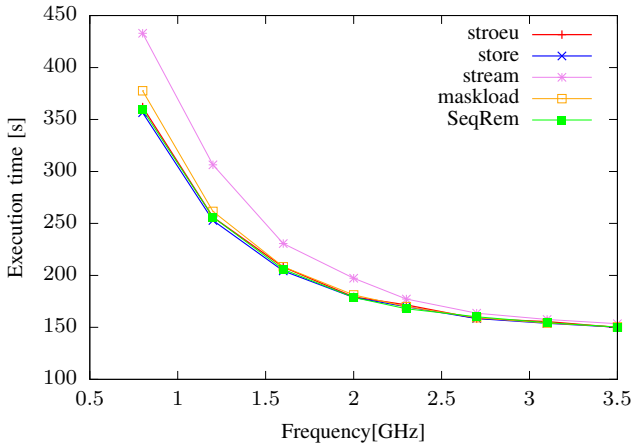

Figure 4: Execution time of the Gaussian elimination versions from Sec. II on Haswell architecture depending on CPU frequency.

instructions. These exceptions arise at the execution of the program version with a higher amount of `maskload` instructions for the Haswell architecture, the use of the `stream` instruction on the Sandy Bridge architecture and slightly more with the use of the aligned load and store operations for the Sandy Bridge architecture.

IV. Performance Evaluation of the Program Versions

In this section, we present the measurements and discuss the differences in execution time for the different program versions. The five program versions of Sec. II are executed on the three processors described in Sec. III.

A. Evaluating execution time

The Fig. 3, 4 and 5 display the execution times of the different program versions in dependence to the processor frequency. As expected, a higher processor frequency leads in all diagrams to a shorter execution time and the qualitative

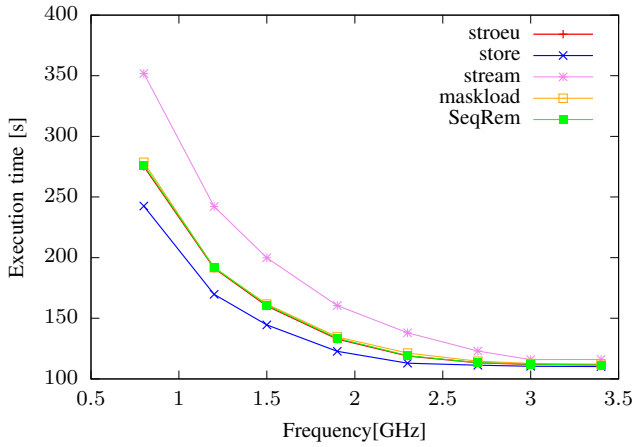

Figure 5: Execution time of the Gaussian elimination versions from Sec. II on Skylake architecture depending on CPU frequency.

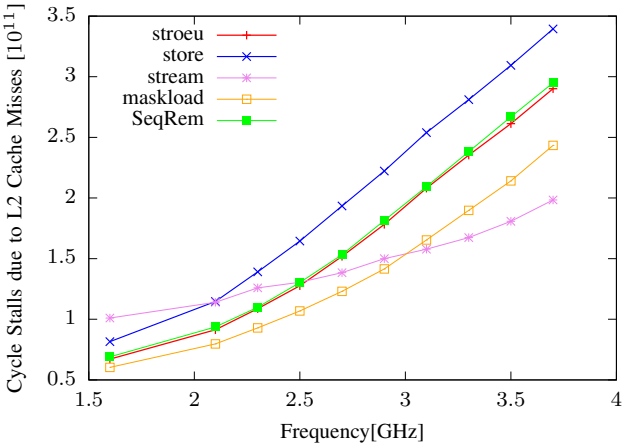

Figure 6: Cycle Stalls due to level 2 cache misses of the Gaussian elimination versions from Sec. II on Sandy Bridge architecture depending on CPU frequency.

behavior is similar. However, the effects of different AVX instructions on performance are thus revealed by the relation of the execution time of the program versions to each other. The program version using the `stream` instruction has the longest execution time for all architectures. This might be caused by the Write Through strategy that is applied with the `stream` instruction which bypasses the cache when writing data. Thus, the processor has to wait for completion of the write operation (*write-wait*) before another `stream` instruction can be executed.

The *write-waits* are a significant problem occurring for the Gaussian elimination, which has a high number of loads and stores with only little computation per element in between. In other algorithms, that implement a lower number of streaming stores the *write-waits* may be hidden by other computations, loads or Write Back stores.

The Sandy Bridge architecture was the first architecture to support AVX instructions and many improvements to hardware for AVX have been made since. This is also reflected in the example of the program version executing a higher number of `maskload` instructions. For the Sandy Bridge architecture the *maskload* program version takes a higher execution time than the remaining three program versions. For the Haswell architecture the execution time is only slightly higher and for the Skylake architecture there is no difference in execution time between a `maskload` (with a full true-mask) and a `loadu` instruction.

A comparison between the *storeu* program version and the *SeqRem* program version demonstrates the influence of a vectorized remainder against a sequential remainder loop. The measurement results of the *storeu* and the *SeqRem* program versions are nearly identical ($< 0.5\%$). In combination with the results of the *maskload* program version, this leads to the conclusion, that the use of masked instructions has a worse performance than regular load/store operations, but are at least as performant as a sequential program execution.

For the Sandy Bridge architecture the aligned `load` and `store` instructions exhibit a better performance than the unaligned ones. The difference between aligned and unaligned instructions is eliminated for the Haswell architecture. For the Skylake architecture the performance enhancement of aligned instructions is again visible. Presumably, the architectural changes between Sandy Bridge and Haswell architecture improved the unaligned instructions, whereas the architectural improvement from Haswell to Skylake architecture improved the aligned instructions.

B. Influence of Cache-Waits on execution time

The memory properties of a program can support the classification of its performance properties. One way to get information about the memory properties is to take a look at the cache usage of the program versions.

Figure 6 displays the number of CPU cycles stalled due to waits for pending operations on level 2 cache for the Sandy Bridge architecture. For most of the program versions from Sec. II the relation of the curves is directly inverse to their execution time of Fig. 3. This behavior is expected due to the limitation of memory bandwidth that gets visible more clearly if the program executes the implemented calculations faster.

The *stream* program version produces a lower rise in cycle stalls in dependence to the processor frequency than the other four program versions. The lower rise in the diagram can be explained with the operation inside the `stream` instruction: The Write Trough operation. The Write Trough operation does not write data into the cache but directly to main memory. Thus, waiting for a write operation is not counted as a wait for any cache and thus does not get counted for level 2 cache stalls. When regarding other resource stalls, i.e. general stalls, the results for the *stream* program version are much higher than for the other program versions. This observation reinforces the previous statement of the worse execution time of the `stream` instruction resulting from *write-waits*. The difference is presented for the Sandy Bridge architecture in Fig. 6 but is also observ-

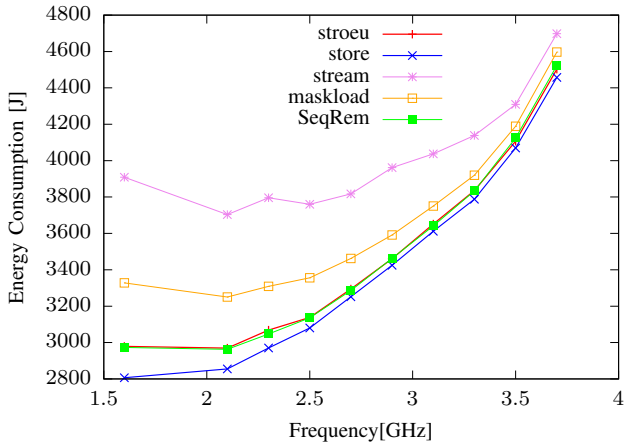

Figure 7: Energy consumption of the Gaussian elimination versions from Sec. II on Sandy Bridge architecture depending on CPU frequency.

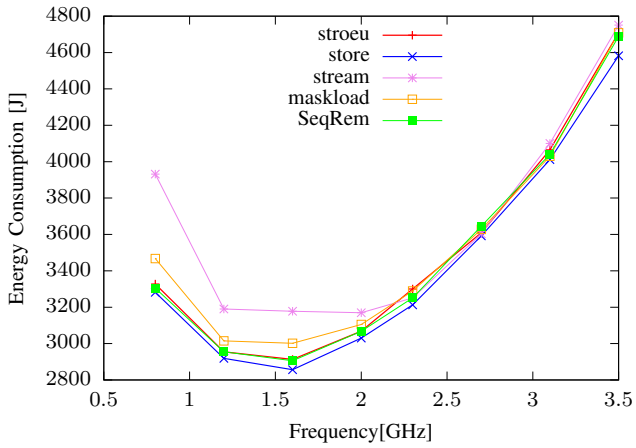

Figure 8: Energy consumption of the Gaussian elimination versions from Sec. II on Haswell architecture depending on CPU frequency.

able for the Haswell and Skylake architectures. Since the investigations for this article do not exploit parallelism, the level 3 cache displays a similar behavior.

V. Examining the energy efficiency

The main question of this article is the behavior of the energy efficiency of different AVX instructions. This section discusses the energy and power consumption of the five program versions from Sec. II. The results are presented as *Energy to Solution* and *Power to Solution* from which other metrics, such as Energy-Delay-Product, can be derived.

A. Evaluation of the energy consumption

One metric to discuss the energy efficiency of program execution is the energy consumed by the processor during the execution of the program version. The Fig. 7, 8 and 9 present the energy consumption of the program versions from Sec. II depending on the processor frequency. Similar

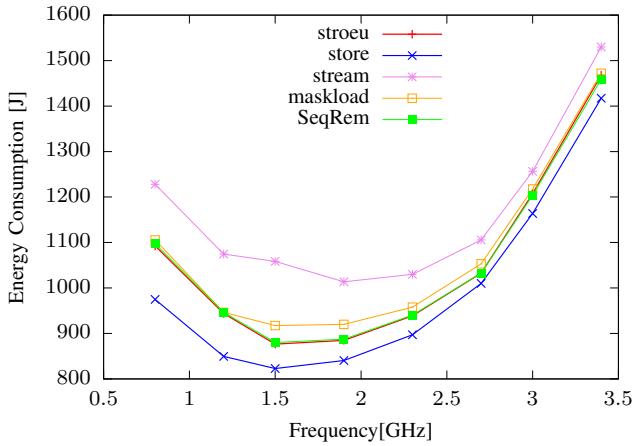

Figure 9: Energy consumption of the Gaussian elimination versions from Sec. II on Skylake architecture depending on CPU frequency.

to the results of the performance discussion, the *stream* program version has the highest (worst) energy consumption for all architectures. The *maskload* program version consumes more energy on the Sandy Bridge and Haswell architecture. Executing the remainder with a sequential remainder loop does not change the energy consumption against a vectorized remainder. In contrast to the performance discussion, the program version using aligned stores consumes less energy for all three architectures.

The lowest energy consumption is achieved with a frequency between 1.5GHz and 2.0GHz for all program versions and architectures. The dependency of the energy consumption on the processor frequency produces a U-Shape with deviations. Specifically, the U-Shape of the *stream* program version creates a U-Shape with a broader base, i.e. a flatter U-Shape. A similar behavior is shown by the *maskload* program version on the Haswell and Skylake architectures.

The different program versions produce their highest difference in energy consumption for the lower frequencies. For the higher frequencies the execution of the program versions is mostly affected by the memory transfer time, as already discussed in Sec. IV. The dependence on memory bandwidth limits the capabilities of vectorization and thus makes idle or waiting time a significant fraction of the program execution.

B. Differences in power consumption

In many cases the implementation with different vector instructions changes energy consumption in the same way as it changes the execution time of the program execution. Some exceptions can be found by regarding the power consumption of the program versions, where $power = \frac{energy}{time}$.

The power consumption is calculated from the averaged measurement results for execution time and energy consumption of each execution. The power consumption of a program execution strongly depends on the processor

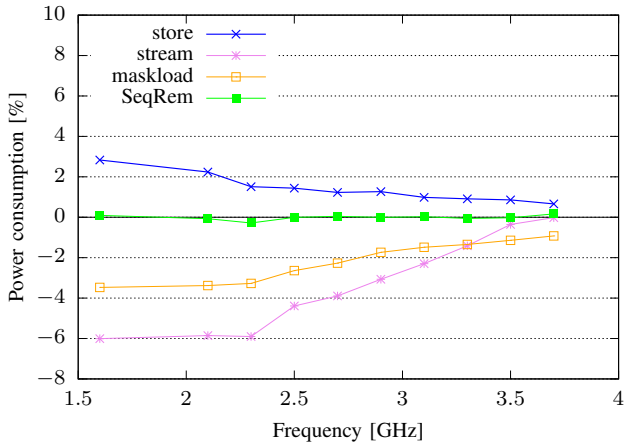

Figure 10: Difference of power consumption of the Gaussian elimination versions from Sec. II to the *storeu* program version in percent on Sandy Bridge architecture depending on CPU frequency.

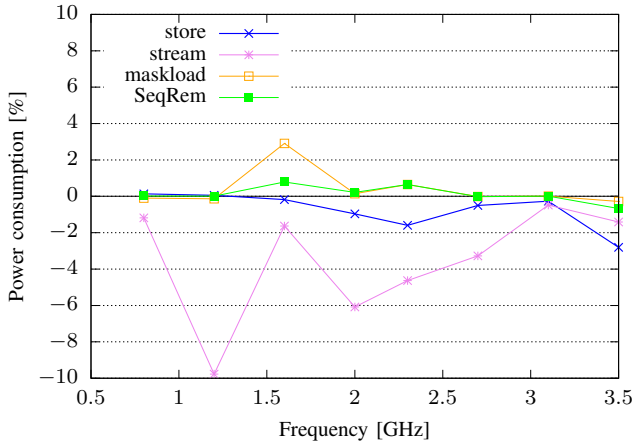

Figure 11: Difference of power consumption of the Gaussian elimination versions from Sec. II to the *storeu* program version in percent on Haswell architecture depending on CPU frequency.

frequency [7]. Thus, to discuss the differences between the five program versions the Fig. 10, 11 and 12 display the power consumption as difference from the *storeu* program version in percent. In general, a processor consumes more power when more transistors are active, i.e. the processor gets hotter, which often comes with a shorter execution time and less energy consumption.

Overall, the five program versions produce less differences for higher frequencies, which demonstrates the dependency on memory bandwidth rather than computing capabilities. Additionally, the sequential remainder loop program version has nearly no difference ($< 0.5\%$) to the *storeu* program version with a vectorized remainder.

The *stream* and *maskload* program versions produce a local maximum or peak behavior for the processor frequencies around 1.5GHz for the Haswell and Skylake architectures in Fig. 11 and 12. The peak results from the flatter U-

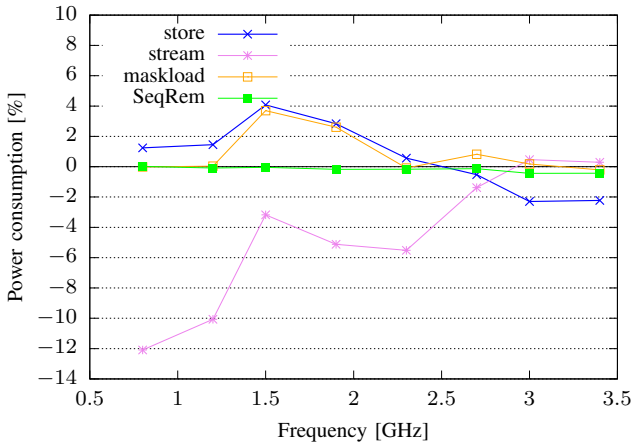

Figure 12: Difference of power consumption of the Gaussian elimination versions from Sec. II to the *storeu* program version in percent on Skylake architecture depending on CPU frequency.

Shape that these two program versions display in energy consumption, where the *storeu* program version (0%-Line) does not follow this behavior.

In Fig. 10 the *maskload* program version generates a lower power consumption for the Sandy Bridge architecture than the *storeu* program version. For the other two architectures the relation is directly inverse or no difference is shown at all. The reason for this is the higher energy consumption of the *maskload* program version on the Haswell and Skylake architecture for which the execution time is identical to the *storeu* program version. For the execution of the *maskload* program version on the Sandy Bridge architecture the execution time is higher (+16% for 1.6GHz) as well as the energy consumption is higher (+12% for 1.6GHz). The difference between these two increased values leads to a lower power consumption.

The program version implemented with aligned stores produces a lower energy consumption than the *storeu* program version for all architectures. However, the execution time is nearly identical on the Haswell architecture and lower on the other two architectures. This leads to a reduced power consumption of the *store* program version on the Haswell architecture. Additionally, for the Skylake architecture the *store* program version produces a constant difference in energy consumption and execution time to the *storeu* program version for higher frequencies. However, the point at which the constancy is occurring is at 2.0GHz for the energy consumption and at 2.7GHz for the execution time. This leads to an inverse relation of the *store* program version in Fig. 12 above 2.7GHz, for which the aligned stores are more power and energy efficient.

VI. Related Work

The energy and power efficiency is subject to different research fields. Especially, in the field of multi-threaded, parallel and distributed computing [3], [8], [9]. In our work we isolate the effects of vectorization on energy efficiency

and leave other techniques of parallel execution applicable on top.

Lien et al. [10] investigate the energy efficiency of multi-threaded vectorized programs. They use three different algorithms for their work: FFTW, Matrix-Multiplication, and blackscholes. They show that vectorization increases energy efficiency, even more with additional multi-threading. For our investigations we isolate the use of vectorization to reason about the impact of different instructions used.

Caminal et al. present an energy efficiency study of the ParVec Suite based on different vectorization strategies [11]. They demonstrate the need for easy user guided vectorization to reduce the energy consumption of program executions. Their main focus is on the results of different user guided vectorization techniques such as OmpSs and Mercurium. The focus of our work is the investigation of differences of vector instructions to create additional knowledge for the use in such user guided vectorization systems.

In [2] Kim et al. describe modifications of source code to increase the performance properties of vectorized programs. They specifically emphasize that the use of continuously stored data elements is one of the key factors for efficient vectorized programs. For this they extensively discuss the use of Struct-of-Arrays instead of Array-of-Structs store order. We considered their findings for creating our program versions and focus on the influence of different instructions.

Hofmann et al. examine the influence on performance of vector instructions with the RabbitCT benchmark in [12]. They demonstrate that the choice of instructions has an influence on the performance of the program execution. Their work examines the additional instructions introduced by the AVX2 instruction set and Intel Xeon Phi instructions. We extend this research by examining the performance and energy efficiency for regular load/store instructions.

VII. Conclusion

In this article, the influence of different load and store AVX instructions with different program versions of a Gaussian elimination are investigated. The investigations demonstrate that the choice of instructions influences the execution time, energy and power consumption. The number of issued AVX instructions may be different, depending on the processor architecture and set of instructions implemented. However, no influence of a different number of issued AVX instructions on the performance or energy properties of the program execution can be derived.

The processor development influences the properties of different instructions, such as for the masked instructions which are improved in the newer processors. The use of streaming store instructions produces the worst behavior due to the memory intensiveness of the Gaussian elimination. Additionally, remainder loops can be vectorized without performance or energy efficiency being negatively influenced. Aligned load and store instructions produce the best results in performance and energy consumption even if additional elements are computed.

A next step in our research will be to identify the root cause of the different number of instructions issued presented in Sec. III. Additionally, the influence of data size and cache usage can be examined with cache optimizations of the basic program versions and comparisons with established library implementations, such as in BLAS or LAPACK.

***Abstract*—Due to the ever changing characteristics of the newly provided hardware, there is the permanent requirement of designing and re-designing software adequately to meet the basic hardware conditions. Especially for well-established software, easy portability of the functional as well as the non-functional properties, such as runtime performance or energy efficiency, would be beneficial, so that the software adapts automatically to the given hardware conditions. In this article, we explore the autotuning potential of several methods from scientific computing. In particular, we consider time-stepping methods and investigate the effect of relevant tuning parameters of the different methods. We also address the question, whether offline or online autotuning approaches are appropriate for the specific method. The methods from scientific computing considered are particle simulation methods, solution methods for differential equations, as well as sparse matrix computations.**

***Index Terms*—offline and online autotuning, performance analysis, portability of efficiency, time-stepping methods.**

I. Introduction

IT IS a well-known fact that the life-span of software is usually much longer than the life-span of the hardware on which it is executed. The common practice is to port and tune the existing software for the new hardware generation by adapting it to the hardware details of the new architecture. Especially, if the software is a complex software system developed over many years, the effort of porting and tuning is high, but the development of a completely new software system would also be too time-consuming. Because of the advent of heterogeneous hardware platforms, the effort for porting, re-designing, tuning or re-developing software is even increasing. The challenge and a major research question is how complex software systems can be developed such that the runtime behavior of the software system can adapt or can be adapted to the ever-changing hardware of a varying heterogeneous type. Specifically, we consider the question whether and how software can gain portable efficiency by self-adaptation, also called autotuning.

In this article, we investigate the tuning potential of important simulation methods from scientific computing and address the question, which techniques can be used to support the tuning towards the development of flexible complex software systems. The simulation methods considered include sparse matrix computations, particle simulation methods, and solution methods for ordinary differential equations. The article provides a systematic investigation of the potential for self-adaptation towards a better runtime performance using offline and online autotuning.

Offline autotuning is performed in a separate offline phase, which is executed at software installation time before the actual software execution and in which the runtime behavior of the software on the given architecture is explored by detailed performance tests with different input scenarios. The test results are used to generate one or several implementations of the software that run efficiently on the given hardware platform for different input sets. After the generation of the software, no further adaptation is performed during production runs. Typical examples for offline autotuning are ATLAS [1] and PHiPAC [2] for dense matrix multiplication. Offline autotuning can be applied if the runtime behavior depends only or mainly on the size of the input set and other characteristics of the input set play only a minor role.

Online autotuning is integrated into the execution of the software. The software observes the performance behavior for the given input set during the runtime and adapts its behavior such that the performance is increased as much as possible. Thus, online autotuning is able to adapt the software behavior to the characteristics of the input set. Examples for online autotuning approaches are Active Harmony [3] or Periscope [4]. The challenge of online autotuning is to integrate the self-adaptation at runtime in such a way that the runtime performance is affected as little as possible.

This article investigates the autotuning potential of simulation methods from scientific computing and discusses the usage of offline and online autotuning approaches. In particular, we provide a detailed performance analysis of the different simulation methods, investigate relevant parameters which have a large influence on the performance, and analyze whether the parameters identified are amenable to autotuning and which autotuning methodology is suitable. Depending on the method from scientific

computing and the parameters identified, different autotuning approaches are best suited for different methods. The article derives a guideline, which method requires which degree for offline and online autotuning.

The rest of the article is structured as follows. Section II gives an overview of relevant aspects of autotuning approaches. Section III considers applications from different areas and discusses their autotuning potential. Section IV discusses related work. Section V summarizes the observations for the different applications and concludes the article.

II. Overview of Autotuning Approaches

In this section, we give an overview of key terms and techniques that are important for applying autotuning for time-stepping simulation methods.

A. Key aspects of self-adaptation

The main terms portability of efficiency and auto-tuning or self-adaptive software are often used as keywords today and we start by giving a precise definition for each of the terms.

An important goal in parallel scientific computing is *portability of efficiency* of simulation algorithms. A performance portable implementation of an application or algorithm can be defined as one that will achieve high performance across a variety of target systems [5]. Depending on the target system, high performance may be quite different, and the definition means high performance for each specific target system. For heterogeneous resources, a major challenge is the diversity of devices on different machines, which provide widely varying performance characteristics [6]. A program optimized for one processor processor may not run as well on the next generation of processors or on a device from a different vendor, and a program optimized for GPU execution is often very different from one optimized for CPU execution.

Adaptation and self-adaptation of software in general refers to the the ability of self-adjustment or self-modification of the software in accordance with changing conditions of environment or structure. This term has first been explored in [7]. Thus, self-adaptive software evaluates its own behavior during execution and changes its behavior when the evaluation indicates that it is not accomplishing what the software is intended to do, or when a better functionality or performance seems to be possible [8].

There are different levels on which software can be tuned or influenced towards a better performance:

- hardware-level: this includes hardware techniques such as dynamic voltage and frequency scaling (DVFS) for energy optimization;
- system-level: this includes scheduling approaches by a compiler or operating system to improve task executions on a parallel target system;
- software-level: this includes modifications at the software-level towards better performance, e.g., source-code transformations such as loop transformations; this captures also the case that the software can adapt itself using knowledge from earlier computing steps.

There are a variety of interactions between these different levels and the final performance improvements achieved for a specific situation may come from performance improvements at different levels. The main focus of this article are performance improvements at the software-level and the questions which methods of self-adaptation are suitable for which application areas.

B. Tuning parameters and possibilities

The efficiency of an application software can depend on many influencing parameters and program transformations, system parameters and characteristics of the input set may have a large influence on the resulting runtime performance or energy efficiency. In this subsection, we provide a short overview.

A new implementation version for a simulation method from scientific computing can be generated by applying correctness-preserving program transformations such as loop interchange, loop distribution, loop unrolling or loop tiling. Moreover, SIMD instruction or memory prefetching techniques can be applied. The result is an implementation version with the same input-output behavior but potentially improved non-functional properties according to a given optimization goal.

Some of the program transformations may be based on the use of transformation parameters. Examples are loop unrolling or loop tiling where an unroll factor or a blocking factor needs to be specified. The selection of a suitable set of program transformations along with their parameter values and an order in which the program transformations should be applied may significantly increase the performance or the energy efficiency. The application of the program transformation could be controlled by a performance model such as the ECM model [9].

The execution of a program implementation may also be influenced by configuration and system parameters. These include the usage of compiler options, the number of threads or processes used for the execution of the implementation and the mapping of these threads or processes to the resources of the given HPC system. For the case of energy efficiency as target function, the selection of the operational frequency for DVFS may also play an important role. For some of the simulation methods, also characteristics of the input set may play an important role for the resulting performance or energy efficiency. Examples are signal processing where the size of the input set may determine which algorithm is the most efficient one [10], [11] or spare linear algorithms where the sparsity and composition of the data structures such as vectors or matrices may play an important role [12], [13]. This behavior can also be observed for particle simulation methods that are considered in this article, where the initial

distribution of the particles may have a strong influence on which simulation method and which implementation leads to the fastest execution.

C. Offline and Online Autotuning approaches

The main emphasis of this article are methods of self-adaptation for the application class of time-stepping simulation methods from scientific computing, since these methods constitute an important class of HPC software. Depending on the characteristics of the specific simulation method and the underlying simulation algorithm, offline or online approaches may be suitable for self-adaptation. In the following, we give an overview.

1) Offline Autotuning: Analyzing the hardware and software for tuning and preselecting parameter sets are main aspects of the offline autotuning. The offline autotuning is performed before the first time step is executed and is performed once.

In this autotuning approach there should be an automated generation of test parameter sets for the identification of the influence of various platform and input parameters, e.g., processor frequency or number of threads. For the quantification of the influences, these parameters will be evaluated and analyzed. This evaluation and analysis can be done with some microbenchmarks. In the offline autotuning approach is also a creation of application-specific performance models, e.g., the Roofline model [14] or the ECM model[9], for the simulation application which can provide additional information. These performance models are evaluated by experiments and facilitate a selection of suitable program variants and configurations regarding all available program variants. The selected program variants are arranged in a decision tree which is provided to the online tuning step, whereby the leaves of the decision tree contain implementation variants considered for the execution and the inner nodes contain conditions to decide which leaves are appropriate. The conditions capture relevant information about the input data that is suitable to identify implementation variants than potentially lead to good runtime results under the conditions given. Depending on the application, the conditions may include the size of the input data and specific properties of the input data such as distribution characteristics for particle simulation methods, distribution patterns for sparse matrix computations, or access distances for solution methods for ordinary differential equations.

2) Online Autotuning: The monitoring and control of the self-adapting behaviour of time-stepping simulation methods are key components of the online autotuning approach. Many mechanisms should be provided to ensure a comprehensive online adaptation process for different simulation methods, which differ significantly in their computational structure, e.g. data arrangement or loop structures. Hence, the following online tuning mechanisms require to be as much application independent as possible in order to be applied to diverse time-stepping simulation methods.

The offline autotuning step pre-selected a diverse set of implementation variants that should be considered for the execution of the time-stepping simulation method. These implementation candidates are processed by a selection and preparation mechanism which ensures a later usage of these candidates. Architectural and algorithmic parameters are determined by an evaluation mechanism and include major properties of the actual input data. This evaluation step is performed before the first time step is executed. The set of determined parameters is used by a search mechanism, which works on parameter configurations and traverses the decision tree built in the offline tuning step. Thus, the search mechanism selects a final set of suitable implementation candidates based on the given parameter configuration. A generic iteration controller mechanism applies the final set of implementation candidates to the first time steps and compares their overall performance. This comparison process determines the best implementation candidate and the appropriate runtime parameters for the execution of the remaining time steps. The monitoring mechanism utilizes the initial comparison of the implementation candidates within the first time steps and observes the overall performance behaviour of the following time steps until the application finishes its execution. Hence, significant deviations of the performance measured can be detected and a new selection of a more suitable implementation candidate can be initiated to react on varying input data properties.

3) Cost estimations: The estimation of resources, e.g. time, energy or memory space, required to solve a given problem can be used to provide upper and lower limits for the appropriate resource. Hence, existing implementations can be rated based on these limits and are more or less suitable to solve a specific problem with actual input data on different HPC-systems or with different execution units, e.g. CPU, GPU or multiple HPC-systems. The cost estimation of a given algorithm or an implementation can be provided by a cost function. The granularity of cost functions can range from estimating whole programs of arbitrary size, which may result in quite complex or merely rough estimations, to specific parts of an implementation, e.g. time-step loops, single loop kernels or basic operations as vector, load or store operations. Since cost functions for loop kernels can be formulated quite accurately, offline autotuning approaches can benefit greatly of such estimation functions to predict the resource consumption of repeating calculations.

Time-stepping simulation methods should ensure an efficient calculation of each time step for varying input data. Thus, several implementations are provided for executing an actual time step, i.e. one loop iteration, and in general perform best with different input data and parameter configurations. Therefore, a selection of implementations has to be applied to limit the number of existing imple-

mentations to match a given requirement, e.g. time or energy consumption. Additionally, the input data may provide further selection criteria for the most suitable implementation variants based on the given cost functions. This leads to a significant reduction of the search space used within the autotuning process and, hence, ensures a faster convergence of the offline tuning step to find the optimal implementation variant for the current execution state.

III. Tuning examples and experimental results

To investigate the potential for self-adaptivity, we consider particle simulation methods, sparse matrix computations, and solution methods for differential equations and analyze their performance behavior with respect to varies tuning parameters, including the degree of parallelism, the operational frequency used, and application-specific parameters such as the grid size for particle simulation methods.

A. Particle simulation methods

We consider particle simulations with long-range interactions caused, e.g., by electrostatic or gravitational forces. The behavior of the particles is simulated by a series of time steps. In each time step, for each particle the simulation computes the forces caused by all other particles and determines the resulting new positions and velocities of the particles. This results in $O(N^2)$ complexity per time step if all interactions are taken into account. Many approaches have been proposed to reduce the complexity, including Fourier-based methods and hierarchical methods. Most of these advanced methods use a splitting approach and distinguish between long-range interactions from far-away particles and short-range interactions from nearby particles. Short-range interactions are typically computed exactly and long-range interactions are typically approximated.

The distinction between short-range interactions and long-range interactions is often performed by using a 3D grid structure with spatial cells. The short-range interactions cover all particles residing in the same or neighboring cells. The size of the spatial cells influences the computational behavior of the simulation and may also have an influence on the resulting accuracy of the simulation. The different advanced particle simulation methods mainly differ in the computation of the long-range interactions. In the following, we consider two different approaches, a Fourier-based approach and a hierarchical tree-based approach based on multipole expansions.

The performance behavior of the particle simulation methods considered depends on different hardware-specific and application-specific parameters. The hardware-specific parameters include the hardware platform used and the number of processes or threads employed. The application-specific parameters mainly include the separation between the short-range and long-range interactions. The number of particles and the initial distribution of the particles may also have a strong influence on the resulting performance of the different methods. In the following, we concentrate on the influence of the number of particles, the number of processors used, and the separation between the short-range and long-range interactions and the resulting grid sizes. The experiments are performed on an Intel Haswell system with two Xeon E5-2683 v3 processors, each equipped with 14 cores and a L3 cache of size 35,840 KB. The performance experiments are performed with two particle systems with non-uniform distribution: a small particle system with $300 \cdot 8^2 = 19,200$ particles and a large particle system with $300 \cdot 8^5 \approx 9.8$ million particles.

Fourier-based methods

Fourier-based methods compute the long-range interactions in Fourier space. Often, fast Fourier-transforms (FFT) are employed. The resulting computational complexity per time step is $O(N \cdot \log N)$, if the particles are sufficiently uniformly distributed [15]. In the following, we use an FFT-based particle simulation method for our experiments. For this method, the separation between the short-range and long-range interactions is determined by the grid sizes used. Figure 1 depicts the resulting execution times for both the small and the large particle system for different grid sizes. The execution times for 4 MPI processes are shown in the left diagram and the execution times for 56 MPI processes are shown in the right diagram. The diagrams show that different grid sizes lead to significantly different execution times due to the differences in the near-field and far-field computations. The optimum grid size that leads to the smallest execution time depends on the number of particles and the number of processes used. For both 4 and 56 MPI processes, the optimum grid size is 32 for the small particle system and 320 for the large particle system. Measurements have shown that these grid sizes are the optimum sizes also for other numbers of processes. For a sequential execution, the optimum grid size remains at 32 for the small particle system and changes to 448 for the large particle system (not shown in a figure).

The development of the execution time for different numbers of MPI processes is shown in Fig. 2 for the small particle system. It can be seen that the relative order between the resulting performance for the different grid sizes does not change with the number of processes.

Hierarchical multipole method

The fast multipole method (FMM) computes the particle interactions based on multipole expansions [16]. In each time step, the method calculates the (gravitational or electrostatic) potential at each particle position, which allows the computation of the new positions and velocities of the particles. The potential is split into a near-field and a far-field potential. To do so, an octree structure is defined, which results from a spatial decomposition

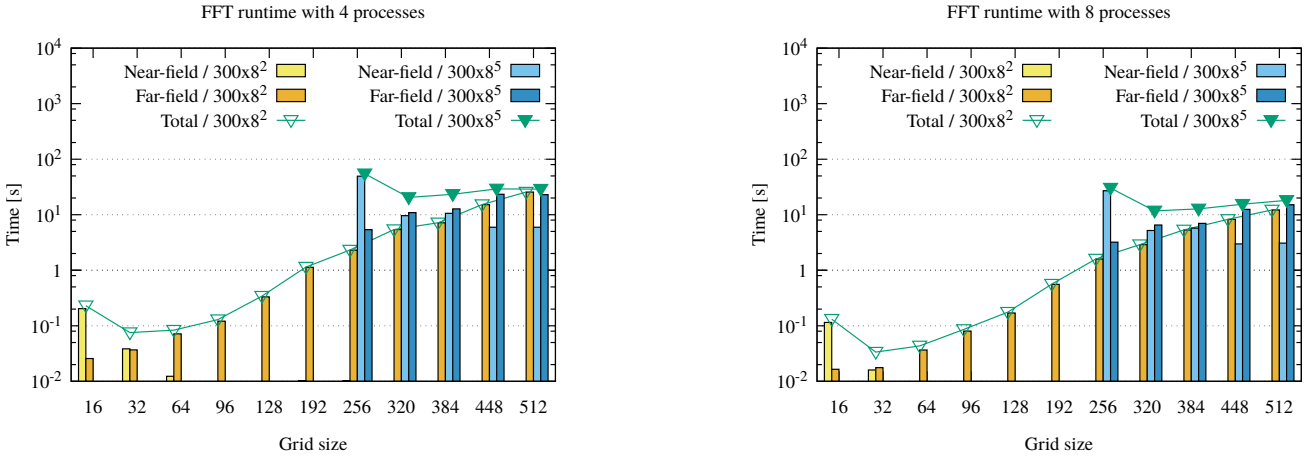

Figure 1. Execution times of the FFT-based particle simulation method for different grid sizes for the small and the large particle system for 4 (left) and 8 (right) MPI processes.

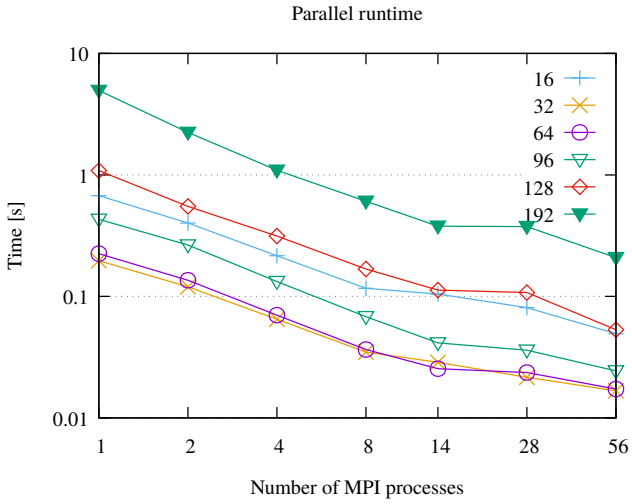

Figure 2. Development of the execution times of the FFT-based particle simulation method for different numbers of MPI processes and different grid sizes between 16 and 192.

into hierarchical boxes, and the particles are sorted into these boxes according to their current position. The spatial decomposition is controlled by a predefined maximum tree depth. For a particle p, the near-field potential is determined by computing the potential at the position of p caused by each of the particles in the same and in neighboring octree boxes. The far-field potential is computed by using approximations for the potential caused by all particles in a specific octree box. These approximations are computed for each octree level. The approximations at suitable octree levels are then used for approximating the far-field potential at a specific particle position. The maximum tree depth determines the separation in the near-field and the far-field potential. The resulting complexity is $O(N)$. In contrast to the FFT-based particle simulation, the FMM does not require that the particles are sufficiently uniformly distributed.

Figure 3 depicts the resulting execution times for both the small and the large particle system for different maximum tree levels. The execution times for 4 MPI processes are shown in the left diagram and the execution times for 56 MPI processes are shown in the right diagram. The figure shows that the maximum tree depth can have a significant influence on the resulting execution time. For the small particle system, the optimum maximum tree depth is 4 for 4 MPI processes, 8 for 8 MPI processes, and 3 for 56 MPI processes. For the large particle system, the optimum maximum tree depth is 7 for 4 MPI processes, 9 for 8 MPI processes, and 10 for 56 MPI processes.

Autotuning-Potential

The experiments of both long-range interaction approaches confirm that the runtime performance is influenced by the particle system size and the separation of the short-range and long-range interactions, i.e., by the grid size or the maximum tree depth. For the hierarchical method, the optimal separation setting to get the best runtime also depends on the number of MPI processes used. Some estimates, e.g., choose high number of MPI processes for better performance, can be done with offline autotuning before the first time step to start with acceptable parameters. To get the optimal parameters they have to be determined with online autotuning. Since the distribution of the particles in the particle system changes after each time step, it is also possible that the optimal parameter setting is changing over time. Thus the online autotuning has to be reapplied after several time steps to respond to imbalances and improve the overall runtime performance. Therefore the performance must be constantly checked for irregularities. For other optimization goals, e.g. energy efficiency, the autotuning-potential behaves the same.

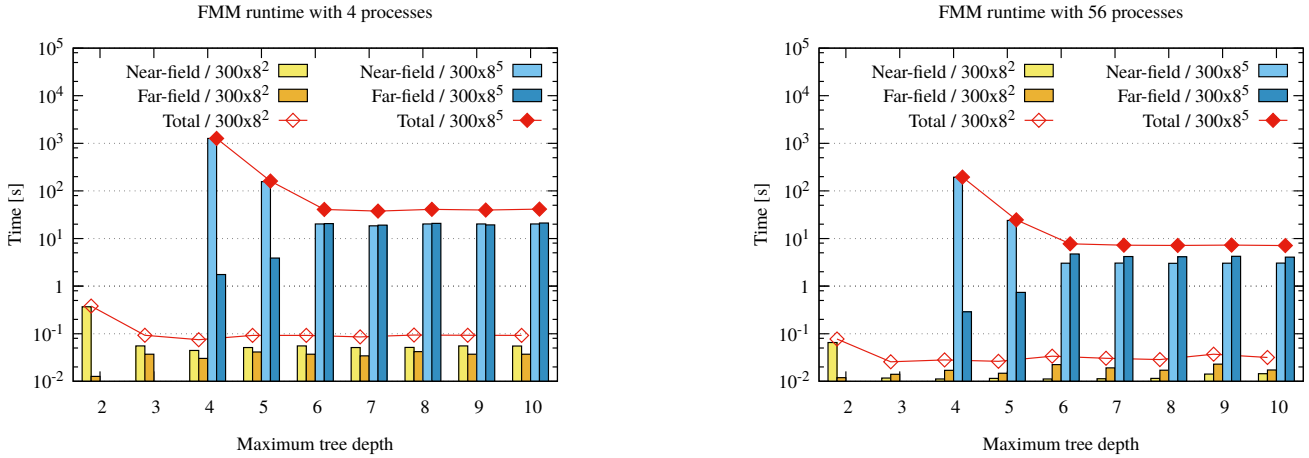

Figure 3. Execution times of the FMM particle simulation method for different maximum tree levels for the small and the large particle system using 4 (left) and 56 (right) MPI processes.

B. *Sparse matrix methods*

Methods performing operations on sparse matrices face additional challenges compared to methods processing dense matrices. Therefore typical calculations as sparse matrix-vector product (SpMV), sparse general matrix-matrix multiplication (GEMM) or solving sets of linear equations using Cholesky factorization have to consider carefully, which memory layout of the sparse input matrices provides the highest benefit in terms of the required performance and given limitations. The sparse property refers to matrices with a significant number of zero matrix elements and, thus, few actual non-zero matrix elements, which in general constitute a rather small fraction of the overall matrix elements.

In the case of the sparse GEMM operation, there is a upper runtime complexity of $O(n^3)$ for a dense matrix memory layout and a simple GEMM algorithm for dense matrices. However, the usage of more suitable sparse matrix memory layouts, called sparse matrix formats (SMF) in the following, is in general based on the exploitation of specific matrix properties of the input matrices and can lead to significant performance improvements. Since the reduction of the number of zero matrix elements stored leads to a better spatial locality when accessing the non-zero matrix elements, memory hierarchies, i.e. the cache hierarchy, can be utilized more efficiently. Hence, performance improvements in terms of time, power and memory consumption can be achieved.

Although the chosen SMF can have a great influence on the performance of the sparse GEMM, the set of parameters influencing performance rather consists of a diverse mix of software and hardware parameters. Solving sparse matrix methods efficiently on a given HPC system relies on several parameters, including the usage of different numbers of threads, the scaling of core and uncore frequency, the availability of SIMD processing units and a proper workload balance within the chosen implementation. Some of the listed parameter influences are considered subsequently with a comparison of three different SMF for a sparse GEMM operation. The SMF chosen are Compressed Sparse Row (CRS), Block Sparse Row (BSR) and Ellpack-Itpack (EIP). The thermal1 matrix with 574,458 non-zero matrix elements is used for the measurements and is taken from the SuiteSparse Matrix Collection [17]. Test systems are a Skylake system with 2× Xeon Gold 6130 processor each with 16 physical cores at 2.1 GHz and a Knights Landing system with a Xeon Phi 7250 processor with 68 physical cores at 1.4 GHz.

The effect of different numbers of threads are depicted in Fig. 4 and show different optimal thread utilizations of the SMF. Moreover, the effect of the nominal core frequency of two different HPC systems can be observed and shows implicitly an inefficient usage of power for certain proposed SMF, e.g. the EIP format can not utilize more than 32 threads for the given test matrix on the Knights Landing system. As an in-depth variable implementation parameter the block size for the BSR format has a significant influence on the achieved runtime as shown in Fig. 5. Comparing different modifiable frequency ranges, the results indicate that the runtime performance of different block sizes can differ such that a specific block size can perform better within a specific frequency range, i.e. the BSR-2 Version can achieve a better runtime within a low frequency range compared to the BSR-16 variant.

Autotuning-Potential

Since a great proportion of the significant parameters for sparse matrix methods are based on hardware properties or on the properties of the input matrices, which are invariant for most sparse matrix methods, a offline autotuning approach implicates the most benefits. Therefore, the application of the proper optimizations can improve the performance required, e.g. runtime, energy consumption or

memory bandwidth utilization. Accordingly, performance models as the Roofline model [14], which have to be created only once for a given hardware configuration, can be used to a great extent for decision making processes of choosing a proper implementation for the desired sparse matrix operation. Furthermore, other performance models, i.e. the Execution-Cache-Memory (ECM) model [18], [9], can provide additional information about memory bound algorithms, which applies to a great proportion of sparse matrix methods. Thus, predictions for a given algorithm can be made for different numbers of threads, so that several optimization goals can be pursued, e.g. optimizing the runtime or finding an optimal number of resources used to satisfy specific energy or memory constraints.

Additionally, an online tuning phase can be used to observe and react to imbalances, which may occur during the execution of the actual problem. This execution behaviour can result due to the initial parameter setup, which was determined in the offline phase. Therefore the necessity for further optimizations can be caused by multiple reasons, e.g. inappropriate estimation of cost functions for kernels executed or data transfer times while using multiple HPC-systems at once. As a result, the runtime or energy measurements may not match the expectations and lead to workload imbalances between different execution units, e.g. CPUs or GPUs. Hence, an online tuning step is desired to adjust the workloads or distribution of data to use all execution resources to full capacity. For a sparse matrix-vector multiplication (SpMV), such an online tuning approach was investigated by [19] and is based on a redistribution of workload between MPI processes if the runtime measurements for the processing of a given number of matrix rows are not similar to measurements of other MPI processes.

Sparse matrix methods benefit the most of an offline tuning phase. However, online tuning approaches can still be applied and are a fine tuning process of the parameters determined in the offline phase. Moreover, the application of online tuning may depend on the actual sparse matrix operation, which should be performed, or the execution units used, e.g. online GPU workload adjustments may get quite complex if the initial data distribution for multiple GPUs has to be modified. Nevertheless, the potential of a mixed tuning approach still contributes to the overall goal of utilizing the given hardware resources to full capacity while optimizing for a given performance goal, e.g. runtime or energy consumption.

C. Solving differential equations

Numerical solution methods for ordinary differential equations (ODEs) compute an approximate solution for a given ordinary differential equation of the form

$$\mathbf{y}'(x) = \mathbf{f}(x, \mathbf{y}(x)) \text{ with } \mathbf{y}(x_0) = \mathbf{y}_0. \quad (1)$$

by performing a series of time steps one after another until the end of the predefined integration interval is reached

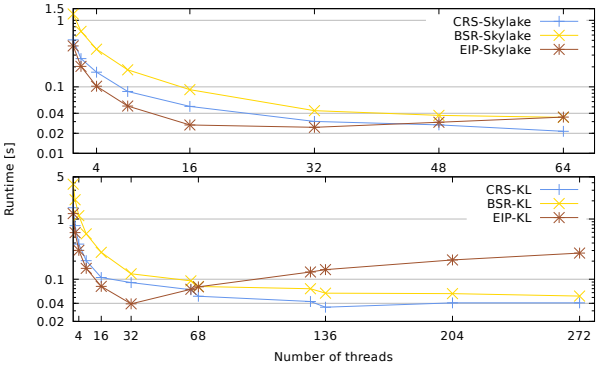

Figure 4. Runtime-Thread scaling of three sparse matrix formats for a Skylake system (top) and a Knights Landing system (bottom).

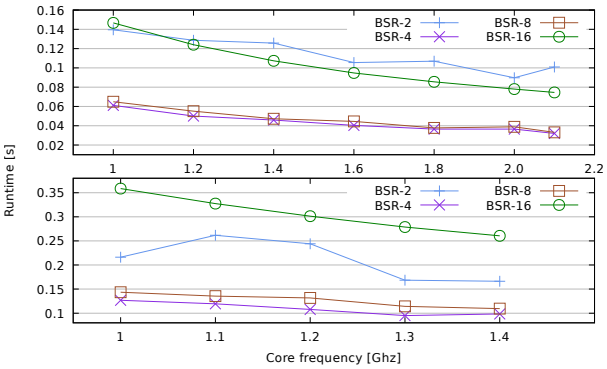

Figure 5. Runtime comparison of the Block Sparse Row matrix format with different block sizes as variable parameter for a Skylake system (top) and a Knights Landing system (bottom). Both diagrams refer to 64 threads used for the BSR variants.

[20]. As example method, we consider iterated Runge-Kutta (RK) methods which perform a fixed number m of computation steps in each time step using the approximation $\mathbf{y}_\kappa$ of the preceding time step. In each computation step, a fixed number s of stage vectors is computed using the stage vectors from the preceding time step and evaluating the function $\mathbf{f}$ defined by the differential equation to be solved. After the last computation step, the stage vectors are combined and an approximation $\mathbf{y}_{\kappa+1}$ for the next point in time is computed. An additional approximation of lower order can be computed additionally for error control and for the selection of the step size for the next time step. Overall, a four-dimensional loop structure results within each time step and many typical loop transformations such as loop interchange, loop unrolling, or loop tiling can be applied.

Taking the parameters of the transformations such as tile sizes and unrolling factors into account, a large number of code variants can be generated and it is not a priori clear, which of these variants will lead to the best performance on a given HPC system. This is an ideal situation for autotuning. A pure offline approach cannot be applied, since the function $\mathbf{f}$ of the differential equation to be solved

may have a large influence on the resulting computational behavior of the different code variants. However, **f** is not known in advance and a numerical solution method should be efficient for different differential equations. On the other hand, a pure online autotuning is also not feasible, since too many code variants would need to be tested. Some of these code variants could be quite slow, leading a further increase of the resulting overhead. Thus, a combination of offline and online autotuning is most promising.

