Obviously, one can expect two deadlocks in the example: two agents both trying to get from an empty buffer and two agents trying to put to a full buffer. In model checking, a verifier typically shows the former deadlock because it requires two *get* operations to be reached. However, the latter deadlock is reached after three *put* operations, which lengthens a counterexample. A model checker searches for first counterexample and then it stops the evaluation. Therefore the latter deadlock may be reported in a second verification run, after a modification of the system to avoid the former deadlock (if the modification does not repair both deadlocks).

V. Deadlock Detection in a Petri Net Equivalent to IMDS Model

The main task of the Dedan program is identification of deadlocks and distributed termination. The Conversion of an IMDS system to a Petri net offers the designer new possibilities:

- identification of some structural properties: structural conflicts, dead code, etc.,
- temporal properties expressed in terms of Petri net,
- observation of the system in a graphical form,
- graphical simulation of a system run.

For this purpose a possibility of export of a model to a Petri net is included in Dedan. A format of ANDL (Abstract Net Description Language [26]) is used, which is the input of Charlie Petri net analyzer [27][28].

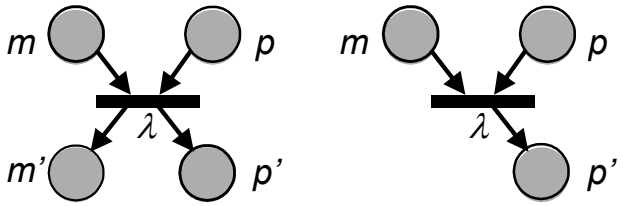

Fig. 1 IMDS actions converted to Petri net transitions: regular action (left) and agent-terminating action (right)

Fig. 1 shows a transition of a Petri net, which corresponds to an IMDS action. The input message and the input state are input places. The output message and the output state are output places (or only the output state in the case of a terminating action, Fig. 1b). The initial marking of the Petri net has tokens in the initial places of server states and initial messages of agents. The graph of reachable markings is equivalent to the LTS of the IMDS system, where states and messages correspond to the places, actions correspond to the transitions and markings correspond to the configurations.

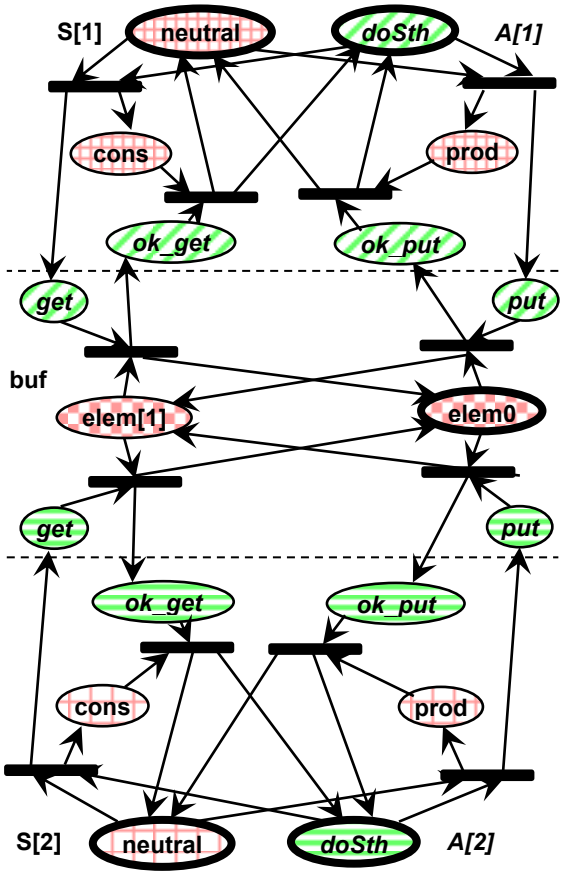

Fig. 2 Petri net representation of the *bounded buffer* system: servers *S*[1..2], *buf*, agents *A*[1..2]

The Petri net corresponding to the *bounded buffer* example is illustrated in Fig. 2. The states and messages in individual servers are grouped and separated by dashed lines. The states of servers are filled red, with patterns individual to every server. The messages are filled green, with patterns individual to every agent. Initial states and initial messages are bold. The servers and their states are in regular font, while the agents and their messages are in italics.

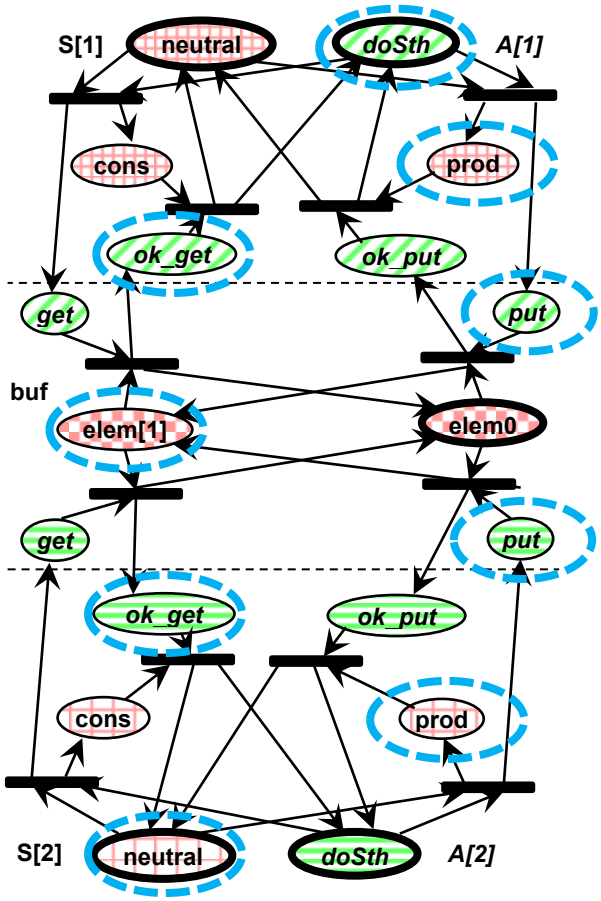

Fig. 3 One of elementary siphons found in the system

As the system falls into a deadlock, there should be siphons that may be emptied. A Petri net may contain a large number of siphons, but some of them are elementary, i.e., they do not contain other siphons [29]. Therefore, only elementary siphons need to be analyzed. The Charlie program reports 49 elementary siphons in the net. Every siphon should be tested for a reachability of its emptying. As an empty state place denotes a state which is absent in a configuration, and an empty message place denotes an absent message, an IMDS configuration should be found in which the siphon's states and messages are absent. A siphon may concern not all of the servers (and/or not all of the agents), in such a way partial deadlocks are found.

One of the siphons found in our example is presented in Fig. 3. It contains states (S[1],*prod*), (*buf*,*elem*[1]), (S[2],*prod*), (S[2],*neutral*) and messages (A[1],S[1],*ok_get*), (A[1],S[1],*doSth*), (A[1],*buf*,*put*), (A[2],*buf*,*put*), (A[2],S[2],*ok_get*).

The siphon emptying is verified by model checking. To do this, the CTL formula **AG** ($\neg$ φ) (it reads: always not φ) is used, where φ is a set of states and messages in a configuration corresponding to a siphon's complement. Often a siphon represents a class of configurations, for example a siphon in Fig. 3 represents all configurations in which server S[1] is not in a state (S[1],*prod*), and thus it may be in one of a subset of states {(S[1],*neutral*), (S[1],*cons*)}. The formula for checking if the siphon cannot be emptied has the form **AG** ($\neg$ ((((S[1],*neutral*)$\vee$(S[1],*cons*)) $\wedge$ (*buf*,*elem0*) $\wedge$ (S[2],*cons*) $\wedge$ ((A[1],S[1],*ok_put*)$\vee$ (A[1],*buf*,*get*)) $\wedge$ ((A[2],S[2],*doSth*)$\vee$(A[2],S[2],*ok_put*)$\vee$ (A[2],*buf*,*get*)))). For verification, internal Dedan model checker is used for typical cases (as it uses explicit state space) and Uppaal [31] for large cases.

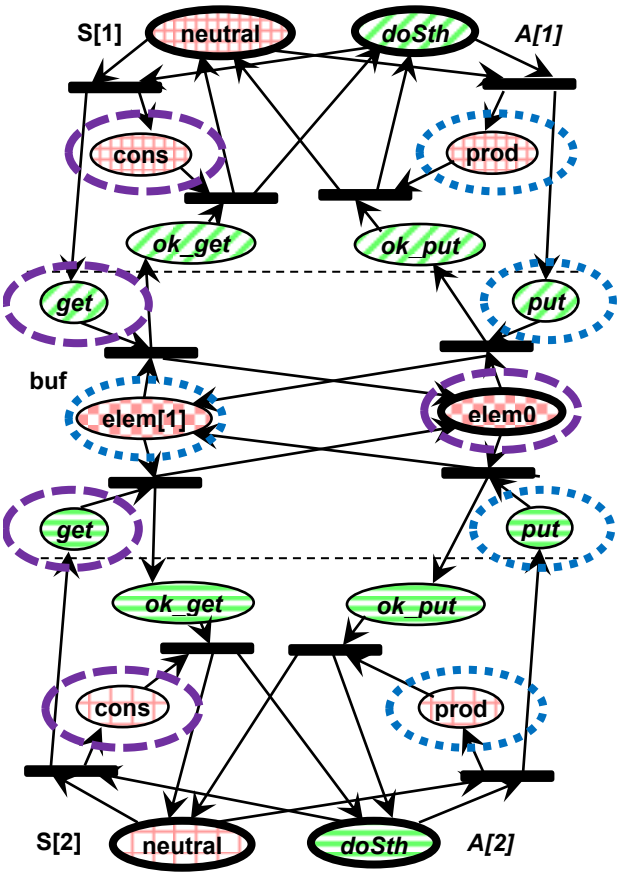

Fig. 4 The two deadlocks identified in the example. The dashed one is associated with the siphon in Fig. 3

The verification results in *false*. This means that the empty siphon is reachable, which denotes a deadlock. States of all three servers S[1],S[2] and *buf* take part in the siphon, so it is a total communication deadlock. Also, both agents A[1] and A[2] take part, denoting a total resource deadlock. Model checker generates a counterexample, in which both agents perform *get* on empty buffer (state (*buf*,*elem0*)). Charlie

reports multiple siphons that may be emptied by two *get* operations on the empty buffer. All these situations constitute a single deadlock (but the counterexamples for individual temporal formulas may differ in the order of issuing *get* by the two agents). The configuration finishing all counterexamples leading to this deadlock is exactly the same. For a partial deadlock, configurations finishing the counterexamples may differ, but only in states/messages of servers/agents not taking part in the deadlock. In the example, all tests for emptying of the siphons either finish in one of the two deadlock configurations, or emptying occurs unreachable (such siphons do not denote a deadlock).