The diagrams in Fig. 6 show the performance of different shared memory implementation variants of the iterated RK method (IRK) for the BRUSS2D example and for different system sizes N. The time per step and component is plotted against the increasing number of threads. BRUSS2D is derived from a reaction diffusion PDE by a spatial discretization on a $N \times N$ grid using the method of lines. The resulting ODE system has dimension $n = 2N^2$. The experiments have been done on a system with two Intel Xeon E5-2697 v3 processors, each equipped with 14 cores and 35 MB L3 shared cache. As RK method we use the LobattoIIIC (8) [20] method with $s = 5$ stages and $m = 7$ computation steps. The code variants [21] utilize data parallelism, the n equations of the ODE system are distributed among the available number of threads p. The variants differ in the loop and the data structures used. Consequently, they have different memory access patterns, resulting in different utilization of the cache and the memory hierarchy. The variants denoted with suffix 'mt' use loop tiling as an optimization technique to further improve the locality of the memory references. Further, four variants (PipeDb1m, PipeDb1mt, ppDb1m and ppDb1mt) exploit a special structure of the function **f** of BRUSS2D by overlapping of vectors and by using pipeline-like computational structure of the computation steps m [21]. These variants only require lock-based local synchronization with neighbor threads, whereas all other variants need global barrier operations.

The diagrams in Fig. 6 indicate that the performance of IRK variants depends on the runtime parameters, such as the dimension of the ODE system and the number of threads executing the program. In particular, following observations can be made: (1) For the same system size, but for different numbers of threads, the order of the implementation variants varies. For example, for $N = 460$ and thread numbers $p < 20$, the variant EAmt offers the best performance, closely followed by the variant E and A. For $p = 20$ all variants require nearly the same execution time. For even larger numbers of threads, the variants EAmt, A and E are the slowest variants. The main reason for the smaller efficiency of these variants for large numbers of threads are the costs of the barrier operations used for synchronization of the threads. The variants A, E, EAmt require two barrier operations per stage in each computation step. All other variants need either only one barrier operation per computation step or use more efficient lock-based synchronization. (2) For

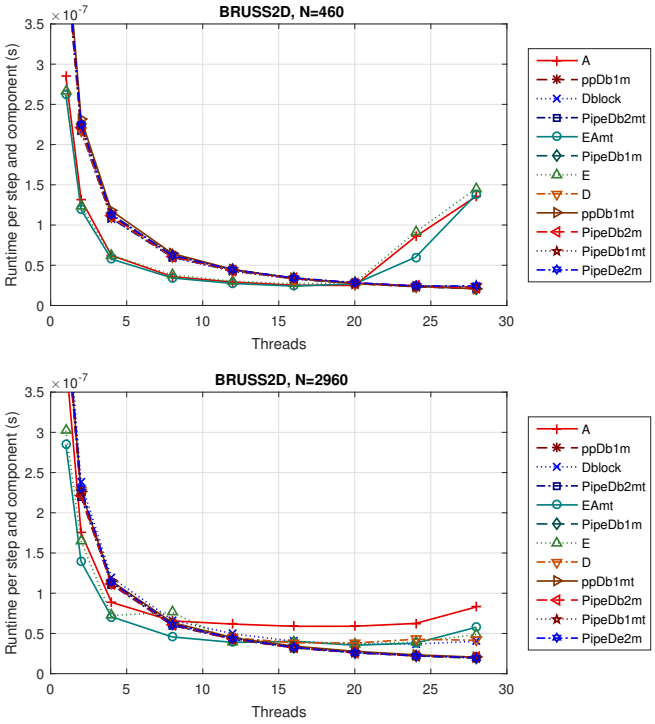

Figure 6. Execution time per step and component of iterated RK method for $N = 460$ (top) and $N = 2960$ (bottom) for different numbers of threads.

the same number of threads, but for different system sizes, different variants obtain the best performance. For example, for $p = 16$ and $N = 460$, the variants EAmt, E and A perform best, whereas for $p = 16$ and $N = 2960$ other variants run faster.

Autotuning-Potential

The experiments confirm that the performance of IRK variants is strongly influenced by the input data. Moreover, our experience shows that the performance of IRK variants also depends on the characteristics of the target architecture, such as the specific multi-core processor design, the cache architecture and the resulting memory latency and bandwidth. Thus, to obtain maximum performance, it is important that an IRK solver can adapt to the characteristics of the underlying architecture and of the ODE problem to be solved. Since usually these parameters are only known at runtime, the best variant cannot be determined at compile or installation time, and offline autotuning is not sufficient. For ODE solvers online autotuning has to be applied, but due to the large search space of candidate implementations and implementation parameters such as tile sizes for loop tiling or factors for loop unrolling, an online autotuning strategy should be supported by offline autotuning. For example, for multi-threaded implementations, offline measurements can be used to estimate the synchronization overhead of different

implementation variants. At runtime this information can be used to avoid the evaluation of variants if their synchronization overhead is too high to outperform variants with lower synchronization.

IV. Related work

The first autotuning approaches were offline approaches for numerical methods for dense linear algebra problems for which the properties of the HPC systems used play the most important role for the execution time. These approaches include ATLAS [1] and PHiPAC [2]. For some application areas, properties of the input data may have a significant influence on the resulting execution time [22]. In these cases, online approaches need to be employed or integrated. An example for such an application area is signal processing, where the size of the problem to be solved determines which algorithm is the most efficient one. Examples for approaches in this direction are FFTW [10] and SPIRAL [11], [23]. For sparse linear algebra problems, the distribution on the non-zeros in the matrix to be processed may have a large influence, see OSKI [12] and SALSA [13]. Several autotuning approaches for specific application areas have been developed on the basis of domain-specific languages (DSL) for the description of the processing algorithms. From these DSL descriptions, a compiler can generate different code variants that can be tested in an online phase. An important application area for these approaches are stencil computations, see PATUS [24], Pochoir [25] and Halide [26] for approaches in this direction. All approaches mentioned above are application-specific, i.e., they have been developed for a specific application area and exploit specific properties of this application area.

Several general autotuning framework have been proposed that work independent from a specific application area. Active Harmony [3] is such a general autotuning framework that aims at iterative parallel applications that can come from many application areas. It includes a source-to-source compiler tool to generate new code variants at runtime according to loop transformations as specified by the user. Active Harmony uses a pure online approach, no offline component is included. Another general autotuning framework is Perpetuum [27], which aims at the selection of tuneable parameters such as block sizes and number of threads. Parcae [28] provides a user-level runtime system and a compiler to translate parallel constructs and patterns into a task-based execution model. PetaBricks [22] and Periscope [4] are other approaches in this direction. A detailed survey of compiler autotuning approaches with an emphasis on machine learning is given in [29].

All approaches mentioned above are either offline or online approaches, depending on the needs of the specific applications area. None of these approaches employs both an offline and an online phase as it is attempted in this paper.

The generation of different code variants is an important part of many autotuning approaches. The polytope model [30] and compiler-based approaches [26] are often used in this context. The resulting number of code variants can be large and efficient heuristic search strategies are important, including Simulated Annealing or Nelder-Mead [31]. OpenTuner [22] provides several search strategies, but other techniques based on machine learning are also investigated [32]. Energy and performance autotuning for two irregular applications, graph community detection using the Louvain method (Grappolo) and high-performance conjugate gradient (HPCCG) have been investigated in [33] for OpenMP multithreaded programs using OpenTuner.

V. Conclusion

In this article we have investigated the tuning potential of important simulation methods from scientific computing. The simulation methods considered include sparse matrix computations, particle simulation methods and solution methods for ordinary differential equations. In particular, a detailed performance analysis has been performed with considerations of relevant parameters. The tuning potential has been investigated for offline and online tuning.

The investigation shows that sparse matrix computations are mainly amenable to offline autotuning, particle simulation methods require the use of online autotuning, and solution methods for ordinary differential equations need a combination of both offline and online autotuning. This is related to the complexity of the input data and the the number of implementation variants available.

The offline autotuning analyzes the hardware and software and pre-selects parameters. With performance models, e.g., the roofline model or ECM model, some predictions can be done. The three applications make different usage of this offline approach. While good parameters can be chosen for sparse matrix calculations, the offline approach is used for the differential equations to reduce the search space used in the online approach.

The online autotuning is good for adjusting the parameters and reacting to imbalances. While the importance of this approach is different for the applications, each time-stepping method can be adjusted at runtime to achieve the best performance. Insufficient decisions from the offline approach can be adjusted. To detect these imbalances, a monitoring must be performed. This monitoring should be application independent and can be done with established tools.

Thus, it is usually advantageous to use both approaches to tune methods from scientific computing. The offline approach to set start parameters as good as possible and to select suitable code variants, and the online approach to fine-tune parameters, react on imbalances and select the appropriate code variant.

***Abstract*—In the paper we present extensive results from analyzing energy/performance trade-offs with power capping observed on four different modern CPUs, for three different parallel applications such as 2D heat distribution, numerical integration and Fast Fourier Transform. The CPU tested represent both multi-core type CPUs such as Intel® Xeon® E5, desktop and mobile i7 as well as many-core Intel® Xeon Phi™ x200 but also server, desktop and mobile solutions used widely nowadays. We show that using enforced power caps we can find points of lower than default energy consumption but mostly for desktop and mobile solutions at the cost of increased execution time. We show with particular numbers how energy consumed, power consumption and execution time change for the point of minimum energy used versus the default configuration with no power limit, for each application and each tested CPU.**

I. Introduction

NOWADAYS the consumption of electric energy by the Information and Communication Technology (ICT) sector reaches extreme values, it is estimated as 269 TWh per year and 2% of global CO_2 emissions. An average data center, having 2 600 m^2 server rooms, causes almost 2 MW IT load [1]. Thus the energy conservation is very important for such environments as well as for mobile/IoT computations where the battery lifetime can be significantly extended by performing various procedures such as power level capping or calculation offload [2].

Considering the microprocessor devices: Central Processor Units (CPUs) and their applications, usually the actual power level used by such a device is proportional to its current workload. However, many modern CPUs are able to control their maximum power level via special API, e.g. RAPL [3]. Thus, in many cases for such CPUs, energy consumption depends not only on the workload, but also on the actual power cap, set by the managing software or directly by the developer.

For CPUs, it is important to distinguish between the power level and energy consumption — the factor is execution time, as it is presented in the following sections, sometimes the same problem is solved using a lower amount of energy (measured in J or kWh), despite the higher (average) power level (measured in W) observed in the device. There is no simple conversion between these two values, but in many cases, there is a spot where limited power causes lower energy consumption. In this paper we are going to analyze such minima — these can be exploited to trade off between energy consumption and execution time.

Our original contribution covers: (i) the presentation and analysis of execution time, power and energy consumption measurements for different power level caps of various CPU types, (ii) evaluation of trade-off between execution time and energy consumption for three representative HPC applications.

The next section describes the related works, the detailed goal of tests is presented, afterwards performed experiments are described, including the testbed applications, systems as well as the obtained results. And finally conclusions and future work are covered.

II. Related work

In the context of high performance computing (HPC), energy consumption and energy efficiency are among the most important challenges. It is important in particular for execution that is energy efficient for various levels of utilization [4]. The authors of [5] investigate software methods aimed at improving energy efficiency in parallel computing. In particular it focuses on load imbalance, mixed precision in floating-point operations. Power consumption of compute components is characterized. Energy efficiency metrics are introduced including dynamic energy improvement for n processors. The taxonomy of methods considered in this work includes power-aware

Supported partially by the Polish Ministry of Science and Higher Education. The experiments were partially performed using high-performance computing infrastructure provided by Centre of Informatics — Tricity Academic Supercomputer & networK (CI TASK) at Gdansk University of Technology.

scheduling and resource management, parallelization oriented including balancing, communication focused, approximation methods with part of computations executed with lower energy usage and slight loss of accuracy. In papers [6] and [7] we modeled energy consumption of parallel applications focusing on various communication routines establishing both functions and coefficients valid for various cluster systems.

In terms of measurement of power consumption and energy usage, several tools and techniques have been used and reported. IgProf which is an open source performance profiler is available for x86 and x86-64 as well as ARMv7 and ARMv8 platforms. The authors of [8] added a module for statistical sampling energy profiling. Measurements have been taken using the RAPL interface. The STREAM benchmark has been used to gather results that demonstrate expected correlation between execution time and energy consumption.

RAPL (Running Average Power Limit) provides counters to take measurements of energy consumption of CPUs, integrated GPUs and memory as well as to set corresponding power limits allowing to manage energy efficiency of a system. Paper [9] focuses on measurement and power limiting for main memory for server platforms. It has been shown that power limits can be enforced with minimization of performance impact of the approach. SPECCPU2000 sub-benchmarks were run for various power limits.

Paper [10] validates DRAM related results from RAPL for desktop and server environments with DDR3 and DDR4 types of memories. RAPL results were compared to actual measurements with matching in general within roughly 20%. Tests were performed with a variety of benchmarks including sleep, HPL Linpack, gcc PAPI, SmallptGPU2 ray-tracer, Kerbal Space Program. RAPL has also been validated in works [3] and [11]. In the latter, the authors concluded that RAPL power estimation is more accurate on IvyBridge than on SandyBridge generation of CPUs. In work [12] and paper [13] the authors investigate power consumption of various components including instruction decoders in x86-64 processor which was done through microbenchmarks. The authors have concluded that decoders consume between 3% and 10% of the total processor package power.

A hybrid hardware/software power capping system called PUPiL was evaluated in [14] for maximizing performance under power capping. The solution was compared to RAPL and e.g. a software-based DVFS control system and a software based decision system. PUPiL showed response time similar to hardware approaches and generally better performance than RAPL under power constraints.

The authors of [15] notice the phenomenon called PERC (Performance-Equivalent Resource Configurations) according to which applications with various configurations of resources show similar performance at various power consumption and use it for their PowerCap algorithm that selects a configuration that follows power limits. The authors claim that the algorithm requires 50% less reconfiguration and 12% more power compared to the DVFS approach.

In paper [16] authors propose an algorithm for scheduling execution of independent jobs on a system with integrated CPU-GPU with consideration of power caps. The authors have shown that throughput has been improved by between 9% and 46% over default schedules.

As an example, in [17] the author has performed detailed analysis of power consumption of Intel® i7-4820K. It should be noted, similarly to our findings for our testbed applications, that the power consumption of an application computing prime numbers reaches roughly 40W at the highest considered frequency at the TDP of the CPU equal to 130W.

The authors of [18] present empirical assessment of vendor provided power capping on a Cray XC40 system and comparison of performance with p-state control. They concluded generally better performance of the latter for many benchmarks in HPC.

III. Motivations and concept of research

Based on the aforementioned related works, we intend to perform detailed research, for a representative set of HPC applications, into energy/performance trade-offs for modern multi- and many- core CPUs using software imposed power caps.

Specifically, we are looking into such a configuration, for each application and each CPU, for which the total energy consumed during computations is minimized, compared to the default configuration without power consumption caps for a CPU i.e. full computational power. For such energy minimized configurations, we are looking into energy/performance trade-offs. It is especially interesting to analyze and observe it for various modern CPUs that differ, in terms of the target market, design and numbers of cores:

- server: Intel® Xeon Phi™ x200 (many-core CPU), Intel® Xeon® E5 (multi-core CPU) present in many workstations and cluster nodes,
- desktop: Intel® Core™ i7 desktop present in many home and office computers,
- mobile: Intel® Core™ i7 mobile present in many laptops and notebooks.

The software power caps as well as energy consumption measurements are implemented using RAPL driver available in modern Intel® CPUs. Due to technical limitations in measuring the impact of our power caps on the whole server we read the energy consumption using RAPL from the Package (CPU + DRAM) and acknowledge it representative and valuable result.

In terms of applications, we use three parallel applications, that differ in the computing paradigms and compute/synchronization overhead ratios:

- geometric single program multiple data stream: heat distribution,
- master-slave: numerical integration and FFT.

This continues our work [19] of analysis of representative parallel applications with consideration of energy usage.

IV. EXPERIMENTS

A. Testbed applications

For the testing purposes we selected three representative problems found in high performance computing (HPC) environment, and accordingly, implemented three applications, which are executed concurrently, and are horizontally scalable, i.e. speeding up with the increase of the core number; however they utilize shared memory for data exchange and synchronization, thus in this case they cannot be distributed between more compute nodes.

The application were implemented in C language v. C99, using OpenMP [20] for processing parallelization. They were compiled by the GCC v. 4.8 with maximal provided optimization (parameter -O3). They use the default OpenMP configuration (omp directive: schedule(auto)) regarding the thread number and computation partitioning, in the execution environment we did not tune up these settings. The applications use the floating point double precision for calculations (C language type: double).

The first application performs a numerical integration of a given function in a specified range. The specified partition is split between working threads and each thread calculates the sum of its range. The intermediate results are stored separately for each thread, although OpenMP is responsible for their reduction (omp directive: reduction(+:)). For testing purposes we defined the function as $f(x) = \frac{1}{1+x}$. The arguments of the application allow to specify the range and the calculation's precision as a number of subpartitions to be integrated.

The second application is a simplified version of the 2D heat distribution simulation (based on the conception proposed in [21]) over the closed square area, divide into $N \times N$ parts and containing a set of working heaters. For test purposes we set $N = 1000$ and introduced one heater located in the area corner. The input parameters cover a speed of heat propagation and a number of iteration to be simulated. The solution uses three memory buffers: (i) a constant heater map in the room, (ii) an input buffer with the current heat distribution, (iii) an output buffer with the heat distribution after performing current step. The buffers (i) and (ii) are swapped after each step of simulation: the output buffer in step i becomes the input buffer of step $i + 1$. The temperature of each square in the room can be calculated independently, thus potentially the above problem can be parallelized (omp directive: for) among threads as well as the threads do not interfere each other, each one has its own area to perform the simulation.

The third application is a parallel implementation of Fast Fourier Transform (FFT). It uses Radix-2 algorithm with Decimation-in-Time parallelization strategy [22]. At the beginning the sequence of N transformed samples (the input data) is parallelly shuffled, then the $log_2 N$ iterations are executed, where the parallel computations over complex numbers are performed: each thread has its own range of the data to process (omp directive: for). The result is placed in the array replacing the input data. For the benchmark purposes the input data is automatically generated.

B. Testbed systems

As a testbed environment we used 4 different systems. Two of them contained server dedicated processors with multi-core (Xeon® E5 v4) and many-core (Xeon Phi™ x200) architectures. Another two systems was based on Intel® Core™ i7 processors, one dedicated for desktop and one dedicated for mobile personal computers. Parameters of aforementioned systems are presented in Table I.

C. Results

Obtained results are presented for each testbed system separately. Therefore, for each of the four systems we present three figures individual for each of testbed applications and one common figure. In the individual figures for each power limit preset (bottom axis) we present execution time of the tested application (left axis) as well as total energy consumed (right axis). The common figure presents average power (left axis) for each test run against the power limit (bottom axis) that was preset for each of three tested applications.

Figure 1 presents results obtained using the testbed system with server Xeon E5 v4 for Fast Fourier Transform, simulation of heat distribution and numerical integration respectively. The most important observation is that the testbed aplications used in experiments are not able to reach the TDP of server Xeon processor. In each case for the experiment with maximum power limit we use less then 50% of available power. However, when the limit is set below 50% of TDP and close to the reference power consumption the average power consumption starts to respect the enforced limit. For this system the benefits of lowering the power consumption can be observed only for one testbed application (FFT) for which we can find the minimum of energy consumed while running calculations with different power limits. Howewer, the minimum is still saving less than 3% of energy comparing to reference run with no limits. The two other applications have the most energy efficient point at their default settings of the power limit.

Figure 2 presents the results obtained using testbed system with another server processor, Xeon Phi x200, again for Fast Fourier Transform, simulation of heat distribution and numerical integration respectively. Although both server processors present far different architectures (multi-core vs. many-core), the results of the experiments are quite similar. The main common feature of experimental results is that again our testbed applications are using less then 50% of available power. The system respects the preset limit in each case until the minimum value (85W) is reached. For two of tested applications (heat distribution and FFT) we observed the minimum of energy consumed for the value of power limit 135W. However, the energy benefits are not significant again (1-3% energy saved). For numerical integration the lowest energy consumption was obtained again when the power limit had its default value.

Figure 3 presents results of the same testbed applications for the first of non-server testbed systems with mobile PC dedicated Intel® Core™ i7 processor. Results for the last system with another Intel® Core™ i7 processor, dedicated

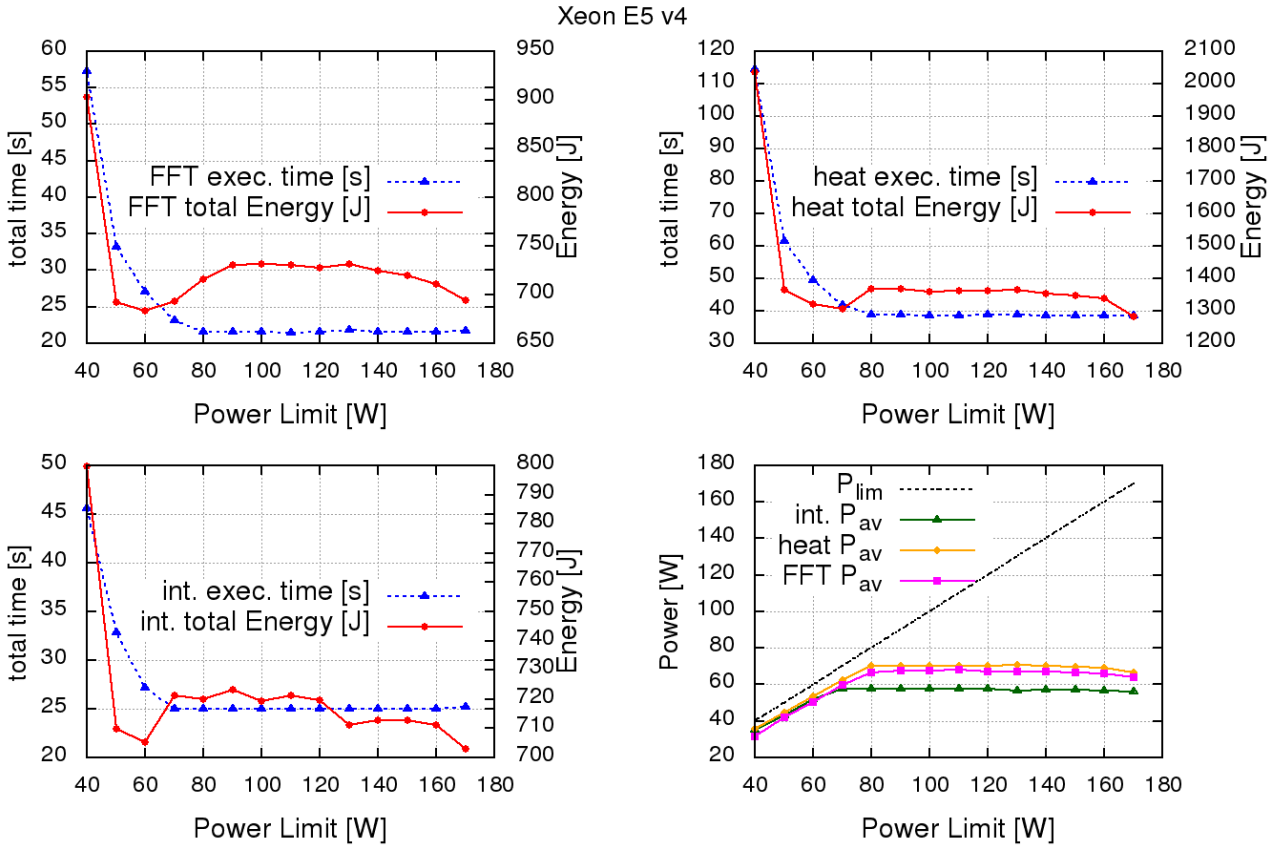

Fig. 1. Tests results for Xeon® E5 v4.

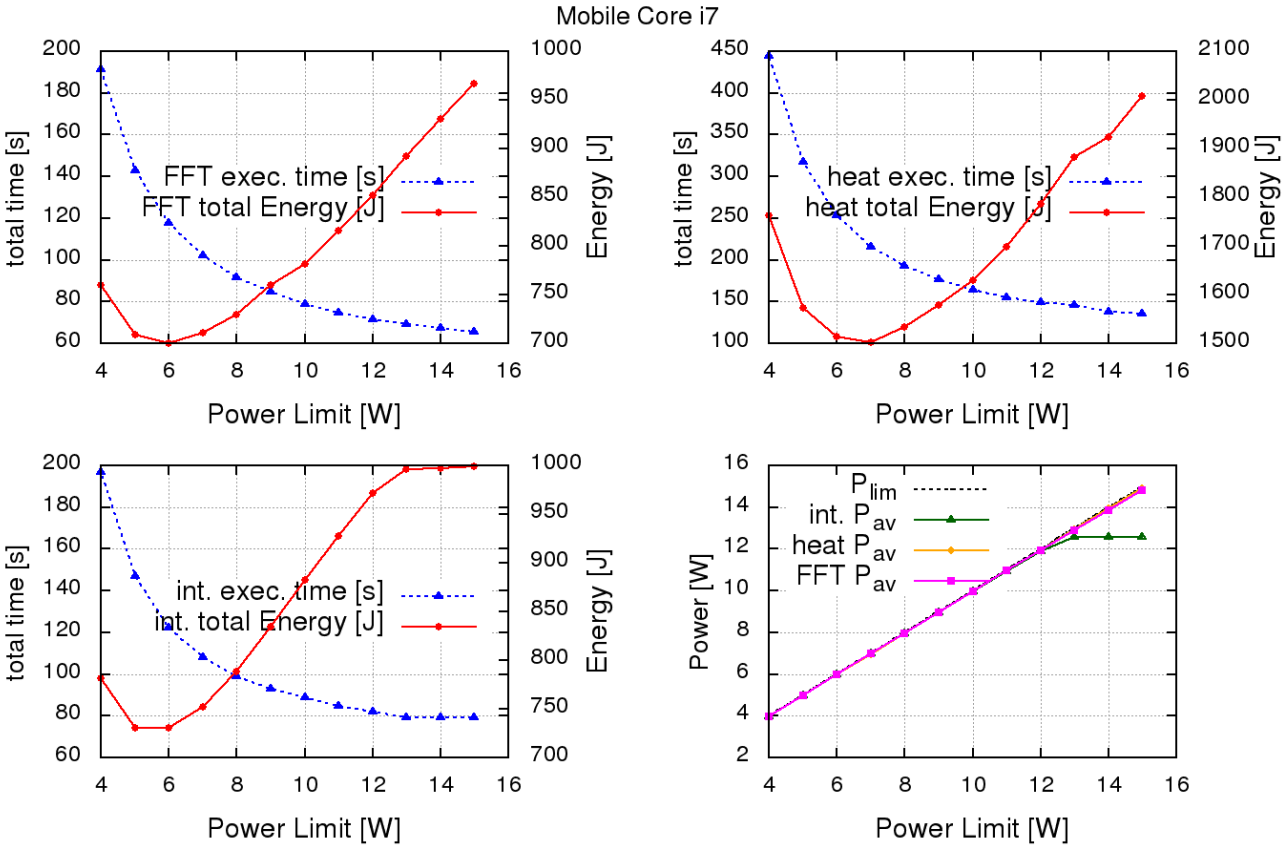

Fig. 3. Tests results for mobile Core™ i7.

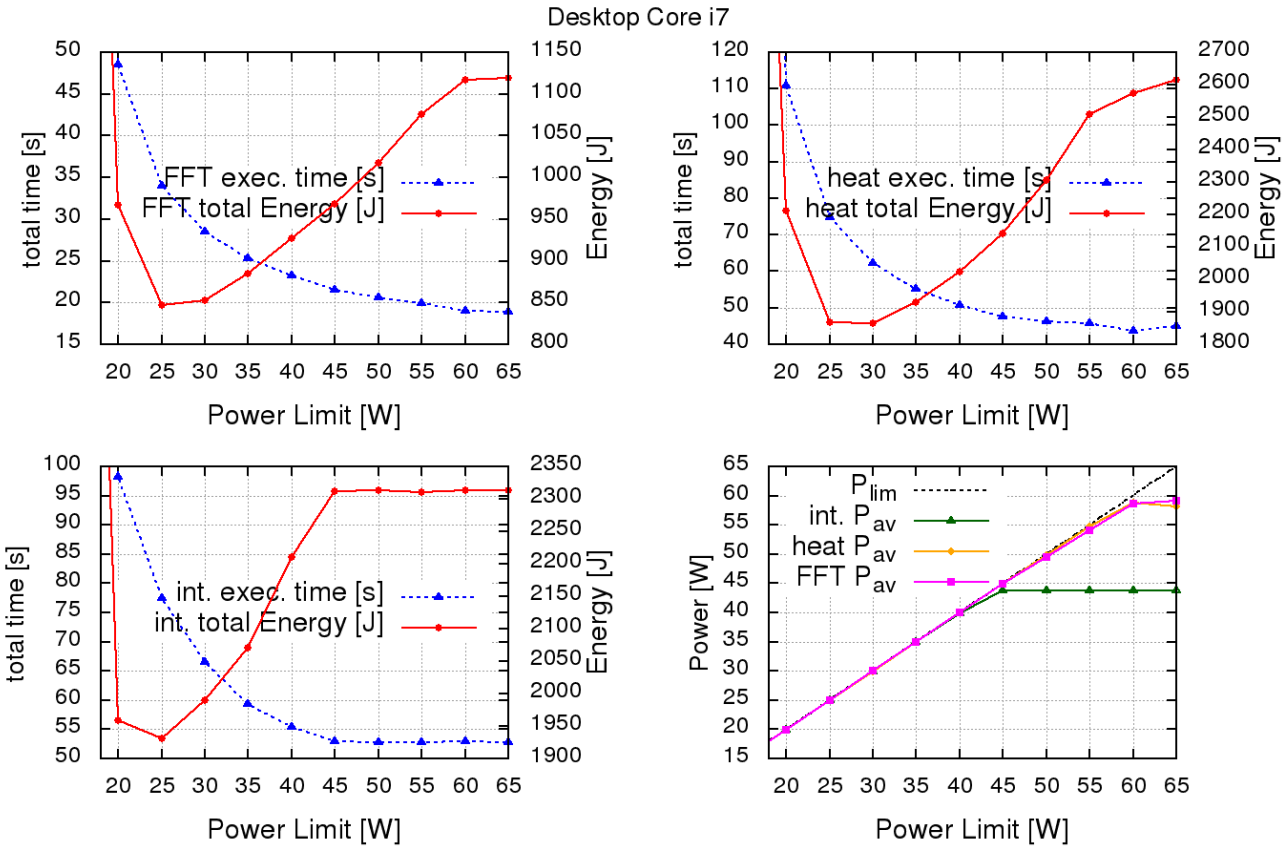

Fig. 4. Tests results for desktop Core™ i7.

TABLE I
TESTBED SYSTEMS USED IN EXPERIMENTS.

System	Processor	Base Frequency	Physical Cores	Logical Cores	Architecture	Cache	RAM
Xeon E5 v4	Intel® Xeon® E5-2620 v4	2.10 GHz	2 x 8	32	Broadwell	2 x 20 MB	128 GB
Xeon Phi x200	Intel® Xeon Phi™ 7210	1.30 GHz	64	256	Knights Landing	32 MB	256 GB
Mobile Core i7	Intel® Core™ i7-5500U	2.40 GHz	2	4	Broadwell	4 MB	16 GB
Desktop Core i7	Intel® Core™ i7-7700	3.60 GHz	4	8	Kaby Lake	8 MB	16 GB

for desktop PC are presented in the last figure, Figure 4. In both mobile and desktop systems the proposed applications seem to generate reasonable load and compared to the server testbed systems much more of available power is used. The level of power consumption is the highest for heat distribution simulation and the lowest for numerical integration. Both systems respect the preset limit well.

For the last two testbed systems we finally observed significant energy consumption benefits caused by limiting the power. The most efficient cases allow to save 25-28% of energy using the Mobile Core i7 system and 16-29% of energy using the Desktop Core i7 system. Of course, as we expected, with gain on energy savings we increase execution time. However, the time loss is much higher than the energy savings. For Mobile Core i7 system execution time increased by 59-86% and for the Desktop Core i7 system the time increase was in range of 38-80%. However, while considering only minimal energy points the time loss might suggest that power limiting is unreasonable, other low energy points with much better performance can be found. If we consider execution time against power limit we can observe that time grows non-linearly with a linear decrease of power limit and the energy consumption has several points besides the minimum in a region below e.g. 20% of energy saved. In such a situation we can search for much better performance with a power limit slightly higher and energy savings level similar to the best possible result. An examplary illustration of the proposed approach could be seen in the results of FFT tests in Figure 4 (top left) where the minimum of energy was obtained for the power limit 25W but for the 30W limit we are able to obtain as good energy savings as in the best case (around 24%) but the time loss drops from 79% to 50%.

D. Conclusions

The results of experiments with limiting the power we proposed and executed on selected testbed systems can lead to several conclusions. First of all, the RAPL driver is able to limit the average power consumption for each of testbed systems and the systems respect the enforced power limit when set between minimal and maximal value. In the experiments we focused on lowering the power consumption and measuring the performance (execution time) and energy consumption during test application runs. We selected the most energy efficient power limit settings and compared the results with the reference values with non-limited (reference) test runs. Table II collects the aforementioned data and correlates them with testbed systems and testbed applications.

The data collected together allows not only for answering the concerns that was a goal of this article but it is possible to compare the performance of the systems and energy efficiency between each other as well. For the testbed applications selected by us for the experiments the best performing system for 2 out of 3 applications was Xeon Phi x200. On the other hand the most energy efficient system was also a server dedicated processor but Xeon E5 v4. Both server systems showed that for such testbed applications the power consumption limiting gives no or unsignificant results of energy saving.

The other pair of testbed systems based on Mobile and Desktop Core i7 processors proved that power consumption limiting can result in significant energy savings but, what is expected, we have to take the loss of performance into account. For the most energy efficient settings which offer between 16% and 29% of energy savings the performance loss is between 38% and 86%. One more conclusion when looking at the power utilisation for the Mobile and Desktop Core i7 systems is that when the testbed application is able to make use of more available power when no limits are set, the better are results of lowering the energy consumption. We can assume that if we had another testbed application that would be able to exploit more of the TDP of our server testbed systems we could probably observe better energy saving results.

V. FINAL REMARKS AND FUTURE WORK

The paper presented the experiments measuring the electrical energy consumption under a set of power caps for three representative HPC applications and four different processors. For some of CPU-application pairs the result analysis shows the existence of energy minima where the power capping provides significant savings — up to 28.8% for Desktop Core i7 executing the Heat Distribution simulation (see Table II for more details).

The future works are going to cover the following issues:

- analysis of the trade-off to find out potential points where values for measures incorporating execution time and energy used would be optimal for a specific application,
- benchmarking other applications, especially those that take more power from our testbed systems,

- power-aware modeling of compute devices in frameworks for simulation of application runs in high performance computing environments such as MERPSYS [23],
- development of a tool for automatic detection of the optimal power settings for the aforementioned time-energy measures using historical data (e.g. via machine learning),
- proposing a new method for minimizing the electrical energy usage dynamically at runtime for various HPC/cloud workloads [24].

We assume that the expectations of the IT industry will generate a high demand for green computing methods used for exchanging time of computations into savings in the energy consumption (e.g. dedicated for off-pick hours of data centers). Thus, we hope that our work will stimulate even more research on the subject.

***Abstract*—Electrical Capacitance Tomography (ECT) is an effective and non-invasive visualization technique, which is used in many industrial applications. Unfortunately, image reconstruction in 3D ECT is a complex computational task requiring operations on large size matrices. In this paper, a new approach to 3D ECT image reconstruction is proposed. A new heterogeneous, multi-GPU, multi-node distributed system has been developed, with a framework for parallel computing and a special plug-in dedicated to ECT.**

I. Introduction

ELECTRICAL Capacitance Tomography (ECT) is a measurement technique that can be used for non-invasive monitoring of industrial processes in 2D [7], 3D [1] and even 4D dynamic mode. ECT is performing the task of imaging of materials with a contrast in dielectric permittivity by measuring capacitance from a set of electrodes placed around the investigated object.

In order to achieve a high quality of 3D image, complex reconstruction algorithms performing many matrix calculations have to be applied. Therefore different solutions accelerating these calculation have been reported in the past by the Authors[8][14], especially these dealing with sparse matrices and Finite Elements Method [9] as well as neural networks approach [5][6] and even fuzzy logic [21].

In this work we propose a novel heterogeneous, multi-GPU (Graphics Processing Unit), multi-node distributed system, with a framework for parallel computing and a special plug-in dedicated to ECT. The system features and its efficiency have been compared to the previously developed distributed system based on the Xgrid platform.

A. Image reconstruction in ECT

The scheme of image synthesis in Electrical Capacitance Tomography is called image reconstruction. It is based on solving the so called inverse problem, in which the spatial distribution of electric permittivity from the measured values of capacitance C is approximated [1] [16].

Image reconstruction using deterministic methods requires execution of a large number of basic operations of linear algebra, such as transposition, multiplication, addition and subtraction [10][15]. Matrix calculations for a large number of elements is characterized by a high computational load. Matrix multiplication is a key operation in ECT imaging and therefore many researchers decided even to build a custom hardware for this purpose.

The LBP algorithm is one the most used reconstruction algorithms, even though it is characterized by low spatial resolution. Nevertheless it is not as computationally complex as other solutions. Moreover there is still active research on improving it's characteristics [17]. It is based on the following equation [3]:

$$\varepsilon = \mathbf{S}\boldsymbol{C}_m \tag{1}$$

where:
ε - electric permittivity vector (output image),
$\mathbf{S}$ - sensitivity matrix,
$\boldsymbol{C}_m$ - capacitance measurements vector.

The Landweber algorithm is based on the following iterative equation:

$$\varepsilon_{k+1} = \varepsilon_k - \alpha\mathbf{S}^T(\mathbf{S}\varepsilon_k - \boldsymbol{C}_m) \tag{2}$$

where:
ε_{k+1} - image obtained in current iteration,
ε_k - image from the previous iteration,
α - convergence factor (scalar),
$\mathbf{S}^T$ - sensitivity matrix, transposed,
$\mathbf{S}$ - sensitivity matrix,
$\boldsymbol{C}_m$ - capacitance measurements vector.

In the case of the Landweber algorithm each iteration improves the overall quality of the output image. As a result acceleration of image reconstruction process is a very important issue. Nevertheless, due to its nature it is necessary to exchange the data (ε_{k+1}) in every iteration.

II. Design assumptions

As a result of the earlier performed studies [8][13] the Authors have developed a new distributed system dedicated to ECT computations. It is specially designed to accelerate matrix computations that are a crucial part of reconstruction

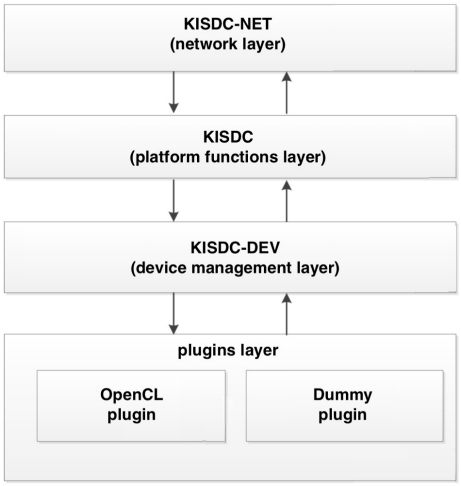

Fig. 1. Activity Diagram for performing calculations using the KISDC platform

algorithms used in ECT [9]. The earlier developed solution was based on the Xgrid platform, used as a network layer. However, the analysis of this system showed the limitations of this solution, and the main conclusion from the previous research [14] was, that the new software for the system should be developed.

A special framework was designed and built that provides software tools needed both for the system architecture expansion and new algorithms development and implementation in a distributed heterogeneous environment. The proposed approach allows for a greater flexibility of the developed solutions, provides tools for their easy testing and enables further acceleration of ECT image reconstruction.

The framework was designed to ensure an efficient use of the computing power of all the devices in which the nodes are equipped. This architecture is scalable and allows users

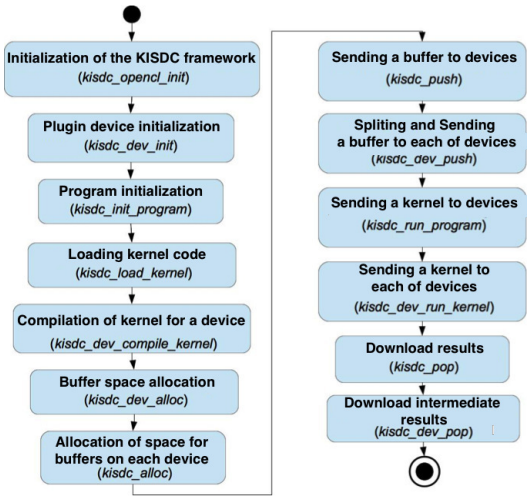

Fig. 2. Activity Diagram for performing calculations using the KISDC platform

to expand the computing power of the system by adding more nodes. The above assumptions pose many challenges in the architecture of the system itself, but their application makes it straightforward to use the environment to speed up computations in existing projects, thus testing and developing new distributed algorithms is much faster.

The system was designed as a modular, layered architecture (Fig. 1). This approach allows limiting the dependencies between the individual modules. Moreover, thanks to this architecture, it is possible to abstract the compute devices using KISDC-DEV module, that hides the type of the hardware from the user and makes all the algorithm written using the provided Application Programming Interface (APIs) hardware-agnostic

Expansion of the computing power of the system is possible through the use of "plug-in" architecture (by adding support for new devices, such as FPGAs). The basic operations of linear algebra were implemented in the system as a set of functions in the form of an API.

```
err = clGetDeviceIDs(platform, gpu ? CL_DEVICE_TYPE_GPU : CL_DEVICE_TYPE_CPU,
    numberOfDevices, &device_id, NULL);
context = clCreateContext(0, 1, &device_id, NULL, NULL, &err);

commands = clCreateCommandQueue(context, device_id, 0, &err);
program = clCreateProgramWithSource(context, 1, (const char **) & KernelSource,
    NULL, &err);

err = clBuildProgram(program, 0, NULL, NULL, NULL, NULL);

kernel = clCreateKernel(program, "matrixmul", &err);

A = clCreateBuffer(context,  CL_MEM_READ_ONLY,  sizeof(float) * count1, NULL, NULL)
    ;
B = clCreateBuffer(context,  CL_MEM_READ_ONLY,  sizeof(float) * count2, NULL, NULL)
    ;
C = clCreateBuffer(context, CL_MEM_WRITE_ONLY, sizeof(float) * count2, NULL, NULL);

err = clEnqueueWriteBuffer(commands, A, CL_TRUE, 0, sizeof(float) * count1, data, 0
    , NULL, NULL);
err = clEnqueueWriteBuffer(commands, B, CL_TRUE, 0, sizeof(float) * count2, data, 0
    , NULL, NULL);

err  = clSetKernelArg(kernel, 0, sizeof(cl_mem), &A);
err |= clSetKernelArg(kernel, 1, sizeof(cl_mem), &B);
err |= clSetKernelArg(kernel, 2, sizeof(cl_mem), &C);

err = clGetKernelWorkGroupInfo(kernel, device_id, CL_KERNEL_WORK_GROUP_SIZE, sizeof
    (local), &local, NULL);

global = count1;
err = clEnqueueNDRangeKernel(commands, kernel, 1, NULL, &global, &local, 0, NULL,
    NULL);

clFinish(commands);
err = clEnqueueReadBuffer( commands, output, CL_TRUE, 0, sizeof(float) * count3,
    results, 0, NULL, NULL );
```

Fig. 3. Simplified code fragment that multiplies the matrix using the OpenCL libraries and single GPU

The use of a heterogeneous system for distributed computing in ECT required the implementation of a series of algorithms without which the proposed system would not work properly. The most important of these are as follows: division of matrices between nodes, basic operations of linear algebra (transposition, addition, subtraction, multiplication), data transfer between nodes, planning and division of tasks, support for heterogeneous devices, support for calculations using graphics cards, supports modern multi-core processors as a set of devices and a possibility to extend existing solutions with pseudo inheritance from implemented layouts.

A. Application Programming Interface

An important aspect of the designed environment is also the API, which greatly simplifies the performance of matrix calculations in a distributed heterogeneous environment. Even for a single computer configuration, the KISDC framework makes it possible to significantly simplify the code (Fig. 4) in

comparison to amount of code required when using another solution, such as for example OpenCL (Fig. 3).

```
pKISDC *KISDC;
KISDC = kisdc_opencl_init();

KISDC->DEV = KISDC->kisdc_dev_init();
KISDC->dummyProgram = KISDC->kisdc_init_program(KISDC,kernel);

A = KISDC->kisdc_alloc(KISDC,SIZE_A_1,SIZE_A_2,1,0);
B = KISDC->kisdc_alloc(KISDC,SIZE_B_1,SIZE_B_2,1,0);
C = KISDC->kisdc_alloc(KISDC,SIZE_C_1,SIZE_C_2,1,0);

KISDC->kisdc_push(KISDC,A,Abuf);
KISDC->kisdc_push(KISDC,B,Bbuf);

paramsArray = (pMemBuf**)malloc(5*sizeof(pMemBuf*));

paramsArray[0] = A;
paramsArray[1] = B;

KISDC->dummyProgram->args = paramsArray;
KISDC->dummyProgram->argc = 2;
KISDC->dummyProgram->out = C;

KISDC->kisdc_run_program(KISDC,KISDC->dummyProgram);
Cbuf = KISDC->kisdc_pop(KISDC,C);
```

Fig. 4. A fragment of code that multiplies the matrix using the KISDC platform and multiple GPUs

The code examples listed in Fig. 4 and Fig. 3 involve a very simple scenario of using GPUs to calculate the product of two matrices (for example in the LBP algorithm). In the case of the algorithms of a higher complexity, the difference in the code sizes for both solutions will be larger and the KISDC implementation will have even a bigger advantage over OpenCL.

Moreover, if instead of one, three or more GPUs are used for computations, a significant changes in the code must be done in each case, when using the CUDA [11] or OpenCL library [19]. Whereas, with the KISDC framework, no changes are necessary. However, this small number of lines written by the programmer corresponds to hundreds of lines of code within the KISDC system.

The KISDC architecture simplifies also performance tests of the developed image reconstruction algorithms in Electrical Capacitance Tomography in various hardware configurations and to implement these algorithms in a distributed system. As shown in the activity diagram (Fig. 2), the process of

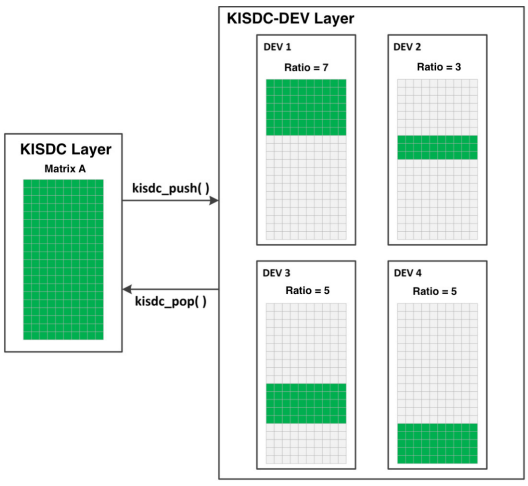

Fig. 5. Data distribution using KISDC platform

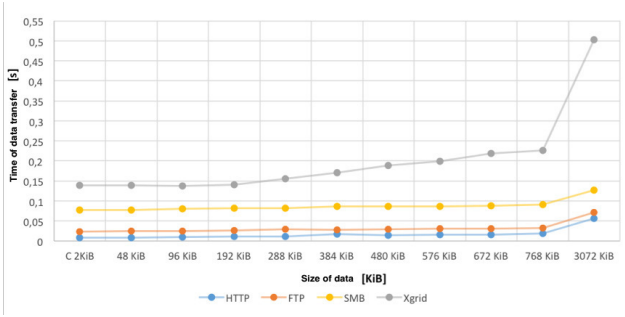

Fig. 6. Comparison of average data transmission times for different network protocols

performing calculations using the KISDC system allows for much more flexibility in the number and type of devices used. This was possible by adopting significant flexibility in the data distribution layer (Fig.5).

III. Test Results

In the previously built distributed system a ready Xgrid platform was applied as a network layer [14]. In the current work the author's KISDC system with KISDC-NET network layer was designed and implemented. While designing the KISDC-NET layer, the existing network protocols were applied and tested in advance in order to choose the best solution.

The network characteristics of the previously developed solution based on the Xgrid system was compared with the new system using other data distribution protocols: HTTP (Hypertext Transfer Protocol), FTP (File Transfer Protocol) and SMB (Server Message Block). On the Basis of the obtained results (see Fig. 6) HTTP protocol has been selected as the best one for the KISDC-NET.

Both distributed systems: the one based on the Xgrid platform and the KISDC have been extensively tested and compared. In both cases the hardware was identical, consisting of two nodes of high computing power, both using 8 thread Intel i7 930 CPUs and Nvidia GPUs (Tesla S1070 + Tesla

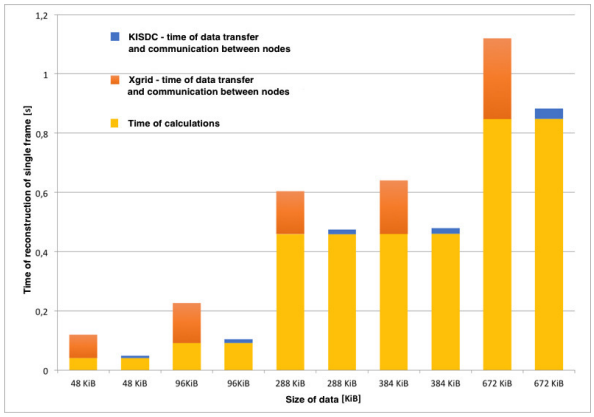

Fig. 7. Comparison of image reconstruction time in Xgrid and KISDC systems for dual computer configuration

C2070 compute devices in the first node and dual GTX 570 in the second).

The comparison of times of a single frame reconstruction in the two node system are shown in Figure 7. Yellow color represents calculation time (the same for the both systems), blue color is related to data transfer time for the KISDC system, and orange color denotes data transfer time for the Xgrid system. For each of the analyzed data sizes, the speed up of image reconstruction expressed in the number of reconstructed frames per second was noted. The most significant acceleration was achieved for 48 KiB and 96 KiB image vectors.

IV. Conclusions

A flexible, distributed computing system for tomographic image reconstruction called KISDC has been designed and developed. The system's framework allows to accelerate any kind of computation dealing with a basic linear algebra operations. However, it should be noted that the KISDC is highly scalable and can be easily extended either by specific OpenCL kernel or by a plug-in providing support for a special kind of calculations.

The work described in this paper was focused on improvement of data management in the distributed system and on reducing delays in the data transmission over the computer network. The comparison of times of data transfer and communication between the nodes shows very clearly that the use of the new developed system with HTTP protocol ensures much better results than with the Xgrid platform. It is also evident that the KISDC system allowed for a significant reduction of the total time of a single frame reconstruction and a major speed up in implementations of both the LBP and the Landweber algorithms.

***Abstract*—The use of the latent factor models technique overcomes two major problems of most collaborative filtering approaches: scalability and sparseness of the user's profile matrix. The most successful realizations of latent factor models are based on matrix factorization. Among the algorithms for matrix factorization, alternating least squares (ALS) stands out due to its easily parallelizable computations. In this work we propose a methodology for comparing the performance of two parallel implementations of the ALS algorithm, one executed with MapReduce in Apache Hadoop framework and another executed in Apache Spark framework. We performed experiments to evaluate the accuracy of generated recommendations and the execution time of both algorithms, using publicly available datasets with different sizes and from different recommendation domains. Experimental results show that running the recommendation algorithm on Spark framework is in fact more efficient, once it provides in-memory processing, in contrast to Hadoop's two-stage disk-based MapReduce paradigm.**

I. Introduction

AMONG the many techniques used to implement recommender systems, collaborative filtering, which is based on comparing the profile of preferences of the users, is a very popular technique in e-commerce applications, due to its good results [1]. Neighborhood-based approaches present scalability problems, given that the algorithm has to process all the data to compute a single prediction. Hence, if there is a large number of users and items, such approaches may not be appropriate for online systems which recommend in real time. Furthermore, these algorithms are more sensitive than model-based to some common problems of recommender systems. One common problem is the sparsity of the matrix that stores the ratings that represent the users' preferences about the available items. This refers to a situation in which transactional or feedback data is sparse and insufficient to identify similarities in users' interests making it difficult and unreliable to predict which consumers are similar [2]. Another recurrent problem in generating recommendations happens when we wish to recommend items that no one in the community has yet rated or interacted with. This is known as the cold-start problem and pure collaborative filtering cannot help in a cold start setting, since no user preference information is available to form any basis for recommendations [3].

Nevertheless, there are models that can help bridge the gap from existing items to new items, by inferring similarities among them. Model-based approaches, instead of directly using the ratings stored, as the neighborhood-based systems, use ratings to learn a predictive model. The model building process is performed by different machine learning algorithms such as Bayesian networks [4], neural networks [5], and Singular Value Decomposition [6]. These approaches tend to be faster in prediction time than the neighborhood-based approaches. However, the construction of the model is a complex task that demands the estimation of a multitude of parameters, and usually requires a considerable amount of time [1].

These problems become more evident when trying to construct recommender systems associated with Websites that have a large number of users and items and, thus, associated with huge databases. Online systems demand high availability and short response time, as they must integrate and quickly process incoming streams of data from all users' activities, in order to generate the recommendations. All this process need to occur with a latency of seconds, as the most promising items selected by the recommendation algorithms have to be showed to the users while they are still browsing the Website. The greater the number of users to serve and items from which to recommend, the greater is the amount of processing required, which increases the time it takes to generate each recommendation. The digital music Spotify platform [7] is a practical example of an online recommender system with high demand: their music personalization service has more than 50 million active users, 30 million cataloged songs and around 20 thousand new songs added per day [8]. Amazon [9] generates recommendations from a database with 253 million products [10] for users of 270 million active customer accounts [11]. An efficient approach is essential in all those cases. Nowadays, to tackle such performance challenges, online recommender systems have combined two strategies: (i) efficient algorithms, that avoid the computational complexity of calculating each of the entries of the high

dimensional and sparse matrix; and (ii) optimized data storage and processing. This means processing real-time information to build a predictive model and present its output in seconds.

In order to solve this problem, some authors have developed a class of model-based collaborative filtering algorithms that are fast and easy to calculate, called latent factor models [12]. They attempt to identify relevant features (latent factors) that explain observed ratings. These features can be interpreted as the preference of the users and the characteristics of the items being recommended. Using these latent factors, it is possible to infer the user's preference and make a recommendation of the better items for him/her. The most successful techniques to perform latent factors modeling are based on matrix factorization [13]. They have become popular recently because they combine scalability and predictive accuracy, and, besides, they offer flexibility for modeling different real situations, being superior to the neighborhood-based methods for producing recommendations because they allow the incorporation of additional information such as implicit feedback, temporal effects, and confidence levels [14]. Recent works suggest modeling only the observed ratings, while avoiding overfitting, through an adequate regularized model [15].

Some parallel algorithms for latent factor models with regularization have been designed aiming at improving the modelling performance. Among them, two can be highlighted: (i) the low-rank matrix factorization with Alternating Least Squares (ALS), which uses a series of broadcast-joins [16], built on top of the open source MapReduce implementation Hadoop [17], and its ecosystem, which we call HadoopMR-Mahout; and (ii) the Alternating Least Squares with Weighted-λ-Regularization (ALS-WR) [18] which has been implemented in Apache Spark's Machine Learning library, MLlib, which we call Spark-MLLib [19]. Scalability and performance are key issues for recommender systems, since computational complexity increases with the number of users and items, but the performance gain for these implementations has not yet been systematically evaluated in any comparative study.

Although ALS Matrix Factorization algorithms are not new, some recent works shows that evaluating solutions that can be faster in specific situations, such as memory restrictions and some other high processing situations that may occur, still needs some attention. Authors of [20] propose some techniques for finding efficient and portable ALS Matrix Factorization for Recommender Systems. They apply thread batching technique and three architecture-specific optimizations for a new solution, and they implement an ALS solver in OpenCL so that it can run on various platforms (CPUs, GPUs, and MICs). Authors of [21] propose a new software solution to improve the performance of Recommender Systems, relying heavily on Apache Spark technology to speed up the computation of recommendation algorithms.

This work aims to conduct an experimental analysis to compare two different scalable implementations of the Alternating Least Squares algorithms (Spark-MLLib and HadoopMR-Mahout) for collaborative filtering recommendation. We performed experiments to evaluate the accuracy of generated recommendations and the execution time of both algorithms, using publicly available datasets with different sizes and from different recommendation domains.

This work is organized as follows. In the next section, we explain the fundamental concepts about model-based approaches for implementing collaborative filtering. In Section 3, we discuss matrix factorization implementations, explaining how parallel implementations improve efficiency of recommender algorithms. In Section 4, we describe the methodology used for the comparative study between the two different implementations of the ALS algorithm, on different recommendation domains and dataset sizes, and present our experimental results for three assessed dimensions: accuracy, efficiency and scalability. In Section 5, we discuss the contributions and limitations of the proposed study, presenting also some topics for future work.

II. Model-Based Collaborative Filtering

The fundamental assumption of CF is that if users X and Y rate n items similarly, or have similar behaviors (e.g., buying, watching, listening), hence they will rate or act on other items similarly. CF techniques use a database of preferences for items by users to predict additional topics or products a new user might like. The problem space can be formulated as a matrix of users versus items, with each cell representing a user's rating on a specific item. This matrix will be referred as ratings matrix from now on.

Under this formulation, the problem is to predict the values for specific empty cells. In collaborative filtering, this matrix is usually very sparse, since each user only rates a small percentage of the total available items. To fill in the missing entries of the ratings matrix, models are learnt by fitting the previously observed ratings. Once the goal is to generalize these observed ratings in a way that allows us to predict future, unknown ratings, caution should be exercised to avoid overfitting the observed data. This can be achieved by modeling the latent factors of the ratings matrix, that is, finding a small set of latent features that explain observed ratings and describe the general characteristics of users and items. The most successful techniques to model latent factors are based on matrix factorization, because they combine scalability and predictive accuracy.

A. Matrix Factorization

Matrix factorization models map both users and items to a joint latent factor space, such that user-item interactions are modeled as inner products in that space. The latent space tries to explain ratings by characterizing both items and users on the same set of factors, which are the characteristics inferred from the observed ratings [18]. The intuition of this method is that it can be equivalent to a summarization. It boils down the world of user preferences for individual items to a world of user preferences for more general and less numerous features (like genre). This is, potentially, a much smaller set of data.

Although this process loses some information, it can sometimes improve recommendation results because this process

smooths the input in useful ways when it generalizes the features that describe the items, making similar what appeared to be distinct at first, thus avoiding overfitting the observed ratings. For example, imagine two car enthusiasts. One loves Corvette, and the other loves Camaro, and they want car recommendations. These enthusiasts have similar tastes: both love a Chevrolet sports car. But in a typical data model for this problem, these two cars would be different items. Without any overlap in their preferences, these two users would be deemed unrelated. However, a matrix factorization based recommender would perhaps find the similarity. The matrix factorization output may contain features that correspond to concepts like Chevrolet or sports car, with which both users would be associated. From the overlap in features, a similarity could be computed. These features correspond to the latent factors, or singular values of the ratings matrix and their correspondence to concepts are not explicit. Also, the exact number of singular values describing a matrix is not previously known, so there is a need to experiment to find the appropriate number of singular values that best summarizes the concepts for a given domain.

Consider a recommender system with m users and n items. Let $R = [r_{ui}]$ be the ratings matrix, where $r_{ui} \in \mathbb{R}^{(m \times n)}$. Matrix factorization models map both users and items to a joint latent factor space of dimensionality k, that is, $\widehat{R}$ is a rank-k approximation of the ratings matrix R. Let $P = [p_u]$ be the user feature matrix, where $p_u \in \mathbb{R}^k$, and $Q = [q_i]$ be the item feature matrix, where $q_i \in \mathbb{R}^k$. So, user-item interactions are modeled as inner products:

$$\widehat{r}_{ui} = q_i^T \times p_u \tag{1}$$

An example of matrix factorization computation is found next on Figure 1. On a system with five users (represented by the upper matrix in the figure) and six items (represented by the left matrix in the figure), the estimation of the rating value of item 3 given by user 4, $\widehat{r}_{43}$, is given by the inner product of the vectors representing item 3, i.e., q_3^T, and user 4 , i.e., p_4.

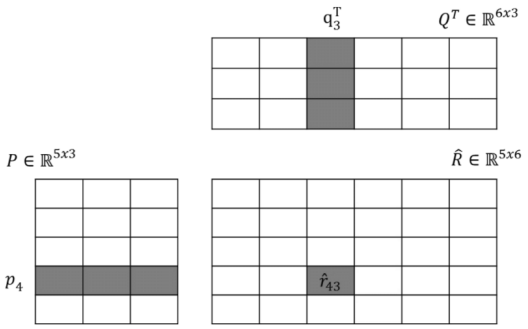

Fig. 1. Sinusoid

The major challenge is to compute the mapping of each item and user to latent factor vectors $q_i, p_u \in \mathbb{R}^k$. The traditional implementation to learn latent factors is the singular value decomposition (SVD), but it suffers from the high portion of missing values in the ratings matrix, because, in general, users have rated only a small set of items [14]. The SVD can be computed one column at a time, whereas for the partially specified case, no such recursive formulation holds [18]. Also, addressing only few known ratings is highly likely to model overfitting [12]. Earlier works relied on imputation [2], [22], which fill in missing ratings and make the ratings matrix dense. However, the data may be considerably distorted by inaccurate imputation and also computing the SVD becomes very expensive after imputation, as it significantly increases the size of the matrices.

More recent works suggested modeling directly only the observed ratings, while avoiding overfitting through an adequate regularized model [15]. This model minimizes the regularized squared error on the set of observed ratings, as shown in Eq. 2, where k is the set of (u, i) pairs for which r_{ui} is known (the training set). The system learns the model by fitting the previously observed ratings. However, solving Eq. 2 with many parameters, when k is relatively large, from a sparse dataset usually overfits the data. The overfitting is avoided by regularizing the learning parameters, whose magnitudes are penalized by the λ constant [23]. This is also known as the Tikhonov regularization [24]. Eq. 2 is solved using a learning algorithm such as the alternating least squares (ALS) [18], which is the focus of this work.

$$min(p, q) \sum_{(u,i) \in k} (r_{ui} - q_i^T p_u)^2 + \lambda(||q_i||^2 + ||p_u||^2) \tag{2}$$

B. Alternating Least Squares (ALS)

Eq. 2 is not convex when both q_i and p_u are unknown. However, fixing one of them turns the optimization into a quadratic problem that can be solved. So, ALS technique rotates between fixing the q_i's and p_u's. When all p_u's are fixed, the system recomputes the q_i's by solving a least-squares problem, and vice versa. This ensures that each step decreases Eq. 2 until convergence.

Although it is computationally more expensive than Stochastic Gradient Descent (SGD), ALS implementation is favorable in at least two cases. The first is when dealing with densely filled matrices, as such in systems centered on implicit data. Because the training set cannot be considered sparse, looping over each single training case (as in the case of SGD) would not be practical. The second case is when the system can use parallelization. The algorithm computes each q_i independently of the other item factors and computes each p_u independently of the other user factors, which allows for massive parallelization of the implementation [18].

When re-computing the user feature matrix P for example, p_i, the i-th row of P, can be re-computed by solving a least squares problem only including r_i, the i-th row of R, which holds user i's interactions, and all the columns q_j of Q that correspond to non-zero entries in q_i. This re-computation of p_i is independent from the re-computation of all other rows of P and therefore, the re-computation of P is easy to parallelize if efficient data access to the rows of R and the corresponding

columns from Q is effectively managed. The sequence of re-computing of P followed by re-computing Q is referred to as a single iteration in ALS. Algorithm 1 summarizes the steps of the ALS algorithm.

From a data processing perspective, computing ALS means that a parallel join occurs between the interaction data R and Q (the item features) in order to re-compute the rows of P. Analogously, a parallel join is conducted between R and P (the user features) to re-compute Q. Finding an efficient execution strategy for these joins is crucial to the performance of any parallel solution, since the required amount of inter-machine communication, as network bandwidth is the scarcest resource in a cluster.

III. Matrix Factorization Implementations

In this section, we discuss previous works that propose matrix factorization implementations to solve the recommendation problem. We describe each of the proposed implementations and the performance results obtained.

A. Traditional Implementations

The Netflix Prize, a competition that began in October 2006, has motivated the progress in the field of collaborative filtering. The nature of the competition has encouraged rapid development, where innovators built on each generation of techniques to improve prediction accuracy. In September 2009 the prize was awarded to the BellKor's Pragmatic Chaos team that managed to achieve the winning RMSE of 0.8567 on the test subset, which represents a 10.06% improvement over Cinematch, Netflix's own recommendation algorithm.

The recommendation strategy used by the winning solution was an ensemble of more than 100 different predictor sets, the majority of which are factorization models, learned by stochastic gradient descent (SGD), applied directly on the raw data.

For single machine implementations, SGD is the preferred technique to compute a low-rank matrix factorization, because it is easy to implement and computationally less expensive then ALS. Unfortunately, SGD is inherently sequential, because it updates the model parameters after each processed interaction. Techniques for parallel SGD have been proposed, yet they are either hard to implement, exhibit slow convergence or require shared-memory.

The SGD implementation used in this solution is described by [25] as possible to be executed to factorize the 17,000 x 500,000 matrix with 40 latent factors on 2G of RAM, a C compiler, and good programming habits. But in the paper describing the winning solution, he did not specify the environment nor the performance of the algorithm, as this was not important for the prize. The algorithms could run for as many as long as needed, since the only evaluated metric was the RMSE.

Finally, in 2012 Netflix announced that they did not implement the Netflix Prize solution algorithm, and they gave two reasons for that. The first reason is that the new methods were evaluated off-line but the additional accuracy gains measured did not seem to justify the engineering effort needed to bring them to a production environment. Also, their focus on improving personalization had shifted since 2007, just a year after the beginning of the competition, when Netflix streaming service was launched. From DVDs to an online streaming service, Netflix as a whole changed dramatically, not only the way the users interact with the service but also the types of data available to use in the algorithms.

As of 2012, Netflix reported having more than 23 million subscribers in 47 countries. Those subscribers streamed 2 billion hours from hundreds of different devices in the last quarter of 2011. Every day they add 2 million movies and TV shows to the queue and generate 4 million ratings. They have adapted their recommendation algorithm to this new scenario, and 75% of what people watch is from some sort of recommendation. This new strategy still runs the learning algorithm in batch, as briefly discussed in the Large-Scale Recommendation Systems Workshop on the ACM Conference Series on Recommender Systems in 2013, held at Hong Kong.

B. Parallel Implementations

Another team participating in the Netflix Prize proposed, in 2008, a parallel implementation of matrix factorization, called the Alternating-Least-Squares with Weighted-λ-Regularization (ALS-WR) [18]. This solution was motivated by two main reasons: the size of the dataset, which was 100 times larger than previous benchmark datasets, resulting in much longer model training time and much larger system requirements; and the fact that the observed ratings corresponded to only about 1% of the complete ratings matrix, which means dealing with a very sparse matrix. Since this implementation was motivated by the Netflix data, it is dealing with observed ratings, or explicit feedback. Thus, it solves the matrix factorization problem with ALS using only the observed ratings. Rewriting Eq. 2, Eq. 3 is obtained, where n_{m_i} and n_{m_u} are the number of observed ratings for the item i, and for the user u respectively. Let I_u denote the set of items i that user u has rated, then n_{m_u} is the cardinality of I_u; similarly I_i denotes the set of users who rated item i, and n_{m_i} is the cardinality of I_i.

$$\begin{aligned} min(p,q) & \sum_{(u,i)\in k} (r_{ui} - q_i^T p_u)^2 \\ & + \lambda \left(\sum_i n_{m_i} ||q_i||^2 + \sum_u n_{m_u} ||p_u||^2 \right) \end{aligned} \tag{3}$$

The solution for Eq. 3 follows the steps demonstrated in Section II-B, but, instead of initializing the matrix Q to random values on Step 1 in Alg. 1, it suggests assigning the average rating for that item as the first row, and small random numbers for the remaining entries. The stopping criterion used is based on the observed RMSE on the validation dataset. After one round of updating both Q and P, if the difference between the observed RMSEs is less than 0.0001, the iteration stops and the obtained P, Q are used to make final predictions on the test dataset.

Algorithm 1 ALS algorithm

```
1: procedure ALS(P, Q)        ▷ Matrices representing user feature matrix and item feature matrix, respectively
2:     Initialize matrix Q with random values
3:     repeat
4:         Fix Q, solve P by minimizing the objective function (the sum of squared errors)
5:         Fix P, solve Q by minimizing the objective function similarly
6:     until Stop criteria is satisfied
7:     return P, Q
8: end procedure
```

In this cited approach, a version that allows for parallel computation of Matlab was used. It creates several separate copies of Matlab, each with its own private workspace, and each running on its own hardware platform, collaborate and communicate to solve problems. Each such running copy of Matlab is referred to as a "lab", with its own identifier (labindex) and with a static variable (numlabs) telling how many labs there are. Matrices can be private (each lab has its own copy, and their values differ), replicated (private, but with the same value on all labs) or distributed (there is one matrix, but with rows, or columns, partitioned among the labs).

Because all of the steps use R, two distributed copies of it were used: one distributed by rows (i.e., by users) and the other by columns (i.e., by items). Both P and Q matrices were distributed computed and updated. While computing P, it is required a replicated version of Q, and vice versa. Thus, the labs communicate to make the replicated versions of these matrices from the distributed versions that are first computed. Matlab's "gather" function performs the inter-lab communication needed for this.

To update Q, it is required a replicated copy of P, local to each lab. The ratings data distributed by columns (items) is used. The data is distributed by blocks of equal numbers of items. The lab that stores the ratings of item i will, naturally, be the one that updates the corresponding column of Q, which is items i's feature vector. Each lab computes q_i for all items in the corresponding item group, in parallel. These values are then "gathered" so that every node has all of Q, in a replicated array. To update P, similarly all users are partitioned into equal-size user groups and each lab just updates user vectors in the corresponding user group, using the ratings data partitioned by rows.

The broadcast step is the only communication cost due to using a distributed, as opposed to a shared-memory, algorithm. This method reported taking up less than 5% of the total run time. The algorithm achieves a nearly linear speedup; for $k = 100$, it takes 2.5 hours to update P and Q once with a single processor, as opposed to 5 minutes with 30 processors.

This first work implemented ALS in parallel Matlab and executed on a Linux cluster, with 30 Xeon 2.8GHz processors and every four processors shared 6 GB of RAM. When applied to the Netflix dataset with 100 latent factors and 30 iterations was computed in 2.5 hours and obtained a RMSE of 0.8985 which is a performance improvement of 5.91% over Netflix's Cinematch system.

After the popularization of the Hadoop platform, the parallelization of the ALS algorithm was revisited with a new proposal for a parallel implementation using a series of broadcast-joins that can be efficiently executed with MapReduce [16]. This implementation has partially contributed to Apache Mahout, the open source machine learning library that runs on top of Apache Hadoop framework, and is publicly available. The evaluation setup was a cluster of 26 machines, each with two 8-core Opteron CPU and 32GB of RAM. The experiments showed that on the Netflix dataset, which consists of more than a million ratings given to 17,700 movies by 480,189 users, it was possible to run 37 to 47 iterations of the algorithm, and it typically converges after 15 iterations [18].

This approach is limited to use-cases where neither Q nor P need to be partitioned, meaning they individually fit into the memory of a single machine of the cluster. A rough estimate of the required memory for the re-computation steps in ALS is $max(|M|, |N|) \times k \times 8byte$, as alternatively, a single dense double precision representation of the matrices Q or P has to be stored in memory on each machine. Even for 10 million users or items and a rank $k = 100$, the estimated required memory would be less than 8 GB, which can easily be handled by today's commodity hardware. Experiment results show that, despite this limitation, this implementation is able to handle datasets with billions of data points.

In such a setting, an efficient way to implement the necessary joins for ALS in MapReduce is to use a parallel broadcast-join. The smaller dataset (Q or P) is replicated to every machine of the cluster. Because all of the steps use R, each machine already holds a local partition of R which is stored in the DFS. Then the join between the local partition of R and the replicated copy of P (and analogously between the local partition of R and Q) can be executed by a map operator. This operator can additionally implement the logic to re-compute the feature vectors from the join result, which means that it is possible to execute a whole re-computation of Q or P with a single map operator.

Figure 2 illustrates the parallel join for re-computing P using three machines. First, the broadcast of Q is done to all participating machines, which create a hashtable for its contents, the item feature vectors. R is stored in the DFS partitioned by its rows and forms the input for the map operator, where e.g., $R(1)$ refers to partition 1 of R. The map operator reads a row r_i of R (the interaction history of user i) and selects all the item feature vectors q_j from the

hashtable holding Q that correspond to non-zero entries j in r_i. Next, the map operator solves a linear system created from the interactions and item feature vectors and writes back its result, the re-computed feature vector p_i for user i. The re-computation of Q works analogously, with the only difference that P is broadcasted and R is stored with partitioning done by its columns (the interactions per item) in the DFS.

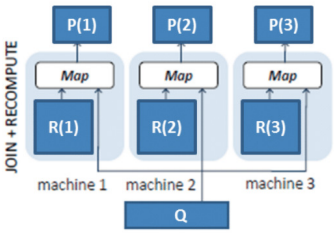

Fig. 2. Parallel recomputation of user features by a broadcast join [16]

This proposed approach is able to avoid some of the drawbacks of MapReduce and the Hadoop implementation described in Section III-A. It uses only map jobs that are easier to schedule than jobs containing map and reduce operators. Additionally, the costly shuffle-phase is avoided, in which all data would be sorted and sent over the network, once the join and the re-computation are done in a single job, which also spare to materialize the join result in the HDFS. This implementation contains multithreaded mappers that leverage all cores of the worker machines for the re-computation of the feature matrices and uses JBlas for solving the dense linear systems present in ALS. The broadcast of the feature matrix is conducted via Hadoop's distributed cache in the initialization phase of each re-computation. Furthermore, Hadoop is configured to reuse the VMs on the worker machines and cache the feature matrices in memory to avoid that later scheduled mappers have to reread the data. The main drawback of a broadcast approach is that every additional machine in the cluster requires another copy of the feature matrix to be sent over the network.

The implementation was also validated on a synthetic dataset called Bigflix, generated from the Netflix dataset and containing 25 million users and more than 5 billion ratings. The performed scale-out test measured the average runtime per job during 5 iterations with 10 latent factors on clusters of 5, 10, 15, 20 and 15 machines. With 5 machines iteration takes about 19 minutes and with 25 machines it was 6 minutes faster.

IV. Experimental Analysis

In this section, we give details of the ALS implementations on Mahout and MLlib libraries that will be executed on Hadoop and Spark respectively. We describe the datasets and the ambient on which the implementations are evaluated, and present the experimental evaluation on the parallel implementations.

A. Datasets

The datasets chosen to run the experiments are from the movies domain (MovieLens) and jokes domain (Jester). Due to copyright problems, Netflix dataset is not available for download anymore. So, to perform the recommendation evaluation on the movies domain, the MovieLens data is frequently used. The MovieLens dataset consists of anonymous ratings of movies and contains approximately 10 million ratings from 71,567 users on 10,681 movies. Ratings are made on a 5-star scale (whole-star ratings only) and each user has at least 20 ratings. The dataset was collected and made available by GroupLens Research, which currently operates a movie recommender based on collaborative filtering, at their webpage. This dataset was previously used to evaluate matrix factorization based methods with neighbor based correction technique, and achieved a best RMSE score of 0.8275 [13].

The Jester dataset consists of anonymous ratings of jokes collected between November 2006 and May 2009. Thus, this data is in a humor domain. It was firstly used to test the Eigentaste recommender and now is freely available for research use. The full data set contains 1,761,439 ratings from 59,132 users on 140 jokes. The ratings are real values ranging from -10.00 to +10.00. Ten percent of the jokes (called the gauge set, which users were asked to rate) are densely rated, others, more sparsely. Two thirds of the users have rated at least 36 jokes. The remaining users have rated between 15 and 35 jokes. The average number of ratings per user is 46, so it is a particularly dense data set compared to Netflix Prize and MovieLens. This dataset was previously used to evaluate matrix factorization based methods with neighbor based correction technique, and achieved a best RMSE score of 4.1229 [13].

B. Mahout ALS Implementation

Mahout 0.9, which was used for this evaluation, presents a MapReduce implementation of ALS that is composed of two jobs: a parallel matrix factorization job, which contains training phase of the ALS algorithm, and a recommendation job that outputs a list of recommended item ids for each user.

Given the ratings matrix (R), the matrix factorization job computes the two intermediate matrices: user-to-feature (P) and item-to-feature (Q). This implementation follows the strategy described in Section III-B, the parallel broadcast-join [16]. Firstly, the smaller dataset (Q or P) is replicated to every machine of the cluster. Also, the ratings matrix is partitioned, and each partition sent to a machine on the cluster, which stores it in the local HDFS. The join between the local partition of R and the replicated copy of P (and analogously between the local partition of R and Q) can be executed by a map operator. This operator can additionally implement the logic to re-compute the feature vectors from the join result, which means that it is possible to execute a whole re-computation of Q or P with a single map operator.

The recommendation job processes the user-to-feature matrix and item-to-feature matrix calculated from the factorization job to compute the top-N recommendations per user. The

```
val Rb = spark.broadcast(R)
for (i <-1 to ITERATIONS){
   P = spark.paralellize(0 until n)
            .map(j => updateUser(j, Rb, Q))
            .collect()
   Q = spark.paralellize(0 until m)
            .map(j => updateUser(j, Rb, P))
            .collect()
}
```

Fig. 3. ALS Spark implementation

predicted rating between user and item is a dot product of the user's feature vector and the item's feature vector.

C. MLlib ALS Implementation

This is a blocked implementation of the ALS factorization algorithm that groups the two sets of factors (referred to as "users" and "items") into blocks and reduces communication by only sending one copy of each user vector to each item block on each iteration, and only for the item blocks that need that user's feature vector. This is achieved by precomputing some information about the ratings matrix to determine the "out-links" of each user (which blocks of items it will contribute to) and "in-link" information for each item (which of the feature vectors it receives from each user block it will depend on). This allows the implementation to send only an array of feature vectors between each user block and item block, and have the item block find the users' ratings and update the items based on these messages.

Because all of the steps use the ratings matrix R, it is helpful to make it a broadcast variable so that it does not get re-sent to each node on each step. Figure 3 shows the ALS Spark implementation. Note in Lines 3 to 5 that collection 0 until u are parallelized and collected to update each array [26]. The ALS recommender accepts as input an RDD (Resilient Distributed Datasets) of ratings (user: Int, product: Int, rating: Double).

D. Experimental Results

The experiments were developed with Python 2.6 and firstly executed in local single machine mode for testing. Then, the final experiments were executed at Amazon Web Services (AWS).

The clusters used for the evaluation consists of t2.small EC2 instances running Ubuntu 64-bit OS with Oracle Java (JDK) 7, Apache Hadoop 1.2.1 and Apache Spark 1.1.1. Each t2.small instance has a 3.3GHz core processor, 2GB of RAM and 15GB of SSD storage. The accuracy and efficiency experiments were conducted on a cluster of 4 machines.

To evaluate these algorithms, the datasets were randomly divided into three non-overlapping subsets, named: training (60%), test (20%), and validation (20%). These datasets are saved on two datanodes of the HDFS, since this is the smaller cluster configuration for scalability experiment.

These two datanodes are accessible for all the workers through the experiments, since Spark is running in the same Hadoop cluster through Spark's standalone mode, that is, by simply placing a compiled version of Spark on each node on the cluster.

1) Accuracy and Efficiency Experiment: To evaluate the quality of the recommendations produced by each of the two implementations, multiple models are trained based on the training set, and that which achieves the smallest root-mean-square error (RMSE), given by Eq. 4, on the validation set after running 20 iterations of the algorithm is chosen as the best fit ALS model [18]. Finally, this model is evaluated on the test set.

$$RMSE = \sqrt{\frac{1}{|S_{val}|} \sum_{(m,n) \in S_{val}} (r_{ui} - \widehat{r}_{ui})^2} \qquad (4)$$

The parameters tested to find the best fit ALS model are combinations resulting from the cross product of the dimensionality of the latent factor space, $k = [2, 4, 6, 8, 10, 12, 14, 16, 18, 20]$ and the regularization parameter $\lambda = [0.10, 0.25, 0.50, 0.75, 1.00]$.

Analyzing the convergence of the Spark-MLlib ALS on the Jester validation set for the number of latent factors (k), we can see that the recommendation quality usually improves when increasing λ until the optimal value of 0.5. Then, the increment worsens the recommendation accuracy. For the HadoopMR-Mahout ALS on the Jester validation set, we observed the same behavior presented by the Spark-MLlib implementation: the recommendation quality usually improves when increasing λ until the optimal value of 0.5 but beyond that, the recommendation is worse.

The best fit Spark-MLlib ALS for the Jester dataset has RMSE on the test set of 4.1339 and 4.1395 for the HadoopMR-Mahout. Both models have the same value for the parameters k and λ, but the MLlib implementation achieves a result 0.13% better, with a training execution time that is more than 10 times faster, in a cluster with 4 t2.small instances, as shown on Table I.

TABLE I
BEST FIT ALS MODEL RESULTS FOR JESTER DATASET

	Spark-MLlib	HadoopMR-Mahout
$k_{BestfitALS}$	20	20
$\lambda_{BestfitALS}$	0.5	0.5
RMSE(Validation Set)	4.1378	4.1385
RMSE(Test Set)	4.1339	4.1395
Execution time (sec)	61.4	671.4

For the MovieLens dataset, the best fit Spark-MLlib ALS is trained with $k = 20$, $\lambda = 0.5$ and RMSE = 0.8099 on the validation set. We observed that the model converges on each value of $\lambda \geq 0.5$ regardless of the feature space size. The RMSE on the test set is 0.8091, which means that the model does not overfit the observed ratings. For the HadoopMR-Mahout ALS modelling results, the best fit is trained with

$k = 20$, $\lambda = 0.5$, and RMSE = 0.8196 on the validation set, the same parameters found for the Spark-MLlib implementation. The convergence behavior found before repeats itself here, for each $\lambda \geq 0.5$ regardless of the feature space size. Also, the RMSE on both implementations for the same regularization parameter is very close: the largest difference is of only 0.0002 or 0.001% of the rating score, represented on a scale of -10.0 to +10.0.

Comparing the best fit ALS models achieved by both implementations, again the Spark-MLlib solution has a better performance: more accurate, with a RMSE on the test set 1.4% smaller than the HadoopMR-Mahout implementation, and more efficient, with execution more than 5 times faster to run (Fig. 4). The results for the MovieLens dataset are summarized on Table II.

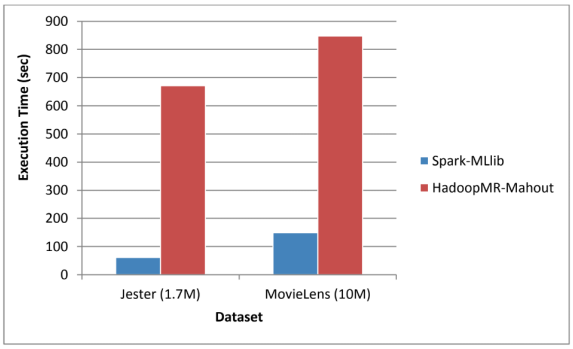

Fig. 4. Execution time for the best fit ALS model on a cluster with 4 machines

TABLE II
BEST FIT ALS MODEL RESULTS FOR MOVIELENS DATASET

	Spark-MLlib	HadoopMR-Mahout
$k_{BestfitALS}$	20	20
$\lambda_{BestfitALS}$	0.1	0.1
RMSE(Validation Set)	0.8099	0.8196
RMSE(Test Set)	0.8091	0.8202
Execution time (sec)	149.1	847.9

2) Scalability Experiment: To test the scalability of these recommender systems, we measure the walltime of 20 iterations of the best fit ALS model on each of the datasets on different cluster sizes, consisting of 2, 4 and 6 AWS EC2 t2.small instances. We observe that the computation speedup does not linearly scale with the number of machines, which is an expected behavior since both implementations have a broadcast of the ratings matrix so every additional machine causes another copy of it to be sent over the network. Comparing the speedup values for the two implementations, shown on Fig. 5, we find that, when training the HadoopMR-Mahout ALS model with 6 machines, it shows an improvement of 1.60x on the Jester dataset and 1.45x on the MovieLens dataset over the execution with 2 machines, and for the Spark-MLlib implementation, executing with 6 machines provides an improvement of 1.86x on the Jester dataset and 2.39x on the MovieLens dataset over the execution with 2 machines.

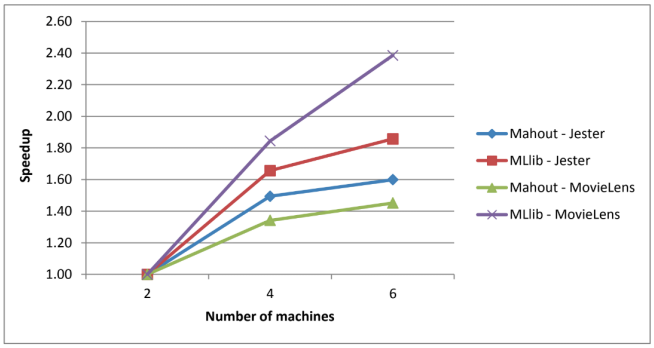

Fig. 5. Speedup for both implementations

As seen in Table III, the distributed and parallel ALS implementation on MLlib executed on the Spark cluster with 6 machines achieved the faster training time for both datasets: 54.7 seconds for Jester that contains about 1.7 million joke ratings, and 115.3 seconds for MovieLens that contains about 10 million movie ratings. By extrapolating these results, we find that a recommender system with a dataset with 100 million ratings input, which is 10 times bigger than the MovieLens dataset, would take about 415 seconds to be trained on a cluster with 6 machines with the t2.small EC2 configuration. If we wished to put such a system into production, we could either utilize more of these general purpose instances or choose machines with more RAM, such as the M3 instances or the R3 memory optimized instances, which suggests that the Spark implementation is suitable for real world use cases.

TABLE III
SUMMARY OF RECOMMENDATION TIME

Dataset	size (# of ratings)	Recommendation time (in sec)
Jester:	1.7 mi	54.7
MovieLens:	10 mi	115.3
100 mi	415	

V. CONCLUSIONS

Alternating Least Squares (ALS) algorithm is an efficient approach in situations where generating online recommendations and processing large datasets is required. In this work, we described two scalable parallel implementations of the ALS algorithm, the Mahout ALS and MLlib ALS. Each one uses a different framework for distributed processing on clusters of commodity hardware, respectively, Hadoop MapReduce and Spark.

We performed an experimental analysis comparing the different implementations of the ALS algorithm for collaborative filtering recommender systems, using datasets from two different domains: MovieLens, from the movies domain, and Jester, from the jokes domain. First we found the best fit ALS model for each of the datasets. Using the optimized parameters to train the ALS models, we performed the evaluation of the implementations in terms of execution time and accuracy results on the test set.

The experimental results showed that Spark-MLlib solution has a better performance than the Mahout ALS in terms of accuracy and efficiency for both recommendation domains. For the Jester dataset, the RMSE on the test set with Spark-MLlib was 0.13% better than with HadoopMR-Mahout, and the training was more than 10 times faster in a cluster with 4 machines. For the MovieLens dataset, the RMSE on the test set was 1.4% smaller on the Spark-MLlib implementation, and the modeling was 5 times faster. This study also featured a scalability experiment, running the best fit ALS model on clusters of 2, 4 and 6 machines. Again, the results were favorable to Spark, since it has a more expressive computational speedup: training time on a cluster with 6 machines was 86% faster on the Jester dataset and 139% on the MovieLens dataset when comparing to execution time on a cluster with 2 machines.

Deploying a recommender system on six t2.small instances available from EC2 took 115.3s for a dataset containing about 10 million ratings, and, by extrapolation, it would take about 415s for a dataset with 100 million ratings. The results suggest that a cluster with at least six t2.small instances or fewer and more potent machines, like M3 or R3 memory optimized instances available on EC2, would run a user's full recommendations measures in a few seconds, which is a suitable time frame for production settings. Future works are desirable in order to keep comparing the recommendation algorithms implementations available in the newer releases of MLlib and Mahout, as well as newer technologies, since both engines for large-scale data processing are rapidly evolving.

5th International Conference on Cryptography and Security Systems

CRYPTOGRAPHY and security systems are two fields of security research that strongly interact and complement each other. The International Conference on Cryptography and Security Systems (CSS) is a forum of presentation of theoretical, applied research papers, case studies, implementation experiences as well as work-in-progress results in these two disciplines.

TOPICS

The main topics of interests include:

- network security
- cryptography and data protection
- peer-to-peer security
- security of wireless sensor networks
- security of cyber physical systems
- security of Internet of Things solutions
- heterogeneous networks security
- privacy-enhancing methods
- covert channels
- steganography and watermarking for security applications
- cryptographic protocols
- security as quality of service, quality of protection
- data and application security, software security
- security models, evaluation, and verification
- formal methods in security
- trust and reputation models
- reputation systems for security applications
- intrusion tolerance
- system surveillance and enhanced security
- cybercrime: threats and countermeasures
- 5G Security
- DDoS attacks: detection and mitigation
- Security of Smart Grid systems

ul. Urbanowicza 2, 01-489 Warszawa, Poland
Email: michal.andrzejczak@wat.edu.pl

***Abstract*—Elliptic Curve Method (ECM) is a well-known method for factoring integers, which is usually used in the Number Field Sieve algorithm as a subroutine for factoring smaller integers than the targeted one. ECM is called many times and can be executed in parallel for different inputs. This method mainly consist of simple operations on elliptic curves. Thus, ECM is suitable for hardware implementations that can efficiently reduce computational time. This work describes a new, improved FPGA-based hardware accelerator for ECM, designed for large scale computations. Our accelerator can operate with an on board ARM processor or with an external host computer. This design can factor several numbers at once and can be easily ported to various FPGA boards. Different methods for improving results (e.g. the use of DSP blocks, cache-registers, reorganizing instruction order) are described and their performance is analyzed. As a result, one of the fastest hardware ECM units is achieved.**

I. Introduction

FACTORIZATION is one of the main hard problems used in construction of cryptosystems. One of the most known and the most popular cryptosystem based on factorization problem is RSA. To the present day, several algorithms for factoring integers have been developed and used in various cases. The best algorithm for factoring integers with large factors used in RSA is Generalized Number Field Sieve (GNFS) [2]. This method require to factor a lot of smaller numbers in one of the main steps of the algorithm and the Elliptic Curve Method can be efficiently used for this. ECM performs many operations on a small data, requiring little memory and can be run many times in parallel with the same probability of factoring chosen number. Thus, special purpose hardware can efficiently improve overall factorization time. In this paper an improved architecture of a hardware accelerator for factoring integers with Elliptic Curve Method (ECM) is presented. Analysis of previous architecture is included and detected weaknesses are described with potential improvements. At the end, influences of several changes in initial design are compared, with the best result more than three times better than previously reported in literature.

II. Elliptic Curve Method

The ECM was proposed by H.W. Lenstra [1] (called Phase 1) in late 80's and its principles are based on Pollard (p-1) method. Later, ECM was extended and improved by Brent [3] and Montgomery [4] (called Phase 2).

Let choose a field K with characteristic different from 2 and 3. The elliptic curve $E_{A,B}$ is the set of points $(X, Y) \in K$ such that

$$Y^2 = X^3 + AX + B$$

where $A, B \in K$ and $4A^3 + 27B^2 \neq 0$ with a special point $O_E = (0 : 1 : 0)$ called a "point at infinity".

For more efficient computer implementation, Montgomery's form of elliptic curve is recommended due to lack of number inversion computation. Montgomery's form can be obtained from Weierstrass form presented above by following change of the variables $X \to (3x + a)/(3b)$, $Y \to y/b$, $A \to (3 - a^2)/(3b^2)$, $B \to (2a^3 - 9a)/(27b^3)$. Homogeneous form of this curve is:

$$by^2z = x^3 + ax^2z + xz^2$$

with the triple $(x : y : z)$ represents the point $(x/z : y/z)$ in affine coordinates. Projective coordinates of curve in Montgomery's form allow all intermediate computations to be performed using only x and z coordinate. The y coordinate can be retrived from two others coordinates, but is not necessary in ECM algorithm.

Let q be an unknown factor of N - the number being factorized. The ECM starts with randomly selecting an elliptic curve $E_{a,b}$ and a random point on it. Computations are performed modulo the number N, as if $\mathbb{Z}/n\mathbb{Z}$ was a field. First step of computations can be done just once. In this step, product of all prime numbers and its powers is computed. Most time consuming operation is done in second step, where scalar multiplication of chosen point by computed product is performed. In the last step, greatest common divisor of resulted z coordinate and a factorized N is computed. Pseudocode for ECM is shown in Listing 1.

Algorithm 1 ECM algorithm, phase 1

Require: a composite number N, random point P_0 on random elliptic curve E, integer bound B_1
Ensure: a factor of N or $fail$
$k \leftarrow \prod_{p \leq B_1} p^{\log_p B_1}$
$Q_0 \leftarrow kP_0$;
$q \leftarrow gcd(z_Q, N)$;
if $q > 1$ **then**
  return q
else
  return $fail$
end if

A. Complexity of the ECM

The complexity of ECM is sub-exponential and is described as:

$$\mathcal{O}(n) = e^{\sqrt{\log p \log \log p}\sqrt{2}+o(1)} M(\log n)$$

where $M(\log n)$ is the complexity of multiplication $\mod n$. First part depends only on factors of the chosen integer. The only way to speed up computations is to execute point multiplication as fast as possible, so basically what this paper is about.

III. Initial Design

The initial design was proposed in [8]. The main idea of that hardware accelerator is to spread as many as possible autonomous ECM units in one FPGA chip. The ECM units have Harvard architecture with separable instruction list and data memory. Design can be described in three levels. First of them, the top level, describe FPGA device and interconnections between main modules and external components. Lower level is about design of ECM unit, interconnections between memory, controllers and arithmetic modules. The last level describes architecture and algorithms used in modules building the ECM unit (modular multipliers, adders, controller).

A. Top level

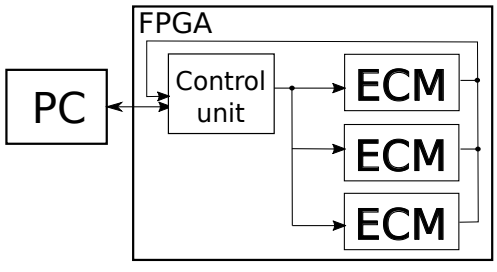

Fig. 1. Top level

In Fig. 1 the top level is shown. FPGA chip is filled by as many ECM units as possible with one global control unit for all of them, responsible for Montgommery Ladder execution, communication with external PC and managing the work units. Connected PC is used for random curves sampling and for last stage of the algorithm, the gcd computation. It is done in this way to maximize logic usage and simplify chip design. Many independent ECM units allow better clock signal distribution. FPGA is responsible only for point multiplication over elliptic curve.

B. ECM level

Every ECM unit is equipped with internal memory, memory controller, microprocessor and 4 arithmetic units (two for modular multiplication, one for addition and subtraction) as shown in 2. During initialization, every ECM unit need random elliptic curve and random point over this curve. Provided curves should be in Montgomery form and every coordinate should be converted to Montgomery domain [5].

The memory controller is responsible for communicating with two way memory bank. Loaded data words are concatenated and put into bus registers. This controller has also internal semaphore table for preventing data override during parallel execution and additional table for storing result address of computed data.

The main controller has ROM memory for instruction and can execute simple commands. Every instruction takes two memory addresses for data input and one address for writing result. There are 5 instructions:

- **ADD** - instruction used for addition
- **SUB** - used for subtraction
- **MULA**- multiplication by first unit
- **MULB**- multiplication by second unit
- **LOADN**- modulus read from memory

These instructions can be used to replace computation path with computations over Edwards curves by simply reprogramming the ROM table.

The ECM unit is equipped with two modular multiplication unit which allow faster point multiplication. This idea was taken from [6].The computation flow for point doubling and addition in Montgomery form ([5]) is shown in Table I) and uses two multipliers in parallel.

C. Module level

Modular multiplication is the most time consuming operation. During every point doubling/addition it is performed 11 times and this number can be reduced to 10. To obtain the lower number of multiplications one coordinate of P_0 must be chosen arbitrarily to simplify computations by selecting $z_{P_0} = z_{P-Q} = 1$. Thus, use of two modular multipliers can increase total throughput. For multiplication, logic based algorithm [7] was used. The aim of that was to have design capable to be deployed on low cost devices without enough DSP modules. This also save logic required for routing to these modules in designs with high percentage of logic usage. Implemented algorithm perform modular multiplication of n - bit numbers in Montgomery form in n clock cycles. Modular reduction in Montgomery's domain is based on efficient hardware bit shift operation and was chosen due to very good performance.

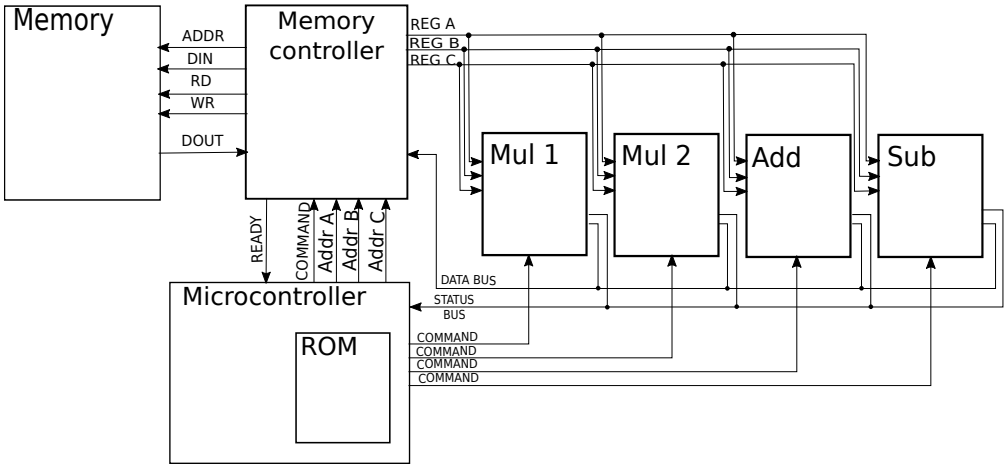

Fig. 2. ECM level

TABLE I
ONE STEP OF SCALAR MULTIPLICATION IN CASE OF $z_{P-Q} = 1$

Adder	Substractor	Multiplier 1	Multiplier 2
$a_1 = x_P + z_P$	$s_1 = x_P - z_P$		
$a_2 = x_Q + z_Q$	$s_2 = x_Q - z_Q$	$m_1 = s_1^2$	$m_2 = a_1^2$
	$s_3 = m_2 - m_1$	$m_3 = s_1 \cdot a_2$	$m_4 = s_2 \cdot a_1$
$a_3 = m_3 + m_4$	$s_4 = m_3 - m_4$	$x_{2P} = m_1 \cdot m_2$	$m_6 = s_3 \cdot a_{24}$
$a_4 = m_1 + m_6$		$x_{P+Q} = a_3^2$	$m_8 = s_4^2$
		$z_{P+Q} = m_8 \cdot x_{P-Q}$	$z_{2P} = s_3 \cdot a_4$

D. Comparision

Basic parameters of this design are shown in Table II in comparison with other results reported earlier in literature. The design was compiled for low cost Altera DE1-SOC board equipped with Cyclone VCSEMA5F31C6 FPGA and for high end Stratix IV targeted for high performance computing.