Fig. 4 shows the two possible deadlocks that finish all reachable emptying of siphons. The ovals surround places of the two identified deadlocks: dashed ovals are associated with the siphon in Fig. 3, which it is caused by two *gets* on an empty buffer. The other deadlock (dotted ovals) is caused by two *puts* on a full buffer. Distinguishing between the two deadlocks is based on the two configurations finishing the counterexamples.

VI. Verification of Systems with Various Structures

Various systems can be modeled in IMDS, not only those having a shape of purely cyclic FMS. Fig. 5 shows some examples of shapes of not purely cyclic systems. In the figure "Ending Strongly Connected Subgraph" is a cycle from which no escape is possible. The pictures are schematic, showing general shape of a system. In IMDS specification every transition has two input places and two output places (or one in the case of agent-terminating action), see Fig. 1.

- "linear" systems (like the example of "two semaphores" described in [2]: users issue *wait* on two semaphores, then they issue *signal*),
- a system with a "*leader*" (initial part) and a main loop, sometimes called "lasso-shaped" [32],
- terminating system with a main loop, for example WF-net system [33],
- similar to lasso-shaped, but with an initial loop.

In some cases, for example in the acyclic system in Fig. 5 (on the top), the system may be easily converted to a cyclic one by connecting initial and terminating places. However in the analysis of distributed systems, especially those following the IoT paradigm, in which autonomous nodes agree their coordinated behavior. Such system may have multiple leaders (for every node) and multiple terminating places, where the nodes reach their goals. An example is Automatic Vehicle Guidance System presented in [24]. In IMDS model, servers implement road segment controllers while agents implement the vehicles. Such a system may be additionally complicated if endlessly-looping nodes are added, for example charging stations where serving agents run in cycles.

It is obvious that most of the leaders contain siphons that may be emptied. Yet, emptying of such a siphon does not denote a deadlock because the system runs further. This is the main difference in deadlock detection between purely cyclic and differently shaped systems.

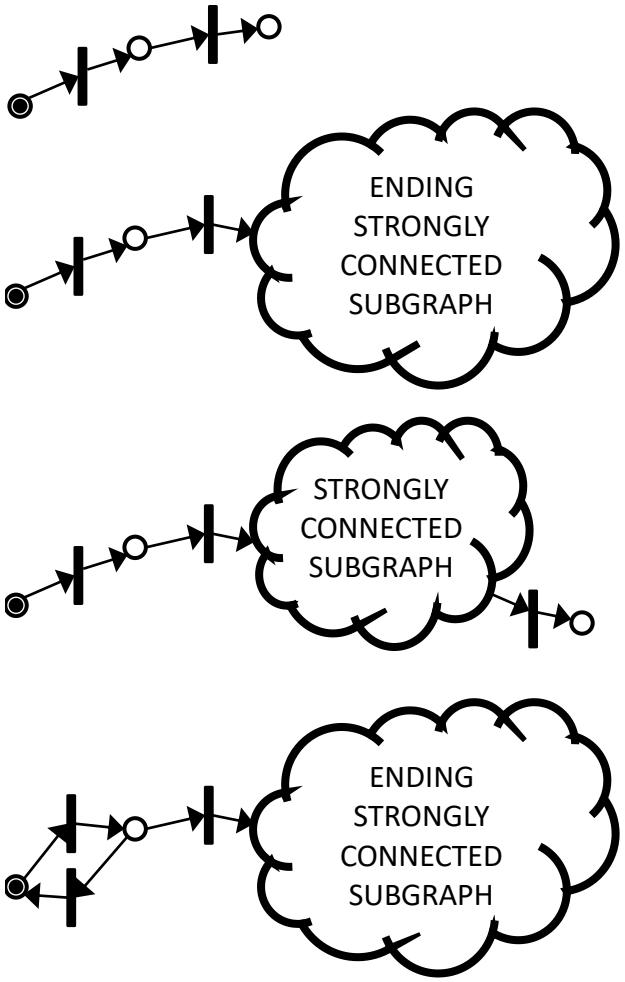

Fig. 5 Examples of acyclic and not purely cyclic systems containing emptyable and reachable siphons which are not deadlocks

A solution of this problem is quite simple: an emptied siphon should be verified if it is a real deadlock or not. This is done using an additional temporal formula, which uses the same subformula φ of an emptied siphon. A deadlock prevents a process from doing any move. Thus, the evaluation of $\mathbf{AG}(\neg \varphi)$ to *false* should be followed by application for every process (server and agent) the formula $\mathbf{AG}(\varphi \Rightarrow \mathbf{EF} \neg \varphi$/restricted to a process). The formula reads: always φ is inevitably followed by not φ. Of course, this procedure may be applied to a system of any shape, cycling or not. For the example of emptyable siphon in Fig. 3 (we can pretend that we do not know that the system is purely cyclic) the verification should be performed as follows:

- φ=((*S*[1],*neutral*)∨(*S*[1],*cons*)) ∧ (*buf,elem0*) ∧ (*S*[2],*cons*) ∧ ((*A*[1],*S*[1],*ok_put*)∨(*A*[1],*buf,get*)) ∧ ((*A*[2],*S*[2],*doSth*)∨(*A*[2],*S*[2],*ok_put*)∨(*A*[2],*buf,get*)),
- check $\mathbf{AG}(\varphi \Rightarrow \mathbf{EF}$ (*S*[1],*prod*)) for server *S*[1],

- check **AG**($\varphi \Rightarrow$ **EF** (*buf*,*elem*[1])) for server *buf*,
- check **AG**($\varphi \Rightarrow$ **EF** ((*S*[2],*prod*)$\vee$(*S*[2],*neutral*))) for server *S*[2],
- check **AG**($\varphi \Rightarrow$ **EF** ((*A*[1],*S*[1],*doSth*)$\vee$ (*A*[1],*S*[2],*ok_get*)$\vee$(*A*[1],*buf*,*put*))) for agent *A*[1],
- check **AG**($\varphi \Rightarrow$ **EF** ((*A*[2],*S*[2],*ok_get*)$\vee$(*A*[2],*buf*,*put*))) for agent *A*[2].

The result depends on a value of a formula for every process:

- *true* for every involved server – no communication deadlock,
- *false* for all involved servers, and all servers are involved – total communication deadlock,
- *false* for some involved servers, or for all servers involved but not all servers are involved – partial communication deadlock,
- *true* for every involved agent – no resource deadlock,
- *false* for all involved agents, and all agents are involved – total resource deadlock,
- *false* for some involved agents, or for all agents involved but not all agents are involved – partial resource deadlock.

In the last three cases concerning agents, only non-terminated agents are taken under consideration, i.e. the agents which messages are present in the configuration corresponding to the emptied siphon.

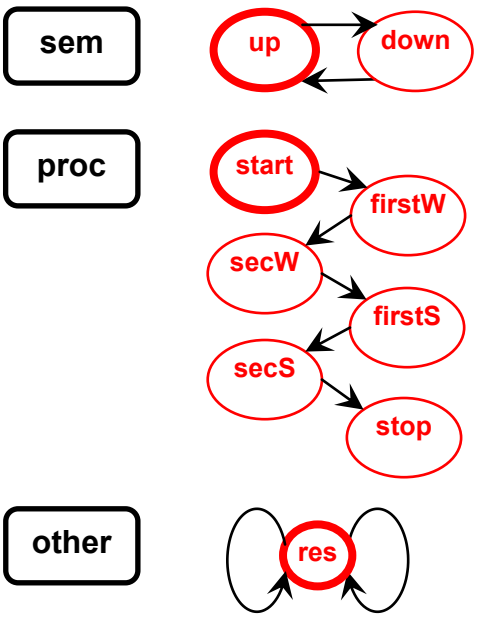

Fig. 6 Automata-like model of servers in *two-semaphores* system, agents not shown

The verification procedure uses several well-known and widely used algorithms. Computational aspects of finding siphons are discussed in [34]: elementary siphons may be found in linear time for a large class of Petri nets (and needs some preprocessings in general case). Also, parallel solutions exist [35].

The complexity of CTL model checking is P-Complete [36], which means that the time of temporal formula evaluation is $|\text{LTS}|\times|\psi|$, where $|\text{LTS}|$ denotes the number of nodes in a Kripke structure (it is the LTS of a verified system) and $|\psi|$ is the length of a formula ψ. Every formula **AG**($\varphi_1 \Rightarrow$ **EF** φ_2) contains two temporal operators, so this evaluation cost is fixed. The verification should be repeated for every siphon, and according to each siphon for every server and every agent, i.e., the complexity is a number of elementary siphons $\times$ (n+k) $\times$ $|\text{LTS}|$, where n is a number of servers and k is a number of agents.

VII. Example System with Leaders

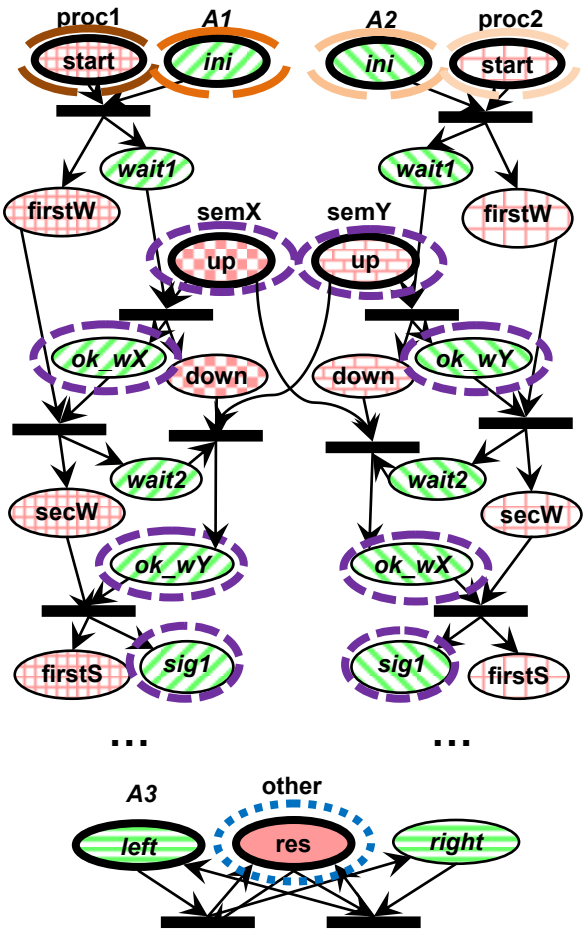

Fig. 7 Petri net representation of the *two-semaphores* system

As an example of system with leaders, we present a *two-semaphores* system consisting of two agents *A1* and *A2*, each one running on its own server (*proc1* and *proc2*). The agents use two semaphores *semX* and *semY*. They use the semaphores "crosswise", i.e., *A1* issues operation *wait* to *semX* than to *semY*, while *A2* does it in opposite order. To show a partial deadlock (not concerning all the servers/agents), the third agent *A3* is added, running on its own server *other* and

performing some looping calculations. The automata-like view of the system is presented in Fig. 6 (only servers' states and actions are shown, input and output messages in actions are omitted).

The system converted to a Petri net if shown in Fig. 7 (a part after second *wait* in the agents is suppressed). The general shape of the system consists in sequences of actions in agents *A1* and *A2*, leading from their start to their termination, and a separated Ending Strongly Connected Subgraph of agent *A3* (depicted in Fig. 8).

A verification in Charlie shows a siphon of an obvious deadlock, shown as places surrounded with denser dashed ovals (violet). This siphon is emptyable and the temporal formulas identifying processes involved show:

- Both agents *A1* and *A2* fall into resource deadlock.
- Both servers *semX* and *semY* fall into communication deadlock.

There is also a siphon containing the place *res* (dotted oval, dark blue), but it is not emptyable - this does not denote a deadlock. There are four such siphons in the system (three of them are not indicated in the figure).

Four siphons formed by places *proc1.start, proc2.start, A1.proc1.ini* and *A2.proc2.ini* are emtyable (they are depicted as sparsely dashed ovals on the top of Fig. 7), but the temporal formulas show that these siphons do not denote deadlocks. They are typical leader siphons.

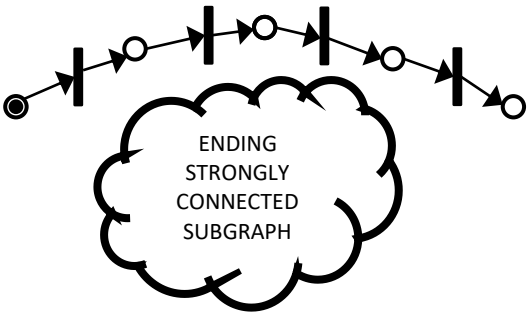

Fig. 8 General shape of the *two-semaphores* system. The chain - servers *proc1, proc2, semX, semY* and agents *A1, A2*. The cycle – server *other* and agent *A3*.

Summing up:

- A partial communication deadlock of processes *semX* and *semY* is identified, in which processes *proc1, proc2* and *other* are not involved.
- A partial resource deadlock of processes *A1* and *A2* is identified, in which process *A3* is not involved.
- Four not emptyable siphons are found (no-deadlock siphons).
- Four emptyable leader siphons are found (no-deadlock siphons).

VIII. Example Application to Automatic Vehicle Guidance System

We chose an Automatic Vehicle Guidance System (AVGS) verification to illustrate an application of our method. The AVGS system consists of a set of road segments (identifiers are taken from cardinal directions) with their controllers modeled as servers, for example on a crossing depicted in Fig. 9. The controllers are very simple: they allow or deny a vehicle to take up a road segment, depending on its freeness or occupation. Vehicles are modeled as agents. When more than one vehicle approaches the crossing, routes for all the vehicles are prepared, for instance using a genetic algorithm. A route connects an entrance segment (*A...*) and a target segment (*T...*) of vehicle's travel. Obviously, in the model every route terminates. The routes are tested for deadlock freeness using siphon detection and temporal verification, described in this paper. This can be performed automatically, because in our methodology deadlock detection formulas are independent on the structure of a verified system. Deadlock-free route sets are executed while routes exposed to deadlocks are rejected. If a new vehicle appears, the whole procedure is repeated from current positions of all the vehicles on the crossing and approaching ones.

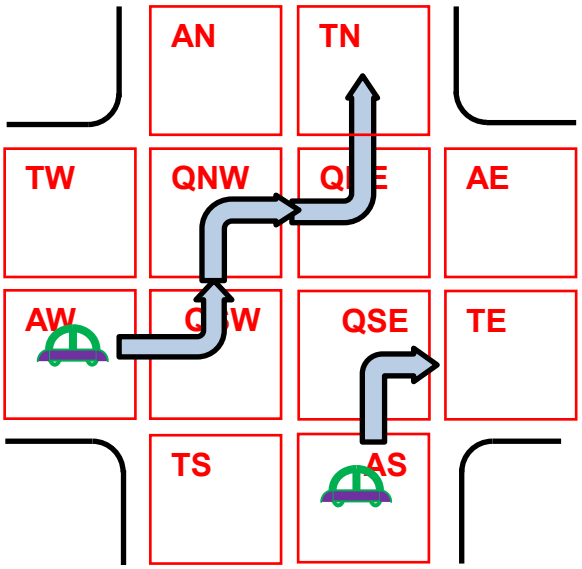

Fig. 9 Automatic Vehicle Guidance System

The described procedure may find solutions unusual in ordinary vehicle traffic, for example one of the routes shown in Fig. 9 causes a vehicle to apply left side traffic for a while. Also, safe routes may be fond even if one road segment is blocked, for example by a broken vehicle. In verification, AVGS is similar to the *two-semaphores* system, without server *other* and agent *A3*.

Other examples of systems that are based on terminating processes, which may be modeled using our approach, is taxi

service [37], business processes [38] or multi-agent systems based on Belief-Desire-Intention paradigm [39]

IX. Conclusions

An approach to deadlock detection is presented which is based on coupling IMDS formalism with Petri net structural analysis and model checking. The methodology allows to find total and partial deadlocks in two perspectives: servers communicating by messages and agents communicating by states of servers. As a result, communication deadlocks and resource deadlocks are identified, which highlights communication duality in distributed systems. Also, the specification in IMDS clearly identifies processes running in a system, which is sometimes difficult in ordinary Petri nets.

The methodology finds multiple deadlocks in a distributed system, preserving locality of decisions, autonomy of servers, and asynchrony of behavior and communication. In some rare cases, in which siphons can be emptied in various ways, not all deadlocks are identified in a single run, but the procedure may be repeated after correction of found deadlocks. However, we have not found any real-life example of a system with such feature, typically all deadlocks are found in a single run.

The presented deadlock detection procedure may be applied for system of arbitrary shape: cycling like a class of FMS systems, terminating like WF-nets, lasso-shaped, or IoT systems compound of multiple terminating and looping autonomous nodes.

A collection of programs is used for the described procedure: Dedan for specification, Charlie for siphon identification, internal Dedan model checker and Uppaal for verification. In the future, the whole procedure will be integrated in Dedan. This will allow to check for deadlocks and to perform other types of structural analysis in a uniform environment.

In the future, a timed version of the prosed procedure is planned, with application of UPPAAL timed automata [40].

Acknowledgment

Extensive discussions with Wlodek Zuberek helped to significantly improve the article, especially in the new formulation of IMDS.

***Abstract* — This paper discusses the problem of time-constrained job-shop scheduling with technological machine breakdown prediction. The first section gives short characteristics of the field of research, and describes the effects of machine failure on job completion times. Secondly, the discussed problem is represented by means of mathematical equations and solved with original algorithms for machine failure prediction and implementation of redundant service times, and finally, the proposed solutions are verified by means of simulation. In the computational experiment stage a typical production case with taking into account 3 machines failure was considered. The last part of this paper draws conclusions from the study and presents directions of future research work.**

I. Introduction

Job scheduling has been receiving considerable attention of researchers [1]–[2]. Scheduling problems are approached from the perspective of production systems [3]–[4], dynamic character and randomness [5], time-dependence [6]–[7], and its relevance to industrial conditions [7]. In each of its aspects scheduling is governed by a variety of constraints that must be accounted for in scheduling.

We may distinguish two broad categories of constraints considered in scheduling: Resource-Constrained Scheduling and Time-Constrained Scheduling [8]–[9]. Although this division concerns mainly the field of project scheduling [10]–[11], it may be nonetheless found in scheduling of production as well [12]–[14].

Numerous constraints are discussed in the job-shop environment, yet they tend to be included as limiting constraints, for the sake of simplification of given scheduling problems [15]. Therefore, Robust Scheduling has been attracting an increasing amount of focus as it addresses the presence and the negative effect of various conditions and factors influencing the execution of production jobs [16].

II. Completion Time and Machine Failure Effect

Scheduling production jobs is most frequently considered under the objective function C_{max} – makespan/completion time of all jobs. This parameter is implemented in both analysis of test problems (aimed at evaluating the effectiveness of solutions) [17], as well as in determining job completion times [2], [6]. In practical industrial applications scheduling must strictly follow the C_{max} as exceeding these times and missing order delivery times may enforce contractual fines and lead to losing customers [2]. It is therefore a typical time constraint.

Apart from time constraints, there is a wide variety of factors that may only be addressed and resolved by implementing suitable methods and solutions. Scheduling Under Machine Failure is one of the most frequently considered factors, which is of considerable importance to observing order deadlines and therefore to time-constrained scheduling, as downtime of one technological machine may negatively affect the schedule through delaying jobs (Fig. 1).

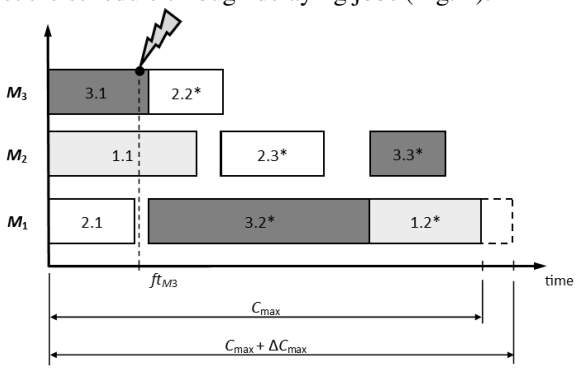

Fig. 1 M_3 machine failure and its impact on makespan (* – delayed jobs)

III. Problem Formulation

The job-shop scheduling problem consists in assigning jobs from the set of jobs $J = \{J_1, J_2,..., J_n\}$ to the set of available machines $M = \{M_1, M_2,..., M_m\}$ so that the schedule is optimised according to the objective function. Processing job J_j on machine M_i is described as operation. Simultaneously, we must consider the technology of processes, which is described by the matrix of machine orders $MO = [o_{ij}]$. Times of particular operations are described by the matrix of processing times $PT = [pt_{ij}]$. The size of matrices MO and PT is $m \times n$ [15].

This work was not supported by any organization

In order to implement the machine failure constraint, each machine must be described by means of the following sets:

- $FT_{Mi} = \{ft_{Mi1}, ft_{Mi2},..., ft_{Min}\}$, describing potential failure times of machines (expressed in hours),
- $P_{Mi} = \{p_{Mi1}, p_{Mi2},..., p_{Min}\}$ describing the probability of machine failure,
- $TB_{Mi} = \{tb_{Mi1}, tb_{Mi2},..., tb_{Min}\}$ defining time buffers (length of potential service times in minutes).

Moreover, implementing job completion time constraints requires that the schedule based on the set of feasible solutions accounts for the machine failure and adheres to the objective $C_{max} = C_{max} + \min(\Delta C_{max})$.