IV. ANALYSIS AND IMPROVEMENTS

The reported results for initial design are very competitive. However, deep analysis of proposed solution indicates several bottlenecks which may be improved to achieve much better performance.

Fig. 3 shows data dependency graph for point multiplication. Every arrow represents memory read operation and circles are the arithmetic operations with result write to memory. Memory controller is capable only to read from memory to one register at once which result in doubling the same operation. Moreover, data is loaded almost immediately after being write to memory in several cases.

A. Memory improvements

Analysis of the simulation diagrams proved that memory operations give one of the biggest slowdown on design. Every arithmetic operation needs two load operations of operands (which is done by sequential memory loads, concatenated at the end) and one write operation of result, done in similar manner. For 192-bit length numbers and 32-bit size memory, communication overhead takes around 20 clock cycles for one operation.

Simple solution for this problem is to increase memory base size to decrease this overhead. Increasing memory base size from 32-bits to 128-bits can decrease the number of memory calls from 21 to 6 clock cycles. Size of the design increase slightly with this improvements, further called **opt1**.

On the other hand, situation when one variable is loaded twice in a row or written and read in next step is very common. The first issue can be solved by expanding instruction set by load instruction for two operands at once. Several cases when the same data is loaded for two arithmetic units can be improved by splitting arithmetic instructions for more atomic operations. Instead one arithmetic instruction, where attributes are addresses in memory, we use load to register instructions and execute arithmetic operation instruction (without any arguments). .

The second issue needs additional cache registers for temporary results. Adding these registers slightly increases design size, but offered overall performance by FPGA chip is improved. With this change it is possible to replace order list. New orders can be more atomic. With atomic instructions the program size increase, but there is no need in memory controller to be responsible for parallel data access. 4 temporary registers were added to design. With these registers and with direct result to input operation, memory usage is limited only

TABLE II

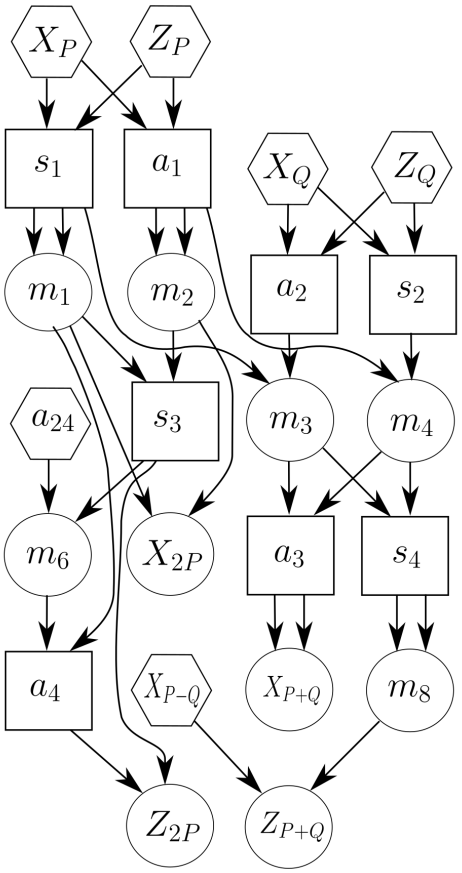

Fig. 3. Data computation graph for point multiplication

to load first coordinates for first bit of ladder and load one coordinate (a_{24}) for every bit. The intermediate results can be stored in these 4 additional temporary registers or can be directly passed to input of another arithmetic unit. The saved memory can be used in Phase 2 to store more pre computation results and improvements from **opt1** are less significant in overall result and are not included in this design, called **opt2**

Instructions have no longer the same format. Arithmetic instructions are not taking any arguments, they operate on data provided to special input registers loaded earlier. Extended instruction set with description is shown in Table III

TABLE III
EXTENDED INSTRUCTION SET WITH FORMAT DESCRIPTION

Name	**Description**
RLOAD	Load data from one register to another one. Can be used to load data for two registers at once
MLOAD	Memory load to one or two registers
MULA	Start multiplication in unit A
MULB	Start multiplication in unit B
ADD	Start addition
SUB	Start subtraction
WAITFOR	Waits for end of computation in selected module

After memory operation optimization and with the new instruction set, data computation graph is changed. Fig. 4 presents improved data computation graph. All coordinates loaded from memory are marked by gray color and correspond to first improvement. Second improvement is presented with red circles marking data loaded for different modules in one load operation. Double loads for integer squaring or doubling are marked by one pointer. Values stored in temporary registers are marked with dots.

B. Multiplication unit replacement

The other way to increase number of checked elliptic curves is to speed-up multiplication computation. The modular multiplication based on logic gates takes n clock cycles and to decrease this number DSP multiplication algorithms should be used. Algorithm for modular Montgomery multiplication proposed by Itoh [9] was selected. Multiplier is parametrized by radix and multiplication is performed in n^2 steps, where:

$$n = \frac{\text{number length}}{radix}$$

Optimal selection of radix is crucial for overall performance. Bigger radix needs more DSP (Digital Signal Processing) blocks used for integer multiplication. The size of multiplier (in Logic Elements) increase as increase the number of DSP blocks needed, because of longer paths used to route signals to these blocks. The best results have been achieved for radix 32, requiring only 3 DSP blocks per multiplication and executing

TABLE IV
IMPROVEMENTS COMPARISION

Parameter	Initial	opt1	opt2	opt3	Stratix IV opt3
Logic:	30 060	31 394	30 982	25 566	372 951
Logic usage(%):	97 %	98 %	97 %	80 %	92 %
DSP:	-	-	-	66	654
Max. clock freq.	88 MHz	88 MHz	85 MHz	90.1 MHz	151 MHz
Num. of Units	10	10	9	11	109
Clock cycles per bit	1580	1374	1215	481	481
Clock cycles in phase 1:	2 101 400	1 827 420	1 615 950	639 730	639 730
Curves/sec:	418	480	473	1546	25 557
Improvement factor:	**1**	**1.14**	**1.13**	**3.69**	**3.72**

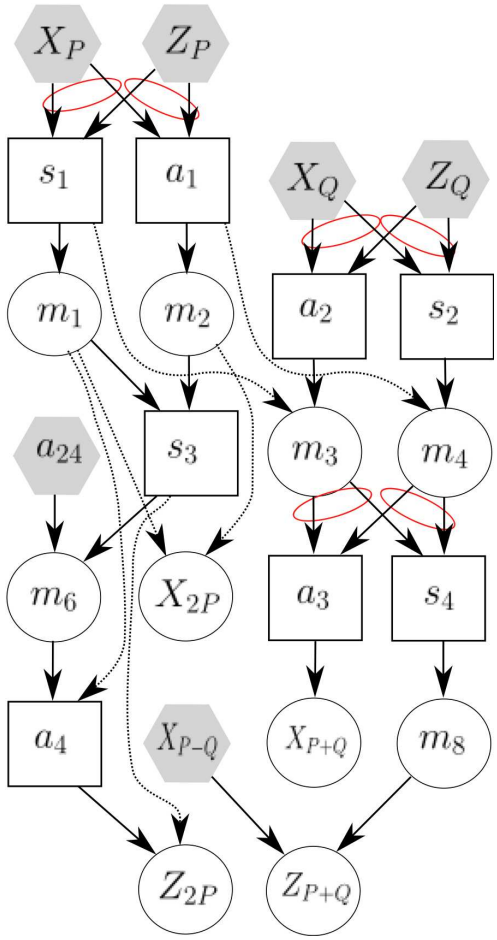

Fig. 4. Data computation graph for improved point multiplication

in 54 clock cycles. Bigger radix significantly decrease the maximum clock frequency, due to longer propagation paths and require more DSP block, which lead to higher logic utilization. Variant with shorter radix executes in more clock cycles and leave many DSP blocks unused in global view.

The replacement of multiplication algorithm saved around 150 clock cycles per each call of this function. Two modules are used at once, so in general around 750 clock cycles are saved compared to previous used logic based algorithm. Moreover, DSP-based module requires less logic element and Quartus Prime compiler was able to fit one more ECM unit in targeted Cyclone V device. For 11 ECM units the compiler needs 25 566 ALM (Adaptive Logic Modules) which is 80% of all available resources. Adding one more ECM unit is not possible. For 12 ECM units compiler can not place all of them close to hardware multipliers, so longer routing path are needed. For targeted Cyclone V, 33 091 ALM is required and it is above 100% of available resources. Multiplier replacement is called **opt3**

Improvements were implemented incrementally. Every next design contains improvement from previous versions. Table IV compares results of constructed modules. The last column contains compilation data for Stratix IV GX530, used to check throughput of initial design. This one is much bigger than the low cost Cyclone V and can be used in practice to factorize numbers in GNFS. Achieved results are 3.72 times better than at the beginning. The total number of sieved curves is the highest one from reported in literature.

V. CONCLUSIONS

An improved hardware architecture for factoring integers has been presented. Careful analysis of algorithm and hardware design lead to architectural changes resulting 3.72 times faster device. The most efficient was the change of multiplication algorithm, which reduced almost half of the total number of computations. Additional temporary registers may be more significant for total computation time if the base of memory was not increased and memory operations will still take almost four times more. With all improvements combined, the fastest architecture is obtained.

Recently Intel introduced new more powerful devices called Stratix 10. Further works will adapt described design for new devices. Preliminary simulations shows around 180 thousands curves per second for one of the biggest devices from the new family.

***Abstract*—5G networks are expected to be a set of slices which are virtual subnets designed for specific applications. A crucial requirement for providing proper functioning of the network and its security is proper isolation of slices. The aim of this paper is to propose a new method of determination of the isolation level of a slice. We propose a Graph-based model of the sliced network, which has a layered structure. In each layer, the appropriate network elements have their own isolation level. The lowest layer of the Graph-based model represents virtual network elements with isolation traits used for calculating their isolation level. Climbing to the top of the stack of layers one can calculate, successively, isolation level for a network's physical element, a link, subnetworks and, the End-to-End slice's isolation level. We present numerical examples, where suitable traits are specified and the isolation level in each layer is calculated.**

I. Introduction

NETWORK slicing is a key technology for 5G network [1]–[3]. In 5G, transmission quality, network performance and services' reliability are expected to be on extremely high-level (e.g., the bandwidth over 300 Mbps, very small latency of few milliseconds and support up to 200,000 devices/km^2 with 99.999% reliability level, see [4]–[6]). Unfortunately, some quality parameters are impossible to be satisfied simultaneously. Therefore, the network is divided into slices, where each slice is designed for services with required values of network parameters. In such a case, a crucial problem is secure isolation of slices to prevent inter-slice harmful interaction or even attacks and to provide sufficient Quality of Service in each slice, see [7], [8]. Providing proper slices' isolation is now extensively studied, both, from experimental and theoretical points of view.

Even before the concept of 5G network have been rigorously formulated, experimental research related to future networks caused a need of isolation of functions and processes. Different kinds of testbeds have taken into the isolation property. For instance, the COMCON (COntrol and Management of COexisting Networks) project [9] has been created to design novel control and management mechanisms for supporting the coexistence of networks in the Future Internet. It has considered several use cases to evaluate a reference architecture providing some isolation of specialized networks with certain functionalities to provide their dependable and predictable work. Another testbed, described in [10], was specialized for network experiments with disconnected mobile nodes. Here, the isolation property has been required for precise measurements of network's properties. The paper [11] presents a scheme (possibly inside OMF, the wireless testbeds managerial framework) that exploits wireless testbeds functionality by introducing spectrum slicing of the testbed resources. Since in wireless testbeds slicing there are inter-dependencies among the resources, the isolation of experiments is there a hard task. The paper [12] gives an approach allowing virtualization of testbeds to realize several services like environment control, virtual radio control, slice feedback, and a virtual radio isolation. At least two of them provide the isolation of slices: the environment control is responsible for maintaining control and performance isolation across different environments while virtual radio isolation service is required for isolating the radio resources used by each slice due to the inherent nature of the wireless medium.

Practical experiments concerning isolation are presented in paper [13]. The authors consider OpenVZ and User Mode Linux (UML) for virtualization of the ORBIT wireless testbed and evaluate their relative merit. Their results show that the operating system level virtualization mechanism outperforms UML in terms of system overheads and performance isolation. To measure isolation, they propose two performance measurement metrics: transient response and cross coupling between experiments. The transient response is the instantaneous change in throughput of an experiment running on one slice caused due to time varying change in offered load on another slice, while the cross coupling is the difference in throughput with virtualization as a percentage of the throughput without virtualization. Both measures are estimated in experiments. Another experimental testing of isolation can be found in [14], where the authors compare the container-based approach and general virtual machines (Xen). They show that both approaches give comparable isolation features (with respect to fault isolation, resource isolation, and security isolation), while the container-based approach gives better efficiency expressed in terms of overall performance (throughput, latency, etc.) and/or scalability (measured in number of concurrent VMs), what reflects better performance isolation.

Some approach to numerical evaluation of isolation loss using, both, experimental and theoretical results, has been proposed in the paper [15]. Usually in VM environments, the performance isolation is calculated based on performance loss ratio. For containers, we can consider misbehavior and orchestration and management, so the measurements that only

take performance loss into consideration are not sufficient. In the paper [15] the authors propose a performance isolation measurement model that combines the performance loss and resource shrinkage of containers. They also validate their model experimentally using the open- source container project Docker.

In contradiction to widely applied container-based virtualization [16] as a solution for isolating resources of users or slices, the authors of the paper [17] propose an alternative to enable the isolation, based on commodity OS, utilizing existing features in commodity OS. Assigning every user-id in the OS a dedicated and isolated network the address and the routing table, this method enhances the commodity OS with the property of network name-space isolation.

Except of nodes-located information processing, isolation is also required in network processing. For instance, paper [18] proposes a method to share the host's global IP address for all the guest slivers on a node and isolate their network usage in port-space. In programmable networks all VMs can be configured with the same IP and MAC addresses as the host so that any Ethernet frames from outside can be received by a VM or host. To isolate the packets of different VMs, each VM is assigned with a range of port numbers. The port range of each VM can be got from the database of PLC node. As a result, the corresponding flow entries (forwarding rules) are installed after a VM is launched. Each VM can only listen on the ports that assigned to it. The OVS switches packet based on the destination port number. without address translation. The paper [19] combines the programmable switch OpenFlow with network virtualization and design the INP platform OFIAS, i.e., OpenFlow In A Slice. With the flexibility of OpenFlow and the scalable multiplexing of virtualization, OFIAS can smoothly support multi-party INP with good isolation performance.

Next to purely experimental investigations made in testbeds, more theoretical approaches to isolation can be found in the literature. For instance, in the paper [20] the authors present a framework that improves current infrastructure by extending link virtualization with a new component which they call Multi-Hop Virtual Link. In their proposal this component may be implemented as a tunnel which traverses multi-hop physical nodes. For more virtual links, a Link Switch Engine is applied for strong isolation of switch ability offered to different virtual links. The authors propose to allocate separate hardware to each virtual link providing strong isolation among multiple virtual links.

A next step in making a concept of isolation very practical tool for networks is proposing not only qualitative description and experimental validation of isolation, but also its formal modeling and quantitative representation of its level (estimated of calculated from the model). Such a need has been observed, both, in practical investigations and more theoretical research. For instance, the CONFINE IP Project, Community Networks Testbed for the Future Internet [21], has considered the sliver isolation, covering two different aspects for all resources (nodes and a network): the resources isolation and performance isolation. The resource isolation means that a slice does not interfere with the operation of other slices and is completely separated from the others: it cannot access the data of other slices, cannot kill their processes, and cannot access the core management system (it is secure). Performance isolation means providing mechanisms to guarantee performance on a predictable level with sufficient (up to a certain point) amount of available resources. To make such a concept functional one should describe these intuitive properties and expectation with some measurable parameters.

A milestone of formal modeling of slices is the paper [22], where the authors have presented an abstraction that supports programming isolated slices of the network. The proposed semantics of slices ensures that the processing of packets on a slice is independent of all other slices. Further, in the paper they formally define slices and propose algorithms for compiling slices. Finally, the authors describe a tool for automatic verification of formal isolation properties on a level of network packets processing.

Among experimental papers, a more complete pattern of slices isolation gives the paper [23]. The authors consider several resultant parameters to estimate slices isolation (all for several container-based virtualization implementations), which are: Computing Performance, Memory Performance, Disk Performance, Network Performance, Performance Overhead in HPC Applications, all of them measured according to their own methodology. Finally, they use an Isolation Benchmark Suite (IBS) [24], [25], which includes six different stress tests: CPU intensive test, memory intensive test, a fork bomb, disk intensive test and two network intensive tests (send and receive). Such parameters are suitable for estimating performance of isolated systems in different virtualization environments.

The recent trend of isolation modeling is calculation of overall parameters of the sliced network, like its performance properties, e.g., end-to-end (E2E) delay for a slice [26], using detailed transmission or nodes' parameters. In this paper we propose a new Graph-based model suitable for isolation modeling of slices. It uses several isolation parameters (proposed in our earlier paper [27] and makes possible to establish a common level of isolation for an E2E slice in the 5G network.

The rest of the paper is organized as follows. In Section 2 we introduce a Graph-based model of slices and isolation. It uses hierarchical graphs and makes possible to calculate isolation level on a given level of abstraction. Section 3 is an overview of parameters and properties suitable to model isolation of network's elements. In Section 4 we give a mathematical background for calculating isolation level presenting suitable methods and formulas. In Section 5 we illustrate the theoretical results of previous Sections with two numerical examples, while Section 6 concludes the paper and outlines future work.

II. Graph-based model of slices and isolation

All communication networks can be considered as a set of interconnected layers, including their different elements and roles. The same approach can be also applied to 5G networks

(see Figure 1). The highest layer represents a high-level view on 5G network which includes two main subnetworks: RAN and CN and the gateway between them. The lower layer refers to all resources located in a selected subnet. The next layer contains a physical resource which can be described by some properties and parameters that define it. The required virtual resources can be located in the last layer. The virtualization was made based on the mentioned earlier properties.

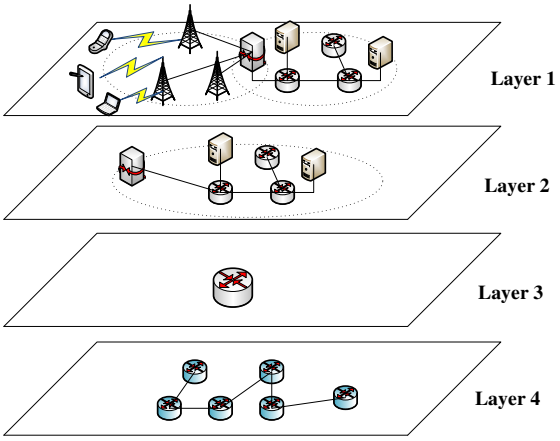

Fig. 1. The 5G network layer decomposition.

Of course, such a general decomposition must be appropriately adapted and transformed to represent a slice-based 5G network with an isolation assurance. For that reason, a new Graph-based layered model of the network has been created.

A. Model assumptions

The described model has been created based on a few assumption, such as:

- RAN, CN and every resource (e.g., router, link, switch, server, etc.) are represented as hypergraphs;
- properties of resources are represented as graph vertices;
- one property can be divided into several virtual properties used in a slice's structure and a value can be assigned to each of them; based on these values it is possible to create requirements how a slice can be created or validate if it is possible to create a slice with a defined set of properties;
- the stratification enables to consider isolation on many levels (e.g., in Layer 5 isolation exists between properties), so it is easy to show a slice as a path with vertices which represent virtual properties.

B. Graph-based model

Our proposed Graph-based architecture is shown in Figure 2. The architecture includes 5 layers. Each of them represents different aspect of slicing:

- Layer 1: the layer consists of hypergraphs with all resources of RAN and CN. Moreover, both areas have common part (common resources which match RAN slice and CN slice, e.g. gateway connecting RAN and CN);
- Layer 2: the layer is represented by selected hypergraph of one of area: RAN or CN with sub-hypergraphs (or a second level hypergraph) The sub-hypergraphs apply to all physical resources in this area;
- Layer 3: the sub-hypergraph in this layer refers to dedicated resource which has several properties (in isolation sense), the graph vertices;
- Layer 4: in this layer a property is a graph vertex which can be virtualized;
- Layer 5: this layer includes all virtual properties, created from a vertex in Layer 4, which are the foundations of slices.

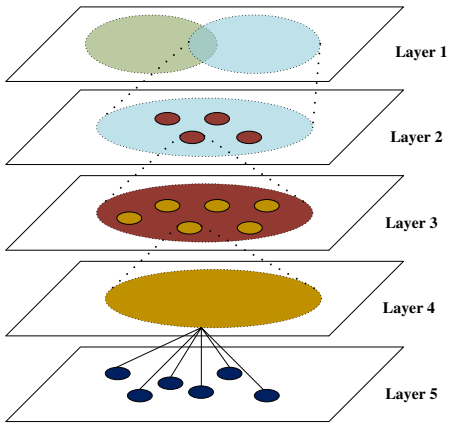

Fig. 2. The 5G Graph-based model.

III. Properties and Parameters of Isolation

In the paper [27] network has been described in terms of *properties* and *parameters*, called in general the *traits*. Both should be normalized; in the paper [27] has been proposed an example method for this operation. The method assumes that each trait's value is preprocessed with the *normalization function* $g : \Lambda \rightarrow \Omega$, where Λ is the trait's domain and Ω is a continuous subsection of the real line $\mathbb{R}$; further in this paper we will assume that $\Omega = [0, 1]$. Different types of traits could have different normalization functions, however the Ω should be common for all the traits. The normalization function for the one trait could change between vertices as well, see [27]. The value $\alpha = \inf_{x \in \Omega} x$ will be assigned to the *worst value* of the trait (from the isolation point of view). The value $\omega = \sup_{x \in \Omega} x$ will be assigned to the *best value* of the trait (from isolation point of view). In the paper [27] there were defined the following trait families:

- *raising trait*: higher trait's value is better (e.g., available link's throughput in $Mbit/s$);
- *falling trait*: lower trait's value is better (e.g., link's BER);

- *Gaussian trait*: trait is the raising trait for $x < \gamma$ and the falling trait for $x > \gamma$, where $\gamma = const$ (e.g., jitter in the packets stream).

The normalization function should satisfy the following assumptions:

- $g(x) \leq g(y)$ iff y is a better trait's value than x;
- $g(\beta) = C$, where C is a constant dependent on the Ω set and the β was defined in [27] as the trait's *typical value*. In the paper [27] was proposed $C = \frac{\alpha+\omega}{2} = 0.5$.

The Table I contains the example of normalization functions for typical values' domains. Some functions could be parametrized by additional parameters independent from functions' arguments, e.g. β, γ, q, r parameters from the Table I.

IV. Calculating the isolation level

At the beginning, we need to define types of vertices. Let us assume that the subset of vertices from the Layer $\mathcal{L}$ is indicated as $\{V_1, V_2, \ldots, V_n\}$. These vertices can be classified as:

1) *similar vertices*, when all of them are described by a common set of traits $\Pi = \{\pi_1, \pi_2, \ldots, \pi_m\}$;
2) *non-similar vertices*, otherwise.

In fact, the second type of vertices is generalization of the first vertices' type. This observation will be used in a further part of this Section.

A. Isolation-merging function

1) Calculation for similar vertices: For the vertex $V_k, k = 1, 2, ..., n$ we will define a vector $\mathbf{I_k}$ of isolation traits as:

$$\mathbf{I_k} \stackrel{\text{def}}{=} \left(p_{k,1}, p_{k,2}, \ldots, p_{k,m}\right)^T. \tag{1}$$

Now we can propose a formula for calculating the isolation level $\mathbf{I}$ for the Layer $\mathcal{L}$ as:

$$\mathbf{I}(\{V_1, V_2, \ldots, V_n\}) \stackrel{\text{def}}{=} F(\mathbf{I_1}, \mathbf{I_2}, \ldots, \mathbf{I_n}), \tag{2}$$

where the function $F : (\Omega^m)^n \to \Omega^m$ is a *general merging function*. In this paper we will assume that traits are independent, so the function F can be defined as:

$$F(\mathbf{I_1}, \mathbf{I_2}, \ldots, \mathbf{I_n}) = \begin{pmatrix} f_1(p_{1,1}, p_{2,1}, \ldots, p_{n,1}) \\ f_2(p_{1,2}, p_{2,2}, \ldots, p_{n,2}) \\ \vdots \\ f_m(p_{1,m}, p_{2,m}, \ldots, p_{n,m}) \end{pmatrix}, \tag{3}$$

where $f_i : \Omega^n \to \Omega$, for $i = 1, 2, \ldots, m$, is a *merging function*. This model is a first level of an approximation, where each trait could be changed independently and one's trait's value does not affect other trait's value.

Now let consider the merging function $f(x_1, x_2, \ldots, x_n)$ and mark as $x_{min} = \min\{x_1, x_2, \ldots, x_n\}$ and $x_{max} = \max\{x_1, x_2, \ldots, x_n\}$. Let assume that the function satisfies the following assumptions:

$$(\forall x \in \Omega) \quad f(x, x, \ldots, x) = x, \tag{4}$$

$$\begin{gathered}(\forall 1 \leq k \leq n)(\forall x_k \leq y_k) \\ f(x_1, x_2, \ldots, x_k, \ldots, x_n) \leq f(x_1, x_2, \ldots, y_k, \ldots, x_n).\end{gathered} \tag{5}$$

Those assumptions define our view over the isolation - if the system is built from the components with the same trait's value, then the system has the same trait value as those components (4), and the isolation will not decrease when a component of a system has been enhanced (5). From these two assumptions one can deduce the following inequalities:

$$\begin{gathered}f(x_1, x_2, \ldots, x_n) \leq f(x_{max}, x_2, \ldots, x_n) \leq \\ \leq f(x_{max}, x_{max}, \ldots, x_n) \leq \cdots \leq f(x_{max}, x_{max}, \ldots, x_{max}) = \\ = x_{max},\end{gathered} \tag{6}$$

$$\begin{gathered}f(x_1, x_2, \ldots, x_n) \geq f(x_{min}, x_2, \ldots, x_n) \geq \\ \geq f(x_{min}, x_{min}, \ldots, x_n) \geq \cdots \geq f(x_{min}, x_{min}, \ldots, x_{min}) = \\ = x_{min}.\end{gathered} \tag{7}$$

The function which satisfies the inequalities:

$$x_{min} \leq f(x_1, x_2, \ldots, x_n) \leq x_{max} \tag{8}$$

will be called *the mean function*, see [28]. An example of a mean function is the generalized weighted mean (the power mean):

$$\omega_q(x_1, x_2, \ldots, x_n) = \left(\frac{\sum_{i=1}^n w_i x_i^q}{\sum_{i=1}^n w_i}\right)^{\frac{1}{q}}, \tag{9}$$

where $\sum_{i=1}^n w_i > 0$ and $w_i \geq 0$. The parameter q is a real number; there are the following important border-case formulas:

$$\begin{cases}\omega_{-\infty}(x_1, x_2, \ldots, x_n) = \min\{x_1, x_2, \ldots, x_n\}, \\ \omega_0(x_1, x_2, \ldots, x_n) = \sqrt[n]{x_1 x_2 \ldots x_n}, \\ \omega_{+\infty}(x_1, x_2, \ldots, x_n) = \max\{x_1, x_2, \ldots, x_n\}.\end{cases} \tag{10}$$

2) Calculations for non-similar vertices: More common situation is when not all considered vertices are described only by one set of traits. Let us assume that the vertex V_k is described by the set of traits $\Pi_k = \{\pi_{k,1}, \pi_{k,2}, \ldots, \pi_{k,m_k}\}$ and let us define $\Pi = \cup_{k=1}^m \Pi_k = \{\pi_1, \pi_2, \ldots, \pi_{|\Pi|}\}\}$. The goal of the reasoning is to represent the merged isolation in a space common for all vertices. Now, let us introduce the set $\Omega^* = \Omega \cup \theta$, $\theta \notin \Omega$, which has the following properties:

$$\begin{cases}(\forall x \in \Omega) & x \not> \theta, \\ (\forall x \in \Omega) & x \not< \theta, \\ (\forall x \in \Omega) & x \neq \theta.\end{cases} \tag{11}$$

The element θ is a special element, e.g. the imaginary unit i satisfies (11) when $\Omega = [0; 1]$. The aim of this value is to indicate that for considered trait and vertex the trait's value does not exists (it is undefined). Let us define the function $T_k : \Omega^{m_k} \to (\Omega^*)^{|\Pi|}$:

$$T_k \begin{pmatrix} p_{k,1} \\ p_{k,2} \\ \vdots \\ p_{k,m_k} \end{pmatrix} \stackrel{\text{def}}{=} \begin{pmatrix} r_{k,1} \\ r_{k,2} \\ \vdots \\ r_{k,|\Pi|} \end{pmatrix}, \tag{12}$$

TABLE I
EXAMPLES OF TYPICAL NORMALIZATION FUNCTIONS, BASED ON [27]

Λ	**Parameter family**	**The worst value**	**The best value**	**Typical value**	**Function** $g(x)$
$\mathbb{R}$	raising\falling	0	$\pm\infty$	β	$g(x) = 1 - 2^{-\frac{x}{\beta}}$
$\mathbb{R}$	falling\rising	$\pm\infty$	0	β	$g(x) = 2^{-\frac{x}{\beta}}$
$\mathbb{R}$	raising	$-\infty$	$+\infty$	$\beta;\beta \neq 0$	$g(x) = \left(1 + e^{\frac{\beta - x}{\lvert\beta\rvert}}\right)^{-1}$
$\mathbb{R}$	raising	$-\infty$	$+\infty$	0	$g(x) = (1 + e^{-x})^{-1}$
$\mathbb{R}$	falling	$+\infty$	$-\infty$	$\beta;\beta \neq 0$	$g(x) = \left(1 + e^{\frac{x - \beta}{\lvert\beta\rvert}}\right)^{-1}$
$\mathbb{R}$	falling	$-\infty$	$+\infty$	0	$g(x) = (1 + e^{x})^{-1}$
$[q;r] \in \mathbb{R}_{\geq 0}$	raising	q	r	$\frac{q+r}{2}$	$g(x) = \frac{x-q}{r-q}$
$[q;r] \in \mathbb{R}_{\geq 0}$	falling	r	q	$\frac{q+r}{2}$	$g(x) = \frac{r-x}{r-q}$
$\mathbb{R}$	Gaussian	$\pm\infty$	γ	β	$g(x) = 2^{-\left\lvert\frac{x-\gamma}{\beta-\gamma}\right\rvert}$

where

$$r_{k,j} = \begin{cases} \text{value of } \pi_j \text{ for } V_k, & \text{when } \pi_j \in \Pi_k \\ \theta, & \text{otherwise.} \end{cases} \tag{13}$$

Now, one can define a general merging function F^* for non-similar vertices as:

$$F^* : (\Omega^*)^{n|\Pi|} \to (\Omega^*)^{|\Pi|}. \tag{14}$$

According to equation (3), we can write:

$$F^*(\mathbf{I_1}, \mathbf{I_2}, \ldots, \mathbf{I_n}) = \begin{pmatrix} f_1^*(r_{1,1}, r_{2,1}, \ldots, r_{n,1}) \\ f_2^*(r_{1,2}, r_{2,2}, \ldots, r_{n,2}) \\ \vdots \\ f_{|\Pi|}^*(r_{1,|\Pi|}, r_{2,|\Pi|}, \ldots, r_{n,|\Pi|}) \end{pmatrix}, \tag{15}$$

where the function $f^* : (\Omega^*)^n \to \Omega^*$ is a non-similar vertex's version of the merging function f. According to equations (4,5), the following assumptions upon the f^* could be made:

$$(\forall x \in \Omega^*) \quad f^*(x, x, \ldots, x) = x, \tag{16}$$

$$\begin{gathered} (\forall 1 \leq k \leq n)(\forall x_k \leq y_k) \\ f^*(x_1, x_2, \ldots, x_k, \ldots, x_n) \leq f^*(x_1, x_2, \ldots, y_k, \ldots, x_n), \end{gathered} \tag{17}$$

$$f^*(x_1, x_2, \ldots, x_n) = \theta \iff x_1 = x_2 = \cdots = x_n = \theta. \tag{18}$$

The equation (17) requires that the values x_k and y_k must be comparable. The θ element does not satisfy this condition for any other value from the Ω^* set, according to the (11). Consequently, when one defines trait's value for an already existing vertex, the merged trait's value with isolation merging function could be higher, lower or stay at the same point.

The $f^*(x_1, x_2, \ldots, x_n)$ function could be calculated in the following way: let the $Z = (z_1, z_2, \ldots, z_{n'})$ be a string of elements from $X = (x_1, x_2, \ldots, x_n)$ created by selecting all elements except the elements equal to θ. Then, we can use e.g. (9) formula for calculations, using only values from Z. The weights should be the same for the element $z_k; 1 \leq k \leq n'$ and the corresponding element from X.

3) Choosing the merging function: The following aspects should be considered for choosing an appropriate merging function.

- Interpretation of the merged trait, e.g. available throughput for a path of vertices is upper-bounded by a minimal value, so the merging function could be defined as $f(x_1, x_2, \ldots, x_n) = \min\{x_1, x_2, \ldots, x_n\}$.
- Implementation constraints: the integer-valued weights and function's parameters could result in more accurate and faster calculations; the operations upon integers are faster than on typical IEEE 754 [29] double precision numbers. The *money-like* types which allow exact operations are slower than hardware supported types.
- Precision constraints: each operation on non-integer number suffers from the finite precision problem, which causes losing the information on the less-important part of a number. Using large number of operations (multiplication, adding, power) leads to very uncertain results.
- The expected value of a merging function: the normalization function defines the central element $C = g(\beta)$ of Ω (i.e., 0.5 for the set $\Omega = [0, 1]$) as a typical value which should be close to the expected value of the merging function. This value could depend on the number of merged properties and the function's internal parameters, like the parameter q for the generalized mean. The Figure 3 shows how the mean value changes for the generalized mean function. Only the arithmetical mean ($q = 1$) from this functions family satisfies, for all $n > 1$, the equation:

$$\mathbb{E}\left(f_q(x_1, x_2, \ldots, x_n)\right) = g(\beta). \tag{19}$$

- The shape (e.g. convexness) of a merging function: traits are interpreted with some logic, e.g.:

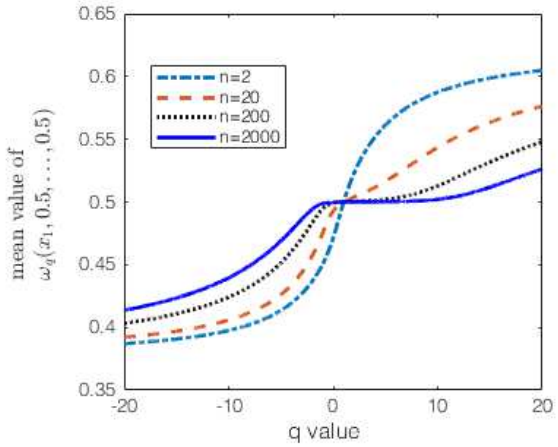

Fig. 3. Mean value of ω_q function for various number of traits n and the parameter q.

- *The OR logic*: the merged trait's value is more strongly dependent on large values than on small ones. This kind of traits should be merged with convex functions. An example trait is *number of CVE vulnerabilities* for a network's node.
- *The AND logic*: the merged trait's value is more strongly dependent on small values than on large ones. This kind of traits should be merged with concave functions. An example trait is *encryption strength* in number of key's bits for a network's node.
- *The neutral logic*: the merged trait's value depends on the small and large values equally. This kind of traits should be merged with function which satisfies the following equation:

$$\frac{\partial^2}{\partial x_k^2} f(x_1, x_2, \ldots, x_k, \ldots, x_n) = 0. \tag{20}$$

B. Calculating the isolation vector

The isolation vector for a network could be calculated recursively by calculating isolation vectors for subnetworks and a group of vertices from a layer. This *bottom-up* method allows adding special information, which should be included into the calculation process, and which cannot be defined for vertices in lower layers.

C. The comparison problem for vectors

From practical point of view, it is very important to compare calculated isolation vectors which are defined over a common set of traits. Two vectors, which have only one different trait's value, are easy to compare. When multiple traits' values are different, the situation is much more complicated. In mathematical terms the aim is to define the linear order for the set $(\Omega)^{|\Pi|}$; the θ value could be omitted, because each trait should be defined for at least one vertex in a graph, so the final vector has all non-θ values. Such an order could be defined by assigning to each of isolation vectors a number, which can be compared. This assignment is provided by *the extracting function* $\Phi : (\Omega)^{|\Pi|} \to \Omega$. This function should satisfy following inequalities for each $x_k \in \Omega$:

$$\frac{\partial}{\partial x_k} \Phi(x_1, x_2, \ldots, x_k, \ldots, x_n) \geq 0, \tag{21}$$

$$\frac{\partial^2}{\partial x_k^2} \Phi(x_1, x_2, \ldots, x_k, \ldots, x_n) \leq 0. \tag{22}$$

The inequality (21) means that the extracting function is raising for each of its parameters. The inequality (22) describes the assumption that the function is concave for each parameter.

D. Extracting the single value

The following example function family, which satisfies the assumptions (21, 22) could be used for extracting the single value for an isolation vector:

$$\Phi_q(x_1, x_2, \ldots, x_k, \ldots, x_n) = 1 - \left(\frac{1}{n} \sum_{i=1}^{n} (1 - x_i)^q \right)^{\frac{1}{q}}. \tag{23}$$

This function has the following partial derivatives:

$$\begin{aligned} &\frac{\partial}{\partial x_k} \Phi_q(x_1, x_2, \ldots, x_k, \ldots, x_n) = \\ &= \left(\sum_{i=1}^{n} (1 - x_i)^q \right)^{\frac{1}{q}-1} \frac{(1 - x_k)^{q-1}}{n} \geq 0, \end{aligned} \tag{24}$$

$$\begin{aligned} &\frac{\partial^2}{\partial x_k^2} \Phi_q(x_1, x_2, \ldots, x_k, \ldots, x_n) = \\ &= \frac{1 - q}{n^2} \left(\sum_{i=1}^{n} (1 - x_i)^q \right)^{\frac{1}{q}-2} (1 - x_k)^{q-2} \sum_{i=1; i \neq k}^{n} (1 - x_i)^q . \end{aligned} \tag{25}$$

If $q \geq 1$, then the second derivative calculated in the equation (25) is non-positive, so the assumption defined in equation (22) is satisfied.

V. Examples

In this section we consider two examples: calculating the isolation of a single node in a network and calculating the isolation over an E2E path for a single slice. The second example contains a list of steps which are included in the isolation assessment process.

A. Example 1. Single node

Let us consider a single network element with traits, traits' values and normalization functions defined in the Table II. The normalization functions are fitted to expected traits' domains, which is the main reason during selecting the normalization function. We assumed for the trait *symmetric encryption algorithm's strength* that at this moment the largest available (and practically used) key size is 256 bits. Theoretically, the key could have any length (e.g. one-time keys for stream ciphers), but very large key size is impractical as well, so in such typical case will not be considered as an option. Since the domain is constrained to the range of integer numbers, the linear normalization function for this trait was chosen.

TABLE II
SET OF NORMALIZATION FUNCTIONS AND NORMALIZED VALUES FOR A SINGLE NODE

Parameter	Value	Normalization function	Normalized value
Symmetric encryption algorithm's strength $\begin{cases} a = 0 \\ b = 256bits \end{cases}$	160 bits	$g(x) = \frac{x-a}{b-a}$	0.625
Average time between vulnerabilities assessments $\beta = 4h$	$8h$	$g(x) = 2^{-\frac{x}{\beta}}$	0.25
Amount of electromagnetic radiation $\beta = 25dB\mu V/m$	$55dB\mu V/m$	$g(x) = \left(1 + e^{\frac{x-\beta}{\lvert\beta\rvert}}\right)^{-1}$	0.2315

The isolation vector for this vertex (which is a representation of this single node scenario) is $(0.625, 0.25, 0.2315)$. We can *extract the single value* from this vector using the function $\Phi_2(x_1, x_2, x_3)$:

$$I_{final} = 1 - \sqrt{\frac{\sum_{i=1}^{3}(1-x_i)^2}{3}} = \\ = 1 - \sqrt{\frac{(1-0.625)^2 + (1-0.25)^2 + (1-0.2315)^2}{3}} = \\ = 0.3433. \tag{26}$$

B. Example 2. A simple end-to-end slice

The process of isolation analysis is defined as follows:

1) definition of use-case to be modeled;
2) definition of all network resources to be modeled (nodes and links);
3) definition of each resource affiliation to RAN and/or CN;
4) for each resource definition of relevant isolation parameters and properties to be determined or measured;
5) for CN, RAN and E2E definition of relevant isolation parameters and properties to be determined or measured;
6) choosing a set of functions to normalize isolation parameters and properties;
7) choosing a set of functions to calculate isolation from parameters and properties;
8) choosing a set of functions to compare two or more isolation tuples;
9) definition of a slices spanned across previously defined resources;
10) for each layer, calculation of slices' isolation, with a previously chosen set of functions;
11) performing comparison, if needed, with a previously chosen set of comparison functions.

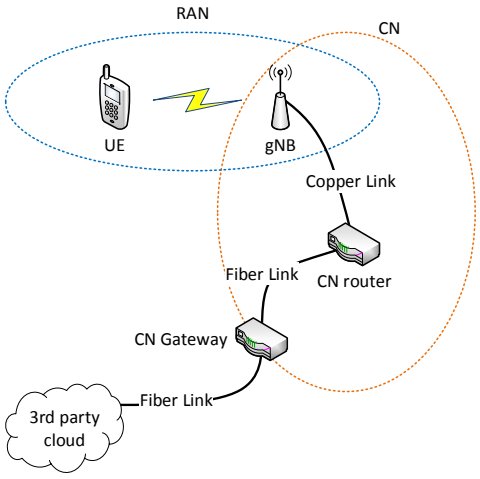

Fig. 4. The example of a network scenario for the purpose of isolation analysis.

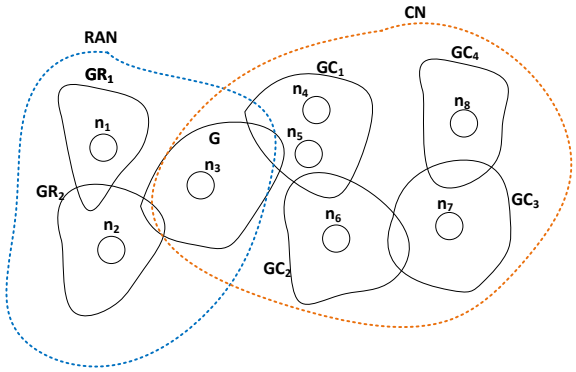

Fig. 5. The representation of the selected piece of network in the Graph model.

As an example, the simple network is analyzed in context of E2E calculation of isolation (see Figure 4). RAN network consists of a single User Equipment (UE), which connects with gNB node using Radio Link. CN consists of three types of equipment: gNB (which is common for RAN and CN), CN Router and CN Gateway. gNB is connected with CN router using Copper Link and CN Router is connected with CN Gateway using Fiber Link. CN Gateway is connected with a 3rd-party-vendor cloud using Fiber Link, which is considered outside of RAN and CN.

The described piece of network can be represented as a graph structure using the Graph model (see Figure 5)

RAN and CN are the hypergraphs which include sub-hypergraphs: GR_x, GC_x and G (GR_x - RAN sub-hypergraph of the element x, GC_x - CN sub-hypergraph of the element x, G sub-hypergraph of the gateway). Each sub-hypergraph has several nodes (n_i) which present the properties. Every property can be virtualized: v_1n_1, v_2n_1, v_3n_1, etc. (v_in_j means a virtual property "i" of a physical property "j").

According to the process of E2E isolation analysis, each step may be described as follows:

1) **Use case definition:** in a network depicted in the Figure 4 a slice is being configured from UE to CN gateway. There is a need to assess isolation level of the slice based on the equipment and media used to serve this slice. There are two types of routers in CN which can be chosen in the network's implementation (it is assumed that each of them has assessed the same chosen parameters and properties). There is a need to assess the isolation of the slice while the first and the second types of routers are chosen. The isolation in these two cases should be compared to choose a solution with better isolation for a slice. The analysis should be performed only on Layers 1, 2 and 3 of the model.
2) **Network resources to be modeled:** in the analysis there should be modeled the following resources:
   - User Equipment in RAN;
   - Radio Link in RAN;
   - gNB as a gateway between RAN and CN (affiliated to RAN and CN);
   - Copper Link in CN;
   - CN Router in CN;
   - Fiber Link in CN;
   - CN Gateway as a gateway between CN and 3rd-party-cloud (affiliated to CN).

   Figure 5 represents the network for the isolation analysis in a graph form.
3) **RAN-CN affiliation:** the affiliation was described in the previous point.
4) **Parameters and properties for elements:** the following isolation parameters and properties were identified for each resource:
   - User Equipment in RAN (GR_1):
     - slicing application: programming language used (e.g., Java), enumeration (n_1).
   - Radio Link in RAN (GR_2):
     - symmetric encryption algorithm strength: the number of bits, a nonnegative integer (n_2).
   - gNB as a gateway between RAN and CN (G):
     - average time between vulnerabilities assessments: hours, a nonnegative real number (n_3).
   - Copper Link in CN (GC_1):
     - symmetric encryption algorithm strength: the number of bits, a nonnegative integer (n_4);
     - amount of electromagnetic radiation: i.e., dBV/m, a real number (n_5).
   - CN Router in CN (GC_2):
     - average time between vulnerabilities assessments: hours, a nonnegative real number (n_6).
   - Fiber Link in CN (GC_3):
     - symmetric encryption algorithm strength: the number of bits, a nonnegative integer (n_7).
   - CN Gateway as a gateway between CN and 3rd-party-cloud (GC_4):
     - average time between vulnerabilities assessments: hours, a nonnegative real number (n_8).
5) **Parameters and properties for CN, RAN and E2E:** the following isolation parameters and properties were identified:
   - Core Network (CN):
     - symmetric encryption algorithm strength;
     - amount of electromagnetic radiation;
     - average time between vulnerabilities assessment.
   - Radio Access Network (RAN):
     - symmetric encryption algorithm strength;
     - programming language used;
     - average time between vulnerabilities assessment.
   - End-to-End (E2E):
     - symmetric encryption algorithm strength;
     - programming language used;
     - amount of electromagnetic radiation;
     - average time between vulnerabilities assessment;
     - (produced by extracting the single value from other traits) isolation level.
6) **Choose a set of functions to normalize isolation parameters and properties:** These functions are defined in the Table III.
7) **Choose a set of functions to calculate isolation from parameters and properties:** We will use as *the isolation-merging function* the following formula:

$$\omega_{-1}(x_1, x_2, \ldots, x_n). \tag{27}$$

   for calculating the isolation inside the RAN or CN part of the network and the weighted version of this mean for calculating isolation E2E for these two parts of the network. The value $q = -1$ is used, because it is very fast to implement, it is a merging function with the *AND logic*. The Figure 3 shows that this function has the mean value very close to 0.5 (the central element of the Ω set), which is advisable.
   We use the weighted function for merging isolation between CN and RAN for flattening an impact of each graph's vertex in results. The weights are defined in the column *Weights* in the Table V. Since the gNB node (and in consequence its vertex in the Graph model) belongs to RAN and CN as well, its impact is doubled. To avoid this excessive influence, the subnetworks on the path should be separated.
8) **Choose a set of functions to compare two or more isolation tuples:** We will use the proposed method for calculating the final isolation and the calculated final isolations (the I_{final} values) will be used for comparisons of the slices' isolation levels.
9) **Define a slice spanned across previously defined resources:** We assume in this scenario that the slice is from UE to the 3rd-party-cloud and contains all devices and links between these nodes.
10) **For each layer, calculate slices isolation with a previously chosen set of functions:** The results of

TABLE III
SET OF NORMALIZATION FUNCTIONS AND NORMALIZED VALUES

Part	Element	Parameter	Value	Normalization function	Normalized value	Typical values / margin values
RAN	UE in RAN	Programming language used	C++ (0.75)	N/A	0.75	N/A
	Radio Link in RAN	Symmetric encryption algorithm strength	160 bits	$g(x) = \frac{x-a}{b-a}$	0.625	$\begin{cases} a = 0 \\ b = 256bits \end{cases}$
gNB	gNB as a gateway between RAN and CN	Average time between vulnerabilities assessments	8h	$g(x) = 2^{-\frac{x}{\beta}}$	0.25	$\beta = 4h$
CN	Copper Link in CN	Symmetric encryption algorithm strength	128 bits	$g(x) = \frac{x-a}{b-a}$	0.5	$\begin{cases} a = 0 \\ b = 256bits \end{cases}$
		Amount of electromagnetic radiation	$55dB\mu V/m$	$g(x) = \left(1 + e^{\frac{x-\beta}{\lvert\beta\rvert}}\right)^{-1}$	0.2315	$\beta = 25dB\mu V/m$
	CN Router in CN	Average time between vulnerabilities assessments	12h	$g(x) = 2^{-\frac{x}{\beta}}$	0.125	$\beta = 4h$
	Fiber Link in CN	Symmetric encryption algorithm strength	256 bits	$g(x) = \frac{x-a}{b-a}$	1	$\begin{cases} a = 0 \\ b = 256bits \end{cases}$
	CN Gateway as a gateway between CN and 3rd party cloud	Average time between vulnerabilities assessments	4h	$g(x) = 2^{-\frac{x}{\beta}}$	0.5	$\beta = 4h$

TABLE IV
ISOLATION INSIDE RAN AND CN

Part	Parameter	Values	Merged values
RAN	Average time between vulnerabilities assessments	0.25	0.25
	Encryption algorithm strength	0.625	0.625
	Programming language used	0.75	0.75
CN	Encryption algorithm strength	0.5, 1	$\frac{2}{\frac{1}{0.5}+\frac{1}{1}} = 0.6667$
	Amount of electromagnetic radiation	0.2315	0.2315
	Average time between vulnerabilities assessments	0.25, 0.125, 0.5	$\frac{3}{\frac{1}{0.25}+\frac{1}{0.125}+\frac{1}{0.5}} = 0.2143$

TABLE V
ISOLATION VECTOR VALUES

Parameter	Values	Weights	Isolation vector's values
Programming language used	0.75	1	0.75
Encryption algorithm strength	0.625, 0.6667	1/3, 2/3	$\frac{1}{\frac{1/3}{0.625}+\frac{2/3}{0.6667}} = 0.6522$
Average time between vulnerabilities assessments	0.25, 0.2143	1/4, 3/4	$\frac{1}{\frac{1/4}{0.25}+\frac{3/4}{0.2143}} = 0.2222$
Amount of electromagnetic radiation	0.2315	1	0.2315

calculations are in Tables IV and V. From the obtained results presented in the Table V, we can build the *isolation vector* $(0.75, 0.6522, 0.2222, 0.2315)$ for this example network. One can *extract the single value* from this vector using the function $\Phi_2(x_1, x_2, x_3, x_4)$:

$$I_{final} = 1 - \sqrt{\frac{\sum_{i=1}^{4}(1-x_i)^2}{4}} = 0.4128. \qquad (28)$$

11) **Perform comparison, if needed, with a previously chosen set of comparison functions:** The defined slice has I_{final} in a medium level and it could be improved. From the Table V we can choose the worst isolation trait (by its value): **Average time between vulnerabilities assessments**. In this scenario this trait is merged from RAN and CN with different weights and with different values. The vertex to improve could be determined by exhaustive search where all traits, except current vertex's traits, has origin values and the current vertex's trait's value is set to 1 (the ω value). The result of this search is summarized in the Table VI. The *CN Router in CN*'s trait's value should be improved, because enhancement of this element could make the biggest effort on the I_{final} value. Let us assume now, that we improved this trait's value to $4h$ (0.5 after normalization). After this operation, the value of this trait in the isolation vector is 0.3333 and the $I_{final} = 0.4481$.