IV. Suggested problem solution

The solution we propose to the scheduling problem under time and machine failure constraints employs algorithms based on actual historical data, which are recorded in the sets of failure times $T_{Mi} = \{t_1, t_2,..., t_n\}$ and repair times $RT_{Mi} = \{rt_1, rt_2,..., rt_n\}$. Each set is specified individually for each machine.

A. Failure prediction algorithm

The first algorithm defines the key times in the schedule where failure may occur. Executed algorithm produces information regarding failure times (FT_{Mi}) and failure occurrence probability (P_{Mi}). The subsequent steps of the algorithm are as follows:

1. Define machine M_i and load data from set T_{Mi}.
2. Determine sequence and sort observations in an increasing order:
$$\{(t_i,d_i)\}_{1\le k\le n} \quad (1)$$
where: t_i – failure times,
d_i – number of occurrences.
3. Filter data – delete outliers.
4. Estimate the survival function based on:
$$\hat{S}(t) = \begin{cases} 1, & dla \quad t < t_1 \\ \prod_{t_i \le t} \frac{r_i - d_i}{r_i}, & dla \quad t_1 < t \end{cases} \quad (2)$$
where: r_i – the total number of failures expressed by:
$$r_i = \sum_{j=i}^{k} d_j \quad (3)$$
5. From the survival function determine failure times and failure probability (Fig. 2).

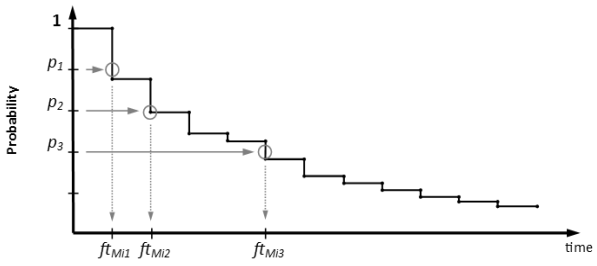

Fig. 2 Determining failure times from survival probability

6. Determine probability of failure:
$$p_{Mij} = 1 - p_i \quad (4)$$
7. Save data in sets FT_{Mi} and P_{Mi}.

Execution of this algorithm enables to pinpoint the times in the schedule where redundant time buffers should be implemented.

B. Algorithm for estimation and implementation of redundant time buffers

The second proposed algorithm determines the span of the service times and their implementation in order to make the schedule robust to failures. The algorithm is composed of the following steps:

1. Load observations from RT_{Mi} and sort in an increasing order.
2. Filter data – delete outliers.
3. Divide into two subsets according to:
$$RT_{Mi} = \{RT_{Mi1}, RT_{Mi2},\ldots, RT_{Mi8}\} \quad (5)$$
where: RT_{Mij} – subset of repair times, and:
$RT_{Mi1} = \{rt_i \in (0; 60>\}$
$RT_{Mi2} = \{rt_i \in (60; 120>\}$
…
$RT_{Mi8} = \{rt_i \in (420; 480>\}$
4. Define service buffer times – determine subset of RT_{Mi} of maximum weight – determine auxiliary sets RT'_{Mi} and TB'_{Mi}:
$$RT'_{Mi} = \left\{\overline{\overline{RT_{Mi1}}}, \overline{\overline{RT_{Mi2}}},\ldots,\overline{\overline{RT_{Mi8}}}\right\} \quad (6)$$
$$\underset{\max(RT'_{Mi})}{\vee} TB'_{Mi} = RT_{Mij} \quad (7)$$
$$TB'_{Mi} = \{rt_i \in \langle \min(RT_{Mij}); \max(RT_{Mij}) \rangle\} \quad (8)$$
where: RT_{Mij} – maximum weighted subset.
5. Estimate service time buffers:
$$TB_{Mi} = \{tb_{Mi1}, tb_{Mi2},\ldots, tb_{Min}\} \quad (9)$$
$$tb_{Mij} = \frac{\max(TB'_{Mi})}{n_p} \cdot j \quad 10)$$
where: j – number of element of set TB_{Mi},
n_p – number of considered levels of probability (elements of set P_{Mi}).
6. Take (p_{Mij}, ft_{Mij}) from sets FT_{Mi} and P_{Mi}.
7. Determine control probability:
$$p_{kMil} = \frac{l}{n_p} \quad (11)$$
where: $l = \langle 1,2,\ldots,n_p \rangle$.
8. Select buffer according to:

```
IF pMij ≤ pkMi1
   select buffer tbMi1 (minimal)
ELSE IF pMij > pkM1 and pMij ≤ pkMi2
   select buffer tbMi2 (where tbMi2 > tbMi1)
   ...
```

```
ELSE IF p_Mij > p_kMi(n-1) and p_mi ≤ p_kMin
   select buffer tb_Min (where tb_Min > tb_Mi(n-1)
END IF
```

9. Implement selected buffers of set TB_{Mi} in points defined by elements of set FT_{Mi} – in case buffers double – select higher.

The presented algorithm determines time buffers which make the schedule robust to failure of technological machines.

C. Schedule optimisation for makespan

As a result of execution of proposed algorithms the obtained schedule becomes robust. However, in order to meet the specified deadlines for orders, the most suitable schedule should be selected. Hence, the schedule selected from the group of solutions will be the one that offers the optimum solution to $\min(\Delta C_{\max})$ constraint. In the following case then, the best scheduling methods will be the exact ones and methods based on expert knowledge.

V. Simulation tests

The proposed solutions were verified by executing the scheduling process in job-shop conditions. The scheduling concerned 8 production orders processed on a stock of 5 machine tools. The processing times, the job order, and the number of jobs assigned to machines were randomly generated with available software, on the basis of the following assumptions:

- processing times cannot exceed one shift (maximum processing time is 7.5 h),
- machine loading is specified at 75%,
- machine routing is predetermined and not subject to change.

Moreover, the schedule allowed for the failure of 3 technological machines. The machine failure data was obtained from actual historical data of a production company. The source of information about machines failure times were electronic forms collected by maintenance department. In the data-treatment process authors used RStudio software with selected libraries. 3 failure probability levels were considered: $p_{Mi1} = 0.25$, $p_{Mi2} = 0.5$ and $p_{Mi3} = 0.75$. The results of the executed prediction algorithm are shown in Table 1.

TABLE I.
RESULTS OF MACHINE FAILURE PREDICTION ALGORITHM EXECUTION

Probability level	Predicted failure times [h]		
	M_1	M_2	M_3
$p_{Mi1} = 0.25$	$ft_{M11} = 8$	$ft_{M21} = 8$	$ft_{M31} = 8$
$p_{Mi2} = 0.50$	$ft_{M12} = 16$	$ft_{M22} = 16$	$ft_{M32} = 24$
$p_{Mi3} = 0.75$	$ft_{M13} = 40$	$ft_{M23} = 32$	$ft_{M33} = 48$

Execution of time buffer algorithm determined redundant service buffers and their implementation times (Table 2).

TABLE II.
DETERMINED SERVICE BUFFERS

Implementation time	Buffer length [min.]		
	M_1	M_2	M_3
after 8 h	$tb_{M11} = 20$	$tb_{M21} = 20$	$tb_{M31} = 20$
after 16 h	$tb_{M12} = 40$	$tb_{M22} = 40$	$tb_{M31} = 20$
after 24 h	$tb_{M11} = 20$	$tb_{M21} = 20$	$tb_{M32} = 40$
after 32 h	$tb_{M12} = 40$	$tb_{M23} = 60$	$tb_{M31} = 20$
after 40 h	$tb_{M13} = 60$	$tb_{M21} = 20$	$tb_{M31} = 20$
after 48 h	$tb_{M12} = 20$	$tb_{M22} = 40$	$tb_{M33} = 60$

The effectiveness of the proposed solutions was assessed by means of the following criteria:

- criterion $C_{\max}$,
- criterion y_J – the number of critical operations in reference to technology (operations of one job),
- criterion y_M – the number of critical operations in reference to machines.

The conducted verification tests implemented the following popular dispatching rules: FCFS, EDD, LPT and SPT. In the computational experiment stage LiSA software (*Library of Scheduling Algorithms*) was used. The tests were carried out on a typical PC-class computer. Subsequently, the obtained robust schedule was optimised under the specified objective function. The results of the calculations are shown in Tables 3–4.

TABLE III.
VALUES OF CRITERION C_{MAX}

Dispatching rules	C_{max} value [h]		
	Nominal schedule	Robust schedule	Optimized schedule
LPT	48	67	47.83
SPT	46	54.50	
FCFS	43.5	56.50	
EDD	49	63.17	

Implementation of service time buffers leads to delaying the makespan (Table 3). The mean delay is 14.77 h, which amounts to approx. 2 shifts. The delay in completion time of all jobs, however, increases the stability of production and indicates the feasible production completion time, simultaneously accounting for technological machine failure.

Determination of the actual production completion time allows preventing potential contractual fines. In the case of strictly specified order delivery deadline, implementation of the proposed algorithms and optimisation with the use of expert knowledge produces a robust algorithm under the specified completion time constraint. In the presented problem the schedule was optimised according to the defined objective function, in which case the makespan generally became slightly delayed, and in 2 cases was shortened; therefore the obtained schedules did meet the constraint $\min(\Delta C_{\max})$.

TABLE IV. VALUES OF CRITICAL OPERATIONS

Dispatching rules	Number of critical operations [–]					
	Nominal schedule		Robust schedule		Optimized schedule	
	y_J	y_M	y_J	y_M	y_J	y_M
LPT	17	20	3	12	4	12
SPT	11	17	6	9	5	10
FCFS	8	20	4	11	4	10
EDD	9	18	4	10	4	10

The robust schedule was characterised by the decreased number of critical operations – both in terms of processed jobs and operations on particular machines (Table 4). Both robust and optimised schedules showed a nearly 50% drop in the number of such operations, compared to the nominal schedule. The abovementioned leads to increasing the stability of production and reducing uncertainty and nervousness, as even if the failure of the machine should occur, the allocated service time absorbs the potential negative impact of failure on processing subsequent operations.