C. Discussion of the results

The I_{final} values are below the 0.5, which should be expected, because the traits' values in both examples are generally low or medium. In this scenario the trait's values are higher than 0, so the ω_{-1} function could be used for merging isolation. If zero values for the traits are expected, the parameter q should be greater than 0. Such a situation

TABLE VI
SEARCHING FOR THE BEST VERTEX TO IMPROVE THE WORST TRAIT: THE RESULTS

Vertex	**Origin trait's value**	**Max. available merged value in RAN**	**Max. available merged value in CN**	**Max. trait's value in the isolation vector**
G - gNB as a gateway between RAN and CN	0.25	1	0.2727	0.3333
GC_2 - CN Router in CN	0.125	0.25	0.4286	**0.3636**
GC_4 - CN Gateway as a gateway between CN and 3rd party cloud	0.5	0.25	0.2308	0.2353

could happen if linear functions are used for normalization or one of the properties' values is zero.

A change in the Step 11 for the Example 2 is small, because in the isolation vector there exists a parameter with the value 0.2315, which has a significant impact on the I_{final} and which should be improved.

The procedure for finding the best vertex and its trait to improve the isolation is defined in a heuristic way. There is a space for further improvements and research. In this case we assumed that each trait has the same merging function, but it could be trait-dependent, and it should be considered by the algorithm executed in the Step 11. This algorithm also could consider the cost of each trait's improvement in a vertex.

VI. CONCLUSIONS AND FUTURE WORK

In this paper the Graph-based quantitative description of networks' slices isolation has been proposed. We have presented a model which can be used to represent in a transparent way a slice in 5G Network, allowing its detailed analysis and supporting additional calculations. As an example of such calculations we have considered the problem of estimating the isolation level of the end-to-end slice and also isolation level of each network's element, both, physical and virtual. Moreover, we have proposed a general framework and the mathematical rules defining how the isolation of that slice can be calculated. Finally, in the paper we have included examples of isolation calculation for a single node and for the end-to-end scenario of a single slice. The numerical results proved to be promising, indicating possibilities of application of our approach in slices management and optimization.

The paper presents a research on its initial state. In our opinion the future work on the presented topic should be continued. Among others, it should include the following issues:

- Validation and verification of the presented Graph model by modeling different scenarios;
- Development of methods for comparing different types of slices;
- Proof of concept application development;
- Development of a set of parameters and properties for devices and links;
- Development of better algorithm for selecting a trait and graph's vertex to improve the isolation;
- Research of integration of the presented model with 5G MANO systems.

***Abstract*—Nowadays the practice of researching pseudorandom number generators (PRNG) becomes more scalable because of its spreading in many spheres of computer science and, especially, cybersecurity. The problem is that existing generators are still have many disadvantages in terms of velocity, complexity or flexibility. Thus, the area of researching new algorithms of generating pseudorandom sequences is more than just applicable method, but the target for multiplying cybersecurity from the hardware to application level.**

This leads to make the set of available and useful PRNG larger and better by their features, like velocity, performance, simplicity in realization. These features match PRNG, based on cellular automata (CA), but not all rules, used in CA are appropriate for their transition functions. Bent functions are perfectly complement statistical weakness of some rules because of their non-linearity without loss of other features.

I. Introduction

MODERN society is vulnerable enough for hacking attacks, which are very large-spectered, from hardware attacks (on microchips) to web hacking (or application level hacking). Since, the first thing for computer science society and cybersecurity itself, is to protect personal data of users, which is the main aim for hackers. When we say "protect personal data", it comes cryptography methods in the first sight, like ciphers or lightweight cryptography, or coding theory. The basement of majority of cryptographical methods is generating random numbers, which can be both physically processed and mathematically. This paper is about second one, to be more exact, about pseudorandom number generator, based on homogenous structures using bent functions.

A. Homogenous structures overview

Lets take the set of k-dimensional vectors Z^k, set of 1 and $0 - E_n$, ordered set $V = (\alpha_1, \alpha_{(h-1)})$, where α_i is k dimensional vector from Z^k. Besides, lets determine a function $\phi = \phi(x_0, x_1, , x_{(h-1)})$, $\phi : (E_n)^h \rightarrow E_n$, additionally $(\phi(0, 0, ..., 0) = 0)$. As the result we'll get "four" $\sigma = (Z^k, E_n, V, \phi)$. That will be formal determinition of Homogenous structures (HS) [7], where E_n set of states of one cell in ϕ - local transition function.

Generally, HS are usually represented by ordered set of many Moore automata [13], which have states of other automata as input. To understand which of automata can influence on another one special scheme or neighborhood template can be used. There are several schemes, that are usually used in HS, like Moore's scheme (2 dimensional scheme, where target cell, surrounded by square of cells 3x3 if radius $r = 1$, or 5x5 if radius $r = 2$) or Neuman's one (2 dimensional scheme, where non diagonal cells surrounding the target one)

HS can be determined as dynamical discrete systems, where time and space are discrete. Changing of states of cells is conditioned by function ϕ, which is also included in rule. The rule is like a finite automaton with input, transition function and output.

Without loss of formalization and main idea, here and further term HS will be replaced by Cellular automata (CA), as this term is more widespread. Sharing CAs by complexity feature, it can be seen that there are two types of them: uniform CA (when all the grid have one rule and only one neighborhood template) or non-uniform CA (several neighborhood templates or(and) several rules). From this, perfomance features of both CA types are almost the same, besides memory (non-uniform needs more memory space for keeping rules and neighborhood templates). To save boards of the grid of CA, we will consider, that 2-dimensional grid is about toroidal form (without distortion in sizes).

Time spacing is a method of producing sequences with periodically interruptions in reading bits for one or several evolutions (iterations). That means, that only several iterations will influence on resulting bit sequence.

Site spacing is a method of producing sequences with periodically skipping of some bits in the grid in every iteration.

Widely spread so-called Wolfram's notation [17] for the rules. Firstly, lets call configuration the set of ones and zeros (two-state CA, where the sequence is considered as random number) at particular discrete moment of time. Further rule numbers are also suggested by Wolfram. Wolfram's rule 30 as an example:

How Wolfram's rules can be encoded goes further. For

example, $f(111) = 0, f(110) = 0, f(101) = 0, f(100) = 1, f(011) = 1, f(010) = 1, f(001) = 1, f(000) = 0$, is denoted rule 30.

B. Pseudorandom number generators (PRNG) overview

Random numbers are needed in different applications, i.e. in the cryptography area and coding theory. A number of algorithms need repeatable random numbers, based on deterministic algorithms, it is more correct to call such numbers pseudorandom, since they differ from the true random sequences obtained as a result of natural physical process.

Random number generators should have a number of properties if they are to be successfully applied in long stochastic models, like those used in computational physics. The most important properties from this point of view are good results in standard statistical tests for randomness, computational efficiency, a long period (the minimum number between repetitions) and the reproducibility of the sequence, e.g. NIST Test Suite. Considering several examples of PRNG, let's pay attention to Linear Congruential method and LFSR. They are quite simple, but perfectly describe the main idea of pseudorandom numbers.

C. Bent function

Bent functions are boolean functions with an extreme value nonlinearity. The measure of nonlinearity is an important characteristic boolean functions in cryptography. Linearity and properties close to it testify to the simple structure of this function and, as a rule, represent a large source of information about many other of its properties.

The nonlinearity of a function f is the distance from f to a class of affine functions. We denote the nonlinearity of the function f in terms of N_f :

$$N_f = d(f, A(n)) = \min_{g \in A(n)} d(f, g)$$

where $A(n)$ is class of affine functions.

The formula for calculating N_f by the Walsh-Hadamard transform:

$$d(\langle a, x\rangle, f) = \hat{f}(a) = 2^{n-1} - \frac{1}{2}\max_{a \in Z_2^n} |\hat{f}(a)|$$

Let $f \in P_2(n)$, write for it the Parseval equality:

$$\Sigma_{a \in Z_2^n} \hat{f}^2(a) \geq 2^n$$

We have 2^n non-negative summands whose sum is 2^{2n}. Consequently $\max\limits_{a \in Z_2^n} \hat{f}(a) \geq 2^n$, from which it follows that $\max\limits_{a \in Z_2^n} |\hat{f}(a)| \geq 2^{\frac{n}{2}}$. Therefore

$$N_f = 2^{n-1} - \frac{1}{2}\max_{a \in Z_2^n} |\hat{f}(a)| \leq 2^{n-1} - 2^{\frac{n}{2}-1}$$

The function $f \in P_2(n)$ is called maximally nonlinear if $N_f = 2^{n-1} - 2^{\frac{n}{2}-1}$

Definition: A bent function is a Boolean function with an even number of variables for which the Hamming distance from the set of affine Boolean functions with the same number of variables is maximal.

The properties of bent functions:

1) bent functions exist only for even n;
2) bent functions depend statistically on all their arguments;
3) let f be a bent function, and h belong to the class of linear functions. Then $f \oplus h$ belongs to the class of bent functions;
4) Let $(f \in P_2(n), g \in P_2(m)$ - be functions of disjoint sets of variables. Then $f \oplus h$ is a bent function if and only if f and g are bent functions.

We give examples of bent functions of a different number of variables.

for $n = 4$:

$$f(x_0, x_1, x_2, x_3) = x_0x_1 + x_2x_3$$
$$f(x_0, x_1, x_2, x_3) = x_0x_1 + x_2x_3 + x_0 + x_1$$

for $n = 6$:

$$f(x_0, x_1, x_2, x_3, x_4, x_5) = x_0x_1 + x_2x_3 + x_4x_5$$
$$f(x_0, x_1, x_2, x_3, x_4, x_5) = x_0x_1x_2 + x_1x_3x_4 + x_0x_1 + x_0x_3 + x_1x_5 + x_2x_4 + x_3x_4$$

for $n = 8$:

$$f(x_0, x_1, x_2, x_3, x_4, x_5, x_6, x_7) = x_0x_1x_2 + x_1x_3x_4 + x_2x_3x_5 + x_0x_3x_6 + x_2x_4 + x_1x_6 + x_0x_4 + x_0x_5 + x_3x_7$$

From the point of view of cryptography, the important criteria that a Boolean function f of n variables must satisfy are the following :

- equilibrium - the function f takes values 0 and 1 equally often;
- the propagation criterion $PC(k)$ of order k - for any nonzero vector $y \in Z_2^n$ weight at most k, the function $f(x + y) + f(x)$ is balanced;
- the maximum nonlinearity - the function f is such that the value of its nonlinearity N_f is maximal;

II. Algorithm of generating pseudorandom numbers on CA using Bent functions

The main idea of algorithm is in using CA Rules and bent functions to generate pseudorandom sequences of bits by usage of simple XOR operation to improve statistical features of CA sequences. Unique features of bent functions, like non-linearity and simplicity allows to generate quite random sequences in the grid of CA. Also, in terms of hardware or software implementation bent functions are simple enough to realize. As a result, we will get deterministic bent function output with n inputs of CA cells with Wolfram's notation rules.

A. Grid

From the point of view of geometry grid in our algorithm is represented by 2-dimensional parallelogram with sizes p and q, divided by equal cells, which contains only one of two possible states 0 or 1. Actually, the grid can be chosen with random sizes, but it is strongly recommended to create the grid, where p and q are prime numbers. It can improve periodical feature of output sequence. Let's divide this grid into two blocks, where

one block is for CA rule and another one is for bent function sequence. Every block b_i is 2 dimensional parallelogram with sizes l_{b_i} and w_{b_i}. Obviously, each block consists of $l_{b_i} * w_{b_i}$ cells. But result output sequence will be only from block with CA rule.

The matter is the fact, that the grid should be filled with initial states to produce next evolutions. For this reason there are a number of ways to do it. As we need deterministic algorithm and minimum of memory usage, it must be simple way to fill the grid. The method, describing below is called NESW (NESW- North, East, South, West). Formally, we take a result of size multiplication $l_{b_i} * w_{b_i}$ of each block b_i and start filling it cyclically from the South-West corner of block with the bits of received number, moving to the North till the edge of block or almost filled cell, then moving to the East, South and West, repeating conditions. This method also reminds spiral moving to the center of the grid of the block. The whole process is demonstrated on the Fig. 1

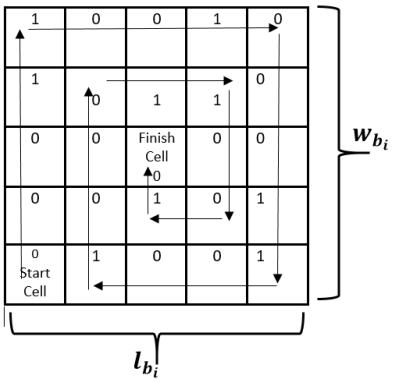

Fig. 1: b_i block grid view with NESW scheme of filling

B. Bent functions

As it mentioned before, traditional pseudorandom generators on CA use rules by Wolfram's notation, e.g. $Rule30$ or $Rule90$ and $Rule150$ together for better results. Another option is using some Boolean functions for changing states of cells in the grid, but these functions were linear. In this paper we research possiblity of using non-linear functions (bent functions as denoted before). But bent functions exist only for even number of arguments. And standard templates of neighborhood don't match for this condition. Fortunately, we can choose neighborhood template for the CA. Actually, we can choose as many templates as a number of blocks is and use different bent functions with only one restriction - possible lack of memory. Other sides of this method is flexible enough for realization.

So, we have m blocks in the grid and can choose $t_n \leq m$ templates of neighborhood and $t_f = t_n$ number of bent functions. We define target cell as a cell, which next state would be defined by bent function output.

Defining conditions for templates and bent functions:

1) number of cells in each $i-$th template. including target cell, must be even;
2) obviously number of cells is equal to number of arguments of appropriate bent function in the same block;
3) each b_i block has abstract toroidal form without size distortions;
4) target cell could be chosen anywhere in neighborhood template.

Now, using bent function $f(x_0, x_1, x_2, x_3) = x_0x_1 + x_2x_3 + x_0 + x_1$ lets see how our target cell will change on the next iteration (other cells should be changed also, but we want to check the output of function).

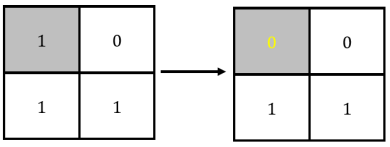

Fig. 2: How bent function works

C. Result

As we defined before the first block is our clasical CA with its own rule, but not all the rules produce statistically strong sequences. To improbe this scenario, we propose the second block in the grid, which would be producing by bent function. After needed number of evolutions block $b_1 XORing$ with block b_2 bit by bit, with appropriate size of sequence. So far, it can be concluded, that resulting sequence in block b_1 would be much more statistically strong. Thus, we can increase the set of rules, which produces strong, random and flexible sequences of bits.

D. Repeating

As our algorithm is deterministic, that leads to repeating evolution of CA with the same input and initial states. For this aim it can be generated abstract key to pass it through the channel for checking identity. So, the key K may be interpreted like the following sequence of bits. We use symbol | to mark concatenation.

$$K = p|q|l_{b_1}|w_{b_1}|...|l_{b_m}|w_{b_m}|t_{v_1^1}|t_{v_1^2}|...|t_{v_m^1}|t_{v_m^2}|V_1|...|V_m|T$$

where $t_{v_i^j}$ is the size of template parallelogram, including all possible cells in the template. And V_i are sent like the sequence of bits, where each bit, if it is 1 than cell is in the template, and when it is 0, than out of template.

Here are numbers of cells, instead of which should placed 1 or 0. T is bit sequence for determining all of bent functions, using in algorithm and other needed meta information. Thus, in spite of the fact that we must send such a long sized key, we can put some data in the boundary cells, placed around our main grid in order to save correct transition of state in case of software realization.

III. Test results

Our algorithm was tested with the help of NIST Test Suite, which developed for testing RNG and PRNG. The process of test involved: generation sequences of bits by our algorithm (1000000 bits), testing .txt file with sequence with NIST Test Suite. We tested various numbers of bent functions up to 16 arguments with different neighborhood templates appropriately, NESW method of filling the grid with initial states. Results of tests are averaged for all the experiments.

Head parameter of NIST Test Suite, showing the quality of sequence is $P-value$, which shows the difference between testing sequence and random sequence. The test statistic is used to calculate a $P-value$ that sumarizes the strength of the evidence against the null hypothesis. For these tests, each $P-value$ is the probability that a perfect random number generator would have produced a sequence less random than the sequence that was tested, given the kind of non-randomness assessed by the test. If a $P-value$ for a test is determined to be equal to 1, then the sequence appears to have perfect randomness. A $P-value$ of zero indicates that the sequence appears to be completely non-random. A significance level (α) can be chosen for the tests. If $P-value \geq \alpha$, then the null hypothesis is accepted; e.g., the sequence appears to be random. If $P-value < \alpha$, then the null hypothesis is rejected; e.g., the sequence appears to be non-random. The parameter α denotes the probability of the $TypeI$ error (if the data is, in truth, random, then a conclusion to reject the null hypothesis (e.g., conclude that the data is non-random) will occur a small percentage of the time) [10]. α is equal to 0.01.[10]

Here is the table (Fig. 3), which shows the difference on the NIST Test Suite between "clear" usage of $Rule30$ - $rule30$ column, with bent function of 4 arguments - $bent4$ column and bent function of 6 arguments - $bent6$ column. All bent functions were balanced: $f(x) + f(x + y)$ form, where x denotes vector of arguments, and y - random vector.

For $bent4$ variant we used the following function:

$$f(x_0, x_1, x_2, x_3) = x_0x_1 + x_1x_2 + x_2x_3$$

and as random vector was $y = 1011$

For $bent6$ variant we used the following function:

$$f(x_0, x_1, x_2, x_3, x_4, x_5) = x_0x_1 + x_2x_3 + x_4x_5$$

and as random vector was $y = 101110$

There will be represented results of average tests on about 100 rules without bent functions and with them of 4 and 6 arguments of Proportion criteria (Fig. 4) and P-value criteria (Fig. 5)

IV. Conclusion

In spite of the fact, that not all the rules in classical CA can't be strongly recommended for generating pseudorandom sequences and numbers, we can find a way to increase statistical features up to hundred times with only using bent functions without loss of velocity and simplicity. Thus, the main advantage of this idea is that the set of using rules enlarges and can be used in a different way with results near needed distribution.

Abstract—**This paper describes an algorithm for creating hash function, resistant for quantum computer. The given approach is based on the problem of solving a system of polynomial equations in integers, where the number of equations is less than the number of unknown parameters. The developed algorithm is parameterized so the result of the hash function depends on several parameters, therefore, it will take considerably longer to select the solution of the task. The avalanche effect is about 50%, collision is impossible because the task to find a solution of the described system of equations with a degree greater than 3 is algorithmically unsolvable. This hash function was developed for blockchain to ensure its integrity, but it can also be used in any application where a hash function is needed.**

I. Introduction

SINCE Peter Shor has been demonstrated the solvability of the problem of discrete logarithm factorization using quantum computer in 1995 [1], there was become actually a post-quantum cryptography. It was necessary to develop such algorithms that could not be solved with the help of quantum computers.

Blockchain technology become popular for different kinds of applications: in banking, gambling, registries and etc. It uses hash function – cryptographically primitive for supporting invariability and consistency of data.

Hashing in blockchain is the process of converting an array of input data of arbitrary length into an output bit string. Hash function uses for making a digest of blocks or some another data, stored not only in blockchain. Hash functions guarantee the "irreversibility" of data.

But inventing quantum computers will force to develop a hash function resistant to the quantum computers.

In developing the hash function algorithm for the blockchain technology, some requirements is important: hash function should be resistance to collisions of first and second kind and it should have a high avalanche effect.

A. Motivation

At present, post-quantum cryptography is based on four approaches that guarantee resistance to quantum computers These are Code-based cryptography, Hash-based Digital Signature Schemes, Multivariate Public Key Cryptography, Lattice-based Cryptography [2].

Our algorithm is based on problem where the number of equations is less than the number of unknown parameters.

B. Algorithm Idea

As already mentioned, post-quantum cryptography is based on algorithmically unsolvable problems. We describe two complexity problems (we call it A and B) that are suitable for us. Our approach is constructed on Problem B, Problem A is its particular case. The work of Aitai [3] is equivalent to Problem A. In this section, we will show the transition from problem A to problem B and justify using of these computational problems.

Problem A. It is needed to find the solution of a system of linear Diophantine equations in integers.

Strongly underdefinished system of equations or a system where the number of equations is substantially less than the number of unknowns is given:

$$\sum_{j=1}^{n} a_{ij}x_j = d_i \; a_{ij}, d_i \in \mathrm{Z},$$

$$i = 1,2,\dots,m, j = 1,2,\dots,n, n > m$$

If there are restrictions, such as $x_j \geq 0,\ j = 1,2,\dots,n$ or $x_j \in \{0,1\}, j = 1,2,\dots,n$ - this task becomes the task of integer programming. Particularly interesting for encryption is the case where $n > m$ (it is a strongly underdefinished system of linear equations). In particular, if $m = 1$ and $x_j \in \{0,1\}, j = 1,2,\dots,n$, then this task is the task of the knapsack problem or subset-sum problem.

The scheme of the hash function, described by M. Aitai in 1996, is a special case of problem A. In the original article it tells about the lattice theory, but we show that the problem on lattices is equivalent to the described problem A.

Let us describe the scheme of the hash function of M. Aitai.

A randomly selected matrix $\mathrm{A} \in \mathrm{Z}_p^{n\times m}$ of dimension $n \times m$ is chosen, where $n < m$. Vector $\mathrm{x} \in \mathrm{Z}_p^m (d < p)$ will be hashed.

For this the system $\mathrm{A}x = mod(p) \in \mathrm{Z}_p^n$ is calculated, where $\mathrm{A}x$ is the hash of the vector x.

Note, that the parameters are set: n, m, q, $d > 1$, $n < m$, $q > d$, $\mathrm{A} \in \mathrm{Z}_p^{n\times m}$.

We note that the solution of equation $\mathrm{A}x = mod(p) \in \mathrm{Z}_p^n$ is a problem A, which is guarantees a solution. Consequently, the solution of the system of linear equation where the number of equations is less than the number of unknowns is equivalent to the problem on lattices.

This work was not supported by any organization

Problem B. It is necessary to find a solution of a system of polynomial equations in integers.

$$f_i(x_1, x_2, \dots, x_n) = 0, i = 1,2, \dots, m$$

Problem B is algorithmically unsolvable. In addition, if the degrees of polynomials ≥ 3 and $n > m$, then the problem is algorithmically unsolvable in integers. This conclusion follows from solution of 10th Hilbert problem.

In this paper, we consider a variant of constructing a hash function based on the problem B. In this type of hash function, a set of parameters can be used to enhances the persistence of the hash function. If you build a set of hash functions that depends on a large number of parameters, you get an object of the Universal hash type [4].

II. Algorithm Description

As our algorithm is parametric, first we need to choose parameters. In based version the parameters is: module *p*, size of dimension $m \times n$, set of starting coefficients $\propto_1, \propto_2, \dots, \propto_n$, size of block *b*, rules of forming summands $h_1(x), h_2(x), \dots, h_m(x)$.

Let us consider algorithms parameters. We also have developed requirements for parameters for the better result.

All calculations will be performed on the module *p*. The module should be a sufficiently large prime number.

We will generate some set of vectors according to special rules derived from the parameters $\propto_1, \propto_2, \dots, \propto_n$, $\propto_i \in Z_p^n, i = 1,2, \dots, n$, where n - is an arbitrary integer. The dimension of these vectors is *n*.

Suppose that some hashed document is described by a set of numbers $x = (x_1, x_2, \dots)$. Each number is a certain number of bits, assembled into a conditional block. Our block can be 8, 10, 12, etc. bit. The size of the block in bits *b* is another parameter of our algorithm.

A rule of generation of functions $h_1(x), h_2(x), \dots, h_m(x)$ should be defined as a parameter. It will determine the order of formation of the terms of our hash function.

The computation procedures of the proposed algorithm are illustrated as following.

Step 1: data preparation.

On this step, we prepare a string of decimal integers $x = (x_1, x_2, \dots, x_m)$ according to the input file.

Next, we prepare a matrix A = $(a_1, a_2, \dots, a_m)$, forming on the set of starting coefficients $\propto_1, \propto_2, \dots, \propto_n$. Vector a_i construct as a recurrent sequence according to the formula $a_i = \propto_1 a_1 + \propto_2 a_2 + \dots + \propto_n a_n$

Step 2: constructing a hash function.

Then the following vector will be a hash:

$$H(x) = [a_1 h_1(x) + a_2 h_2(x) + \dots + a_m h_m(x)] mod(p)$$

Functions $h_1(x), h_2(x), \dots, h_m(x)$ in hash function can be implemented as follows, but we can choose any rule for forming $h_i(x)$:

$$H(x) = [a_1 x_1 x_2 + a_2 x_2 x_3 + \dots + a_m x_m x_1] mod(p)$$

The size of the output string of the hash function is $n \times m$.

Step 3: modifications.

On the large file we have a high probability when some terms will be a zero. The main cause of it is a rule of forming a recurrent sequence, when zero in some terms is cumulated. To avoid it in a base version of algorithm we use a cyclic shift. In another version, we can use replacing on zero-component to fixed number which can be a parameter too.

Thus, we have constructed a hash-scheme with parameters, where the parameters are: module *p*, vector dimension *n*, block size *b*, terms generation rules $h_1(x), h_2(x), \dots, h_m(x)$.

III. The Toy Example

On the first step parameters is chosen. It is a simple number p, which will be a module; for example here p = 4049, the dimension of the vector n = 4, m = 4, the size of the block is b = 6 bits, the rule of generating multipliers in the term is $x_i x_{i+1}$, window size is 2, coefficients $\propto_1, \propto_2, \propto_3, \propto_4$ = (3174,3507,860,1294).

On the first step, we preparing a data.

Data from the file represented as decimal integers is x_1, x_2, ..., where each *x* is 6 bits. We separate 32 bits file on block of 6 bit and convert to decimal integers and the result is (34, 16, 23, 63).

Next, we need to generate coefficients A from starting coefficients $\propto_1, \propto_2, \dots, \propto_m =$ (3507,860,1294,3174)

$$\begin{pmatrix} \propto_1 \\ \propto_2 \\ \propto_3 \\ \propto_4 \end{pmatrix}, \propto_i \in \mathrm{Z}_{4049}, i = 1,2,3,4$$

Each a_k is calculate using recurrent sequence. On first step it will be $a_k = 3507a_{k-1} + 860a_{k-2} + 1294a_{k-3} + 3174a_{k-4}$.

Let a_i is:

$$a_0 = \begin{pmatrix} 1 \\ 0 \\ 0 \\ 0 \end{pmatrix}; \; a_{-1} = \begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \end{pmatrix}; \; a_{-2} = \begin{pmatrix} 0 \\ 0 \\ 1 \\ 0 \end{pmatrix}; \; a_{-3} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \end{pmatrix}$$

Consequently:

$$a_1 = \begin{pmatrix} 3507 \\ 860 \\ 1294 \\ 3174 \end{pmatrix}$$

When we read the elements of a file by 2 items and calculate the product, it can turned to 0, if any one term turns to 0. Therefore, it is necessary to provide a decision of this problem in this case. We make a cyclic shift of numbers in vector a_i on 1 positions.

Next step we need to construct and calculate hash function:

$H(x) = [a_1 x_1 x_2 + a_2 x_2 x_3 + a_3 x_3 x_4 + a_4 x_4 x_1] mod(p)$

Let us construct the first term for the hash $a_1 x_1 x_2$:

$$\begin{pmatrix} 3507 \\ 860 \\ 1294 \\ 3174 \end{pmatrix} \times 34 \times 16 = \begin{pmatrix} 729 \\ 2205 \\ 3459 \\ 1782 \end{pmatrix} mod(4049)$$

Now the next vector according to the recurrence sequence should be calculated:

$$a_2 = 3174\begin{pmatrix}729\\2205\\3459\\1782\end{pmatrix} + 3507\begin{pmatrix}1\\0\\0\\0\end{pmatrix} + 860\begin{pmatrix}0\\1\\0\\0\end{pmatrix} + 1294\begin{pmatrix}0\\0\\1\\0\end{pmatrix} = \begin{pmatrix}1325\\2858\\3321\\3664\end{pmatrix} mod(4049)$$

We calculate the product from the document data to the generated vectors:

$$\begin{pmatrix}1325\\2858\\3321\\3664\end{pmatrix} \times 16 \times 23 = \begin{pmatrix}1720\\3053\\3379\\35\end{pmatrix} mod(4049)$$

Modify the first two terms of hash:

$$\begin{pmatrix}729\\2205\\3459\\1782\end{pmatrix} + \begin{pmatrix}1720\\3053\\3379\\35\end{pmatrix} = \begin{pmatrix}2449\\1210\\2769\\1817\end{pmatrix} mod(4049)$$

And so on by induction. The final result of hash function will be (1679, 1137, 1883, 213).

IV. Possible modifications

The described algorithm can be modified as follows.

Modification 1. The nonlinear case of the formation of terms for the hash function should be considered.

We need to define a rule where the data from the input file will be combined and be distributed according to the hash function.

For example,

$$Ax = [a_1x_1x_2x_3 + a_2x_2x_3x_4 + \cdots + a_mx_mx_1x_2]mod(p)$$

The operations of multiplication are made on modulo p. Thus, we can consider other types of polynomials for the nonlinear case.

Modification 2. The nonlinear case should be considered when multiplications are made according to some multiplication table.

This table can be generated according to the hashed data.

V. Security Proof

C. Theoretical Foundation

For a hash function f will be cryptographically stable, it must satisfy the follow three basic requirements which most hash functions are based in cryptography:

1. Irreversibility or resistance to restoration of the prototype: for a given value of a hash function *y*, a data block *x* for which $f(x) = y$ must not be computed.
2. Resistance to collisions of the first kind or restoration of the second inverse images: for a given message *x* it must be computationally impossible to find another message *z* for which $f(x) = f(z)$.
3. Resistance to collisions of the second kind: it must be computationally impossible to select a pair of messages *x, z* having the same hash.

These requirements are not independent:

1. An invertible function is unstable to collisions of the first and second kind.
2. A function that is unstable to collisions of the first kind is not resistant to collisions of the second kind; the converse is not true.

Let us consider how the collision for our variant of the hash function will look. Let the same hash function be given for two different *x* and *z* documents:

$$H(x) = [a_1h_1(x) + a_2h_2(x) + \cdots + a_mh_m(x)]mod(p)$$

$$H(z) = [a_1h_1(z) + a_2h_2(z) + \cdots + a_mh_m(z)]mod(p)$$

Collision means that if $x \neq z$, but $H(x) = H(z)$.

Suppose for our algorithm the source document is known. Then, taking into account that the vectors $a_1, a_2, \dots, a_m$ are formed according to the parameters and the special rules to the function $h_i(x), i = 1,2, \dots, m$ calculations, the attacker is aware of the following information: vectors $a_1, a_2, \dots, a_m$, $\alpha_i = h_i(x), i = 1,2, \dots, m$ and $v = \sum_{j=1}^{m} \alpha_i a_j \, mod(p)$. The vector *v* is a hash of the document.

We need to solve equation $H(x) = d$ to find collisions, but this problem is equivalent to problem B, described in the section I.B of this article.

Thus, we demonstrated that a collision is theoretically possible. However, we affirm that there is no sense to find a collision for our algorithms, since the problem is algorithmically unsolvable if there are polynomials in the system of equations with a degree greater than 3.

For cryptographic hash functions it is also important that with the slightest change in the argument, the value of the function changes greatly (avalanche effect). In particular, the value of a hash should not give a leak of information, even about individual bits of the argument. This requirement is the key to the crypto-stability of algorithms for hashing user passwords to obtain keys.

D. Implementation Details

Describing algorithm was implemented in Python 3.3 for testing; measurements were made on a computer with an Intel Core i5-4210U of 2 cores, operating at 2.4Ghz. The PC contains 8 Gb RAM.

For testing avalanche effect, we calculated the hash function from the source file, changed an arbitrary bit in the source file and calculated the hash function from the modified file. Then a bitwise comparison was made. In the case of any documents of any size, when changing 1 bit in the source file, the hashes of the primary and modified files coincide only by 47-50% with a bitwise comparison.

Moreover, the best parameters at which the maximum number of discrepancies is reached is a sufficiently large prime number and the large dimension of the vector K is about 100.

The speed of the algorithm is about 0.007 sec for a 1 kb file, an average of 70 seconds for a 500 kb file, an average

500 seconds for a 1 mb file. The algorithm works both with text data, and with photo, video and audio content. Obviously, realization of this algorithm should be optimized to reduce the processing speed of the file.

VI. Conclusion

In this article is proposed an algorithm of hash function resistant to quantum computer. This algorithm uses algorithmically unsolvable problem of finding a solution to a system of polynomial equations in integers. Our algorithm is parametrized, which increases the decision-making time. It is resistant to collisions, because the problem on which the algorithm is built is algorithmically unsolvable (in the case where the degree of the polynomial is greater than 3). The avalanche effect is about 47-50% with a bitwise comparison. The algorithm can work both with text data, with photo, video and audio contents.

This algorithm was developed for blockchain technology to increase its resistance to attacks by quantum computer. It can also be used in any application where a hash function is needed.

***Abstract*—Web application firewall is an application firewall for HTTP applications. Typical WAF uses static analysis of HTTP request, defined as a set of rules, to find potentially dangerous payloads in the requests. Generally, these rules cover common attacks such as cross-site scripting (XSS) and SQL injection which are server-related attacks. Cross-site scripting is client-side attack however the server is attacked and forced to return malicious response. Rule-based approach becomes useless when the attack is client-related, for example employing malware on the banking site. Malware allows to change the transfer data. This scenario is hard to detect because the browser displays valid transfer data and data is changed to the thieves' accounts number at the communication stage.**

In this paper we introduce a new web-based architecture for protecting web applications against CSRF attacks in malicious environemnt. In our approach we extend a classic, static WAF approach with historical and behavioral analysis, based on actions performed by the user in the past.

I. Introduction

ONE OF the ideas to increase Web applications security was Web Application Firewall, a proxy server used to defend web apps against attacks usually employed in the application layer in contrary to classic firewalls. WAFs are located between classic firewall and the application server. Such architecture allows the firewall to mitigate attacks on lower layers and WAF to detect and mitigate attacks on application layer. Both groups of mentioned attacks can have similiar consequences such as Denial of Service. DoS attacks, well known from lower layers[7], can also be performed on the application layer[5]. In [9] authors analyze 63 other articles about HTTP-GET flood attacks.

However, the application layer introduces a wide range of new threats to be detected and removed by WAF. OWASP Top Ten [10] is a powerful awareness document for web application security which represents a broad consensus about the most critical web application security flaws. The OWASP Top Ten list includes flaws, such as injections, cross-site scripting, cross-site request forgery, insecure session management, insecure direct object references, security misconfiguration, using components with known vulnerabilities and others. Most of web application firewalls focus on the technical attacks such as injections, cross-site scripting or cross-site request forgery while it is hard to detect other types such as insecure direct object references or business logic flaws because they are strictly application-dependent.

We are going to use request forgery attacks as an example of successful business attacks to present our new approach to detect and mitigate malicious requests. The most popular type of request forgery attacks are cross-site request forgery attack (CSRF) which makes a logged-on victim's browser send a forged HTTP request, together with the victim's session cookie and any other automatically attached authentication information to a vulnerable web application. In other words, the attacker forces the victim's browser to generate requests, which from the vulnerable application's perspective are legitimate. For this reason, on the server side we are not able to detect this only based on the technical attributes of the query. Although this is not a sophisticated attack, it indicates that the key players (Facebook, LinkedIn, etc.) had suffered from it.

Another type of request forgery attack is server-side request forgery (SSRF) and request forgery generated by malicious software. The SSRF differs from CSRF that the attacker forces a vulnerable application server to send a request. In the second type the attacker installs malicious software of victim's device which later sniffs the authentication data (eg. SMSes on the smartphone) and sends authenticated requests. According to reports by Symantec [11] and Kaspersky Lab [4] the malicious software is a significant problem with more than 30% of user computers subjected to at least one Malware-class attack and more than 170 mobile applications for credentials stealing in 2016. The financial Trojan threat landscape is dominated by three malware families: Ramnit, Bebloh (Trojan.Bebloh), and Zeus (Trojan.Zbot), responsible for 86 percent of all financial Trojan attack activity in 2016. Most anti-malware solutions is based on the detection of their presence.

Many commercial WAFs use signature-based techniques, attempting to find the malicious inputs appearing in the signature database. One can enumerate known WAFs, such

as F5, Juniper, Modsecurity and many others. In the scope of request forgery attacks the defense technique is to tokenize the requests. Such solutions are not only used by WAFs but many application frameworks provide such middleware as well.

Unfortunatelly, the use of tokens as the factor, which authenticate the requests is not sufficient in the malicious environemnt. In this paper, we are focused on a popular case of request forgery attack performed by malicious software installed on clients device (eg. mobile phone) and propose a mechanism to detect such attacks. The current Web Application Firewalls assume that the clients' devices is free from malicious software. This assumption in times of common malware can not take place.

The major contributions of the presented results can be summarized as follows:

- We present a successful request forgery attack on the application defended by classic WAF when client has malware installed.
- We propose new architecture for protecting web applications against request forgery attacks performed by malicious software.
- We extend our WAF proposal to include Two-Factor Authorization mechanism and user's history analysis.

The content of this paper is structured as follows. We discuss the related work in Section II. In section III we introduce the notation and describe the successful request forgery attacks leading to authorization bypass. Section IV describes our approach to detect and mitigate malicious business actions such as requests performed by malware. It includes the description of architecture, the detection algorithm. Finally, section V concludes this paper and describes the futher work.

II. Related Work

In the literature method of protecting web applications are not widely discussed. Researchers focus on non-standard attacks that can not be detected on classic firewalls and design new mechanisms for detecting these specific attacks.

In [3] authors propose an automatic method of HTTP attacks signature generation. Their approach relies on the use of a service-specific, semantic-aware anomaly detection scheme that combines stochastic learning with a model structure based on the HTTP protocol specification. The proposed soluction assume that the clienct is free from malicious software.

The article [8] proposes an approach that uses ontology models to detect web application attacks in HTTP protocol. Authors created three models of correct request, correct response and an attack. The HTTP requests are analyzed for compliance with the model and marked as a potential attack when forbidden values are found. This approach is similar to the whitelist approach, which is time-consuming and leads to many false positive alarms.

The authors in article [6] concentrate on SQL injection attack and propose the detection mechanism employing graphs and Support Vector Machine. The algorithm converts SQL query to the graph and uses previously trained SVM to detect SQL injection. The drawback of this algorithm is that it focuses only on the detection of tautology which is the first phase of the attack. When the mechanism blocks such query it can be considered as the presence of vulnerability.

In [1] authors conducted a review of the literature on popular web application attacks from OWASP Top 10 list, such as injections, access control or session management. Among the analyzed mechanisms were source code static analysis, dynamic detection of forbidden values and more complex such as comparison of responses which dropped responses outlying from the norm. The most popular solutions were based on the detection of forbidden values and authors stated that there does not exist a solution that is capable of detecting all injections, even in only one category such as cross-site scripting, because of many special cases of such flaw. All the discussed protection mechanisms assume that the client is free from malicious software.

III. Authorization bypasss with request forgery attacks

The aim of authorization bypass attacks is to perform an unauthorized action on behalf of authroized user. There exist many attack vectors and scenarios. In this section we describe four examples of such attacks, beginning with the simplest one employing social engineering techniques, to more complicated which uses malicious software.

A. Notation

We are going to use the following notation to describe the attack flows. The steps described correspond to the numbers in square brackets on matching figures.

- Actors:
  - $Client$ - the mobile or web client of the system,
  - WAF - web application firewall,
  - $Server$ - system endpoint server (reverse proxy),
  - $Attacker$ - an attacker (eg. malware).
- Messages:
  - $CREDENTIALS_{Client}$ - Client's credentials,
  - $SESS_{Client}$ - Client's session created by Server,
  - $EMAIL_{MAL}$ - malicious e-mail message with malicious link,
  - REQ_{BA} - a request to obtain form for business action BA,
  - $RESP_{FORM:BA}$ - a response that contains the form of business action BA,
  - $DATA_{FORM:BA}$ - form data to performa a business action BA,
  - $MODDATA_{FORM:BA}$ - modified (by malware) form data to performa a business action BA with malicious result,
  - $RESP_{BA}$ - a response that confirms the execution of business action BA,
  - $RESP_{MODBA}$ - a response that confirms the execution of modified business action BA,
  - $CSRF_{TAG}$ - a anti-CSRF tag,
  - $2FA_{OTP}$ - one time password from 2FA device, mandratory to authorize business action,

- Actions:
  - $ClickLink(EMAIL_{MAL})$ - user clicks the link from malicious e-mail,
  - $Verify(CREDENTIALS_{Client})$ - Server verifies Client's credentials and creates new session for him,
  - $WafVerify(Data)$ - WAF verifies the correctness of Data,
  - $CreateUser(DATA_{FORM:USER})$ - Server creates user record with form data,
  - $FormTag(RESP_{FORM:BA})$ - WAF creates a form tag to prevent CSRF attack,
  - $DoBA(DATA_{FORM:BA})$ - Server executes business action BA using form data,
  - $Intercept(Data)$ - Attacker intercepts data,
  - $ModifyBA(DATA_{FORM:BA})$ - Attacker modifies business action attributes (form data),
  - $AdditionalAuthRequired(Data)$ - WAF checks whether additional authorization is required for given action described by data,
  - $Send2FARequestForData(MODDATA_{FORM})$ - WAF sends challange to 2FA device for given business data for additional authorization,
  - $AbortForSecurityReason()$ - Client aborts operation (hacking attempt found).

B. The CSRF attack using a malware to bypass RSA Token and WAF

In this example we present an attack which bypasses the RSA Token and Web Application Firewall with the use of financial Trojan like ZEUS. RSA Token is a two-factor authentication device which generate a cryptographically-secure token to authorize the business action. ZEUS malware, on the other hand, allows to change the bank transfer data in online banking system. The attack is hard to detect by user because the browser displays valid transfer data and data is changed to the thieves' account number during the communication. Two-factor authorization, which does not user a device that displays the decription of operation to be authorized, is not effective for this type of attack.

The case background is the following. The Client has a bank account in the bank which requires that the transactions commissioned on the online service must be confirmed using one time password (OTP) generated by RSA Token. Client's device is infected with malware that is specialized in stealing money from the bank transaction system (eg. ZEUS).

The scenario of the attack is presented on figure 1.

(1) The Client logs in to the bank system.
(2) WAF performs static analysis if request is technically correct.
(3) Request was validated and pass to the banking system.
(4) The system validated the data entered.
(5) System created the session and returned it to the client.
(6) He wants to transfer money to his contractor.
(7) WAF verifies request.
(8) Pass it to the banking system.
(9) WAF receives form.
(10) WAF tags it with CSRF token.
(11) WAF sends it back to the user.
(12) The account number to which he wants to transfer the money is not added to any trusted transfer templates - the system will require authorization and one time password (OTP) code from the RSA Token.
(13) Malware detects an attempt to perform a transfer and, at the communication stage.
(14) Malware swaps the contractor account to the Attacker's account.
(15) A malicious request is sent to the system.
(16) WAF validates modified request.
(17) Pass it to the system.
(18) System performs transfer to Attacker's account.
(19) Malware, on the summary screen of the transfer, presents the Client with the account number of the contractor. The unaware Client gives the OTP code and authorizes the transfer to the Attacker's account.

IV. The new architecture for protecting web applications against request forgery attacks performed by malicious software

In this section we describe our approach to extend WAF security with behavioral analysis. The solution we want to propose increases the security and usability of the application that the WAF protects. It reduces the risk of a successful attack, even if your device is infected with malware.

We introduce behavioral analysis and user action history. The user request is analyzed by WAF before it reaches the target system. The WAF analyzes whether the user has performed similar actions in the past and whether they have been successfully commissioned. The similarity is calculated on the base of technical and business attributes describing actions. When the requested action is similar, the WAF does not require additional authorization. If not, the WAF asks for additional authorization to confirm the operation for the data entered. It would speed up the use of the target system and minimize the risk that the user confirms the operation with input altered by the Attacker.

A. History analyze and the similarity function

The added value of our solution to the classic Web Application Firewall is the Hisotry Analyzer module. With this module we are able to detect potencial abuse using cross-site request forgery. The key element of the proposed solution is the similarity function. We are going to use the following model to describe the proposed solution. In order to implement historical analysis, we need to introduce a concept of action. Actions, ie, business orders that a user has performed on a system that protects the WAF. The module checks to see whether similar operations have been performed by the user in the past. Similarity is calculated using an algorithm 1. If the action is similar to past operations, additional authorization is not required.

Definition 1. Technical attributes.

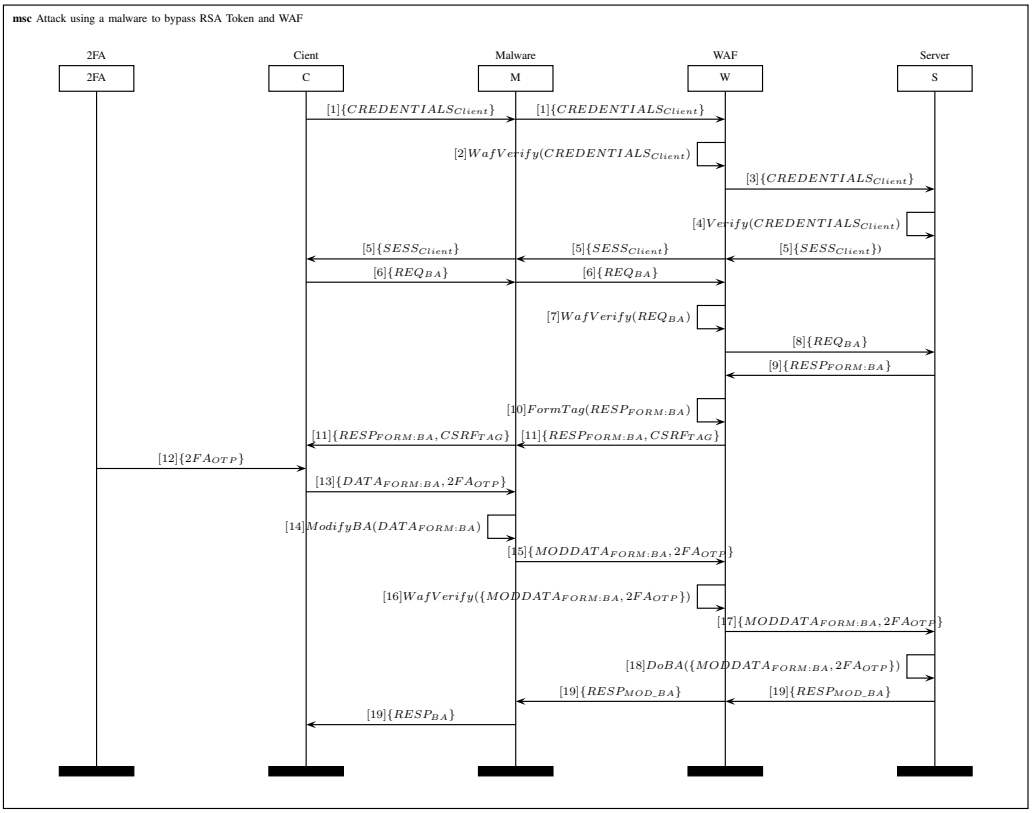

Fig. 1. Attack using a malware to bypass RSA Token and WAF.

$$T = \{t_1, t_2, ..., t_n\}$$
$$VT = \{vt_1, vt_2, ..., vt_n\}$$

The T set is a set of technical attributes and the VT set contains all of possible values of technical attributes. Technical attributes are not directly related to business data; they are rather a description of where and from what machine the action was initiated. This can be an ip address, browser fingerprint, country, time zone, and so on.

Definition 2. Business attributes.

$$B = \{b_1, b_2, ..., b_n\}$$
$$VB = \{vb_1, vb_2, ..., vb_n\}$$

The B set is a set of business attribute, the VB set represents all of possible values of business attributes. For example, the account number of the destination, the amount of the transfer for the service that executes the transfer.

Definition 3. Other variables.

$$Boolean = \{true, false\},$$
$$R,$$
$$Time$$

The $Boolean$ set is a set of boolean values, the R - set represents real numbers and $Time$ is a set of all possible timestamps

Definition 4. Actions and set of all possible actions.

$$A = \{a_1, a_2, ..., a_n\}$$
$$a_n = (T, B, VT, VB, Boolean, Boolean, Time)$$

The A set is a set of all possible actions and the a_n represents an action. This is a collection of all actions provided by a WAF-protected system with information about the actions taken by the user at a specific time along with the specific business effect. An action is defined by sets of technical and business attributes along with their values, two boolean values which states whether an action has been authorized with additional mechanisms and whether it has been allowed, and action's timestamp.

Definition 5. Function additionalAuthRequired

$$additionalAuthRequired(A \times 2^A) \rightarrow Boolean$$

Function $additionalAuthRequired$ returns whether additional authorization is required for given action.

Definition 6. Return elements.
The functions $attrs$, $values$, $time$ and $passed$ are return the elements of an action tuple a_i passed as an argument.

Definition 7. History.
The function $history$ is defined as follows: $history(a_i, A_m) \rightarrow A_n$, where $a_i \in A$, $A_m \subset A$ and

$A_n \subseteq A_m : a_j \in A_n \iff (passed(a_j) \wedge (time(a_j) <= time(a_i)))$

Definition 8. actionSimilarityThreshold function.

$$actionSimilarityThreshold(a_i) = max(similarityThreshold(vbt_i), \forall vbt_i \in 2^{VB \cup VT} : vbt_i \subseteq values(a_i))$$

Function $actionSimilarityThreshold$ returns similarity threshold for given action based on its attributes. It is calculated as the maximum similarityThreshold for all possible subsets of action's values of attributes

Definition 9. additionalAuthRequired function

$$additionalAuthRequired(a_i, A_m) = \begin{cases} true, & similarity(a_i, A_m) <= \\ & actionSimilarityThreshold(a_i) \\ false, & otherwise \end{cases}$$

The function $similarity$ depends on the method to be used to compare actions. The algorithm of calculating the similarity of action is presented in Alg. 1. In this state of study we are using simply algorithm based on weighted wage. The values of the similarity function are taken later in the verification ($additionalAuthRequired$) that the action is similar enough to those previously performed that no further verification is needed.

Algorithm 1: Function that returns the similarity between the action and the history

```
SIMILARITY (a_i, A_n)
    inputs: Action and Action set
    output: Similarity factor
    tmpSum ← 0
    tmpWage ← 0
    foreach a_j ∈ history(a_i, A_n) do
        foreach attr_i ∈ attrs(a_j) do
            if value(attr_i, a_i) ≈ value(attr_i, a_j) then
                tmpSum ← tmpSum + wage(attr_i)
            tmpWage ← tmpWage + wage(attr_i)
    if tmpWage = 0 then
        return 0;
    return tmpSum ÷ tmpWage;
```

V. Conclusions

In the article we presented the weaknesses of Web Application Firewalls which use signature-based and rule-based static analysis. We presented a successful request forgery attack on the application defended by classic WAF when client has malware installed.

To protect against such attacks we introduced an approach, based on historical and behavioral analysis of user requests, which reduces the need for additional forms of authorization. After sufficiently collecting and analyzing user's history, the additional authorization appears only in the situation that actually requires it. Such approach increases the responsiveness and general feel of the application.

In the future work, we plan to implement the proposed system and check the efficiency and accuracy of it.

***Abstract*—Certain families of graphs can be used to obtain multivariate polynomials for cryptographic algorithms. In particular, in this paper, we introduce stream ciphers based on non-bijective multivariate maps. The presented symmetric encryption algorithms are based on three families of bipartite graphs with partition sets isomorphic to $\mathbb{K}^n$, where $\mathbb{K}$ is selected as the finite commutative ring. The plainspace of the algorithm is $\Omega = \{x | \sum x_i \in \mathbb{K}^*, x \in \mathbb{K}^n\} \subset \mathbb{K}^n$, $\Omega \cong \mathbb{K}^* \times \mathbb{K}^{n-1}$. We describe the algorithm for the case $\mathbb{K} = \mathbb{Z}_{2^m}$, $m \geq 2$. In fact, we use the relation $d * d_{dec} \equiv 1 (\mathbf{mod}\ 2^{m-1})$, $d, d_{dec} \in \mathbb{Z}^*_{2^{m-1}}$ to obtain encryption polynomial map of degree greater than or equal to $d+2$ and decryption map of degree greater than or equal to $d_{dec}+2$. We assume d_{dec} grows with the growth of parameter m, because this makes cryptanalysis very difficult task. Symmetric encryption and decryption algorithms for users are numerical recurrent processes, not requiring generation of encryption and decryption maps in their symbolic forms. They use arithmetical operations of addition, subtraction, and multiplication. That's why the algorithms are robust (execution speed is $O(n)$). To break the algorithm an adversary must use linearization attacks for recovering non-bijective "decryption map" of degree greater than $d_{\mathrm{dec}}+2$ in its symbolic form. To achieve this, the adversary needs at least $O(n^{d_{\mathrm{dec}}}+2)$ pairs of plaintext and corresponding ciphertext to restore the non-bijective map of degree greater than or equal to $d_{dec}+2$. We present tables for evaluation of execution time for m = 8 with various length of passwords and sizes of files. Computer simulations demonstrate good mixing properties of the encryption functions.**

FEW graph based algorithms have been implemented since 1998 (see [1] - [25]). So there is some history of the usage of sparse algebraic graphs in symmetric cryptographical algorithms. The following known graphs defined over finite commutative ring $\mathbb{K}$ were used: $D(n, \mathbb{K})$ (see [1], for $\mathbb{K} = \mathbb{F}_q$ graphs were defined and investigated in [26], [27]), $W(n, \mathbb{K})$ (Wenger graphs defined in [28]), graphs $A(n, \mathbb{K})$ introduced in [45] and graphs $\widetilde{D(n, \mathbb{K})}$ of [25]. Popular choices of $\mathbb{K}$ are finite fields $\mathbb{F}_{127}$, $\mathbb{F}_{2^7}$, $\mathbb{F}_{2^8}$, $\mathbb{F}_{2^{16}}$ and $\mathbb{F}_2^{32}$ and rings modular arithmetics $\mathbb{Z}_{2^7}$, $\mathbb{Z}_{2^8}$, $\mathbb{Z}_{2^{16}}$. We present this research history in the next section.

In section 3 we introduce a class of bivariate graphs containg all the above mentioned graphs. Such concept is convenient for uniform description of encryption scheme and observation of common properties of graphs from this class (section 4). We compare graphs and related algorithms corresponding to different families ($W(n, \mathbb{K})$, $D(n, \mathbb{K})$, $A(n, \mathbb{K})$ and $\widetilde{D(n, \mathbb{K})}$) in section 5.

Here the reader can find remarks on multivariate cryptography and its connections with cryptographical applications of Algebraic Graph Theory.

RSA is one of the most popular cryptosystems. It is based on a number factorization problem and on Euler's Theorem. Peter Shor discovered that factorization problem can be effectively solved by using a theoretical quantum computer. It means that RSA could not be a security tool in the future postquantum era. One of the research directions leading to a postquantum secure public key is the Multivariate Cryptography which uses a polynomial maps of affine space $\mathbb{K}^n$ defined over a finite commutative ring $\mathbb{K}$ into itself as encryption tools (see [29]). This is a young promising research area because of the current lack of known cryptosystems with the proven resistance against attacks with the use of Turing machines. Other important direction of Postquantum Cryptography is the study of Hyperelliptic Curves Cryptosystems. We have to say that classical elliptic curves encryption will be not secure in the Postquantum era.

Applications of Algebraic Graph Theory to Multivariate Cryptography were shown in our talks at Erdös Centennial (2013, Budapest) and Central European Conference on Cryptology 2014 (Alfred Renyi Institute, Budapest) [30], [31]. Talks were devoted to algorithms based on bijective maps of affine spaces into itself. Applications of algebraic graphs to cryptography started with symmetric algorithms based on explicit constructions of extremal graph theory and their directed analogues (see survey [11], [32]). The main idea is to convert an algebraic graph in a finite automaton and to use the pseudorandom walks on the graph as encryption tools.

This approach can also be used for the key exchange protocols. Nowadays the idea of "symbolic walks" on algebraic graphs, when the walk on the graph depends on parameters given as special multivariate polynomials in variables depending from plainspace vector, appears in several public key cryptosystems. Another source of graphs suitable for cryptography is connected to finite geometries and their flag system (see [33] and further references).

Multivariate cryptography started from the study of potential for the special quadratic encryption multivariate bijective map of $\mathbb{K}^n$, where $\mathbb{K}$ is an extention of finite field $\mathbb{F}_q$ of characteristic 2. One of the first such cryptosystems was proposed by Imai and Matsumoto and cryptanalysis for that system was invented by J. Patarin. A survey on various modifications of this algorithm and corresponding cryptanalysis can be found in [29] or [34].

One of the first uses of non-bijective map of multivariate cryptography was in the *oil and vinegar* cryptosystem proposed in [35] and analyzed in [36]. Nowadays, this general idea is strongly supported by publication [37] devoted to security analysis of direct attacks on modified unbalanced oil and vinegar systems. It looks like such systems and rainbow signature schemes may lead to promising Public Key Schemes of Multivariate Encryption defined over finite fields. Non-bijective multivariate sparse encryption maps of degree 3 and ≥ 3 based on walks on algebraic graphs $D(n, \mathbb{K})$ defined over general commutative ring and their homomorphic images were proposed in [38]. Security of the corresponding cryptosystem rests on the idea of hidden discrete logarithm problem. U. Romańczuk-Polubiec and V. Ustimenko combine an idea of "oil and vinegar signature cryptosystem" with the idea of linguistic graph-based map with partially invertible decomposition to introduce a new cryptosystem [38]. This algorithm can be implemented with the use of families $D(n, \mathbb{K})$ and $A(n, \mathbb{K})$ and natural homomorphism between them. Finally, in [39] "hidden RSA multivariate encryption" based on graphs $D(n, \mathbb{K})$ were proposed.

In this paper we modify the encryption map (private key) of the above mentioned cryptosystem in terms of family of bivariate graphs defined over the commutative ring $\mathbb{K}$. These maps have multivariate nature despite the "numerical implementation" in symmetric ciphers mode with the plainspace isomorphic to $\mathbb{K}^* \times \mathbb{K}^{n-1}$.

I. On some implementation of algorithms based on bijective maps

We worked on a software package that allows us to investigate strongly symmetric cases of stream ciphers based on graphs $W(n, \mathbb{K})$, $D(n, \mathbb{K})$, $\widetilde{D(n, \mathbb{K})}$ and $A(n, \mathbb{K})$, where $\mathbb{K}$ is the arithmetic ring. Some cases are already implemented by our team at the level of prototype model.

In very special cases the algorithms were previously implemented. The first implementation of $D(n, \mathbb{K})$ encryption was done in 2000 at the University of South Pacific (USP, Fiji Islands). The research team was composed by Prof. V. Ustimenko, PhD Dharmendra Sharma (currently professor of University of Canberra), postgraduate students V. Gounder and R. Prasad (see [2], [3]). The work was supported by the University Research Committee of the University of South Pacific (USP) grant. The implementation of this case on asymmetric mode was discussed in [5]. The chosen case for $\mathbb{K}$ was $\mathbb{F}_{127}$, which is the closest prime number to the size of ASCII code alphabet. It means that one has to delete just the *delete* service symbol and can encrypt arbitrary files of type txt. The chosen string was $\alpha_i(x) = x + d_i$, where d_i are elements of chosen ring $\mathbb{K} = \mathbb{F}_{127}$ chosen in pseudorandom fashion. So that was a case of shifting encryption.

The affine transformations L_1 and L_2 were simply identities. Implemented cipher on ordinary PC was rather robust in performance, but with average mixing properties. It's been used at USP digital network working for campuses and USP centers located in 11 island countries of South Pacific region. The package was also used by ORACLE based system of the bursary office (see [8]). Recently group of students from Okanagan college (affiliated with the University of British Columbia) implemented that stream cipher on a cluster network of PC's. It was used for a large data encryption [10]. The implementation of that security algorithm for protection of Geo Information Systems was described in [6], [7].

Another case for $\mathbb{K} = \mathbb{Z}_{256}$ and graph $D(n, \mathbb{K})$ was implemented under the Research Committee of Sultan Qaboos University (SQU, Oman) grant. The research team was composed of professors Vasyl Ustimenko and Abderezak Tousane and students Rahma Al Habsi and Huda Al Naamani. The software uses one to one correspondence between element of $\mathbb{Z}_{256}$ and symbols of binary alphabet. It allows encryption of various file types (with extension doc, jpg, htm, avi, pdf, ...) in a way that encrypted file is presented in the same format with the plaintext. The symmetric algorithm was used at academical networks of SQU and Kiev Mohyla Academy [9], [10].

The cases of $D(n, \mathbb{K})$, where $\mathbb{K}$ is the finite field $\mathbb{F}_{2^7}$ $\mathbb{F}_{2^8}$, $\mathbb{F}_{2^{16}}$, the shifting encryption was implemented and investigated in [20].

The systematic study of shifting encryption for cases of shifting encryptions of $D(n, \mathbb{K})$ was conducted at UMCS (Lublin, Poland). J. Kotorowicz used arithmetical rings $\mathbb{Z}_2^7$, $\mathbb{Z}_2^8$, $\mathbb{Z}_2^{16}$ for the implementation with various affine transformation τ_L and τ_R (see [14], [16]). The encryption was essentially faster than in all previously known cases. The selected affine transformation leads to an encryption with very good mixing properties: the change of a single character of the plaintext or the change of a single character of the encryption string $d_1, d_2, \ldots, d_s$ causes the change of at least 98 percent of the ciphertext characters. In [23] these cases were implemented for graphs $A(n, \mathbb{K})$ with very similar results on the mixing properties. In the case of $\tau_R = {\tau_L}^{-1}$ it can be proved that the order of $A(n, \mathbb{K})$ and $D(n, \mathbb{K})$ based encryption map grows with the growth of parameter n. The comparison of orders was completed through the study of cycles structures of $A(n, \mathbb{K})$ and $D(n, \mathbb{K})$ encryptions. Results demonstrated similarity in both cases.

M. Klisowski implemented $D(n,\mathbb{K})$ and $A(n,\mathbb{K})$ shifting encryption on symbolic level in the cases of finite fields $\mathbb{F}_{2^7}$ $\mathbb{F}_{2^8}$, $\mathbb{F}_{2^{16}}$ $\mathbb{F}_{2^{32}}$ ([21], [22], [24]). In [40] A. Wróblewska proved that shifting $D(n,\mathbb{K})$ encryption is given by a cubical multivariate map. A similar result for $A(n,\mathbb{K})$ based encryption was stated in [41]. Simulation results of [22], [23] allow to estimate time of generation of these maps as functions of parameter n and densities of such multivariate cubic encryption and decryption maps. A comparison of cases $A(n,\mathbb{K})$ and $D(n,\mathbb{K})$ for the above fields an be found in [24]. Similar results for cases of Boolean rings of sizes 2^7, 2^8, 2^{16}, 2^{32} are obtained via computer simulations.

The PhD Thesis of M. Klisowski [42] contains the first results on $D(n,\mathbb{K})$ and $A(n,\mathbb{K})$ based multivariate maps which are not defined via shifting encryptions. He used symbolic strings of kind $\alpha_1(x) = x+c_1, \alpha_2(x) = x+c_2, \ldots, \alpha_{s-1}(x) = x + c_{s-1}$, $\alpha_s(x) = x^3 + c_s$ with constants c_i, $i = 1, 2, \ldots, s$ for special fields $\mathbb{F}_q$ in which $x^3 = b$ has unique solution. It was shown that such a choice makes direct linearization attacks impossible.

The first implementation for the case of Wenger graph based encryption was completed at the University of Sao Paolo (USP, Brasil) (see [12] and further references). Professors V. Futorny and V. Ustimenko chose field $\mathbb{F}_{253}$ which size is the closest from below prime to the size of binary alphabet. This research was partially supported by FAPESP foundation (grant for international cooperation with USP). Computer simulation demonstrated high speed of encryption. In [12] authors evaluated the diameter of graph $W(n,\mathbb{F}_q)$ and proved that the family of these graphs $W(n,q)$, $n \leq q$ is a family of small world graphs.

Professor Routo Terada (USP, Brasil) suggested to investigate the behaviour of these algorithms under linearization attacks. Computer simulation supports the conjecture on a good resistance of the encryption scheme to such attacks.

The idea of using graphs $A(n,\mathbb{K})$ in cryptography was proposed by U. Romańczuk-Polubiec and V. Ustimenko in [45]. Evaluation of the order of encryption map based on $A(n,q)$ was presented in [23]. A theoretical study of orders and cycles can be found in [44], [45].

Some stream ciphers defined via graphs $\widetilde{D(n,\mathbb{K})}$ were proposed by M. Polak and V. Ustymenko in [25]. Furthermore, M. Polak compared LDPC codes corresponding to $A(n,\mathbb{K})$, $D(n,\mathbb{K})$ and $\widetilde{D(n,\mathbb{K})}$ in [49].

The importance of such graphs was justified in [44]. The encryption algorithm was implemented and some properties (speed, mixing properties, order) were investigated in the paper.

II. On the class of bivariate graphs

Let $\mathbb{K}$ be a commutative ring. We define $T(n,\mathbb{K})$ as a bipartite graph with the set of vertices $V(T) = P \cup L$, $P \cap L = \emptyset$. We call $P = \mathbb{K}^n$ a set of points and $L = \mathbb{K}^n$ a set of lines (two copies of a Cartesian power of $\mathbb{K}$ are used). We will use two types of brackets to distinguish points $(p) \in P$ and lines $[l] \in L$:

$$(p) = (p_1, p_2, \ldots, p_n) \in P,$$

$$[l] = [l_1, l_2, \ldots, l_n] \in L.$$

p_i, l_i $(1 \leq i \leq n)$ are elements of $\mathbb{K}$. We say that vertex (p) (point (p)) is incident with the vertex $[l]$ (line $[l]$) and we write: $(p)I_T[l]$, if the following relations between their coordinates hold:

$$\begin{cases} p_2 - l_2 = e_2^1 p_1 l_1 \\ p_3 - l_3 = e_3^1 p_1 l_2 + e_3^2 l_1 p_2 \\ \vdots \\ p_s - l_s = e_s^1 p_1 l_{i_s} + e_s^2 l_1 p_{j_s} \\ \vdots \\ p_n - l_n = e_n^1 p_1 l_{i_n} + e_n^2 l_1 p_{j_n} \end{cases} \quad (1)$$

where $e_2^1, e_s^1, e_s^2 \in \{0, 1, -1\}$, $1 \leq i_s < s$, $1 \leq j_s < s$. So the incidence relations for graph $T = T(n,\mathbb{K})$ are given by condition $(p)I_T[l]$. The set of edges consists of all pairs $\{(p), [l]\}$ for which: $(p)I_T[l]$. Let us consider the case of finite commutative ring $\mathbb{K}$, $|\mathbb{K}| = k$. As it instantly follows from the definition, the order of our bipartite graph is $|V(T)| = 2k^n$ and the number of edges is $|E(T)| = k^n \cdot k = k^{n+1}$. Graphs $T = T(n,\mathbb{K})$ are k-regular. In fact, the neighbour of a given point (p) is given by above equations, where parameters $p_1, p_2, \ldots, p_n$ are fixed elements of the ring and symbols $l_1, l_2, \ldots, l_n$ are variables. It is easy to see that if we set l_1 then this choice uniformly establishes values $l_2, l_3 \ldots, l_n$. So each point has precisely k neighbours. In a similar way we observe that the neighbourhood of any line also contains k neighbours. Notice, that the order and degree of our graph defined via strings i_s, j_s, e_2^1, e_s^1, e_s^2, where $s = 2, 3, \ldots, n$, does not depend on the strings.

Let us consider some examples.

Wenger graphs $W(n,\mathbb{K})$

In 1991 Wenger defined the family of bipartite, p-regular graphs $H_n(p)$, where p prime number [28]. In [26] Lazebnik and Ustimenko introduced straight forward generalization $W(n,q)$ of these graphs via change of $\mathbb{F}_p$ to $\mathbb{F}_q$, where q is a prime power. They used special Lie algebra and proved that the family of bipartite, q-regular graphs $W(n,q)$, where q is prime power and $n \geq 2$. Graphs $W(n,q)$ are defined for all prime powers and $H_n(p) = W(n,p)$ are defined only for primes.

The set of vertices of infinite incidence structure (P, L, I) is $V = P \cup L$ and the set of edges E consists of all pairs $\{(p), [l]\}$ for which $(p)I[l]$. Bipartite graphs $W(n,q)$ have partition sets P_n (collection of points) and L_n (collection of lines) isomorphic to vector space $\mathbb{F}_q^n$, where $n \in \mathbb{N}_+$. Let us use the following notations for points and lines in graph $W(n,q)$:

$$(p) = (p_1, p_2, p_3, \ldots, p_n) \in P,$$

$$[l] = [l_{1,}, l_2, l_3, \ldots, l_n] \in L.$$

The point (p) is incident with the line $[l]$, and we write $(p)I_W[l]$, if the following relations between their coordinates hold:

$$\{\ l_i - p_i = p_1 l_{i-1}, \tag{2}$$

for $2 \leq i \leq n$. The graphs $W(n, \mathbb{F}_q)$ have cycles of length 8.

One can change finite field $\mathbb{K}$ for general commutative ring $\mathbb{K}$ and work with graph $W(n, \mathbb{K})$.

Graphs $A(n, \mathbb{K})$

Graphs $A(n, \mathbb{K})$, formally appearing as graphs $E(n, \mathbb{K})$ in [43], are used as tools for the study of $D(n, \mathbb{K})$ properties. Later on the graphs $E(n, \mathbb{K})$ were presented with another name as an independent family $A(n, q)$ for the first time in [45] for cryptographic applications.

Let us use the following notations for points and lines in the graph $A(n, \mathbb{K})$:

$$(p) = (p_1, p_2, p_3, \ldots, p_n) \in P,$$
$$[l] = [l_{1,}, l_2, l_3, \ldots, l_n] \in L.$$

The point (p) is incident with the line $[l]$, and we write $(p)I_A[l]$, if the following relations between their coordinates hold:

$$\begin{cases} l_2 - p_2 = l_1 p_1 \\ l_3 - p_3 = p_1 l_2 \\ l_4 - p_4 = l_1 p_3 \\ l_i - p_i = p_1 l_{i-1} \text{ for odd } i \\ l_i - p_i = l_1 p_{i-1} \text{ for even } i \end{cases} \tag{3}$$

for $3 \leq i \leq n$.

Graphs $D(n, \mathbb{K})$

The following interpretation of a family of graphs $D(n, \mathbb{K})$ in case $\mathbb{K} = \mathbb{F}_q$ can be found in [27]. By I_D we denote the incidence relation for this graph. Let us use the following notations for points and lines:

$$(p) = (p_1, p_2, p_3, \ldots, p_n) \in P,$$
$$[l] = [l_{1,}, l_2, l_3, \ldots, l_n] \in L.$$

Two types of brackets allow us to distinguish points from lines. Points and lines are elements of two copies of the vector space over $\mathbb{K}$. Point (p) is incident with the line $[l]$, and we write $(p)I_D[l]$, if the following relations between their coordinates hold:

$$\begin{cases} l_2 - p_2 = l_1 p_1 \\ l_3 - p_3 = p_1 l_2 \\ l_4 - p_4 = l_1 p_2 \\ l_i - p_i = p_1 l_{i-2} \text{ for } i \bmod 4 \equiv 2 \text{ or } i \bmod 4 \equiv 3 \\ l_i - p_i = l_1 p_{i-2} \text{ for } i \bmod 4 \equiv 0 \text{ or } i \bmod 4 \equiv 1 \end{cases} \tag{4}$$

where $3 \leq i \leq n$.

The set of vertices is $V = P \cup L$ and the set of edges E consists of all pairs $\{(p), [l]\}$ for which $(p)I_D[l]$. Bipartite graphs $D(n, \mathbb{K})$ have partition sets P (collection of points) and L (collection of lines) isomorphic to vector space $\mathbb{K}^n$, where $n \in \mathbb{N}_+$.

Graphs $\widetilde{D(n, \mathbb{K})}$

Formal definitions for the family of graphs $\widetilde{D(n, \mathbb{K})}$ were presented in [25].

Construction of projective limits graphs of $\widetilde{D(n, \mathbb{K})}$ appears in papers motivated by results on embeddings of Chevalley group geometries in the corresponding Lie algebras and construction of blow-up for an incidence system of Weyl groups in [46], [47]. Moreover, this structure is the base for construction of family of graphs $D(n, \mathbb{K})$ (see [25, 27]).

Let us use the analogical notations for points and lines in graph $\widetilde{D(K)}$:

$$(p) = (p_1, p_2, p_3, \ldots, p_n) \in P,$$
$$[l] = [l_{1,}, l_2, l_3, \ldots, l_n] \in L.$$

In the incidence structure $\widetilde{(P, L, I)}$ the point (p) is incident with the line $[l]$, and we write $(p)I_{\widetilde{D}}[l]$, if the following relations between their coordinates hold:

$$\begin{cases} l_2 - p_2 = l_1 p_1 \\ l_3 - p_3 = p_1 l_2 \\ l_4 - p_4 = l_1 p_2 \\ l_5 - p_5 = l_1 p_3 - p_1 l_4 \\ l_i - p_i = p_1 l_{i-1} \text{ for } i \bmod 3 \equiv 0 \\ l_i - p_i = l_1 p_{i-2} \text{ for } i \bmod 3 \equiv 1 \\ l_i - p_i = l_1 p_{i-2} - p_1 l_{i-1} \text{ for } i \bmod 3 \equiv 2 \end{cases} \tag{5}$$

for $3 \leq i \leq n$.

Graphs from families $D(n, \mathbb{K})$ and $\widetilde{D(n, \mathbb{K})}$ are bipartite, k-regular, where $|\mathbb{K}| = k$. The girth of graphs from the described families increases with the growth of n. In fact $D(n, q)$ is a family of graphs of large girth and there is a conjecture that $\widetilde{D(n, q)}$ is another family of graphs of a large girth.

All graphs from the considered families are k-regular, bipartite and the set of vertices is $V = P \cup L$, $P \cap L = \emptyset$. They are sparse graphs.

It is clear that there is a natural homomorphism of $T(n+1, \mathbb{K})$ onto $T(n, \mathbb{K})$ of "deleting the last coordinate" that sends $(x_1, x_2, \ldots, x_n, x_{n+1})$ to $(x_1, x_2, \ldots, x_n)$ and $[y_1, y_2, \ldots, y_n, y_{n+1}]$ to $[y_1, y_2, \ldots, y_n]$. It means that there is a well defined projective limit $T(K)$ of graphs $T(n, \mathbb{K})$, $n \to \infty$. Bivariate graphs form a special subclass of so called *linguistic graphs* for which natural projective limits are defined in a similar way.

Recall that the girth $g = g(\Gamma)$ of the graph Γ is the length of its minimal cycle.

Let us assume that the girth $g(n)$ of graphs $T(n, \mathbb{K})$ is unbounded. The obvious inequality $g(n+1) \geq g(n)$ holds. It means that projective limit $T(\mathbb{K})$ has to be a $|\mathbb{K}|$-regular forest. We have such situation in cases of graphs $A(n, \mathbb{F}_q)$ and $D(n, \mathbb{F}_q)$ If $q \geq 2$ then $A(\mathbb{F}_q)$ is a single tree presented by the above equations. Graph $D(F_q)$ is an infinite forest containing infinitely many trees.

Projective limit $W(\mathbb{F}_q)$ of Wenger graphs is an infinite connected graph containing cycles of length 8.

III. General encryption algorithm

We can convert graph $T(n,\mathbb{K})$ to finite automaton in the following way. Let $\mathrm{v}=(v_1,v_2,v_3,v_4,\dots,v_n)\in V(T(n,\mathbb{K}))$ (or $\mathrm{v}=[v_1,v_2,v_3,v_4,\dots,v_n]\in V(T(n,\mathbb{K}))$) and $N_\alpha(\mathrm{v})$ be the operator of taking neighbor of vertex v where the first coordinate is α:

$$N_\alpha(v_1,v_2,v_3,v_4,\dots,v_n)\to[\alpha,*,*,*,\dots,*],$$
$$N_\alpha[v_1,v_2,v_3,v_4,\dots,v_n]\to(\alpha,*,*,*,\dots,*),$$

where $\alpha\in\mathbb{K}$. The remaining coordinates can be determined uniquely using relations describing the chosen graph $T(n,\mathbb{K})$.

We convert $T(n,\mathbb{K})$ to finite automaton via joining v an $N_\alpha(\mathrm{v})$ by directed arrow with weight α. We assume that all vertices of the graph are accepting states.

A bit more interesting object is a symbolic bivariate automaton. Let $\mathrm{a}(x)=(\alpha_1(x),\alpha_2(x),\dots,\alpha_s(x))$ be a string of elements from $\mathbb{K}[x]$ (totality of polynomials in variable x with coefficients from K).

We introduce operator $N^s_{\mathrm{a(x)}}(\mathrm{v})$, where v is a point or a line with coordinates $v_1,v_2,\dots,v_n$, of taking the last vertex u of the path v, $\mathrm{v}_1=N_{\alpha_1(v_1)}(\mathrm{v})$, $\mathrm{v}_2=N_{\alpha_2(v_1)}(\mathrm{v}_1)$, …, $\mathrm{v}_s=N_{\alpha_s(v_1)}(\mathrm{v}_{s-1})=\mathrm{u}$.

We refer to $N^s_{\mathrm{a(x)}}$ as a computation of the symbolic automaton with the string

$$\mathrm{a(x)}=(\alpha_1(\mathrm{x}),\alpha_2(\mathrm{x}),\dots,\alpha_\mathrm{s}(\mathrm{x}))$$

$\alpha_i\in\mathbb{K}[x]$, $i=1,\dots,s$ and initial state $\mathrm{v}=(v_1,v_2,v_3,v_4,\dots,v_n)\in T(n,\mathbb{K})$ (or $\mathrm{v}=[v_1,v_2,v_3,v_4,\dots,v_n]\in T(n,\mathbb{K})$). We can consider $F_s(\mathrm{v})=N^s_{\mathrm{a(v_1)}}(\mathrm{v})$ as a map on $P\cup L$.

It is easy to see that the restriction of this map on P is a polynomial transformation of $P=\mathbb{K}^n$ into P (parameter s is even) or L (parameter s is odd) of kind

$$\begin{aligned}x_1&\to f_1(x_1,x_2,\dots,x_n),\\ x_2&\to f_2(x_1,x_2,\dots,x_n),\\ &\vdots\\ x_n&\to f_n(x_1,x_2,\dots,x_n).\end{aligned}$$

Notice that generally F_s is not a bijection. Let us consider an invertibility condition for F_s.

Proposition III.1. *Let the equations of kind $\alpha_s(x)=b$, $b\in\mathbb{K}$ have exactly one solution. Then map F_s is invertible.*

Proof: It is easy to check that if $F_s(\bar{x})=\bar{y}$ then $F_s^{-1}(\bar{y})=\bar{x}$. It is easy to see that $f_1(x_1,x_2,\dots,x_n)=\alpha_s(x_1)$. Let p be some point from P_n and $F_n(\mathrm{p})=(c_1,c_2,\dots,c_n)$ (point or line). Then the equation $\alpha_s(x_1)=c_1$ has a unique solution η. So we can compute $\eta_1=\alpha_1(\eta)$, $\eta_2=\alpha_2(\eta)$, …, $\eta_{s-1}=\alpha_{s-1}(\eta)$.

We can compute the chain $\mathrm{c}=(c_1,c_2,\dots,c_n)$, $N_{\eta_{s-1}}(\mathrm{c})=\mathrm{c}_1$, $N_{\eta_{s-2}}(\mathrm{c}_1)=\mathrm{c}_2$, …, $N_{\eta_1}(\mathrm{c}_{s-2})=\mathrm{c}_{s-1}$, $N_\eta((\mathrm{c}_{s-1}))=\mathrm{c}_s=(p_1,p_2,\dots,p_n)$ with $\eta=p_1$. So F_n is a bijection. ■

Notice that $N^s_{\mathrm{a}(x)}$ for $\mathrm{a}(x)$ of kind $\alpha_1(x)=\beta_1(x)$, $\alpha_2(x)=\beta_2(\alpha_1(x))$, $\alpha_3=\beta_3(\alpha_2(x))$, …, $\alpha_s(x)=\beta_s(\alpha_{s-1}(x))$ is a composition of ${N^1}_{\beta_1(x)}$, ${N^1}_{\beta_2(x)}$, …, ${N^1}_{\beta_s(x)}$. In this case invertibility of each $\beta_i(x)$, $i=1,2,\dots,s$ guarantees the bijectivity of $N^s_{\mathrm{a}(x)}$. We refer to such case as recurrently defined string.

Let L_1 and L_2 be sparse affine bijective transformation of the affine space (free module in other terminology) $\mathbb{K}^n$

$$\begin{aligned}L_1=T_{A,b}:\bar{x}&\longrightarrow\bar{x}A+b,\\ L_2=T_{C,d}:\bar{x}&\longrightarrow\bar{x}C+d,\end{aligned}$$

where $A=\left[a_{i,j}\right]$ and $C=\left[c_{i,j}\right]$ are $n\times n$ matrices with $a_{i,j},c_{i,j}\in\mathbb{K}$. It is clear that

$$\begin{aligned}L_1^{-1}&=T^{-1}_{A,b}=T_{A^{-1},-bA^{-1}},\\ L_2^{-1}&=T^{-1}_{C,d}=T_{C^{-1},-dC^{-1}}.\end{aligned}$$

Let F_n be a polynomial map of $\mathbb{K}^n$ to itself. We refer to $G_n=\tau_L F_n\tau_R$ as affine deformation of F_n.

Symmetric algorithm

We can use the data on the graph $T(n,\mathbb{K})$, the symbolic computation given by the string $\mathrm{a}=\mathrm{a}(x)$ of polynomials $\alpha_1(x)$, $\alpha_2(x)$, …, $\alpha_s(x)$, where $\alpha_s(x)$ is a bijective map of $\mathbb{K}$ to itself and affine transformations L_1 and L_2 in the following encryption scheme.

Correspondents Alice and Bob agree on a private encryption key

$$K_p=(L_1,L_2,\alpha=(\alpha_1,\alpha_2,\dots,\alpha_s)),$$

and keep the key in secret. Messages are written using characters belonging to the alphabet $\mathbb{K}$. So the plainspace is K^n and its elements must be treated as points (or lines) of the graph. To encrypt they use the composition

$$L_1\circ N^s_{\mathrm{a}}\circ L_2.$$

Notice that the computation has to be executed in numerical level:

1) Correspondent Alice writes plaintext $\mathrm{p}=(p_1,p_2,\dots,p_n)$ and treats it as point of the bivariate graph.
2) She computes parameters $\mu_i=\alpha_i(v_1)$ for $i=1,2,\dots,s$.
3) She computes p_0 as $L_1(\mathrm{p})$, p_1 as $N_{\mu_1}(\mathrm{p}_0)$, p_2 as $N_{\mu_2}(\mathrm{p}_1)$, …, p_s as $N_{\mu_s}(\mathrm{p}_{s-1})$.
4) She computes the ciphertext c as $L_2(\mathrm{p}_s)$.proo

Alice and Bob can use their knowledge about triple (L_1, L_2, a) for the decryption. Let us assume that Bob receives the ciphertext c from Alice. To decrypt the ciphertext Bob proceeds as follows:

1) He has to compute c_0 as ${L_2}^{-1}(\mathrm{c})$.
2) He treats the string of coordinates of this tuple as a vertex of the graph, which is a point in case of even s or the line in case of odd s with coordinates c_1^0, c_2^0, …, c_n^0.
3) Bob must find a solution η of $\alpha_s(x)=c_1^0$ and form a string $\eta_0=\eta$, $\eta_1=\alpha_1(\eta)$, $\eta_2=\alpha_2(\eta)$, …, $\eta_{s-1}=\alpha_{s-1}(\eta)$.
4) He computes c_1 as $N_{\eta_{s-1}}(\mathrm{c}_0)$, c_2 as $N_{\eta_{s-2}}(\mathrm{c}_1)$, …, c_s as $N_{\eta_0}(\mathrm{c}_{s-1})$.
5) He computes the plaintext p as ${L_1}^{-1}(\mathrm{c}_s)$.

Remark III.2. *In the case of identity maps L_1 and L_2 one can try Dijkstra's algorithm for finding the shortest path between plaintext and ciphertext. Notice that its complexity is $O(v \log v)$, but here v is exponential q^n. Therefore we get worse complexity even than brute force search via the key space.*

In the case of recurrently defined symbolic computation as above the encryption bijective map is $F_s = L_1 N^1{}_{\beta_1(x)} N^1{}_{\beta_1(x)} \dots N^1{}_{\beta_s(x)} L_2$. As we already see, this encryption transformation is equivalent to $L_1 N^s{}_{\mathrm{a}(x)} L_2$, where $\mathrm{a}(x) = (\beta_1(x), \beta_2(\beta_1(x)), \dots, \beta_s(\beta_{s-1}(\dots(\beta_1(x)))))$. Recurrently defined symbolic computation is an example of the polynomial map with an invertible decomposition in the sense of [31]. It has various applications in the development of multivariate key exchange protocols and asymmetric multivariate algorithm. The most popular case of implementation is related to graphs $D(n, \mathbb{K})$ (see [1, 21]) and $A(n, \mathbb{K})$ (see [22, 23]), where $\mathbb{K}$ is a finite field of arithmetical rings $\mathbb{Z}_m$ and strings of kind $\beta_1 = x + d_1$, $\beta_2 = x + d_2$, $\dots$, $\beta_s = x + d_s$, where $d_i + d_{i+1}$, $i = 1, 2, \dots, s-2$ are regular elements of the ring $\mathbb{K}$. We refer to such case as shifting encryption.

Let us consider the case of strong symmetric encryption, when the function is $\alpha_s(x) = ax+b$, with a regular (invertible) element of $\mathbb{K}$. In this case it is easy to show that degrees of encryption map F_n and decryption map ${F_n}^{-1}$ are the same. The advantage of this case is its universality. One can implement it in case of arbitrary chosen finite ring $\mathbb{K}$.

IV. On the properties of bivariate graph based bijective encryption maps

The girth G of simple graph G is the length of its shortest cycle. As it was established in [27] the girth of the graph $D(n, \mathbb{F}_q)$ is $\geq n+5$. So in the case of shifting encryption the map with the password $x + d_1$, $x + d_2$, $\dots$, $x + d_s$, $s < n+5$ the encryption map F_n has no fixed points. So ciphertext is always different from the plaintext. Let us consider deformated shifting encryption of kind $\tau_L F_n \tau_R$. We assume that affine maps τ_L and τ_R are fixed. Correspondents are able to change string $d_1, d_2, \dots, d_s$ for another one.

We assume that $d_i + d_{i+1} \neq 0$ for $i = 1, 2, \dots, s-2$. Such choice means that encryption map corresponds to the path of length s. The inequality $g(D(n, q)) \geq n + 5$ implies that different strings of length $s < (n+5)/2$ produce different ciphertexts. So even in the case when τ_L and τ_R are known to adversary the complexity of attacks without an access to unencrypted information is bounded from below by $q^{(n+5)/2}$.

In [44] these results were generalized for the case of general commutative ring $\mathbb{K}$. Let $\mathbb{M}$ be a multiplicative subset of $\mathbb{K}$, i. e. $\mathbb{M}$ is closed under the ring multiplication and it does not contain 0. We say that a string $d_1, d_2, \dots, d_s$ is $|\mathbb{M}|$-regular if $d_i + d_{i+1} \in \mathbb{M}$ for $i = 1, 2, \dots, s-2$. It was proven that different M-regular strings of length $s < (n+5)/2$ produce distinct ciphertexts from the same plaintext. So in the case of $|\mathbb{K}| = k$, $|\mathbb{M}| = m$ the resistance to attacks without access to unencrypted data is bounded from below by $mk^{(n+5)/2-1}$.

It was proven that graphs $A(n, \mathbb{F}_q)$ form a family of graphs of increasing girth $h(n)$ that tends to infinity as n grows. The speed of growth of $h(n)$ needs further evaluation. In [44] it was proven that different $|\mathbb{M}|$-regular strings of length $s < n$ produce different encryption maps.

Results on $|\mathbb{M}|$-regular strings of length restricted maps are obtained in terms of dynamical systems corresponding to graphs $D(n, \mathbb{K})$ and $A(n, \mathbb{K})$.

Let us assume that maps τ_L and τ_R are identities and consider the groups of transformations $GD(n, \mathbb{K})$ and $GA(n, \mathbb{K})$ generated by shifting encryption maps corresponding to strings of even length. In [40] was proven that all elements of $GD(n, \mathbb{K})$ are cubical transformations of affine spaces P_n and L_n. Similar result for $GA(n, \mathbb{K})$ is stated in [44]. As it follows instantly from this result transformation $F'_n = \tau_L F_n \tau_R$ and its inverse are cubical transformations.

The cryptanalytic corollary of this statement is justification of linearization attacks on stream ciphers corresponding to stream ciphers based on graphs $D(n, \mathbb{K})$ and $A(n, \mathbb{K})$.

Let correspondents use the transformation F'_n. The adversary has knowledge on the general scheme of open algorithm but not on the data for τ_L and τ_R and shifting string. So he knows about cubic nature of encryption. We assume that he has access to the unencrypted information and is able to intercept quite many pairs of kind (p, c), where p is plaintext and c corresponding ciphertext.

Then adversary writes G_n which is a formal cubical map in standard form with the unknown coefficients in front of monomial terms. He or she is able to solve system of $O(n^3)$ equations of kind $G_n(\mathrm{c}) = \mathrm{p}$ and restore the map G_n. So adversary could control the communication channel. The complexity of such direct linearization attack is $O(n^{10})$.

V. On the implementation of graph based stream cipher based on non bijective maps

Let us describe an implemented algorithm, which can run in the case of arbitrary commutative ring $\mathbb{K}$ and arbitrary bivariate graph $T(n, \mathbb{K})$. We slightly modify the above described symmetric algorithm based on bivariate graphs $T(n, \mathbb{K})$ which is not a case of shifting encryption. Firstly, we take a symbolic computation for string $\mathrm{a} = \mathrm{a}(x) = (\alpha_1(x), \alpha_2(x), \dots, \alpha_s(x))$, with $\alpha_i(x) = x^d + d_s$, $i = 1, 2, \dots, s$ where d is mutually prime with the order of $\mathbb{K}^*$. So equation $x^d + d_s = c$, $x \in \mathbb{K}^*$ has at most one solution. We take L_1 as an affine bijective transformation of kind $x_1 \to x_1 + x_2 + \dots + x_n$, $x_2 \to l_2(x_1, x_2, \dots, x_n)$, $x_3 \to l_3(x_1, x_2, \dots, x_n)$, $\dots$, $x_n \to l_n(x_1, x_2, \dots, x_n)$, where l_i are linear functions from $K[x_1, x_2, \dots, x_n]$. Correspondents will use the plainspace

$$\Omega = \{(x_1, x_2, \dots, x_n) | x_1 + x_2 + \dots + x_n \in \mathbb{K}^*, \\ x_i \in \mathbb{K}, i = 1, 2, \dots, n\}.$$

They will use $L_1 N^s_{\mathrm{a}(x)} L_2$ as encryption map. To execute computation in time $O(n)$ they take finite parameter s and use loaded tables for $\alpha_i(x)$, $i = 1, 2, \dots, s$ (one dimensional arrays $a_i(x)$, $x \in \mathbb{K}^*$). So they will compute $L_1(\mathrm{p}) = \mathrm{v} = (v_1, v_2, \dots, v_n)$, form sequence $\mu_i = \alpha_i(v_1)$, $i = 1, 2, \dots, s$

  return x

and compute recurrently $\mathrm{v}_i = N_{\mu_i}(\mathrm{v}_{i-1})$, $i = 1, 2, \ldots, s$. They form the ciphertext c as $L_2(\mathrm{v}_s)$.

To decrypt they will take $\mathrm{c}_0 = (c_1^0, c_2^0, \ldots, c_n^0)$ as ${L_2}^{-1}(\mathrm{c})$ and find a solution η for the equation $x^d + d_s = c_1^0$. Loaded table of values for ${\alpha_s}^{-1}$ will allow to find η fast. Next they form a string $\eta_0 = \eta$, $\eta_1 = \alpha_1(\eta)$, $\eta_2 = \alpha_2(\eta)$, $\ldots$, $\eta_{s-1} = \alpha_{s-1}(\eta)$. So users take string $\mathrm{c}_1 = N_{\eta_{s-1}}(\mathrm{c}_0)$, $\mathrm{c}_2 = N_{\eta_{s-2}}(\mathrm{c}_1)$, $\ldots$, $\mathrm{c}_s = N_{\eta_0}(\mathrm{c}_{s-1})$. Finally they get plaintext as $L^{-1}(\mathrm{c}_s)$.

The case of this symmetric algorithm appears as a private key for a cryptosystem introduced in [39] with the plainspace $\mathbb{Z}_m^n$.

We selected string of polynomials as $\alpha_i = x^d + d_i$, $d_i \in \mathbb{K}$, $i = 1, 2, \ldots, s$ and special linear transformations L_1 and L_2, given by the lists of linear forms.

We can theoretically evaluate degrees of encryption d_{enc} and decryption d_{dec}. In cases of graphs $D(n,\mathbb{K})$ and $A(n,\mathbb{K})$, these parameters are bounded below by some constants depending from parameters α_i, $i = 1, 2, \ldots, s$. We can select string of parameters and get d_{dec} large enough to make cryptoanalysis a difficult task. In case $\widetilde{D(n,\mathbb{K})}$ the degrees are even larger, they have size $O(n)$. Notice that direct linearization attacks are formally impossible because the encryption map is not a bijective one.

The implementation of the algorithms in the present work was done using the Python programming language, in particular version 2.7. The code doesn't use any out-of-the-box libraries for facilitating operations with matrices. The tests for measuring the processing time have been executed on a machine with Intel Core2 Duo CPU 9600 1.60GHz x 2, RAM memory 4.8 GB, operating with Ubuntu 16.04 LTS. The complexity of the algorithms is of order $O(sn)$, where s is the length of the password. In particular, we implement this stream cipher for case of $\mathbb{K} = \mathbb{Z}_{256}$ and $\alpha_i(x) = x^3 + d_i$ ($d = 3$ and $d_{\mathrm{dec}} = 43$), $i = 1, 2, \ldots, s$ without using loaded tables for functions. A description of the "nonlinear part" of encryption process, i. e. computation of N_{a}^s is presented below. We recommend a password for which d_2 and $d_i - d_{i+2}$, $i = 1, 2, \ldots, s-2$ are regular elements of the ring.