VI. CONCLUSION

It must be remarked that scheduling production jobs in industrial applications is inherently connected with a wide range of potentially disruptive factors, which ought to be treated as constraints. This paper presented scheduling under constraint of completion time of all jobs and machine failure. The proposed algorithms were verified in simulation, which proved their effectiveness and applicability. Future research works should be continued and could incorporate other factors occurring in job scheduling, such as alternating processing times, transport between workstations, *etc*). The proposed algorithms and methods could be implemented in the real production environments – at the managerial and production planning departments for instance.

e-mail:j.wikarek@tu.kielce.pl

***Abstract*—The article presents the problem of academic teachers' competences configuration in the context of the university course timetabling problem (UCTP). Usually when solving UCTP, the set of available academic teachers and the competences they have is defined. The sets of lecture rooms, subjects (courses), student groups, time-slots, etc. are also known. Problems can emerge when it is not possible to find a satisfactory UTCP solution due to the missing sufficient number of specific academic teachers' (lecturers') competences, which is reflected in the possibility to teach specific classes (courses). In order to detect early such a situation and effectively manage the available and required lecturers' competences, a mathematical model of lecturers' competences configuration has been formulated in the form of a MILP (Mixed Integer Linear Programming) problem. Its solution has a direct impact on UTCP. The article also presents the implementation of the model in the LINGO solver environment and computational experiments.**

I. Introduction

University course timetabling problem (UCTP) is a problem in operation research, which raises interest in the communities both in the area of operational research (OR) and artificial intelligence (AI). In the most general manner, UCTP can be defined as the allocation of students and academic teachers (lecturers) to classes (courses) with consideration given to the available resources such as: lecture halls, laboratories and research workrooms. Additionally, the allocation must take place in appropriate periods (time-slots) that most often include a semester of teaching classes divided into single units (these are most often weeks). It is assumed that before starting work on an UCTP solution the number of all the resources and their availability are known; also, the characteristic features of the resources are known, such as: number of seats in the halls, number of students in particular student groups, the set of competences held by particular lecturers, whether a given room has a multimedia overhead projector, etc. With regard to the lecturers, each of them may have a certain set of competences, which is usually directly reflected in the list of courses which he or she may offer. Apart from the sets of resources with specific properties and time-slots, there are also numerous constraints for UCTP. The most important of them include the allocation of the lecturers and student groups to the halls, limited teaching load (teaching hours) per lecturer in a given semester, limited capacity of the lecture halls, laboratories and research workrooms, etc. Very often, there are also additional time restrictions related to preferences and availability of the lecturers as well as requirements for different courses. At the beginning of every semester, the dean, or the head of the department, faces the problem of an optimal solution to the UCTP problem.

Let's ask the question, what is going to happen, if it turns out, when solving UTCP, that it is impossible to find any acceptable solution due to a certain resource? The answer seems to be evident: the accessibility and/or the number of the given resource should be increased. Unfortunately, it is not always easy. It is particularly difficult with regard to the resource of lecturers' competences which are available when solving UCTP, as this requires them to complete additional training, studies, internships, and/or employment of new lecturers. The article proposes a model for the problem of managing and configuration such competences. On its basis an answer can be given to two key questions:

a. Do we have the appropriate resource of lecturers' competences, which will allow an UCTP solution to be found according to the rules (not exceeding the teaching load excessively)?
b. What and how many competences are missing to find an UCTP solution? What is the minimum number of the missing competences that guarantees an UCTP solution?

Fig. 1 presents the location of the problem of competences configuration in the context of UCTP. The main contribution of the presented research is a unique model for the problem of lecturers' competences configuration in the form of a MILP (Mixed Integer Linear Programming) problem [1]. The examined problem can be classified as a problem of resource distribution (teaching loads) with constraints, among others concerning the teaching load. Additionally, the implementation of the model in the MP solver environment and numerous computational experiments have been presented.

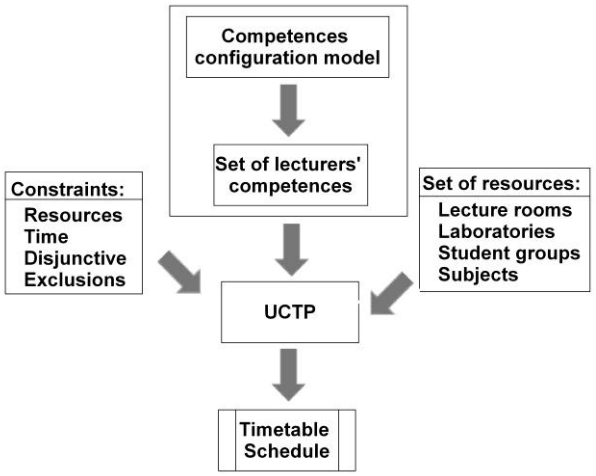

Fig. 1 Place of the competences configuration problem in the context of UCTP

II. LITERATURE REVIEW

For the first time the timetabling problem appears in [2] as a problem consisting of three sets of (i) teachers, (ii) classes and (iii) timeslots. Since then, the timetabling problem has been the subject of interest of many scientists and practitioners [3-6]. Over the years, many approaches have been developed to modeling and solving the principal variety of the problem, the so-called UCTP. The most important of them include: (a) operational research (OR) methods based on Integer/Linear programming (IP/ILP), Graph Coloring (GC), (b) methods and techniques of constraint programming (CP) and constraint logic programming (CLP), (c) metaheuristic methods, such as Case Base Reasoning method (CBR), Genetic Algorithms (GAs), Ant Colony Optimization (ACO), Partial Swarm Optimization (PSO), Variable Neighborhood Search (VNS), Tabu Search Algorithm (TS), etc., (d) hybrid methods and (e) multi-agent methods [7-10]. Practically, the competences configuration problem has not been considered in any of the presented approaches; it has been assumed that the set of lecturers with specific competences is given prior to finding an UCTP solution.

III. PROBLEM DECRIPTION

The competences configuration problem is discussed for the selected organizational unit of the university, which can be: chair, department or faculty. In the given organizational unit, lecturers are employed $E=\{e_1, \ldots, e_k, \ldots, e_{ZE}\}$ where ZE – number of lecturers employed in the unit. Each of the lecturers k has a certain teaching load allocated s_k i.e. the minimum number of hours to be realized in the given period (semester, academic year etc.). For instance, according to the valid law at Polish universities the teaching load is most often: 150, 210, 240, or 360 hours per academic year. In practice many lecturers teach courses in the number of hours exceeding their teaching load. For this reason, z_k coefficient has been introduced. If $z_k=1$, this means that lecturer k agrees to teach courses in the number of hours exceeding the teaching load (otherwise $zk=0$). *Wsp* coefficient has also been introduced, which determines by which percent a lecturer's teaching load can be exceeded without the need to obtain his or her consent (currently it is 15%). Certain types of courses are allocated to the given organizational unit (different forms for the given subject: lectures, projects, laboratory classes etc.) $P=\{p_1,\ldots, p^i, \ldots, p_{ZP}\}$ where ZP – number of types of courses in particular subjects assigned to the organizational unit. Each type of courses i has a specified number of hours l_i in which it is realized. In addition, for all classes the number of student groups h_i is defined. Lecturers of a given unit have certain qualifications (competences) to teach certain types of courses (coefficient $g_{i,k}=1$ means that lecturer k, without any further training, courses or postgraduate studies, etc. may offer subject i, otherwise $g_{i,k}=0$).

A. Illustrative example

In the example chair at a technical university, 18 different teaching courses are provided $P=\{p_1,\ldots, p_i, \ldots, p_{18}\}$. Each course has two characteristic parameters i.e.: the number of teaching hours in a semester and the number of student groups for which it is provided. The respective numerical data are presented in Table 1.

TABLE I.
DATA DESCRIBING THE SUBJECTS FOR THE ILLUSTRATIVE EXAMPLE.

courses	P_1	P_2	P_3	P_4	P_5	P_6	P_7	P_8	P_9
Number of hours taught under the course	15	15	30	15	30	15	30	15	15
Number of student groups assigned to the course	1	2	1	2	1	2	1	2	1
courses	P_{10}	P_{11}	P_{12}	P_{13}	P_{14}	P_{15}	P_{16}	P_{17}	P_{18}
Number of hours taught under the subject	15	30	15	30	15	30	30	30	15
Number of student groups assigned to the course	2	1	3	1	3	1	3	1	3

In the considered organizational unit, four lecturers are employed. Each of the lecturers has competences authorizing him or her to teach specific groups of courses, which have been specified in Table 2 (where "1" means having qualifications certifying the given competence, and "0" means that it is missing). The respective numerical data are presented in Table II.

Each of the lecturers has an allocated teaching load in the number of 150 hours in a given semester and each of them

expresses his or her consent to teach excess hours (exceeding the teaching load).

For the so described problem, two primary questions come up:

Q1. Is there any allocation of the courses that will guarantee that all the lecturers realize the teaching load without the need to change competences?

Q2. If it is not possible to allocate the courses without changing the competences, how to minimize the number of new/changed competences (additionally, it can be required that change of the competences of any of the lecturers should not be greater than *B* times)?

For the so allocation problem, a mathematical model has been formulated (Chapter B), its implementation has been made in the LINGO solver language (Appendix A) and computational experiments have been conducted (Chapter C).

B. Competences management problem model

The mathematical model has been formulated in the form of a MILP problem. Table 3 presents the description of parameters, indexes and decision variables of the model. Table 4 presents the description of constraints. The function minimizing the number of changes in the competences of the lecturers has been adopted as the objective function (1). The above model allows you to find the answer to question Q2. In order to answer the Q1 question instead of (1) we introduce an additional restriction (10).

Table III.
DESCRIPTION OF PARAMETERS, INDEXES AND DECISION VARIABLES OF THE MODEL.

Symbol	Description
	Sets
P	Set of lecturers
E	Set of courses
Indexes	
k	Index $k \in P$
i	Index $i \in E$
	Parameters
l_i	Number of hours taught under the course *i*, $i \in E$
h_i	Number of student groups assigned to the course *i*, $i \in E$
s_k	Number of hours of the teaching load of lecturer $k \in P$
z_k	If the lecturer *k* has given their consent to overtime hours $z_k=1$, otherwise $z_k=0$
$g_{i,k}$	If lecturer *k*, without any further training, may teach courses *i* $g_{i,k}=1$, otherwise $g_{i,k}=0$, $i \in E$, $k \in P$
wsp	Percent exceeded teaching load without lecturer's necessary consent
A	Arbitrarily high constant
B	Maximum number of changes in competences for lecturer *k*
	Decision variables
$X_{i,k}$	Number of student groups for course *i* which will be taught by lecturer k $i \in E$, $k \in P$
$Y_{i,k}$	If the competences of lecturer *k* to teach course *i* have been changed $Y_{i,k}=1$ otherwise $Y_{i,k}=0$, $i \in E$, $k \in P$

$$\min \sum_{i \in E} \sum_{k \in P} Y_{i,k} \quad (1)$$

$$X_{i,k} \le (G_{i,k} + Y_{i,k}) \cdot A \forall i \in E, k \in P \quad (2)$$

$$\sum_{k \in P} X_{i,k} = h_i \forall i \in E \quad (3)$$

$$\sum_{i \in E} l_i \cdot X_{i,k} \ge s_k \forall k \in P \quad (4)$$

$$\sum_{i \in E} l_i \cdot X_{i,k} \le wsp \cdot s_k \forall k \in P : z_k = 0 \quad (5)$$

$$\sum_{i \in E} \sum_{k \in P} Y_{i,k} \le B \quad (6)$$

$$Y_{i,k} = 0 \forall i \in E, k \in P : g_{i,k} = 0 \quad (7)$$

$$X_{i,k} \in C^+ \forall i \in E, k \in P \quad (8)$$

$$Y_{i,k} \in \{0,1\} \forall i \in E, k \in P \quad (9)$$

$$Y_{i,k} = 0 \forall i \in E, k \in P \quad (10)$$

Table IV.
DESCRIPTION OF CONSTRAINTS AND OBJECTIVE FUNCTION

Constraints	Description
1	Minimum number of changed competences (Q2)
2	Only the employees having appropriate competences can teach the course which requires them
3	Each course is provided for the designated number of student groups.
4	The constraint ensures that the teaching load is realized
5	The constraint does not allow the teaching load to be exceeded by more than *wsp*, if there is no lecturer's consent
6	Change/extension of the competences may happen only a specified number of times;
7,8,9	Binarity and discreteness
10	No possibility to change competences (Q1).

C. Computational experiments

For the proposed model (Chapter 3.B) using the LINGO environment [11] and the implementation model (Appendix A), computational experiments have been conducted. The experiments have been concerned with the illustrative example (P1) and other organizational units such as: chair, department and faculty (P2..P6). The obtained results are presented in Table V and Table VI.

Table V.
RESULTS OF CALCULATIONS

Nr	Unit	ZP	ZE	V	C	T	Q1	Q2
P1	Chair 1	18	4	132	121	1	YES	0
P2	Chair 2	16	6	177	145	1	NO	1
P3	Depart. 1	40	15	1159	717	2	NO	3
P4	Depart. 2	60	20	2287	1267	3	NO	1
P5	Faculty 1	120	50	6170	6352	10	NO	4
P6	Faculty 2	160	80	13040	13290	25	NO	6

ZP Number of curses ZE Number of lecturers
V Number of decision variables C Number of constraints
T Calculation time

Detailed results for the illustrative example (P1) are presented in Table VI.

Table VI
DETAILED RESULTS OF CALCULATIONS FOR P1

k	i	$X_{i,k}$	$Y_{i,k}$	k	i	$X_{i,k}$	$Y_{i,k}$
1	1	1	0	3	5	1	0
1	4	1	0	3	6	2	0
1	11	1	0	3	7	1	0
1	12	3	0	3	15	1	0
1	16	2	1	3	16	1	0
2	2	2	0	4	8	2	0
2	3	1	0	4	9	1	0
2	4	1	0	4	10	2	0
2	13	1	0	4	17	1	0
2	14	3	0	4	18	3	0

IV. CONCLUSION

The work presents the problem concerning lecturers' competences configuration. A MILP model has been proposed for this problem, which has been implemented in the LINGO package environment. Before starting work on an UCTP solution, it is necessary to designate the set of the missing competences and supplement them. As a result of solving the problem of lecturers' competences configuration (Table V), we obtain information how many and what competences are missing, which lecturers should supplement them, and we obtain the allocation of the lecturers to the classes and the student groups, namely we partly/initially solve UCTP. The received allocation meets the constraints related to the teaching load for different lecturers. As part of further works, research is planned on modeling and solving UCTP integrated with the configuration model (Chapter B) and additional logic constraints are to be introduced [12,13] related to lecturers' preferences as to the times and forms of the curses, halls etc. It is also planned to apply the method of hybrid modeling and solving to the above-mentioned problem [14-16].

***Abstract*—Juxtapositioning manually created business process models with diagrams generated using process discovery algorithms exposes high complexity of the latter. As a consequence, their formal verification requires significant computational resources due to a large state space. Nevertheless, an analysis of the generated model is needed to assure its correctness and the ability to represent source data. As a solution to this problem, we present an approach for constraint-based generation of a complete workflow log for a given BPMN model. In this paper, we propose a method to extract directed subgraphs representing token flows in the process together with a set of predefined constraints. Likewise, in the case of process simulation, these constraints ensure the correctness of the generated traces. Ultimately, the obtained results can be compared to the original workflow log used for process discovery in order to verify the obtained model.**

***Index Terms*—business process management, process verification, workflow logs, constraint programming**

I. Introduction

BUSINESS process models aim to represent knowledge about workflows which take place in an organization. Such chains of different activities are represented by graphical diagrams that hold information about their dependencies, execution conditions, alternative flows and other properties included in the used modeling notation. Creation of a process model may be performed manually by a process designer who builds the diagram in a graphical editor or prepares other representations such as UML activity diagram [1], structured text [2], natural text description [3] or a spreadsheet representation [4]. Another way to design a model is to discover it from event logs generated by existing IT systems [5], [6].

Although process mining appears to be a convenient technique which does not require much effort in the phase of process modeling, the discovered workflow models can suffer from various defects. Such flaws can be caused either by the imperfection of the selected algorithm [7] or by corrupted logs [8]. Raw data recorded from real system may be characterized by missing events, imprecise or incorrect data, as well as irrelevant artifacts.

Several methods were developed to evaluate discovered models. They include simulations performed on a generated Petri Net which represents the workflow [9], application of evaluation metrics [10], as well as validating models against temporal logic formulae [11]. In order to improve data analyzed by a process miner, the technique of real-time log monitoring can be applied [12]. Another related approach consists in generating synthetic traces based on a structured declarative model [13].

The existing methods can be used to improve quality of process mining from various perspectives, however they tend to operate on different workflow representations, such as raw event data or Petri Nets, without considering the output model. The purpose of the proposed method is to evaluate the created business process model and verify its behavior by generating its admissible execution traces. The synthetic log can be then compared to the set of real execution sequences obtained from a computer system in order to indicate areas of imperfection and take corrective actions, such as changing the mining algorithm or refining log data. A schematic illustration of our approach is presented in Figure 1.

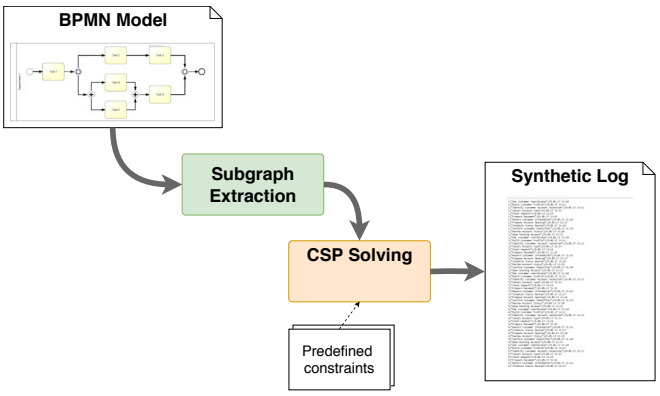

Figure 1. Overview of the proposed approach.

This paper is organized as follows: Section II provides an overview of Business Process Management which includes its definition and phases. Section III describes the concept of a BPM lifecycle and its aspects. A definition of workflow log was presented in Section IV and followed by a brief description of process mining, where logs are used to extract process knowledge, which was provided in Section V. Our main contribution is included in Sections VI and VII where we proposed methods to determine the number of traces in a process log, as well as presented a constraint-based model to generate a synthetic set of traces. Concluding remarks and plans for future works were summarized in Section IX.

II. Business Process Management

Business Process Management (BPM) [14] is a modern approach to improving organization's workflow, which focuses on reengineering of processes to obtain optimization of procedures, increase efficiency and effectiveness by constant process improvement.

The key aspect of BPM is a Business Process (BP). Although there is no single definition of a Business Process, the existing definitions have many things in common [15], [16], [17], [18]. A BP is usually described as a collection of related activities which transform different kinds of clearly specified inputs to produce a customer value, mainly considered as products or services and organizational goals, as output.

Different definitions emphasize various aspects of such defined processes. Davenport described a process highlighting the importance of producing an output for a customer – how work is done [15]. Definition of Eriksson and Penker emphasizes how work is performed rather than describing products or services, results of a process [19]. Jacobson, in turn, underlined that a process should be customer-oriented and meet an individual customer's needs [20]. A wider conceptualization of process was presented by Melao and Pidd [21]. They gave four perspectives on business process to understand BPs more fully. In their approach, BPs can be seen as either deterministic machines, complex dynamic systems, interacting feedback loops or social constructs.

Thus, Business Process Management requires a specification of many aspects, such as goals, inputs, outputs, used resources, activities and their order, impact to other organizational units, customers and owners for each of managed processes to enable real benefits. It unifies the previously distinct disciplines such as Process Modeling, Simulation, Workflow, Enterprise Application Integration (EAI), and Business-to-Business (B2B) integration into a single standard [22].

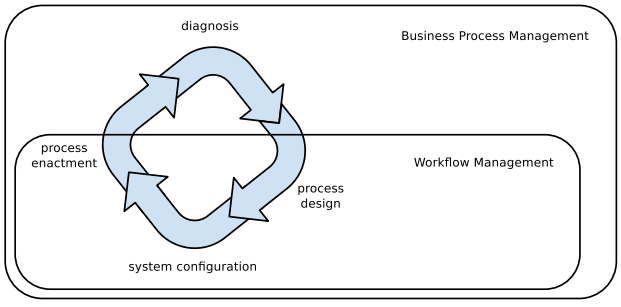

Figure 2. Comparison of Workflow Management and Business Process Management (based on [23]).

Therefore, BPM is often considered as either a legacy or the next step after workflows. Workflow Management Coalition (WfMC) [24] defines a workflow [25] in terms of automation of a business process during which documents, information or tasks are passed from one participant to another for action, according to a defined set of procedural rules. According to van der Aalst et al. [23], BPM is a broader term than Workflow Management (WFM). BPM supports business processes using methods, techniques, and software in designing, enacting, controlling, and analyzing processes involving humans, organizations, applications, documents and other information sources. It is restricted to operational processes, thus it excludes processes that cannot be made explicit.

A simple approach to process management distinguishes four phases of supporting processes [23]:

1) *process design*, in which the process is designed or redesigned,
2) *system configuration*, in which the design is implemented by configuring process management system,
3) *process enactment*, in which the operational business process is executed using the configured system,
4) *diagnosis*, in which the process is analyzed or verified to identify things that can be improved.

The relationship between WFM and BPM is presented in Figure 2. As one can observe, BPM extends the traditional WFM approach. In the case of the WFM systems, they do not support diagnosis phase, and such features as simulation, verification or validation of process designs.

III. BPM Lifecycle

Although many aspects of BPM have been debated in literature, one of the fundamental BPM issues is a repeating sequence of steps, the so-called Business Process Management Lifecycle (see Figure 3). The main idea behind the BPM lifecycle is to manage and improve BPs over business changes. Due to the use of clearly defined phases, BPM enables the continuous maintenance and the evolution of processes. During iterations, such parameters of business processes as cost, time, quality of output or customer satisfaction can be improved causing an improvement of the whole process.