VI. CONCLUSION

The paper presents a class of stream ciphers defined in terms of graphs given by equations over the finite commutative ring $\mathbb{K}$. The algorithm has multivariate nature: plaintext is a tuple from the free module $\mathbb{K}^n$, key string is also an element of $\mathbb{K}^m$, the encryption map is polynomial transformation of $\mathbb{K}^n$ into itself. Users have options to vary parameters n and m and ring $\mathbb{K}$. If the parameter m is bounded by a constant, then the speed of numerical recurrent of encryption is $O(n)$. The key can be given as a sequence of polynomials in a single variable x. We observe results on simplest case of key strings $x + d_1$, $x + d_2$, $\ldots$, $x + d_s$ obtained by theoretical studies and via computer simulation in case of finite fields or arithmetical rings of kind $\mathbb{Z}_{2^m}$. In case of graphs $D(n,\mathbb{K})$ and $A(n,\mathbb{K})$ simple conditions on d_i ensure that different keys produce distinct ciphertexts and allow to estimate the complexity of adversary attacks without access to plaintext. In the above

Algorithm 2 Encoding with graph $D(n, \mathbb{Z}_{256})$

Input: password $p = (p_0, p_1, \ldots, p_{k-1})$, message $m = (m_0, m_1, \ldots, m_{n-1})$
Output: encrypted message
$x = m$
for $i = 0, 1, ..., k-1$ **do**
  if $i \mod 2 = 0$ **then**
    $y_0 = (m_0^3 + p_i) \mod 256$
    $y_1 = (x_1 + x_0 \cdot y_0) \mod 256$
    if $n \geq 2$ **then**
      $y_2 = (x_2 + x_0 \cdot y_1) \mod 256$
      if $n \geq 3$ **then**
        for $j = 3, 4, \ldots, n$ **do**
          if $j \mod 4 \equiv 3$ or $j \mod 4 \equiv 0$ **then**
            $y_j = (x_j + x_{j-2} \cdot y_0) \mod 256$
          else
            $y_j = (x_j + x_0 \cdot y_{j-2}) \mod 256$
  else
    $x_0 = (m_0^3 + p_i) \mod 256$
    $x_1 = (y_1 - y_0 \cdot x_0) \mod 256$
    if $n \geq 2$ **then**
      $x_2 = (y_2 - y_1 \cdot x_0) \mod 256$
      if $n \geq 3$ **then**
        for $j = 3, 4, \ldots, n$ **do**
          if $j \mod 4 \equiv 3$ or $j \mod 4 \equiv 0$ **then**
            $x_j = (y_j - y_0 \cdot x_{j-2}) \mod 256$
          else
            $x_j = (y_j - y_{j-2} \cdot x_0) \mod 256$
if $k \mod 2 \equiv 1$ **then**
  return y
else
  return x

Algorithm 3 Encoding with graph $\widetilde{D(n, \mathbb{Z}_{256})}$

Input: password $p = (p_0, p_1, \ldots, p_{k-1})$, message $m = (m_0, m_1, \ldots, m_{n-1})$
Output: encrypted message

  return x

mentioned case encryption and decryption maps are cubical and adversary after the interception of $O(n^3)$ pairs of kind plaintext-ciphertext can conduct a linearization attack in time $O(n^{10})$. In case of $\widetilde{D(n, \mathbb{K})}$ the degree of both maps grows linearly with the growth of parameter n, which makes the search for the inverse map via linearization attacks a difficult task. Additionally, authors started investigation of bijective and non-bijective encryption maps with keys of kind $x^d + d_1$, $x^d + d_2$, ..., $x^d + d_s$, where $d > 1$.

In the non-bijective case the plainspace is large subset of $\mathbb{K}^n$ and the adversary has to restore the multivariate encryption transformation E and search for polynomial map E' such that EE' fixes each plaintext. Known methods do not allow to solve this task in polynomial time. Special case with high degree E' is implemented. Loaded tables for x^d allow a fast encryption of text even in case of large parameter d.

***Abstract*—Group anonymity, as an instance of information hiding, means that an agent is not identifiable within a group of agents with respect to an observer. In this paper we define group anonymity in security protocols by taking into account two types of observers: honest agents, as local observers of the protocol execution, and intruders (active or passive), as global observers of the protocol execution. It is shown that an action may be group anonymous in a protocol under a passive intruder but not in the same protocol under an active intruder, and vice versa. In case of basic-term actions, group anonymity in a protocol under an active intruder implies group anonymity in the same protocol under a passive intruder. A broad spectrum of relationships between group anonymity for various types of actions is developed, as well as relationships between group anonymity, minimal anonymity, and role interchangeability. Finally, the decidability and complexity status of the decision problems induced by these concepts is completely discussed. Thus, it is shown that group anonymity and role interchangeability are undecidable in unrestricted protocols. Group anonymity is complete for NEXPTIME when it is restricted to basic-term actions and bounded security protocols, and it is complete for NP when it is restricted to basic-term actions and 1-session bounded security protocols.**

***Index Terms*—Security protocol, anonymity, decision problem, epistemic logic**

I. Introduction

OVER the last two decades there has been a growing interest in methods for anonymous communication and in developing techniques for reasoning about information hiding properties in security protocols [1], [2], [3], [4], [5], [6], [7], [8], [9], [10], [11], [12], [13], [14], [15], [16], [17], [18], [19], [20], [21], [22], [23], [24], [25], [26]. This is mainly due to the applications of the anonymous communication to various fields such as e-voting, e-commerce, e-mail, e-cash and so on.

Information hiding embraces many forms such as *anonymity*, *unlinkability*, *indistinguishability*, *role interchangeability*, *undetectability*, *unobservability*, and *identity management*. In an effort to standardize the terminology on information hiding, Pfitzmann and Hansen have written and maintained since 2000 a consolidated proposal of terminology on information hiding properties [23].

Anonymity is a prominent information hiding property to which a lot of research has been dedicated. Using a multi-agent system and epistemic logic based framework, Halpen and O'Neill [11] classified the anonymity into:

- minimal anonymity – an action performed by an agent is not always seen by an observer;
- group anonymity – an agent who performed some action is not "identifiable", by an observer, within a set of agents. Sender and recipient anonymity in [23] are instances of group anonymity.

Contribution: In two earlier papers [24], [26], we have investigated the minimal anonymity in security protocols. In this paper we do the same for group anonymity. Using the framework developed in [24], [26], we define group anonymity for security protocols. As we are using six types of send actions and six types of receive actions, our approach covers a large spectrum of group anonymity concepts met in the literature on information hiding properties. Several basic relationships between all these concepts of group anonymity are established in the paper.

Anonymity is a property that depends on the observer of the protocol execution. We consider two types of observers: honest agents and the intruder. An honest agent is a local observer of the protocol execution; he can only record information about the actions which involve him. The intruder is a global observer of the protocol execution who can record all actions in the protocol execution. Honest agents and the intruder as observers may have incomparable deductive powers due to the fact that honest agents may know secret information unknown to the intruder, while the intruder may have more information about the actions performed in the protocol. This is clearly reflected in the results obtained in the paper.

As we prove in our paper, group anonymity highly depends on the intruder type: passive or active. Thus, we show that there are group anonymous actions in protocols under passive intruders which are not group anonymous if the intruder is active. That is, an active intruder may destroy the group anonymity property of an action. More interestingly is that the converse holds true as well: there are group anonymous actions in protocols under active intruders which are not group anonymous if the intruder is passive. That is, an active intruder may induce some degree of anonymity in security protocols.

The relationships between minimal anonymity, group anonymity, and role interchangeability are also discussed. Thus, we show that any group anonymous exclusive action is minimally anonymous (in the same security protocol), and any role interchangeable observable action is group anonymous (in the same security protocol).

As decision problem, group anonymity is proven undecidable in unrestricted security protocols. If we restrict group anonymity to basic-term actions and bounded security protocols, then it is complete for NEXPTIME. If one more restriction is added by requiring just 1-session protocol executions, then group anonymity becomes complete for NP.

Related work: The seminal work that marked the development of a formal study of anonymity-related properties is that of David Chaum [1], [2], [3] who proposed a method by which an agent can send a message to some other agent without revealing his identity. Since then, several formalisms for anonymity have been proposed. Thus, [4] proposes a formalization of anonymity in the CSP framework. [6] and [11] focus on anonymity in security protocols and multi-agent systems, respectively, by using an epistemic logic framework. These two papers have greatly influenced the research on anonymity based on an epistemic logic formalism [12], [15], [20], [24], [25], [26]. The roots of our paper can be traced back to these two papers too. While [6], [11] have just offered the basis for an epistemic logic based approach to anonymity, [24], [26] have proposed a rich inference system to reason about anonymity in security protocols. Moreover, based on this, many results on minimal anonymity, such as decidability and complexity results, have been developed in [24], [26]. Our paper continues along the same line, by offering a large spectrum of results on group anonymity in security protocols.

A rather different but very interesting approach to anonymity was proposed by Hughes and Shmatikov [8] by using *function views*. The *cryptographic protocol logic* (CPL) proposed in [27] came as an ambitious general framework for formalizing a very large class of security properties. While CPL seems very expressive, the model checking problem for it is undecidable and not too much about decidable fragments and proof systems for the core CPL is known.

Structure of the paper: The paper is organized into seven sections. The formal model we use in this paper for security protocols is recalled in Section 2. The group anonymity concepts studied in this paper are introduced in Section 3, while Section 4 presents basic properties of these concepts. Section 5 is dedicated to the study of the decidability status of the decision problems induced by our group anonymity concepts, while Section 6 discusses complexity issues. We conclude in Section 7.

Due to the space limitation, the proofs of the results were not included in the final version of the paper.

II. Modeling Security Protocols

The formalism used in this paper to model security protocols is precisely the one in [28], [29], [30], [24], [26]. Therefore, we will only recall its basic notations and terminology (for more details the reader is referred to the papers cited above).

A *security protocol signature* is a 3-tuple $\mathcal{S} = (\mathcal{A}, \mathcal{K}, \mathcal{N})$ consisting of a finite set $\mathcal{A}$ of *agent names* (or shortly, *agents*) and two at most countable sets $\mathcal{K}$ and $\mathcal{N}$ of *keys* and *nonces* (numbers once used), respectively. It is assumed that:

- $\mathcal{A}$ contains a special element denoted by I and called the *intruder*. All the other elements are called *honest agents* and Ho denotes their set;
- $\mathcal{K} = \mathcal{K}_0 \cup \mathcal{K}_1$, where $\mathcal{K}_0$ is the set of *short-term keys* and $\mathcal{K}_1$ is a finite set of *long-term keys*. The elements of $\mathcal{K}_1$ are of the form K_A^e (A's public key), or K_A^d (A's private key), or K_{AB} (shared key by A and B), where A and B are distinct agents;
- some honest agents A may be provided from the beginning with some *secret information* $Secret_A \subseteq \mathcal{K}_0 \cup \mathcal{N}$, not known to the intruder. $Secret_A$ does not contain long-term keys because they will never be communicated by agents during the runs;
- the intruder is provided from the beginning with a set of nonces $\mathcal{N}_I \subseteq \mathcal{N}$ and a set of short-term keys $\mathcal{K}_{0,I} \subseteq \mathcal{K}_0$. It is assumed that no elements in $\mathcal{N}_I \cup \mathcal{K}_{0,I}$ can be generated by honest agents.

The set of *basic terms* is $\mathcal{T}_0 = \mathcal{A} \cup \mathcal{K} \cup \mathcal{N}$. The set $\mathcal{T}$ of *terms* is defined inductively: every basic term is a term; if t_1 and t_2 are terms, then (t_1, t_2) is a term (meaning concatenation of messages); if t is a term and K is a key, then $\{t\}_K$ is a term (meaning t encrypted by K). We extend the construct (t_1, t_2) to $(t_1, \ldots, t_n)$ as usual by letting $(t_1, \ldots, t_n) = ((t_1, \ldots, t_{n-1}), t_n)$, for all $n \geq 3$. Sometimes, parenthesis will be omitted. Given a term t, $Sub(t)$ is the set of all *sub-terms* of t (defined as usual). This notation is extended to sets of terms by union.

The length of a term is defined as usual, by taking into consideration that pairing and encryption are operations. Thus, $|t| = 1$ for any $t \in \mathcal{T}_0$, $|(t_1, t_2)| = |t_1| + |t_2| + 1$, for any terms t_1 and t_2, and $|\{t\}_K| = |t| + 2$, for any term t and key K.

The *perfect encryption assumption* we adopt [31] states that a message encrypted with a key K can be decrypted only by an agent who knows the corresponding inverse K^{-1} of K, and the only way to compute $\{t\}_K$ is by encrypting t with K.

There are two types of actions, send and receive. A *send action* is of the form $A!B : (M)t$, and a *receive action* is of the form $A?B : t$. In both cases, A is assumed an honest agent who *performs the action*, $A \neq B$, $t \in \mathcal{T}$ is the *term of the action*, and $M \subseteq Sub(t) \cap (\mathcal{N} \cup \mathcal{K}_0)$ is the *set of new terms of the action*. $M(a)$ denotes M, if $a = A!B : (M)t$, and the empty set, if $a = A?B : t$; $t(a)$ stands for the term of a. When $M = \emptyset$ we will simply write $A!B : t$. For a sequence of actions $w = a_1 \cdots a_l$ and an agent A, define the *restriction of w to A*, denoted $w|_A$, as being the sequence obtained from w by removing all actions not performed by A. The notations $M(a)$ and $t(a)$ are extended to sequences of actions by union.

A *security protocol* (or simply, *protocol*) is a triple $\mathcal{P} = (\mathcal{S}, \mathcal{C}, w)$, where $\mathcal{S}$ is a security protocol signature, $\mathcal{C}$ is a subset of $\mathcal{T}_0$, called the set of *constants* of $\mathcal{P}$, and w is a non-empty sequence of actions, called the *body* of the protocol, such that no action in w contains the intruder. Constants are publicly known elements in the protocol that cannot be re-instantiated (as it will be explained below). As usual, $\mathcal{C}$ does not include private keys, elements in $Secret_A$ for any honest agent A, or elements in $\mathcal{N}_I$, $\mathcal{K}_{0,I}$ and $M(w)$. Any non-empty sequence $w|_A$, where A is an agent, is called a *role* of the protocol. A role specifies the actions a participant should perform in a protocol, and the order of these actions.

An example of a security protocol is given in Figure 1. In this example, the server S wants to get an opinion from its clients regarding the network services provided by it (the

clients are A and B in our example). Therefore, S generates a fresh short term key K and sends it to A and B. These agents compose some messages (their opinions) t and t' and send them, encrypted by K, to H. When H has collected all the messages (opinions), it forwards them to S.

$$\begin{array}{lcl} S\,!\,A & : & (\{K\})\{K,H\}_{K_{SA}} \\ A\,?\,S & : & \{K,H\}_{K_{SA}} \\ S\,!\,B & : & \{K,H\}_{K_{SB}} \\ B\,?\,S & : & \{K,H\}_{K_{SB}} \\ A\,!\,H & : & \{\{t\}_K,S\}_{K_{AH}} \\ H\,?\,A & : & \{\{t\}_K,S\}_{K_{AH}} \\ B\,!\,H & : & \{\{t'\}_K,S\}_{K_{BH}} \\ H\,?\,B & : & \{\{t'\}_K,S\}_{K_{BH}} \\ H\,!\,S & : & \{\{t\}_K,\{t'\}_K\}_{K_{SH}} \\ S\,?\,H & : & \{\{t\}_K,\{t'\}_K\}_{K_{SH}} \end{array}$$

Fig. 1. A running example

Instantiations of a protocol are given by *substitutions*, which are functions σ that map agents to agents, nonces to arbitrary terms, short-term keys to short-term keys, and long-term keys to long-term keys. Moreover, for long-term keys, σ should satisfy $\sigma(K_A^e) = K_{\sigma(A)}^e$, $\sigma(K_A^d) = K_{\sigma(A)}^d$, and $\sigma(K_{AB}) = K_{\sigma(A)\sigma(B)}$, for any distinct agents A and B. Substitutions are homomorphically extended to terms, actions, and sequences of actions. A substitution σ is called *suitable for an action* $a = AxB : y$ if $\sigma(A)$ is an honest agent, $\sigma(A) \neq \sigma(B)$, and σ maps distinct nonces from $M(a)$ into distinct nonces, distinct keys into distinct keys, and it has disjoint ranges for $M(a)$ and $Sub(t(a)) - M(a)$. σ is *suitable for a sequence of actions* if it is suitable for each action in the sequence, and σ is *suitable for a subset* $C \subseteq \mathcal{T}_0$ if it is the identity on C.

An *event* of a protocol $\mathcal{P} = (\mathcal{S}, \mathcal{C}, w)$ is any triple $e_i = (u, \sigma, i)$, where $u = a_1 \cdots a_l$ is a role of $\mathcal{P}$, σ is a substitution suitable for u and $\mathcal{C}$, and $1 \leq i \leq l$. $\sigma(a_i)$ is the *action of the event* e_i. As usual, $act(e_i)$ ($t(e_i)$, $M(e_i)$) stands for the the action of e_i (term of e_i, set of new terms of e_i). The *local precedence relation* on events is defined by $(u, \sigma, i) \rightarrow (u', \sigma', i')$ if and only if $u' = u$, $\sigma' = \sigma$, and $i' = i + 1$, provided that $i < |u|$. $\stackrel{+}{\rightarrow}$ is the transitive closure of $\rightarrow$. Given an event e, ${}^\bullet e$ stands for the *set of all local predecessors of* e, i.e., ${}^\bullet e = \{e' | e' \stackrel{+}{\rightarrow} e\}$.

Given X a set of terms, $analz(X)$ stands for the least set which includes X, contains t_1 and t_2 whenever it contains (t_1, t_2), and contains t whenever it contains $\{\{t\}_K\}_{K^{-1}}$ or $\{t\}_K$ and K^{-1}. By $synth(X)$ we denote the least set which includes X, contains (t_1, t_2), for any terms $t_1, t_2 \in synth(X)$, and contains $\{t\}_K$, for any term t and key K in $synth(X)$. Moreover, $\overline{X}$ stands for $synth(analz(X))$.

A *state* of a protocol $\mathcal{P}$ is an indexed set $s = (s_A | A \in \mathcal{A})$, where s_A is A's (local) state, for any agent A. The traditional approach to security protocols defines agent states as sets of messages (all messages sent and received by the agent during some computation). This approach is quite sufficient if one wants to reason about confidentiality [28], [29], [30]. However, this is not enough to reason about anonymity properties, where more information about the actions performed by agents in the protocol are needed. One way to solve this is to add *facts* to agent states [6], [24], [26]. A fact is a sentence of the form $P(t_1, \ldots, t_i)$, where P is a predicate symbol and $t_1, \ldots, t_i$ are message terms (facts beginning by the same predicate symbol P will also be called *P-facts*). Using the approach in [24], [26], we will use six classes of facts which are illustrated on the protocol in Figure 1:

1) $sent$-facts. Each agent X who sends a message t to some agent Y records a fact $sent(X, t, Y)$. For instance, when the first action of the protocol in Figure 1 will be performed, S records $sent(S, \{K, H\}_{K_{SA}}, A)$;
2) rec-facts. Two cases are to be considered here:
   a) *passive intruder*. If an action $X\,?\,Y : t$ was performed by X, then X may safely record a fact $rec(X, t, Y)$ because he knows that the message he received is from Y;
   b) *active intruder*. If an action $X\,?\,Y : t$ was performed by X, then X might not be sure whether t comes from Y or from the intruder. In such a case X records a fact $rec(X, t, (Y, I))$ which tells him that t may be from Y or from I.

   If the second action in the protocol in Figure 1 has been performed in some computation, and the intruder was active, then A records the fact $rec(A, \{K, H\}_{K_{SA}}, (S, I))$;
3) $shared\_key$-facts. In the first action of the protocol, the agent S generates a short-term key K and sends it to A. Therefore, K acts as a short term *shared key* between S and A. We use $shared\_key(Z, X, Y, K)$ to mean that Z randomly generated a short term key K to be used by X and Y as a shared-key. In our protocol in Figure 1, $shared\_key(S, S, A, K)$ is the fact to be recorded by A when the first action of the protocol is performed;
4) gen-facts. The message in the first action of the protocol in our running example is *generated by S for A* because it is encrypted by the long term shared key K_{SA}; denote this by $gen(S, \{K, H\}_{K_{SA}}, A)$ and record it in S's state. Similarly, A will record the fact $gen(A, \{t\}_K, S)$ in his state when fifth action of the protocol is performed;
5) $auth$-facts. A message t encrypted by X's private key K_X^d is authenticated by X. The fact $auth(X, (t, \{t\}_{K_X^d}))$ denotes this;
6) hop-facts. These are facts of the form $hop(A, C, B, t)$ whose meaning is that B can only received t from A via C (examples of hope facts can be found in [26]).

According to our discussion above, an agent A state is a pair $s_A = (s_{A,m}, s_{A,f})$, where $s_{A,m}$ is a set of messages and $s_{A,f}$ is a set of facts. Intuitively, $s_{A,m}$ represents the set of all messages the agent A sent or received in some computation from the initial state to the state s_A, and $s_{A,f}$ represents the set of facts which give information about the actions the agent A performed in that computation.

The protocol computation rule in [28], [29], [30] has to be changed accordingly [24], [26]. Given two states s and s' and

an action a, we write $s[a\rangle s'$ if and only if:

1) if a is of the form $A!B : (M)t$, then:
   a) $t \in \overline{s_{A,m} \cup M}$ and $M \cap Sub(s) = \emptyset$;
   b) $s'_{A,m} = s_{A,m} \cup M \cup \{t\}$, $s'_{I,m} = s_{I,m} \cup \{t\}$, and $s'_{C,m} = s_{C,m}$ for any $C \in \mathcal{A} - \{A, I\}$;
   c) the facts in s' are obtained as follows:
      i) add $sent(A, t, B)$ to $s_{A,f}$ and $s_{I,f}$;
      ii) if some term $t_1 = \{t'\}_{K_{AC}}$ or $t_1 = \{t'\}_{K^e_C}$ or $t_1 = \{t'\}_K$ has been built by A in order to build t, where K is a short-term shared key by A and some agent C and A owns this key, then add $gen(A, t_1, C)$ to $s_{A,f}$;
      iii) if some term $t_1 = (t', \{t'\}_{K^d_A})$ has been built by A in order to build t, then add $auth(A, t_1)$ to $s_{A,f}$;
      iv) if some short-term key K has been generated by A to be used as a shared key by two agents C and D, and K is a part of t, then add $shared\_key(A, C, D, K)$ to $s_{A,f}$;
      v) $s'_{C,f} = s_{C,f}$, for any $C \in \mathcal{A} - \{A, I\}$;
2) if a is of the form $A?B : t$, then:
   a) $t \in \overline{s_{I,m}}$;
   b) $s'_{A,m} = s_{A,m} \cup \{t\}$ and $s'_{C,m} = s_{C,m}$, for all $C \in \mathcal{A} - \{A\}$;
   c) the facts in s' are obtained as follows:
      i) add $rec(A, t, (B, I))$ to $s_{A,f}$ and $s_{I,f}$;
      ii) if A received a key K as part of t and he knows that K was generated by some agent C to be shared by A with another agent D, then add $shared\_key(C, A, D, K)$ to $s_{A,f}$;
      iii) if A received a message t' as part of t and he knows that this message comes from some agent C via another agent D, then add $hop(C, D, A, t')$ to $s_{A,f}$;
      iv) $s'_{C,f} = s_{C,f}$, for any $C \in \mathcal{A} - \{A, I\}$.

In the case of a passive intruder (2a) should be "$t \in \overline{s_{B,m}}$" and (2ci) above should be "add $rec(A, t, B)$ to $s_{A,f}$ and $s_{I,f}$". If we remove (1c) and (2c) from the computation rule above, we obtain the standard computation rule in [28], [29], [30].

At each point in the evolution of a protocol, each agent may derive new facts from the facts he owns at that point. The derivation process is guided by deduction rules. In order to present these rules we need first two basic concepts. A message t is called *decomposable* [24], [26] over an agent state $s = (s_m, s_f)$ if $t \in \mathcal{T}_0$, or $t = (t_1, t_2)$ for some messages t_1 and t_2, or $t = \{t'\}_K$ for some message t' and key K with $K^{-1} \in analz(s_m)$, or $gen(A, t, B) \in s_f$ for some honest agents A and B ("$gen(A, t, B)$" covers the case when A generates t for B by encrypting some message by B's public key. A does not know B's corresponding private key but knows how he built t and, from this point of view, we may say that t is decomposable). The function $trace(t, s)$ [24], [26], where t is a message and $s = (s_m, s_f)$ is an agent state, is given by:

- $trace(t, s) = \{t\}$, if $t \in \mathcal{T}_0$;
- $trace(t, s) = \{t\} \cup trace(t_1, s) \cup trace(t_2, s)$, if $t = (t_1, t_2)$ for some terms t_1 and t_2;
- $trace(t, s) = \{t\}$, if t is not decomposable over s;
- $trace(t, s) = \{t\} \cup trace(t', s)$, if $t = \{t'\}_K$ is an encrypted but decomposable message over s.

The deduction rules (Table I) we use are those from [24] with slight modifications [26] (a rule with one or two indexes specifies the current state where the rule should be applied; for instance, $(RShR)_{A,C}$ means that the rule $(RShR)$ should be applied in A's or C's current state. A rule with no indexes means that the rule can be applied in any state). We discuss just one of the rules in Table I, namely $(RShR)$ (for a complete discussion about them, the reader is referred to [26]). According to this rule, if A received a message $\{t\}_K$ encrypted by a short-term key distributed by C to him and to B, then surely B received the key from C.

Given a set M of messages and a set F of facts, denote by $Analz(M, F)$ the set of all facts that can be inferred from F and M. If $s = (s_m, s_f)$ is an agent state, then $Analz(s)$ stands for $Analz(s_m, s_f)$.

III. Defining Anonymity

Anonymity in a security protocol is a property that has to be defined w.r.t. an observer of the protocol execution. In our approach, the observer is either an honest agent (as in [11], [24], [26]) or the intruder (passive [6], [10], or active [24], [26]). Honest agents as observers are limited to observing some of the actions performed by the agents who interact with him, while passive intruders as observers are capable to observe the entire protocol execution. On the other side, honest agents may have more deductive power than passive intruders because they may know secret keys unknown to intruders. Therefore, from the anonymity point of view, honest agents and passive intruder as observers have incomparable powers.

While [6], [10] have considered only passive intruders as observers, in [24], [26] active intruders were taken into consideration too. This is because an action may be anonymous w.r.t. a passive intruder but not w.r.t. an active one, and vice-versa (see [26] and Theorem 5 in this paper).

Observers draw conclusions about protocol executions by analyzing their current states. If two current states are "equivalent", then the conclusions should be equivalent. We formalize this as follows. Given a pair of agent states (s, s') define the binary relation $\sim_{s,s'}$ on message terms by [24], [26]:

- $t \sim_{s,s'} t$, for any $t \in \mathcal{T}_0$;
- $t \sim_{s,s'} t'$, for any term t undecomposable over s and any term t' undecomposable over s';
- $(t_1, t_2) \sim_{s,s'} (t'_1, t'_2)$, for any terms t_1, t_2, t'_1, and t'_2 with $t_1 \sim_{s,s'} t'_1$ and $t_2 \sim_{s,s'} t'_2$;
- $\{t\}_K \sim_{s,s'} \{t'\}_K$, for any terms t and t' and any key K with $t \sim_{s,s'} t'$ and $K^{-1} \in analz(s_m) \cap analz(s'_m)$.

Extend $\sim_{s,s'}$ to facts by $P(t_1, \ldots, t_i) \sim_{s,s'} P(t'_1, \ldots, t'_i)$ if $t_j \sim_{s,s'} t'_j$ for any $1 \leq j \leq i$.

Two agent states $s = (s_m, s_f)$ and $s' = (s'_m, s'_f)$ are called *observationally equivalent* [24], [26], denoted $s \sim s'$, if:

TABLE I
DEDUCTION RULES

$$(S1)\ \frac{sent(A,t,B)}{sent(A,t), sent(A,B), sent(t,B)} \qquad (R1)\ \frac{rec(A,t,x)}{rec(A,t), rec(A,x), rec(t,x)} \qquad (RS)\ \frac{rec(A,t,B)}{sent(B,t,A)}$$

$$(S2)\ \frac{sent(A,B)}{sent(A)} \qquad (R2)\ \frac{rec(A,x)}{rec(A)} \qquad (RGS)_A\ \frac{rec(A,t),\ gen(B,t,A)}{sent(B,t,A)}$$

$$(S3)\ \frac{sent(A,t)}{sent(A), sent(t)} \qquad (R3)\ \frac{rec(A,t)}{rec(A), rec(t)} \qquad (RAS)\ \frac{rec(t),\ auth(A,t)}{sent(A,t)}$$

$$(S4)\ \frac{sent(t,B)}{sent(t)} \qquad (R4)\ \frac{rec(t,x)}{rec(t)} \qquad (SGS)_{A,B}\ \frac{sent(A,t),\ gen(A,t,B)}{sent(A,t,B)}$$

$$(S5)\ \frac{sent(A,t,B),\ t' \in trace(t,s)}{sent(A,t',B)} \qquad (R5)\ \frac{rec(A,t,x),\ t' \in trace(t,s)}{rec(A,t',x)} \qquad (RA)\ \frac{rec(t,\{t\}_{K_A^d})}{auth(A,(t,\{t\}_{K_A^d}))}$$

$$(RG)_A\ \frac{rec(A,\{t\}_{K_{AB}}),\ \neg gen(A,\{t\}_{K_{AB}},B)}{gen(B,\{t\}_{K_{AB}},A)} \qquad (RG')_A\ \frac{rec(A,\{t\}_K),\ shared\_key(C,A,B,K),\ \neg gen(A,\{t\}_K,B)}{gen(B,\{t\}_K,A)}$$

$$(RGR)_{A,B}\ \frac{rec(A,t,(B,I)),\ gen(B,t,A)}{rec(A,t,B)} \qquad (SGR)_{B,C}\ \frac{sent(A,t,B),\ gen(C,t,B), hop(C,A,B,t)}{rec(A,t,C)}$$

$$(RShR)_{A,C}\ \frac{rec(A,\{t\}_K),\ shared\_key(C,A,B,K),\ \neg gen(A,\{t\}_K,B)}{rec(B,K,C)}$$

- $analz(s_m) \cap \mathcal{T}_0 = analz(s'_m) \cap \mathcal{T}_0$;
- $(\forall \varphi \in Analz(s))(\exists \varphi' \in Analz(s'))(\varphi \sim_{s,s'} \varphi')$;
- $(\forall \varphi' \in Analz(s'))(\exists \varphi \in Analz(s))(\varphi' \sim_{s',s} \varphi)$.

That is, s and s' are observationally equivalent if the agent can derive the same meaningful information from any of these two states. In other words, these two states are *indistinguishable*.

Two protocol states s and s' are *observationally equivalent w.r.t. an agent* A, denoted $s \sim^A s'$, if $s_A \sim s'_A$.

It was shown in [24], [26] that the observational equivalence on agent states is an equivalence relation decidable in $\mathcal{O}(f^4 l^4)$ time complexity, where f is the maximum number of facts and l is the maximum length of the messages in the states.

We use a fragment of the epistemic logic in [32], [11] to reason about anonymity. Its syntax is

$$\varphi ::= p \,|\, \varphi \wedge \varphi \,|\, \neg\varphi \,|\, \mathtt{K}_A\varphi$$

where p ranges over a countable set Φ of atomic propositions, A ranges over a non-empty finite set $\mathcal{A}$ of agent names, and φ in $\mathtt{K}_A\varphi$ does not contain any $\mathtt{K}$ operator. Denote by $\mathcal{L}(\Phi,\mathcal{A})$ the set of all formulas defined as above. As usual we use $\mathtt{P}_A\varphi$ as an abbreviation for $\neg\mathtt{K}_A\neg\varphi$.

Let $\mathcal{P}$ be a security protocol. The *truth value of a formula* $\varphi \in \mathcal{L}(\Phi,\mathcal{A})$ *in* $\mathcal{P}$ is defined as follows:

- $\mathcal{P} \models \varphi$ iff $(\mathcal{P}, s) \models \varphi$, for any reachable state s in $\mathcal{P}$;
- $(\mathcal{P}, s) \models p$ iff $(\mathcal{P}, s_A) \models p$, for some agent $A \in \mathcal{A} - \{I\}$;
- $(\mathcal{P}, s) \models \neg\varphi$ iff $(\mathcal{P}, s) \not\models \varphi$;
- $(\mathcal{P}, s) \models \varphi \wedge \psi$ iff $(\mathcal{P}, s) \models \varphi$ and $(\mathcal{P}, s) \models \psi$;
- $(\mathcal{P}, s) \models \mathtt{K}_A\varphi$ iff $(\mathcal{P}, s'_A) \models \varphi$, for any reachable state s' with $s' \sim^A s$;
- for any formula φ without $\mathtt{K}$ operators and any $A \in \mathcal{A}$, $(\mathcal{P}, s_A) \models \varphi$ is defined as follows:
  - if $\varphi = p$ then $(\mathcal{P}, s_A) \models \varphi$ iff $p \in Analz(s_A)$;
  - if $\varphi = \varphi_1 \wedge \varphi_2$ then $(\mathcal{P}, s_A) \models \varphi$ iff $(\mathcal{P}, s_A) \models \varphi_1$ and $(\mathcal{P}, s_A) \models \varphi_2$;
  - if $\varphi = \neg\varphi_1$ then $(\mathcal{P}, s_A) \models \varphi$ iff $(\mathcal{P}, s_A) \not\models \varphi_1$.

We shall simply write $s \models \varphi$ ($s_A \models \varphi$) instead of $(\mathcal{P}, s) \models \varphi$ ($(\mathcal{P}, s_A) \models \varphi$), whenever $\mathcal{P}$ is understood from the context.

The formula $\mathtt{K}_A\varphi$ means "agent A knows φ". It holds in a reachable state s if it holds in any reachable state that is observationally equivalent to s w.r.t. A. $\mathtt{P}_A\varphi$ means "agent A thinks that φ is possible". It holds in a state s if it holds in some reachable state observationally equivalent to s w.r.t. A.

Anonymity in security protocols will be defined for *actions*

performed by agents, w.r.t. some observer. By an *action* we will understand a $sent$-fact (also called $sent$-*action*), or a rec-fact that does not contain terms of the form (B, I) (also called rec-*action*). Therefore, the $sent$-actions are of the form $sent(A, t, B)$, $sent(A, t)$, $sent(A, B)$, $sent(A)$, $sent(t)$, or $sent(t, B)$, while the rec-actions are of the form $rec(A, t, B)$, $rec(A, t)$, $rec(A, B)$, $rec(A)$, $rec(t)$, or $rec(t, B)$. By act we will denote a generic action of the one of the forms above.

Each action, except for $sent(t)$, $sent(t, B)$, $rec(t)$, and $rec(t, B)$, is performed by exactly one agent, namely, the first argument of the corresponding $sent$- or rec-fact. These actions are also called *mono-agent actions*. The actions $sent(t)$, $sent(t, B)$, $rec(t)$, and $rec(t, B)$ may be performed by more than one agent; they will be called *multi-agent actions*. If act is a mono-agent action performed by some agent A, then we also write $act(A)$ just to specify the agent who performs the action. If act is a multi-agent action, such as $sent(t)$, $sent(t, B)$, $rec(t)$, or $rec(t, B)$, we also write $act(t)$ just to specify the message term involved in the action.

Definition 1: Let $\mathcal{P}$ be a security protocol, G a nonempty set of agents, T a finite set of message terms, and X an observer (agent) not in G.

1) A mono-agent action $act(A)$ of $\mathcal{P}$ is *anonymous within G w.r.t. X* if $\mathcal{P} \models \psi(act(A), G, X)$, where $\psi(act(A), G, X) = (\mathtt{P}_X act(A) \Rightarrow \bigwedge_{C \in G} \mathtt{P}_X act(C))$.
2) A multi-agent action $act(t)$ of $\mathcal{P}$ is *anonymous within T w.r.t. X* if $\mathcal{P} \models \psi(act(t), T, X)$, where $\psi(act(t), T, X) = (\mathtt{P}_X act(t) \Rightarrow \bigwedge_{t' \in T} \mathtt{P}_X act(t'))$.
3) An action $sent(A, t)$ is *role interchangeable* within $G \times T$ w.r.t. X if the following property holds:

$$\mathcal{P} \models \mathtt{P}_X sent(A, t) \Rightarrow \bigwedge_{C \in G,\, t' \in T} (\mathtt{P}_X sent(C, t') \Rightarrow \mathtt{P}_X (sent(A, t') \wedge sent(C, t))).$$

A few explanations about these concepts are in order:

- Anonymity of $act(A)$ within G w.r.t. X in $\mathcal{P}$ means that, whenever X thinks that $act(A)$ is possible at some state s then, for any $C \in G$, X thinks that $act(C)$ is possible at some state s' observationally equivalent to s.
- Role interchangeability simply means that, from the observer's point of view, two actions may be interchanged between two distinct agents.

Sender (receiver) anonymity within a set of senders (receivers), as defined in [23], is a special case of anonymity of a mono-agent $sent$-action (rec-action) within a set of agents.

The anonymity concepts introduced in Definition 1(1)(2) are also called *group anonymity* concepts, and the sets G and T in these definitions are called *anonymity sets*. Thus, group anonymity says that the agent who performs an action or the message which purports an action is not identifiable within a set (group) of agents or messages, respectively.

We want to emphasize that the anonymity of an action which contains messages, such as $sent(A, t)$, should not be confused with the secrecy of t. The anonymity of $sent(A, t)$ within G w.r.t. X means that X is not sure whether A sent the message t because he was able to deduce that any member of G sent at some point in the protocol the message t (although X might knew the message t).

Example 2: Figure 2 presents a sequence of inferences in the state s of the protocol in Figure 1, obtained by playing all actions of the protocol (the right hand side column indicates the inference process). It is not difficult to see that:

1.	$shared\_key(S, S, A, K)$	$\in s_S$
2.	$shared\_key(S, S, B, K)$	$\in s_S$
3.	$rec(S, \{\{t\}_K, \{t'\}_K\}_{K_{SH}}, (H, I))$	$\in s_S$
4.	$rec(S, \{\{t\}_K, \{t'\}_K\}_{K_{SH}})$	$3, R1$
5.	$rec(S, \{t\}_K)$	$4, R5$
6.	$rec(S, \{t'\}_K)$	$4, R5$
7.	$\neg gen(S, \{t\}_K, A)$	$\in s_S$
8.	$\neg gen(S, \{t\}_K, B)$	$\in s_S$
9.	$\neg gen(S, \{t'\}_K, A)$	$\in s_S$
10.	$\neg gen(S, \{t'\}_K, B)$	$\in s_S$
11.	$gen(A, \{t\}_K, S)$	$5, 1, 7, (RG')_S$
12.	$gen(B, \{t\}_K, S)$	$5, 2, 8, (RG')_S$
13.	$gen(A, \{t'\}_K, S)$	$6, 1, 9, (RG')_S$
14.	$gen(B, \{t'\}_K, S)$	$6, 2, 10, (RG')_S$
15.	$sent(A, \{t\}_K, S)$	$5, 11, (RGS)_S$
16.	$sent(B, \{t\}_K, S)$	$5, 12, (RGS)_S$
17.	$sent(A, \{t'\}_K, S)$	$6, 13, (RGS)_S$
18.	$sent(B, \{t'\}_K, S)$	$6, 14, (RGS)_S$

Fig. 2. Examples of inferences by the rules in Table I

- $sent(A, t)$ is anonymous within $\{A, B\}$ w.r.t. S (that is, S cannot clearly identify whether A or B sent t);
- $sent(A, t)$ is anonymous within $\{t, t'\}$ w.r.t. S (that is, S cannot clearly identify whether A sent t or t');
- $sent(A, t)$ is role interchangeable within $\{A, B\} \times \{t, t'\}$ w.r.t. S (that is, from S's point of view, A could have send t and B could have send t', or vice versa).

IV. Relating anonymity concepts

A. Basic properties of group anonymity

An action act of a security protocol is called a *basic-term action* if all terms in the action are basic terms. For instance, $sent(A, N_A, B)$, where N_A is a nonce, is a basic-term action, whereas the action $sent(A, \{N_A\}_K, B)$ is not. From definitions we obtain:

Lemma 3: For any basic-term action act, any agent X, and any protocol states s and s', the following property holds: if $s' \sim^X s$ then $s'_X \models act$ if and only if $s_X \models act$.

Proposition 4: A basic-term action $act(x)$ is anonymous within a group G of basic terms w.r.t. X in a protocol $\mathcal{P}$ if and only if, for any reachable state s in $\mathcal{P}$, $s_X \models act(x)$ implies $(\forall y \in G)(s_X \models act(y))$.

Proof. Assume that $act(x)$ is anonymous within a group G w.r.t. X in $\mathcal{P}$, and let s be a reachable state in $\mathcal{P}$ such that $s_X \models act(x)$.

The anonymity of $act(x)$ within G leads to the fact that for any $y \in G$ there exists a reachable state s', observationally equivalent to s w.r.t. X, such that $s'_X \models act(y)$. Lemma 3 leads then to $s_X \models act(y)$. As a conclusion, we obtain

$$s_X \models act(x) \;\Rightarrow\; (\forall y \in G)(s_X \models act(y))$$

The converse is obtained in a similar way. ■

Anonymity highly depends on the intruder type, passive or active. This is shown by Theorem 5 below: there are group anonymous actions in protocols under passive intruders which are not group anonymous if the intruder is active, and vice versa, there are group anonymous actions in protocols under active intruders which are not group anonymous if the intruder is passive.

Theorem 5:

1) There are protocols $\mathcal{P}$, actions $act(x)$, groups G of agents or message terms, and observers X such that $act(x)$ is anonymous within G w.r.t. X in $\mathcal{P}$ under a passive intruder, but $act(x)$ is not anonymous within G w.r.t. X in $\mathcal{P}$ under an active intruder.
2) There are protocols $\mathcal{P}$, actions $act(x)$, groups G of agents or message terms, and observers X such that $act(x)$ is anonymous within G w.r.t. X in $\mathcal{P}$ under an active intruder, but $act(x)$ is not anonymous within G w.r.t. X in $\mathcal{P}$ under a passive intruder.
3) For any protocol $\mathcal{P}$, basic-term action $act(x)$, group G of agents or basic terms, and observer X, if $act(x)$ is anonymous within G w.r.t. X in $\mathcal{P}$ under an active intruder, then $act(x)$ is anonymous within G w.r.t. X in $\mathcal{P}$ under a passive intruder.

The following results relate the group anonymity concepts for various actions.

Theorem 6: Let $\mathcal{P}$ be a security protocol with the property that for any agents $A, X \in \mathcal{A} - \{I\}$, any message t, and any reachable state s, if $s_X \models (rec(t) \wedge auth(A,t))$ then there exists $B \in \mathcal{A} - \{A, I\}$ such that $s_X \models sent(A,t,B)$. Then, the following properties hold in $\mathcal{P}$ (G is a set of agents, T is a set of messages, and X is an observer):

1) If $\bigwedge_{B \in \mathcal{A}-\{A,I\}} \psi(sent(A,t,B),G,X)$ holds in $\mathcal{P}$, then $\psi(sent(A,t),G,X)$ holds in $\mathcal{P}$;
2) If $\bigwedge_{t \in \mathcal{T}} \psi(sent(A,t,B),G,X)$ holds in $\mathcal{P}$, then $\psi(sent(A,B),G,X)$ holds in $\mathcal{P}$;
3) If $\bigwedge_{B \in \mathcal{A}-\{A,I\}} \psi(sent(A,B),G,X)$ holds in $\mathcal{P}$, then $\psi(sent(A),G,X)$ holds in $\mathcal{P}$;
4) If $\bigwedge_{t \in \mathcal{T}} \psi(sent(A,t),G,X)$ holds in $\mathcal{P}$, then $\psi(sent(A),G,X)$ holds in $\mathcal{P}$;
5) If $\bigwedge_{B \in \mathcal{A}-\{I\}} \psi(sent(t,B),T,X)$ holds in $\mathcal{P}$, then $\psi(sent(t),T,X)$ holds in $\mathcal{P}$.

The hypothesis in Theorem 6 is quite natural: if an agent X receives a message authenticated by some agent A, then he draw the conclusion that A sent that message to some other agent B.

Figure 3 pictorially represents the implications in Theorem 6. Moreover, it is not difficult to find examples of protocols

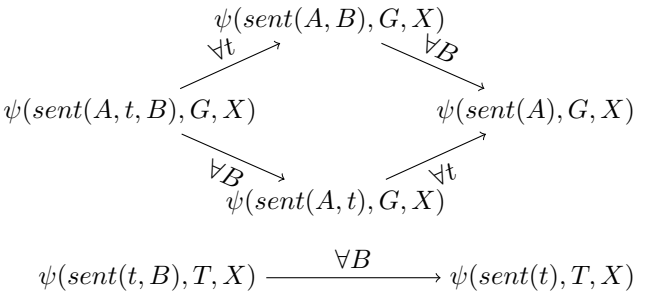

Fig. 3. Relationships between group anonymity concepts

where $\psi(sent(A,B),G,X)$ holds but $\psi(sent(A,t),G,X)$ does not hold, and vice versa. That is, $\psi(sent(A,B),G,X)$ and $\psi(sent(A,t),G,X)$ are incomparable.

Under the *sender identifiability restriction*, Theorem 6 holds for rec-actions too.

Definition 7: Let $\mathcal{P}$ be a security protocol. An action $rec(A,t)$ ($rec(A)$, $rec(t)$, resp.) is *sender identifiable* if, for any X and reachable state s of $\mathcal{P}$ with $s_X \models rec(A,t)$ ($s_X \models rec(A)$, $s_X \models rec(t)$, resp.) there exists B such that $s_X \models rec(A,t,B)$ ($s_X \models rec(A,B)$, $s_X \models rec(t,B)$, resp.).

It is obvious that $rec(A,t)$, $rec(A)$, and $rec(t)$ are all sender identifiable in any protocol $\mathcal{P}$ under a passive intruder. Similar to Theorem 6 we obtain the following result.

Theorem 8: The following properties hold in any security protocol $\mathcal{P}$ (G is a set of agents, T is a set of messages, and X is an observer but not I):

1) If $\bigwedge_{B \in \mathcal{A}-\{A,I\}} \psi(rec(A,t,B),G,X)$ holds in $\mathcal{P}$ and $rec(A,t)$ is sender identifiable, then $\psi(rec(A,t),G,X)$ holds in $\mathcal{P}$;
2) If $\mathcal{P} \models \bigwedge_{t \in \mathcal{T}} \psi(rec(A,t,B),G,X)$ holds in $\mathcal{P}$, then $\psi(rec(A,B),G,X)$ holds in $\mathcal{P}$;
3) If $\bigwedge_{B \in \mathcal{A}-\{A,I\}} \psi(rec(A,B),G,X)$ holds in $\mathcal{P}$ and $rec(A)$ is sender identifiable, then $\psi(rec(A),G,X)$ holds in $\mathcal{P}$;
4) If $\bigwedge_{t \in \mathcal{T}} \psi(rec(A,t),G,X)$ holds in $\mathcal{P}$ and $rec(A)$ is sender identifiable, then $\psi(rec(A),G,X)$ holds in $\mathcal{P}$;
5) If $\bigwedge_{B \in \mathcal{A}-\{I\}} \psi(rec(t,B),T,X)$ holds in $\mathcal{P}$ and $rec(t)$ is sender identifiable, then $\psi(rec(t),T,X)$ holds in $\mathcal{P}$.

B. Minimal and group anonymity

An action act of a protocol $\mathcal{P}$ is *minimally anonymous w.r.t.* X [24], [26] if $\mathcal{P} \models (act \Rightarrow \neg \mathrm{K}_X act)$. Using a multi-agent framework, it has been shown [11] that any *exclusive action* which is anonymous within a group of agents is also minimally anonymous (w.r.t. the same observer). The exclusiveness of an action means that no two different agents can perform the action. This result holds in our framework too.

Definition 9: Let $\mathcal{P}$ be a security protocol and A an honest agent. An action $act(A)$ performed by A is *locally exclusive* if $s_B \models \neg(act(A) \wedge act(A'))$, for any reachable state s of $\mathcal{P}$, any honest agent B, and any honest agent $A' \neq A$.

Proposition 10: If a locally exclusive action $act(A)$ of a security protocol $\mathcal{P}$ is anonymous within G w.r.t. an honest agent H and $|G| \geq 3$, then $act(A)$ is minimally anonymous w.r.t. H.

If the agent H in Proposition 10 is replaced by the intruder, then Proposition 10 might not hold. This is because if an action $act(A)$ is in some state of H, then the action still may be anonymous within some set G w.r.t. H, but it is definitely not minimally anonymous w.r.t. H.

If the local exclusiveness of an action fails to hold, then the conclusion of Proposition 10 may fail too.

C. Role interchangeability and group anonymity

As it was remarked in [12], [20] using a multi-agent framework, role interchangeability implies group anonymity, under certain conditions. We recall this result here in our security protocol framework.

Definition 11: Let $\mathcal{P}$ be a security protocol, $G \subseteq \mathcal{A} - \{I\}$ a set of agents, and $T \subseteq \mathcal{T}$ a finite set of message terms, and X an observer. We say that an action $sent(A,t)$ is $(G \times T)$-*observable w.r.t.* X if the following property holds

$$s_X \models (sent(A,t) \;\Rightarrow\; \bigwedge_{C \in G} \bigvee_{t' \in T} sent(C,t'))$$

for any reachable state s in $\mathcal{P}$.

One can easily prove now the following result:

Proposition 12: Let $\mathcal{P}$ be a security protocol, $G \subseteq \mathcal{A} - \{I\}$ a set of agents, $T \subseteq \mathcal{T}$ a finite set of message terms, and X an observer. If X is not in G and $sent(A,t)$ is role interchangeable within $G \times T$ and $(G \times T)$-observable w.r.t. X, then $sent(A,t)$ is anonymous within G w.r.t. X.

Role interchangeability can similarly be formulated for actions like $sent(A,B)$, $rec(A,t)$, or $rec(A,B)$.

V. Deciding Group Anonymity

In this section we establish several undecidability results for the anonymity concepts defined so far. The proofs are based on the undecidability of the halting problem for counter machines and various reduction techniques.

Each action has a *type* which is a tuple. For instance, $sent(A,t,B)$ has type (s,a,m,a) and $rec(A,t)$ has type (r,a,m), where s stands for "$sent$", r stands for "rec", a for "agent", and m for "message".

Each action type τ induces two decision problems:

1) the *group anonymity problem for type τ actions w.r.t. an honest agent*, abbreviated $GAP(\tau)$, which is the problem to decide, given a security protocol $\mathcal{P}$, a type τ action act, a non-empty set G of honest agents or messages, and an honest agent H not in G, whether act is anonymous within G w.r.t. H in $\mathcal{P}$;
2) the *group anonymity problem for type τ actions w.r.t. the intruder*, abbreviated $GAP_I(\tau)$, which is the problem to decide, given a security protocol $\mathcal{P}$, a type τ action act, a non-empty set G of honest agents or messages, whether act is anonymous within G w.r.t. the intruder.

Now, we can prove the following theorem.

Theorem 13:
1) *$GAP(\tau)$ is undecidable in unrestricted security protocols, for any action type τ.*
2) *$GAP_I(\tau)$ is undecidable in unrestricted protocols, for any $sent$-action type τ.*

In Section IV-B it has been shown that group anonymity implies minimal anonymity in case of exclusive actions. However, exclusiveness is undecidable.

Theorem 14: Local exclusiveness problems is undecidable in unrestricted security protocol.

Role interchangeability is an undecidable problem too. It is the problem to decide, given a security protocol $\mathcal{P}$, an action $sent(A,t)$, a group $G \subseteq \mathcal{A} - \{I\}$ of agents, a finite set $T \subseteq \mathcal{T}$ of message terms, and an honest observer H, whether $sent(A,t)$ is role interchangeable within $G \times T$ w.r.t. H.

Theorem 15: Role interchangeability is undecidable in unrestricted security protocols.

VI. Complexity of Group Anonymity

The group anonymity problem is undecidable in unrestricted security protocols. Clearly, if we focus on bounded security protocols then group anonymity is decidable. In this section we study the complexity of this problem. Recall first a few concepts regarding bounded protocols [30].

Let $\mathcal{P} = (\mathcal{S}, \mathcal{C}, w)$ be a security protocol, $T \subseteq \mathcal{T}_0$ a finite set, and $k \geq 1$. A (T,k)-*run* of $\mathcal{P}$ is any run with the property that all terms in the run are built up upon T and all messages communicated in the course of the run have length at most k. When for $\mathcal{P}$ only (T,k)-runs are considered we say that it is a *protocol under (T,k)-runs* or a (T,k)-*bounded protocol*, and denote this by $(\mathcal{P},T,k)$. A *bounded protocol* is a (T,k)-bounded protocol, for some finite set $T \subseteq \mathcal{T}_0$ and $k \geq 1$.

A *1-session (T,k)-run* of $\mathcal{P}$ is any (T,k)-run of $\mathcal{P}$ obtained by applying each role at most once (not necessarily in its entirety), under the same substitution (i.e., all its events are defined by using the same substitution). Therefore, any 1-session (T,k)-run has length at most $|w|$. When for the protocol $\mathcal{P}$ only 1-session (T,k)-runs are considered we say that it is a *1-session (T,k)-bounded protocol*. A *1-session bounded protocol* is a 1-session (T,k)-bounded protocol, for some finite set $T \subseteq \mathcal{T}_0$ and $k \geq 1$.

In [30] it has been shown that the number of distinct events in a (T,k)-run of a protocol $\mathcal{P}$ is exponential in $poly(size(\mathcal{P}))$, where $size(\mathcal{P}) = |w| + k \log |T|$ and $poly$ is a polynomial. For 1-session (T,k)-runs, the number of events

in each such run is at most the length of the protocol's body. Although the term $log|T|$ is not necessary to define the size of a 1-session (T,k)-bounded protocol, we will use the same protocol size as defined above just for the sake of uniformity with the results in [30].

The following technical lemma [26] will be very useful in estimating the time complexity of our algorithms.

Lemma 16 ([26]): Let $\mathcal{P}=(\mathcal{S},\mathcal{C},w)$ be a (T,k)-bounded protocol, s be the last state of some run of length n of $\mathcal{P}$, A an agent, t be a message of length at most k over T, and φ a fact whose terms have length at most k. Then,

1) it is decidable in $\mathcal{O}(nk^2)$ time whether t is derivable from $s_{A,m}$ (i.e., $t\in\overline{s_{A,m}}$);
2) it is decidable in $\mathcal{O}(n^3k^6)$ time whether $\varphi\in Analz(s_A)$;
3) it is decidable in $\mathcal{O}(n^3k^6|w|)$ time whether $\varphi\in Analz(s_B)$ for some agent B.

The state space of a bounded security protocol is finite and so we are able to decide whether an action $act(x)$ is anonymous within some group G w.r.t. some observer X. An obvious algorithm for deciding this would search the state space twice: first, the algorithm detects a state s with $s_X\models act(x)$ and then, for each $y\in G$, the algorithm searches for a state s' with $s'\sim^X x$ and $s'_X\models act(y)$. As the number of events of a bounded security protocol is exponential w.r.t. the size of the protocol [30], this algorithm has a very high time complexity (w.r.t. the size of the protocol).

If we restrict the group anonymity problem to basic-term actions (Section IV-A) then Proposition 4 shows that only one search through the state space would suffice.

Theorem 17: $GAP(\tau)$ and $GAP_I(\tau)$ are in $NEXPTIME$ for any τ if they are restricted to basic-term actions of type τ and bounded security protocols. Moreover, except for $GAP_I(\tau)$ where τ is a rec-action type, all the other group anonymity problems restricted as above are complete for $NEXPTIME$.

If we restrict more bounded security protocols by allowing only 1-session runs, then we obtain the following results.

Theorem 18: $GAP(\tau)$ and $GAP_I(\tau)$ are in NP for any τ if they are restricted to basic-term actions of type τ and 1-session bounded security protocols. Moreover, except for $GAP_I(\tau)$ where τ is a rec-action type, all the other group anonymity problems restricted as above are complete for NP.

VII. Conclusions

Employing the epistemic logic framework developed in [24], [26], this paper proposes an approach to group anonymity in security protocols. This is formulated with respect to an honest agent and with respect to the intruder. A large spectrum of relationships between, and properties of, anonymity concepts were provided. One of the most interesting properties states that a group anonymous action in a security protocol under a passive intruder might not be group anonymous in the same security protocol if the intruder is active, and vice-versa.

It is shown that group anonymity is undecidable in unrestricted security protocols. Clearly, it becomes decidable in bounded security protocols. More precisely, group anonymity is complete for NEXPTIME if it restricted to basic-term actions and bounded security protocols, and it is complete for NP if it restricted to basic-term actions and 1-session bounded security protocols. These results show how difficult is to prove group anonymity for bounded security protocols. In practice, one has to design decision tools for group anonymity to work on restricted classes of protocols in order to obtain feasible results. We are not aware of any approaches for "practical classes of security protocols". However, there are tools such as MCMAS [33], [34] and PRISM [35] capable to check epistemic formulas on "not very complex" security protocols met in practice.

3rd Workshop on Constraint Programming and Operation Research Applications

THE aim of the CPORA-Workshop on Constraint Programming and Operation Research Applications is to bring together interested researchers from constraint programming/constraint logic programming (CP/CLP), operations research (OR) and artificial intelligence (AI) to present new techniques or new applications in decision support, combinatorial optimization, modeling and control processes arising in manufacturing, transportation, telecommunication, computer networks, logistic systems etc. and to provide an opportunity for researchers in one area to learn about techniques in the others. The aim of this workshop is share ideas, projects, researches results, models, experiences etc. associated with CP/CLP/OR/AI and to give researchers the opportunity to show how the integration of techniques from different fields can lead to interesting results on large and complex problems. Additionally, we would like to stimulate the communication between researchers working on different fields and practitioners who need reliable and efficient modelling and computational methods for industrial and business processes.

Contributions containing of both: the theoretical and practical results obtained in this area are welcome.

TOPICS

- Constraint programming/Constraint logic programming,
- Mathematical programming,
- Constraint Satisfaction Problem,
- Logic programming,
- Hybrid methods,
- Network programming,
- Petri-Nets,
- Knowledge methods,
- Soft computing (FL, GA, NN etc.),
- Answer Set Programming (ASP),
- The boolean satisfiability problem (SAT).

***Abstract*—Visualization of logical formulas for classical propositional calculus gains a new meaning in the context of a huge development of SAT solvers which find solutions of satisfiability problems of bigger and more complex tasks including the ones of industrial meaning. The aim of this work is to create, using modern IT tools, a coherent and widely accessible system in a form of web application, which will be able to provide a coopertive system, as well as will help to visualize, analyze and transform logical formulas. The system itself is now in the initial, however, mature implementation phase. It is open for new ideas and methods. New functionalities have already been introduced but there are plans to create the new ones.**

***Index Terms*—SAT; visualization; graph.**

I. Introduction

SATISFIABILITY problem is the classical and fundamental problem of theoretical computer science in which there can be encoded many other problems [1]. Satisfiability problem is a testing whether exists of a logical value assignment (true/1, false/0) to variables in a particular formula which will satisfy it, namely its logical value will be true. Those types of problems can be applied to many branches and are commonly used, for example in combinatorial optimization [2], graph theory, automated theorem proving, verification of software models [3], [4], [5], [6], and artificial/ambient intelligence [7], [8], [9].

Tools which solve satisfiability problem are called SAT solvers. Their rapid development and routine solving of tasks, which consist of many thousands of variables and clauses, enables practical implementation of reasoning engines which are quite common and easily accessible [10], [11]. There was created a standard of input files recording, known as DIMACS CNF format or simply DIMACS, where the base DIMACS relates to the name of the research center where it was created, namely The Center of Discrete Mathematics and Theoretical Computer Science, and CNF is a reference to the conjunctive form of the normal formula (Conjunctive Normal Form). This form is used to save logical formula in leading solvers based on CDCL method where problem is enclosed in this form in a particular file having DIMACS form. Thanks to using one format it is easy to compare existing SAT solvers and to see new possibilities of creating new, interesting tools based on the same input files which can be related to SAT or similar concepts.

Nowadays, SAT solvers are commonly used in a formal verification of designed systems, especially embedded systems, cyber-physical systems and software drivers. Solvers become more and more popular. Their widespread use is visible in the processes described as Electronic Design Automation (EDA) because designing processes of those sets, especially embedded sets, need to be analyzed carefully as the errors done during their design and production can have detrimental effects and be very costly. The similar situation appears when we talk about drivers which unstable work can interfere with the working of the system core.

Visualization of logical formula can also be a useful, and to some extend helpful, tool in solving satisfiability problem as well as in analysis and preprocessing of formulas as input data for SAT solvers. The graphic form of formula, its shape, regularity or irregularity, consistency or inconsistency can provide us with many valuable pieces of information about the encoded problem, see for example [9, Table 11]. It can also suggest recommended formula preprocessing methods which can speed up the process of searching for a satisfiable solution. That is why visualization helps us to understand the encoded problem better and gives us an opportunity of carrying an additional and quicker analysis of the problem before our attempt to solve it. Last but not least, visual image of a formula can have an aesthetic meaning. The generated visualizations create interesting visual effects which may be attractive for people who have not dealt with SAT topic so far.

The aim of this work is to create widely accessible service in form of web application, built on the basis of modern IT tools, easy to handle and enabling the visualization of logical formulas of propositional calculus which are the input data for SAT solvers based on CDCL method (Conflict Driven Clause Learning). The present system is based on work [12], however, it has been adjusted to the web requirements[1].

The development of solvers which work on the basis of this method needs to be acknowledged as a spectacular one. Every formula can be visualized and analyzed before we start looking for its solution. Although in this work there were presented the well-known visualization methods but there also were proposed new functionalities of the system. The existing program called *DPvis* created by Carsten Sinz, see seminal and fundamental work [13], enables crating different types of graphs on the basis of formulas describing SAT problems. However, this program is hardly accessible and not compatible with demands of the modern and dynamic IT market which can discourage the present and potential users. Under those circumstances, creating the fully web application, see [12], which enables cooperative work in client-server

[1]The planned website for this service is http://forvis.agh.edu.pl.

architecture, built on the basis of modern IT tools and offering SAT problems visualizations, may encourage new users or specialists and provide them with tools which simplify their everyday work.

In the future the service will be extended to provide fluent transition between different methods of formula visualizations or different methods of encoding logical formulas. There are also plans to open the service for related problems according to classical SAT, namely *MaxSAT* (finding the maximal number of clauses, if not all, of the entire formula to be satisfied) and *weighted MaxSAT* (finding an assignment that maximizes the total weight of the satisfied clauses), *Partial MaxSAT*(some clauses are deemed hardinfinite weights, clauses with finite weight are soft), and other problems, which will enable the analysis of fragmentary problem solutions in the context of the whole problem.

II. Preliminaries

Supported file format is a commonly recognized DIMACS CNF format. System should offer a possibility of storing saved files and exporting created visualizations to graphic files within a wide range of formats.

Logical formula F is in CNF form because it is built from conjunction of clauses, which can be presented as $F = \bigwedge_{i=1}^{m} C_i$ that is a conjunction of clauses C_1, C_2, ..., C_m and every clause is built from disjunction of literals $C_i = \bigvee_{j=1}^{n} l_i, j$ where literal l can be a variable x or its negation $\neg x$. The example of logical formula in CNF form is the formula:

$$(x \vee \neg y) \wedge (z \vee y \vee \neg x)$$

DIMACS CNF file is saved as ASCII text file which enables easy transmission between different operational systems or working environments. The file can have lines of comments, so-called line of problem, but its most important part are the following clauses, whereby every of them finishes with number 0. Every clause is built from a sequence of natural numbers where every number clearly identifies one variable (can be from thesaurus of variables). Moreover, every number may be predeceased by minus or not be predeceased, where symbol of minus signifies negation of this variable. Therefore, the particular numbers signify literals. The following file is an example of that:

```
c
p cnf 212 118098
-169 -177 -184 -182 -174 -187 -196 -201 -199
-191 -17 -26 -32 -28 -23 -35 -41 -48 -46 -38
-53 -60 -65 -62 -56 -68 -77 -83 -79 -73 -86

-122 -126 -132 -129 -125 -139 -144 -151 -146
-142 -154 -162 -166 -164 -157 12 13 14 15 0
-169 -177 -184 -182 -174 -187 -196 -201 -199
-191 -17 -26 -32 -28 -23 -35 -41 -48 -46 -38
-53 -60 -65 -62 -56 -68 -77 -83 -79 -73 -86
-93 -100 -97 -89 -103 -109 -117 -113 -108
-122 -126 -132 -129 -125 -139 -144 -151 -146
-142 -154 -162 -166 -164 -157 12 13 14 15
170 171 172 173 178 179 184 185
181 182 175 176 0
```

The size of logical formula within a file does not prove difficulty of the problem itself but, of course, in practice, the time spent on searching for the solutions of the big formulas is longer, sometimes very long. There are tools which aim is to minimize logical formulas which can reduce time of solving the problem significantly. One of the better known tools is *SatELite* program which implements the following techniques [14]:

1) elimination of variables by resolutions – deleting unnecessary variables and equivalent literals;
2) fast subsumption – C_1 clause subsumes C_2 when $C_1 \subseteq C_2$, therefore C_1 may be deleted;
3) self-subsumption – C_1 clause almost fully subsumes C_2 with exception of one literal x which appears in C_2 with a different value. For example, $C_1 = \{x, a, b\}$, and $C_2 = \{\neg x, a\}$. Resolution for x gives $C_1' = \{a, b\}$, which subsumes C_1, therefore C_1 can be added to logical formula and C_1 can be removed.

III. Visualization methods

There are used three basic methods of visualization in this work . It does not cover all planned implementation methods. The present set should be interpreted as an initial proposition for system functionalities. The currently used methods are [13]:

- factor graph,
- interaction graph,
- resolution graph.

Undirected factor graph $G_F = (V, E)$ is a graph where a set of vertices V is created by variables and clauses, therefore $V = X \cup C$, where X is a set of variables and C is a set of clauses. E symbol means a set of edges. The edge is drawn between variable x and clause c when $x \in C$ or $\neg x \in C$. Provided that there exists a problem described by formula: $(\neg x \vee \neg y \vee z) \wedge (y \vee z) \wedge (x \vee \neg z \vee u)$ it is possible to determine the following clauses:

1) $C_1 = (x \vee \neg y)$
2) $C_2 = (\neg x \vee z \vee u)$
3) $C_3 = (x \vee z)$

Construction of factor graph for the problem presented above should start from drawing variables and clauses in form of vertices, see Fig. 1. Later on we draw edges which connect variables with clauses in which they appear, starting from clause C_1. Finally, the graph looks like the last structure in Fig. 1.

In contrast to undirected factor graph, directed factor graph includes the difference between a variable in positive and negative form. It is usually presented using colors, where green means not negated variable and red a negated one. For the analyzed problem, the graph looks like the following one: Fig. 2.

Variable interaction graph $G_I = (V, E)$ is a graph in which a set of vertices V is equal to a set of variables X which is equivalent to $V = X$. E means a set of edges. The edge

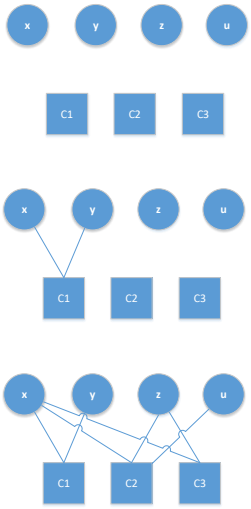

Fig. 1. Structure of a factor graph, and successive construction steps

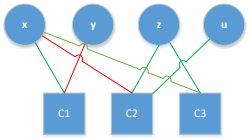

Fig. 2. Directed factor graph

connects two variables: x and y when they appear together in at least one clause ($x \in C_i$ and $y \in C_i$). On the basis of the example from the previous section, there are determined the following clauses:

1) $C_1 = (x \vee \neg y)$
2) $C_2 = (\neg x \vee z \vee u)$
3) $C_3 = (x \vee z)$

The first step to create interaction graph is drawing variables in the form of vertices, see Fig. 3. Later on, starting from C_1 clause, the appearing variables are connected together. When analyzing next clauses, if the particular edge already exists for a pair of variables, it is omitted. Finally, the graph looks like the last structure in Fig. 3.

Resolution graph $G_R = (V, E)$ is a graph in which a set of vertices V is equal to a set of clauses, therefore $V = C$. E means a set of edges. The edge connects two variables C_1 and C_2 only if there is a variable x where $x \in X$, in which X means a set of variables where $x \in C_1$ and $\neg x \in C_2$. Using the previously presented formula and having already determined clauses:

1) $C_1 = (x \vee \neg y)$
2) $C_2 = (\neg x \vee z \vee u)$
3) $C_3 = (x \vee z)$

Construction of the resolution graph starts from drawing clauses in form of vertices, see Fig. 4. Later on the following variables which appear in both C_1 and C_2 clauses are analyzed. Because $x \in C_1$ and $x \in C_2$ there can be drawn an

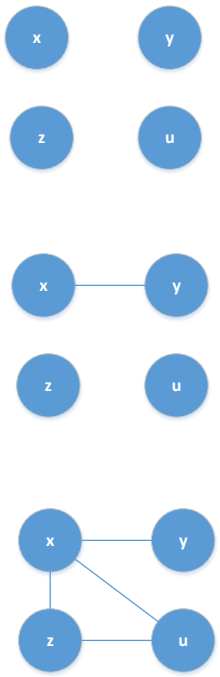

Fig. 3. Structure of interaction graph, and the succseeding, and successive construction steps

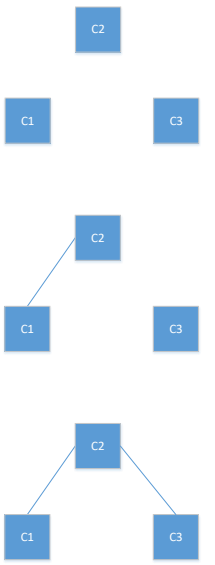

Fig. 4. Structure of resolution graph, and the succseeding, and successive construction steps

edge between the clauses. The redundant edges are omitted. Finally, the graph looks like the last structure in Fig. 4.

The methods of visualization presented above are the basic set of methods. In the future there are plans to introduce the new ones taking into consideration needs and nature of SAT-related problems.

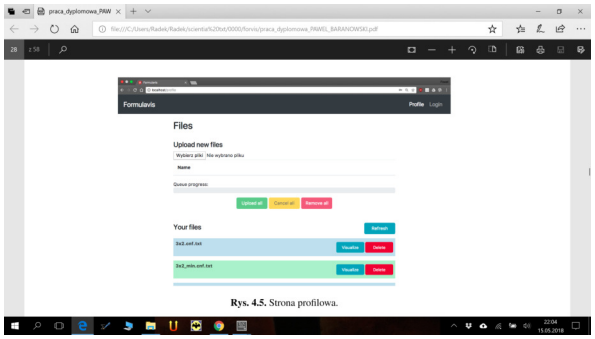

Fig. 5. The screenshot of the system – formula management

IV. Design of visualization system

The implemented system, see Fig. 5, is breifly described. Server application was made using *Python* language together with frame of *Django REST Framework* application [15]. For operation of asynchronous tasks, *Celery* task queue [16], together with *RabbitMQ* [17] message broker, are responsible. Data is stored in *PostgreSQL* database server. Client application, as well as user's interface, was created on the basis of *TypeScript* language using the frame of *Angular 4* application. There was used an effective visualization library based on *JavaScript* language named *vis.js* [18]. Server proxy *Nginx* [19] is responsible for managing the movement between user's graphic interface and server application. The whole project is containerized using *Docker* technology [20]. *Nginx* plays the role of Reverse-Proxy or Forward-Proxy server, see Fig. 6. Reverse-Proxy server helps in:

- hiding the current system which is behind proxy server,
- distributing the movement between application instances of the server,
- pointing the movement towards proper applications,
- compressing the content of data flow,
- manipulating with requests and answers.

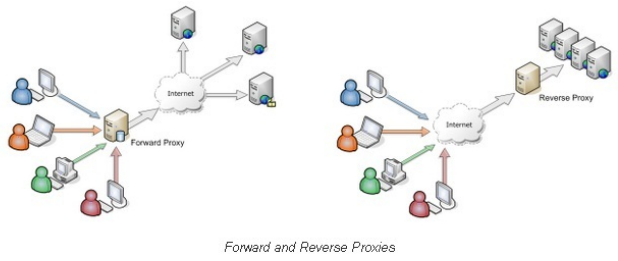

Fig. 6. Difference between Forward-Proxy i Reverse-Proxy server. Source: Vivek Srivastav: Proxy Pass. [In:] http://viveksrivastv.blogspot.com/p/apache-administration.html. Accessed on 1 May 2018.

Celery is a asynchronous task queue based on task distribution using messages. It concentrates on operations performed in the shortest possible time but also it supports planned tasks. Tasks are performed at the same time using one or many executive instances – workers and with the use of multiprocess transformation. Those tasks can be performed asynchronously (it enables the ordering application to perform further work) or synchronically (the ordering application waits for the result). In order to use *Celery*, it is required to use message broker which provides data for workers. The message broker recommended by *Celery* authors is *RabbitMQ*. It is an open source and easy to implement system in *Erlang* language. It supports and monitors asynchronous message sending and their deployment using clusters which enables further development of the system.

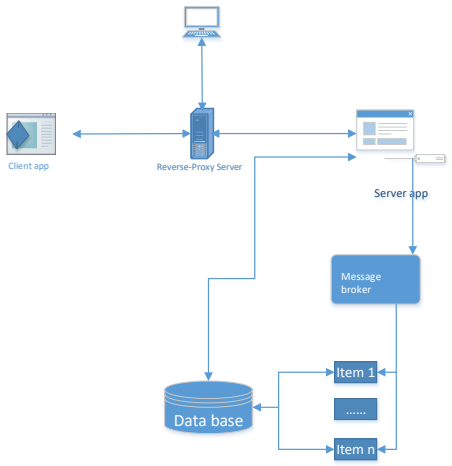

Fig. 7. Structure of logical formula visualization system

The created client application is an interface of the whole system because a target user has an access to it. Thanks to that, the user can log in and log out, upload and delete data from server and, most importantly, display visualizations and save them to file. Implemented application is in the form of browser application. Server application, implemented separately, organizes the whole data processing according to user's expectations. Detailed analysis of this issue exceeds the aim and size of this work, see also Fig. 7.

V. Examples of visualization

There were examined many formulas in terms of possibilities for system work as well as visualization effects. All figures (from 8 to 13) are provided by the designed system, see also [12]. Presentation starts from simple formulas and continues to the most complicated ones. We will start from a very simple example, see also Fig. 8:

```
p cnf 3 2
1 -3 0
2 3 -1 0
```

In interaction graph:

- blue vertices – represent variables,
- edge, shade of edge signifies number of connections between variables (the more of them, the darker the shade is). Interaction graph presents the structure of variables neighborhood within the examined logical formula. On the basis of that there can be performed the analysis if a

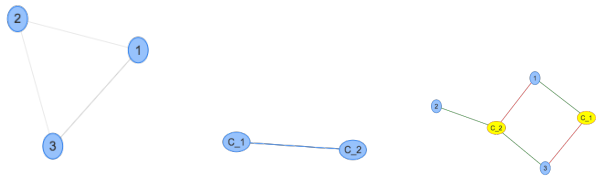

Fig. 8. First example: interaction, resolution and factor graphs

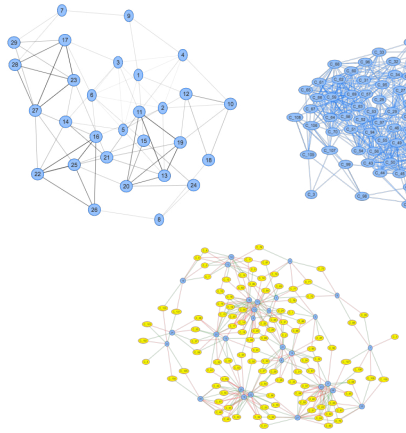

Fig. 9. Second example, interaction, resolution and factor graphs

problem is integral or if it can be divided into parts. What is more, the edges brightness can help to find frequent neighborhoods of variables.

In resolution graph:

- blue vertices – represent clauses.

Resolution graph visualizes the structure of clause dependencies. Vertices are connected by edge if they have one (or more) literals of a different logical value. In directed factor graph:

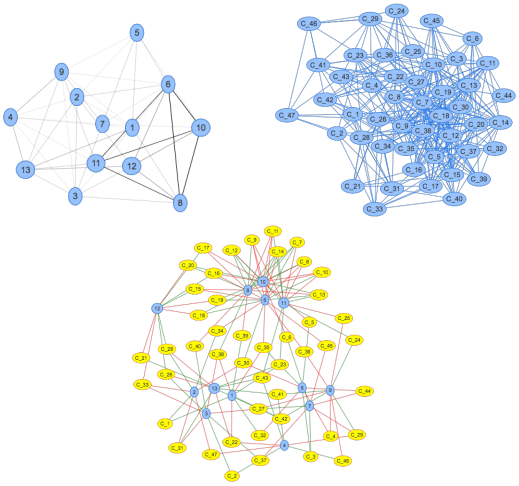

Fig. 10. Second example, after minimalization: interaction, resolution and factor graphs

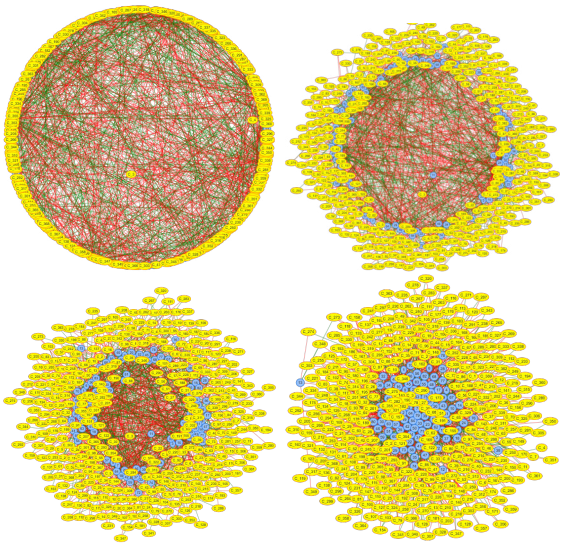

Fig. 11. Third example: stabilization, factor graphs – before stabilization, first screenshot, second screenshot, after stabilization

- yellow vertices – represent clauses,
- blue vertices – represent variables,
- red edge – represents a variable with negation,
- green edge – represents a variable without negation.

Factor graph shows clause dependencies and variables with their logical values.

The next analyzed formula has 29 variables and 109 clauses, and is shown in Fig. 9. After preprocessing, the minimization was performed which gave 13 variables and 47 clauses, see Fig. 10.

In a created system there was implemented graph/formula *stabilization* operation. It means, that the graph was rebuilt in such a way that the edges got a total minimal length. Stabiliza-

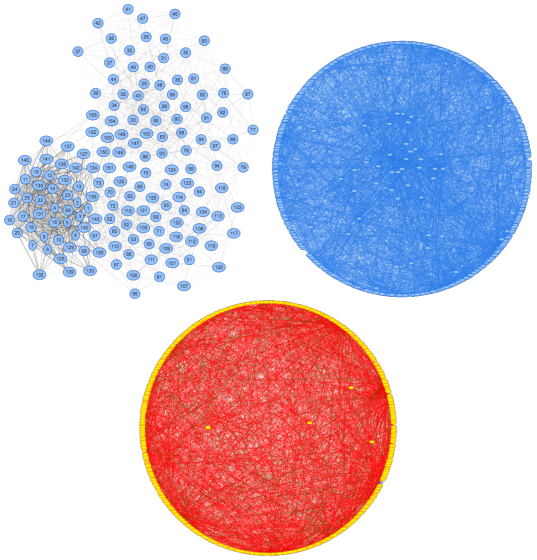

Fig. 12. Fourth example: interaction, resolution and factor graphs

tion helps to get more compact visualizations. The stabilization process can be observed in the case of logical formula of 83 variables and 369 clauses. The next images present the following visualization stages, until its accomplishment, see Fig. 11.

The fourth example: logical formula – 155 variables, 1135 clauses, see Fig. 12.

And the last example: logical formula after minimalization – 42 variables, 133 clauses, see Fig. 13.

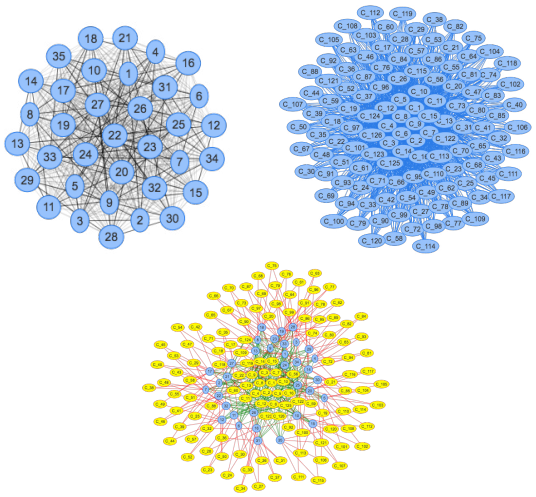

Fig. 13. The last example: interaction, resolution and factor graphs

VI. Conclusion

Visualization project of logical formulas has to be considered as a successful one, however, it is now at its initial stage and it will be continued. The system enables the elementary transformation of formulas and their preprocessing. The aim of the whole project was to create widely accessible tool helping to understand, analyze and examine the structures of problems presented with the use of logical formulas.

The system also offers storing files on the server which requires creating log-in system and the user's profile. It also offers the possibility of interaction with generated graphs, minimization of uploaded formulas and export of visualizations to the selected graphic formats. Its design and implementation aspects are very modern as a result of using the open approach as well as modern software technologies.

There are plans of a further system development by introducing new functionalities, another visualization methods and opening it for other SAT problems, for example MaxSAT.

***Abstract*—Integrated Model of Distributed Systems (IMDS) is a formalism for specification and verification of distributed systems, especially following IoT (Internet of Things) paradigm. The formalism emphasizes such features as asynchrony of actions and communication, locality of decisions, and autonomy in executing actions. In conjunction with model checking, IMDS allows to analyze such features of distributed systems as deadlocks or distributed termination. However, the nature of model checking allows to find one deadlock in a single run of the verifier, which produces a counterexample.**

The conversion of IMDS specification to a Petri net is used to identify multiple deadlocks in one verification, using siphons. Model checking is used to verify if a siphon can become empty, which denotes a true deadlock in a purely cyclic system, like FMS (Flexible Manufacturing Systems). The extension of the verification by temporal checking allows to cover systems with any structure: cyclic, terminating, or with a more complex scheme. In addition, the proposed procedure allows to easily identify processes participating in partial deadlocks. Two types of deadlock can be identified: communication deadlocks and resource deadlocks.

I. Introduction

IMDS (Integrated Model of Distributed Systems [1][2]) is a formalism for describing the behavior of distributed systems, especially for finding deadlocks. A system is modeled as a set of actions, having servers' states and agents' messages on input and on output. In IMDS, a communication dualism is exploited, since the modeled system is represented as server processes that communicate by messages, or alternatively by travelling processes (agents) that communicate by means of servers' states. A model of a distributed system is uniform (that is, it has a single form), but it can be decomposed ("cut") to a set of server processes or a set of agent processes. System actions are combined in sequences to form the processes. An action has a current server's state and an agent's current message on input, and it produces a similar pair (a new server's state and a new agent's message) on output.

The two views of a system (server view and agent view) are obtained by the two possible groupings of a set of all actions into sequences. In the server view, actions of an individual server are grouped into a process (the definition of processes is included in Sect. IIIB). The server's states are the carrier of the server process, and the messages are the communication means between server processes. In the agent view, actions concerning an individual agent conform a process. Messages are internal to a process: they are the carrier of the process. The agent processes communicate via servers' states.

The IMDS formalism was used, together with model checking technique [3], to develop the Dedan program which finds various kinds of deadlock in a verified system [4]. These are: communication deadlock (in the server view), resource deadlock (in the agent view), partial deadlock (in which a subset of system's processes participate) and total deadlock (concerning all processes). A counterexample is generated if a deadlock is found. A counterexample is a path leading from the start of the system to the deadlock.

In Dedan, automatic conversion between the server view and the agent view is performed. Also, observation of a global transition graph and simulation on this graph are possible.

Dedan is built in such a way that the specification of temporal formulas and temporal verification are hidden to a user. The reason is that model checking techniques are seldom known by the engineers. Therefore, the program is constructed in such a way that a user specifies a system and simply "pushes the button" to check for the existence of a deadlock.

The model checking technique has a disadvantage: the evaluation of temporal formula consists in finding a single global configuration (will be defined in Section IIIA) which causes the *false* result, which denotes a deadlock. A *counterexample* is a sequence leading from initial configuration to the deadlock. The designer may repair the erroneous specification and run the verification again. The scheme should be repeated multiple times, until all deadlocks are found and repaired.

The other technique of deadlock identification is finding siphons in a Petri net corresponding to a verified IMDS specification. A siphon is a Petri subnet, which cannot restore tokens if it is emptied [5][6][7]. If an empty siphon is

This work was not supported by any organization

reachable, it denotes a deadlock. The deadlock concerns the processes (server processes and/or agent processes) that take part in the siphon. Therefore, it may be total or partial deadlock. Siphon analysis can find multiple deadlocks in a system, because multiple siphons may exist in a net and the algorithms find all siphons in a single run [7].

Siphon-based deadlock detection is used in some purely cyclic classes of Petri nets, used to model FMS (Flexible Manufacturing Systems) [8][9]. However, many systems cannot be modeled as a cyclic Petri net. Some examples of such systems, for example an IoT (Internet of Things) distributed systems with multiple terminating processes, are mentioned in Section VI.

The previous paper [10] concerned identification of deadlocks in IMDS specifications which correspond to purely cyclic systems, like a class of FMS systems. The contribution of this paper is an application of siphon-based deadlock detection to systems of arbitrary schemes: cycling, terminating or intermediate (some processes are cyclic while other ones terminate). For this purpose an IMDS model is converted to a Petri net. Siphon detection is done in the Petri net, while identification of deadlocks and finding processes involved (partial deadlocks and total deadlocks are identified) is performed using reachability verification and temporal analysis in IMDS specification.

As a siphon may be emptied in different ways, thus it may lead to more than one deadlock. Model checking identifies one example of siphon emptying in a single run. Therefore our procedure does not guarantee identification of all deadlocks in a single run, one deadlock is found per reachable empty siphon. Still, a possibility of identification of multiple deadlocks (one for every emptied siphon) in a single procedure is a benefit. Additionally, the described procedure liberates from constraining siphon-based deadlock detection from purely cyclic systems only.

The described procedure gives a possibility of identification of multiple deadlocks in distributed systems specified in IMDS formalism, preserving communication duality, locality and autonomy of distributed components, and asynchrony of actions and communication.

In this paper, a background of static deadlock detection methods is given in Section II. A definition of IMDS is given in Section III. The definition is formulated differently from the paper [10], where a distributed system was defined using four basic sets: servers, state values, services and agents. The present definition is much easier for readers, because it uses two basic sets: states and messages. The previously used four sets are used in IMDS implementation, mentioned in Section IV, where an example of a bounded buffer is presented. The conversion of IMDS specification to a Petri net, and deadlock detection using siphons and reachability is described in Section V. Section VI presents the application of proposed method to systems with various structures, including acyclic and hybrid ones. An example of a not purely cyclic system containing deadlock siphons and no-deadlock siphons is described in Section VII. A practical example is presented in Section VIII. Section IX concludes the paper.

II. Related Work on Deadlock Detection

Many deadlock detection techniques are described in the literature. Dynamic methods typically use some kind of wait-for graph [11] to discover a deadlock (ant typically to prevent a deadlock or to escape from it).

Static methods use a model of a system and explore it to find deadlocks. Model checking techniques are based on temporal reachability space verification. The activities of the system are expressed in terms of local features of its components, and the global reachability space of the system is constructed. The features of system components are given as temporal formulas and verified by the evaluation of them. Model checkers are often equipped with automatic deadlock detection procedures. Typically, deadlock is identified as "a state with no future", i.e., a strongly connected subgraph containing one state only: the deadlock itself [12]. Deadlock freeness is checked by a CTL temporal formula **AG EX** *true* (for any state a next state exists) [13]. Yet, total termination seems to be analogous state: no future exists. In cyclic system, where termination is not expected, the above formula identifies a deadlock. In terminating systems a deadlock should be distinguished from termination.

Temporal formulas can also be used to check partial deadlocks, in which some processes are involved in a deadlock, but other processes continue their run. Generally, in the case of partial deadlock detection, temporal formulas are based on the structure of verified models to identify deadlocks in individual processes [14]. The disadvantage of such an approach is that temporal formulas need to be developed individually for each analyzed system, using its specific features.

Some other approaches to partial deadlock detection use temporal formulas that are not related to the structure of a verified model. However, such model-unrelated formulas require the system to have specific properties [15][16]. If a system is non-terminating (cycling), a discontinuation of a process is obviously a deadlock [3]. Conversely, a method [17] may be ascribed to terminating processes only. Some detection methods are used for specific architectures of systems. For example, WickedXmas approach uses nodes communicating by queues [18].

Other set of static methods concern Petri nets. Some of them are based on analysis of reachability graph of a Petri net [19]. Total deadlock is a leaf in reachability graph – no outgoing transition is present. Thus, reachability graph analysis is similar to model checking techniques, and typically they are combined as temporal analysis of the graph. In both approaches it is hard to distinguish a deadlock from distributed termination: these methods are addressed to endlessly cycling systems [20].

Alternatively, structural analysis of Petri net can be used. Structural analysis determines properties of models on the basis of their structure, so no exploration of the reachability

space is needed. Structural analysis of deadlocks is based on subnets called siphons [6][7]. It can be shown that if a model is deadlocked, the unmarked places constitute a siphon. Structural analysis of deadlocks systematically finds elementary siphons. Elementary siphons are ones from which other siphons are composed. After siphons identification, they are checked for unmarking possibility. The advantage of these methods is that multiple deadlocks are found in a single verification and both total and partial deadlocks are identified.

The deadlock detection procedure presented in this paper, based on combining siphon identification with temporal analysis, joins the advantages of the two methods and frees from their disadvantages:

- Identification of multiple deadlocks in single verification run.
- Finding both total and partial deadlocks.
- Distinguishing deadlocks from termination.
- Distinguishing between communication deadlocks and resource deadlocks.
- Automated verification, as deadlocks are expressed as formulas not related to specific features of a verified system.
- Verification of systems having arbitrary shape, without limitation to cycling, terminating or other schemes.

III. Integrated Model of Distributed Systems (IMDS)

A. Basic definition

IMDS is defined in [1][2]. In the present paper, the simplified version of IMDS is used, without dynamic process creation, which is suitable for static model checking. The formalism is founded on a basic observation: nodes on a distributed system (which are called *severs* in IMDS) receive messages, execute some actions changing their *states* upon accepted messages and finally send consecutive *messages*. Thus a distributed system may be defined as a relation between a finite set states of the servers $P=\{p_1,p_2,\ldots\}$ and a finite set of messages $M=\{m_1,m_2,\ldots\}$. The relation Λ defining the actions is:

$\Lambda \subset (M \times P) \times (M \times P)$

For an action $\lambda\in\Lambda$, $\lambda=((m,p),(m',p'))$ the first pair (m,p) is its *input* while the second pair (m',p') is its *output*.

A *configuration* T of a distributed system is a set of *current* states and *pending* messages. The messages in a configuration are current as well, but they are called pending to emphasize the fact that an action extracts from the configuration exactly one message, replacing it with a next message, and all other messages addressed to the action's server remain pending at the server. The system starts from its *initial configuration* T_0, containing initial set of states and messages.

Every action $\lambda=((m,p),(m',p'))$ converts a configuration $T_{inp}(\lambda)$ to a new configuration $T_{out}(\lambda)$ by replacing $\{m,p\}\subset T_{inp}(\lambda)$ with $\{m',p'\}\subset T_{out}(\lambda)$. Behavior of a distributed system is described by a Labeled Transition System LTS [21], containing all executions of the system. *Nodes* of the LTS (not called *states* for unambiguousness) are configurations and *transitions* are actions:

$LTS = \langle Q,q_0,W \rangle \mid$
$Q = \{T_0,T_1,\ldots\}$ (nodes);
$q_0 = T_0$ (initial node);
$W = \{(T,\lambda,T') \mid \lambda \in \Lambda,\ T=T_{inp}(\lambda),\ T'=T_{out}(\lambda)\}$
(transitions)

The interleaving way of executing the action is assumed (one action at a time [22]). Since all transitions in the LTS are instantaneous, it is assumed that message passing and actions take zero time. A timed version of IMDS, in which message passing and actions execution takes some periods of time, is also developed. This feature goes beyond the scope of this paper.

To differentiate between messages sent in different purposes (in a context of separate distributed computations), the autonomous sequential computations in a distributed system are extracted. The messages passed in a context of a given computation conform an *agent*. Thus the set of states P is split into subsets for the servers $1..n$ and the set of messages M into subsets for the agents $1..k$:

$P=\bigcup_{i=1..n} P_i$, $M=\bigcup_{j=1..k} M_j$

The subsets are pairwise disjoint:

$i\neq j \Rightarrow P_i \cap P_j=\varnothing$, $i\neq j \Rightarrow M_i \cap M_j=\varnothing$

The initial configuration contains *initial states* of all servers, one state for every server, and *initial messages* of all agents, one message for every agent:

$T_0\cap P_i=\{p_{0i}\}$, $T_0\cap M_i=\{m_{0i}\}$

The input and output state of an action concern the same server and the input and output message of an action concern the same agent:

$\lambda=((m,p),(m',p'))$, $\{m,m'\}\subset M_i$, $\{p,p'\}\subset P_j$

Agents may terminate in special actions of the form $\lambda=((m,p),(p'))$, where an output message is absent.

B. Processes

Is it useful to identify processes in a system, especially for verification purposes. Two "classical" models of distributed processes are used: client-server and RPC [23]. In the former model servers communicate by messages while in the latter one processes migrate forth and back. IMDS contains both models in a single specification, the models are extracted as the two perspectives: *server view* and *agent view*. A server process B in the server view is a sequence of actions connected by states of a server, as input and output states of an action concern the same server. Some actions may be unreachable and thus they would become "orphaned" (not included in any process), so the definition is extended to a set of all actions of a given server (rather than a sequence):

$B_i=\{\lambda\in\Lambda \mid \lambda=((m,p),(m',p')) \vee \lambda=((m,p),(p')),\ p,p'\in P_i\}$

In the agent view, an agent process C is a sequence of actions connected by messages of an individual agent, because input and output messages of an action concern the same

agent. As for server processes, the definition is extended to a set of all actions of a given agent:

$C_j=\{\lambda\in\Lambda \mid \lambda=((m,p),(m',p')) \vee \lambda=((m,p),(p')), m,m'\in M_j\}$

As a result, a distributed system may be decomposed to server processes or to agent processes, giving the server decomposition **B** and agent decomposition **C**:

$\mathbf{B}=\{B_i \mid i=1..n\}$

$\mathbf{C}=\{C_j \mid j=1..k\}$

C. Locality, Asynchrony and Autonomy

An important feature of a distributed system is locality. In IMDS, locality means that no message may cause actions in distinct servers (for a message $m\in M$ and two actions $\lambda_1,\lambda_2\in\Lambda$, $\lambda_1=((m,p_1),(m_1',p_1'))$, $\lambda_2=((m,p_2),(m_2',p_2'))$, $p_1,p_2\in P_i$). Thus, a function *target*: $M\rightarrow S$ assigns a target server for every message. A server component of a message and a state in the input pair of an action must match: $target(m)=s_i$, $p\in P_j$, $i=j$. A configuration contains exactly one state for every server, as this is required for initial configuration, and every action replaces its input state with a next state of the same server. Yet, multiple messages may be pending at given server in a configuration, which is natural. A set of actions in a distributed system determines which messages may be accepted in individual states. If a server allows a message to be accepted, an action is defined for this message together with the current state of the server. If the acceptance of a message is prohibited in a given state, no action is defined for this pair.

Note that every server performs its action autonomously (only the current server's state and the messages pending at this server are considered). Also, the communication is asynchronous: a server process sends a message to some other server process (or in the agent view, an agent sets the server's state for some other agent) regardless of the current situation of a process with which it communicates (and every other process). As a result, the process may be called *autonomous* and *asynchronous*.

D. Deadlocks in IMDS

A deadlock in IMDS is defined as a discontinuation of a process (with an exception of process termination). As there are two views of processes, different type of deadlocks concern server processes communicating by messages and agent processes communicating by states of servers. There may be a communication deadlock that is not a resource deadlock [2].

- a *communication deadlock* of a server process – when there are messages pending at the server, but no matching pair of any message with a current server state will occur;
- a *resource deadlock* of an agent process – when an agent's message is pending at a server but it will never match any current or future state of this server.

For the identification of deadlocks, universal temporal formulas were elaborated [2]. Universality of the formulas means that they are independent on a structure of a given distributed system – only the two facts are concerned: if an action in a process is enabled and if it is executed. Therefore, temporal logic is built inside the verification tool and the user need not know temporal logic nor model checking technique.

The paper [2] presents a terminating distributed system in which two servers, every one containing a semaphore, are used by two agents (the third agent performs some other work to show a detection of a partial deadlock). This shows a communication deadlock in the server view and a resource deadlock in the agent view. The system is presented briefly in Sect VII. Another example [24] is the Automatic Vehicle Guidance System: in the server view the cooperation of the road segment controllers during the piloting of a vehicle is shown, while in the agent view the traffic from the vehicles perspective is presented. The deadlocks in both views are shown. Similar system is mentioned in Sect. VIII. In the IMDS specification of Karlsruhe Production Cell [25], the controllers of individual devices are modeled as servers and the metal plates traveling through the cell are agents. Additional agents server for performing some actions without the plates, for example return to a rest position.

IV. Example – Bounded Buffer

An example of IMDS system is a buffer with producer and consumer agents (each of them starting at its own server). In IMDS notation, sets of servers *S,* agents *A,* state values *V* and services *R* are introduced explicitly. The services are used to distinguish between messages sent in given purposes to the servers (like operations *wait* and *signal* on a semaphore). The messages are triples (a,s,r), $a\in A$, $s\in S$, $r\in R$. The states of servers are pairs (s,v) , $s\in S$, $v\in V$, where v is a value that represents a given state. Thus an action $(m,p)\Lambda(m',p')$ is denoted $((a,s,r),(s,v))\Lambda((a,s',r'),(s,v'))$. Note that the same agent a is used in an input and output message, in such a way a computation is continued. Likewise, the same server s is used in an input and output state. Also, the same server s is in input state and input message, which models an acceptance of a message on a server with its current state.

The server view of the system in Dedan notation is presented below. As in typical programming language, server types are introduced (lines 3, 12), with formal parameters that specify agents and other servers used in actions. Every server has sets of its states (l.4, 13), services (l.5, 14) and actions (l.7-10, 16-19). An action in Dedan is denoted `{a.s.r, s.v}→{a.s'.r', s.v'}`. Servers and agents are declared as variables (l.21-22, server types are omitted in the declaration because they have names equal to variables in this example). Lastly, actual parameters are passed to the servers and initial states are assigned to every server and initial messages are assigned to every agent (l.24-26).

```