Thus, BPM is in fact the application of the management cycle to organization's business processes [26]. The BPM lifecycle starts with specification of organizational and process goals as well as an assessment of environmental factors having an effect on the organization BPs. In the next process design phase, the organization processes are to be identified or redesigned. In this phase, the particular process details should be specified, and the proper variables that will influence the process design should be identified as well. During the next phase the previously specified process models are implemented in the environment, usually manually via procedure handbooks or using BPM or workflow software. Finally, the implemented process can be instantiated and executed. During execution, the performance is monitored in order to control and improve the process. Data produced during the process enactment and monitoring phases, aggregated from multiple process instances, can be used in the evaluation phase, whose purpose is to formulate the results suitable for process improvement.

Our area of research focuses on analyzing process models discovered from event logs and verifying them in terms of admissible execution sequences. Therefore it covers the evaluation phase and its side activities such as auditing event logs as well as providing measures of improvement for the whole process.

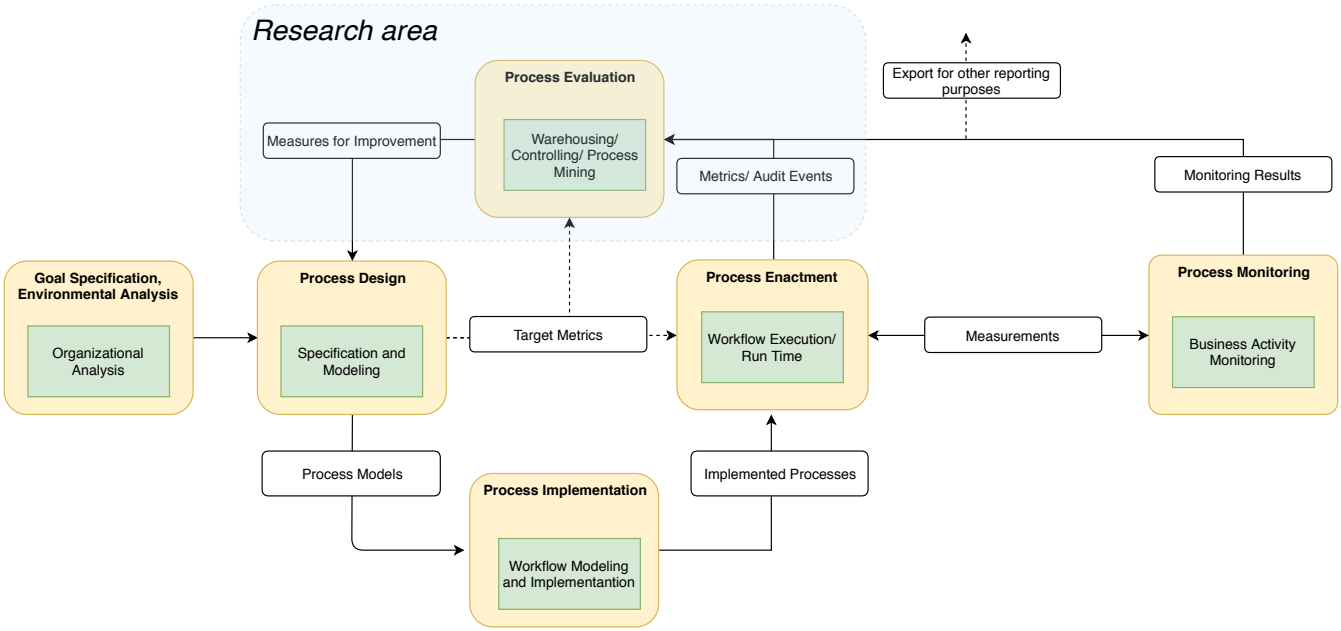

Figure 3. Business Process Management Lifecycle with the indication of our area of research (based on [26]).

IV. Workflow Log

In every business process, regardless whether it is executed manually or by an IT system, completion of each activity should be recorded with a proper timestamp. Such a record is often referred to as a log event [27] and may include information about a person or unit performing the task, as well as its cost and used resources. A set of log events ordered by their completion timestamps is called a workflow trace:

$$\sigma = \{\alpha^{(1)}, \alpha^{(2)}, ...\alpha^{(K)}\}, \tag{1}$$

where α is a log event and K represents the length of the trace.

One of the most important features of an event trace is that all recorded activities are ordered chronologically. In other words, even if two different activities are executed in parallel, their accomplishment time differs and it is always possible to distinguish the one which was completed first. However, as business processes are repeated many times, the order of their completion may differ depending on the instance of the process. In addition, processes may contain alternative gateways that, based on a logical condition, determine which task should be executed and which should remain unused. Therefore, in order to gather the information about the whole process, one should record a workflow trace for a number of times to ensure, that all or nearly all the possible execution sequences were collected. A set of workflow traces is called a workflow log:

$$W = \{\sigma_1, \sigma_2, ...\sigma_L\}, \tag{2}$$

where σ_i are separate workflow traces, also referred to as cases or workflow instances and L is the number of recorded traces.

A workflow log can be considered complete if it covers all the possible execution sequences of the process. In the case when activities are executed in loops, the number of possible traces may be infinite. Therefore, we weaken this requirement to a notion of sufficient completeness explained in Definition 1. It limits the required number of traces to those where the number of repetitions for each log event is equal to the number of cycles which include the corresponding activity.

Definition 1. (Sufficiently complete workflow log) Let G_P be a business process graph [28] representing the analyzed process and S_C be a set of all simple cycles in G_P. Function $C_C(\tau)$ determines the number of occurrences of the vertex representing activity τ in S_C. Workflow log W is sufficiently complete if it contains all the possible execution sequences where the number of occurrences for each activity τ is lower than or equal to $C_C(\tau) + 1$.

V. Process Mining

Process mining is an area of research which focuses on extracting knowledge from event logs [29] which were described in details in Section IV. One of the challenging tasks within process mining is process discovery [30] which includes algorithms able to generate process models in a flexible way, and in some cases without the need of any human actions. Although process discovery methods can produce syntactically correct workflow nets, the result is a general process model which is not directly applicable for execution in a runtime BPMN environment. BPMN diagrams can be obtained directly from event logs [31]. However, they require significant enhancements to be suitable for execution. Such modifications can be based on decision mining [32] which extends the process model by providing conditions for alternative or exclusive gateways.

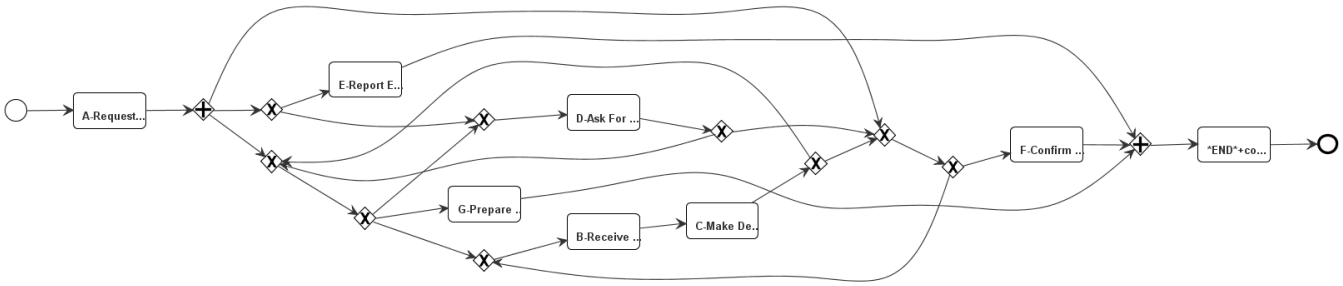

Figure 4. Result of applying a process mining algorithm to a workflow log of 36 traces.

Regarding process execution, the generated model still needs to be validated in terms of structural anomalies which may result in wrong dynamic behavior of a process [33].

Figure 4 presents a BPMN model discovered using ILP Miner [34] based on 36 different execution traces. In this example, the number of parallel and exclusive gateways (11) is higher than the number of activities (8). This implies a large number of routings and may possibly result in various exceptions during execution. Several complexity metrics exist which evaluate the complication level of business process models [35]. From a runtime point of view, the control-flow perspective should be considered. Cardoso et al. [36] propose a set of such metrics of which two can be applied in this case:

- Control Flow Complexity (CFC) which can be calculated as a sum of states induced by all the split gateways. Given n_{out} as the number of outputs of a gateway, each exclusive (XOR) split induces n_{out} states while a parallel split corresponds only to one state, as all the output branches are always used.
- Coefficient of Network Complexity (CNC) which is a quotient of the number of arcs (sequence flows) and the number of all activities, joins and splits in the process.

In the example presented in Figure 4, the Control Flow Complexity is equal to 12 and the Coefficient of Network Complexity has a value of 1.47. It is worth noting that values of these metrics for a simple workflow without any branching elements are equal to 0 and $(n_a + 1)/n_a$, where n_a is the number of activities, respectively.

VI. Determining the Number of Traces in a Process

The first step towards the estimation of the number of distinct traces is based on a business process model. A sequential workflow consisting of one start event, one end event and no gateways produces only one trace. A trivial example of such a process model is shown in Figure 5. However, models representing a simple workflow are rarely used in practice. According to the survey [37], in 90% of BPMN models the number of gateways varies between 5 and 15.

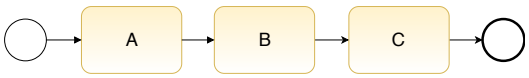

Figure 5. Simple sequential workflow.

In order to analyze business process model from an execution perspective, its token flow must be considered. It is assumed that the start event of a process generates a token which runs through the whole workflow to be consumed by an end event [38]. Although business processes can contain multiple start events, it is not regarded as a good practice as it remains unclear in the BPMN specification whether all the start events should occur before the process execution [39]. When determining a sufficiently complete log we refer to best practices of process modeling [40] following the statement that a well designed process model should contain only one start event which creates exactly one token.

On the other hand, multiple end events are a common practice in business process models, as they may represent different final states (e.g. goal and error states). However, only one of the end events is triggered in a single process instance. It may consume one or more tokens, depending on the number of incoming sequence flows.

Token flow in a business process is managed by logical gateways which determine branching flows. A single token created at the beginning of each process instance can be processed differently depending on the type of a gateway. The following actions are possible for a split gateway with n output branches:

- An exclusive (XOR) gateway places the token in one of the output sequence flows where the corresponding condition is met. As a result n different actions are possible.
- An inclusive (OR) gateway multiplies the incoming token by the number of conditions met. This action is followed by placing the created tokens on the corresponding sequence flows. As at least one output branch must be active, 2^{n-1} actions are possible.
- A parallel (AND) gateway multiplies the incoming token by the number of output branches. This result in only one possible action.

Since a single sequence flow should not transfer more than one token at a time, join gateways are responsible for merging multiple sequence flows into one output branch. An exclusive merge gateway only receives a token from one of its incoming branches and passes it to its output. A more complex situation occurs in case of a synchronization of multiple sequence flows which may be done in the following way:

- an inclusive merge consumes all the tokens created by its corresponding split gateways,
- a parallel merge consumes the tokens for all its input branches.

Each of the synchronizations result in creation of a token and passing it to the outgoing sequence flow except the situation when a parallel merge is declared implicitly by multiple sequence flows leading to an end event.

Since according to the best practices OR gateways should be avoided in BPMN modeling [40] and regarding the fact that in most cases they can be replaced by a sequence of exclusive and parallel gateways [41], this type of routing object was not taken into further analysis. As a consequence, the only flow objects in a well modeled process where token creation or consumption occurs are parallel gateways.

Figure 6 represents a simple BPMN model with one parallel and one exclusive gateway. As stated before in this section, an XOR split gateway generates as many possible states as is the number of its outgoing sequence flows. Thus, in this case there will be two possible execution sequences of the SESE (Single Entry Single Exit) block determined by two exclusive gateways: one sub-trace consisting of task D and one empty sequence. Although the presence of a single AND gateway induces one state, the generated tokens represent separate sequences of activities. As a result they can be executed independently until they reach a synchronization element represented by a parallel merge. Therefore, the first SESE block which follows the start event may also be executed in two ways, namely $\{A, B\}$ and $\{B, A\}$. Besides these two process fragments the remaining activity, denoted as C is executed in every process instance. This analysis leads to a conclusion that the number of execution traces in such a process is a multiplication of the corresponding values calculated for its SESE blocks.

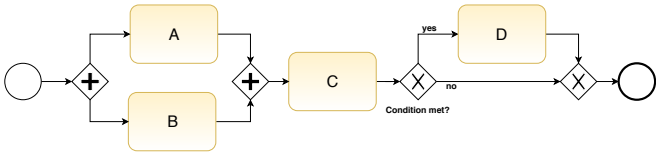

Figure 6. Example process with two basic types of gateways.

As stated before in this section, sequence flows followed by parallel gateways are executed independently. Therefore, if each branch within a SESE block delimited by AND gateways contains exactly one activity, these activities can be executed in any order. The example presented in Figure 6 illustrates a general rule for determining the number of admissible traces in a BPMN model which is expressed in Theorem 1.

Theorem 1. Let $\mathbb{P}$ be a BPMN process model containing a set of exclusive split gateways $\mathbb{G}_{XOR} = \{g_{X1}, g_{X2}, ...g_{Xk}\}$, a set of parallel split gateways $\mathbb{G}_{AND} = \{g_{A1}, g_{A2}, ...g_{Al}\}$ and two corresponding sets of merge gateways, namely $\mathbb{M}_{XOR}$ and $\mathbb{M}_{AND}$. If $\mathbb{P}$ consists of k SESE blocks determined by XOR gateways and l SESE blocks determined by AND gateways where each of l sequence flows contains exactly one activity, then the number of sequence flows in sufficiently complete workflow log W_{SC} can be expressed by Formula 3.

$$|W_{SC}| = \prod_{i=1}^{k} n(g_{Xi}) \cdot \prod_{i=1}^{l} n(g_{Ai})! \tag{3}$$

where $n(g)$ determines the number of outgoing sequence flows of a split gateway.

Proof. Let us assume that each of k exclusive gateways in $\mathbb{P}$ has exactly n outgoing flows. Knowing that every SESE element in a process model can be reduced to a subprocess which is a single BPMN activity [28] and that every XOR gateway allows for n actions, there are n possible states of every k subprocess in $\mathbb{P}$. This implies that the number of all admissible states is equal to n^k. Since the number of outgoing flows may vary for different gateways, $n(g_{Xi})$ has to be multiplied k times. □

VII. Constraint-Based Log Generation

The method presented in Section VI refers to these BPMN diagrams where SESE gateway structures are easily distinguishable. However, in automatically generated process models, as shown in Figure 4, gateways can be nested and the number of merge gateways does not have to match the number of splits. As a result, the number of traces is hardly calculable using analytical methods. Figure 7 shows a simple process model with nested gateways where Formula 3 cannot be applied.

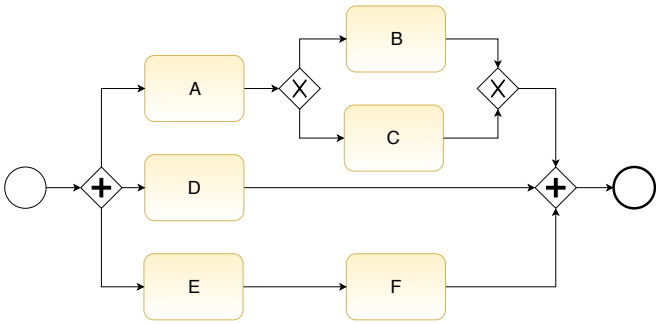

Figure 7. Example process with nested gateway structures.

The BPMN model presented in Figure 7 consist of six tasks formed in a parallel block with three branches. In business process models without loops, the upper limit of the number of traces is equal to the factorial of the number of activities. This would occur if all the tasks in the process were executed independently. In this case, however, there are following constraints which limit the set of possible sequences:

1) A must occur before B or C.
2) B is executed if and only if C is not.
3) E must occur before F.

In the analyzed example such constraints are easily identifiable and they can be expressed in a temporal logic [42]. However, dynamic generation of constraints for a complex

process model requires checking of all the dependencies between each pair of tasks which is an exponential problem. As a solution to this issue, we propose to extract process subgraphs from the model in a such manner that each of the graphs will represent the flow of a single token. It was stated in Section VI that each process instance ends with a single end event. As a consequence, all the generated tokens have to be consumed either by one of the parallel join gateways or by an event. Thus, the method can be applied to those SESE blocks in the process which start with a parallel split and whose last flow object is either a parallel join or an end event with multiple incoming sequence flows.

Let us denote the set of subgraphs as $S_G = \{s_1, s_2, ...s_q\}$. In the model presented in Figure 7, there are three tokens generated at a parallel split gateway and all of them are synchronized by a parallel merge before the end event. As a result, the extraction will provide three subgraphs, each representing tasks on a single branch (see Figure 8).

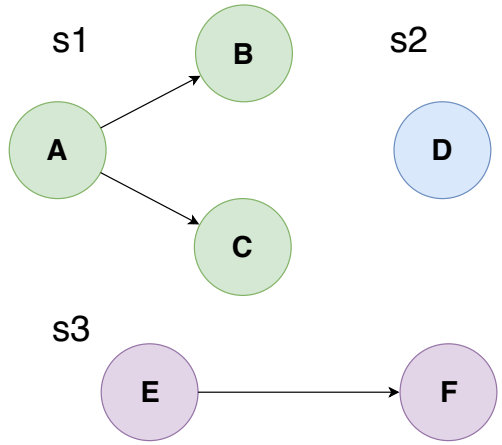

Figure 8. Token flow subgraphs extracted from a business process model.

In order to determine admissible workflow traces, a path should be calculated in every subgraph. The beginning of such a path is a vertex with no incoming edges. A path should end if a vertex with an outdegree equal to zero is reached. In the next step, all these paths are merged to vector β of length $p \cdot q$ where p is the overall number of tasks in the analyzed SESE block and q is the number of extracted subgraphs.

In Constraint Satisfaction Problems (CSP), a state which represents a set of elements must satisfy a collection of finite constraints over variables [43], [44]. CSPs can be solved using the constraint programming technique whose applications include design and modeling [45], as well as planning and scheduling [46]. If the problem is not over-constrained, a CSP algorithm always finds all the admissible solutions for finite domains [44]. Solving a Constraint Satisfaction Problem consists in general of four following steps:

1) Ordering the decision variables according to preference criteria.
2) Assigning values to each of the variables with respect to their domains.
3) Verifying if any of the constraints is violated at any step of the solving process.
4) If a complete or partial constraint-violating assignment is found, backtracking is enforced, and a succeeding set of values is assigned.

In this case, to calculate a process trace, we developed a constraint-based model in MiniZinc environment which consists of the following core elements:

1) Input data:
   - a list of tasks in the analyzed block,
   - vector e_x of maximum numbers of executions for each task (1 by default),
   - adjacency matrices $A_1, ...A_q$ for each subgraph.
2) Decision variables:
   - a subgraph trace matrix S_t of size $q \times p$,
   - a vector of merged traces β,
   - a vector γ of size p representing a workflow trace.

In order to improve the understandability of the code, we define two custom predicates which are further used in the predefined constraints:

- connected – returns true if two tasks are connected in the subgraph represented by its adjacency matrix,

```
predicate connected(src, dest, adj)
    = (adj[src, dest] == 1);
```

- same_block – returns true if a pair of indices of vector β is in the same subgraph trace.

```
predicate same_block(idx1, idx2)
    = (idx1 > 0 /\ idx2 > 0
        /\ idx1 div p == idx2 div p
    );
```

Constraints included in the model can be divided into three main groups, depending on a decision variable to which they are related. Let us briefly present these constraints along with their simplified representations in the MiniZinc language:

1) Subgraph traces:
   - the count of occurrences for each task should be lower then or equal to the input value,

```
forall(i in 1..p, j in 1..q)(
    count_geq(row(S_t,j), i, e_x[i])
);
```

   - the value 0 in the event log represents an idle task,

```
idle_task = 0;
```

   - the last log event should not be preceded by an idle task,

```
forall(i in 1..q)(
    count_neq(row(S_t,i), idle_task,
      last_process_index+1)
);
```

- all tasks after the last log event should be idle,

```
forall(i in 1..p, j in 1..q)(
    if i > last_task_index[j]
    then S_t[j,i] == idle_task
    else S_t[j,i] != idle_task
    endif
);
```

- the first element of a trace should be represented by a subgraph vertex without any incoming edges,

```
forall(i in 1..p, j in 1..q)(
  if S_t[j,1] == i
  then count(row(A_j, i),-1,0)
  endif
);
```

- the last log event should be represented as a vertex without outgoing edges,

```
forall(i in 1..p, j in 1..q)(
  if s_t[j,1] == i
  then count(row(A_j, i),1,0)
  endif
);
```

- if one task directly follows another in a trace, then it is connected by a directed edge in the corresponding subgraph.

```
forall(i in 1..q, j in
  1..last_process_index) (
  connected(S_t[i,j],S_t[i,j+1], A_i)
    \/ (S_t[i,j] == 0
        /\ S_t[i,j+1] == 0)
    \/ (j == last_task_index[1]
        /\ S_t[i,j+1] == 0)
);
```

2) Merged vector β:
   - the vector β is a concatenation of trace matrix rows.

```
forall(i in 1..last_process_index, j
  in 1..q)(
  if i < last_task_index[j]
  then beta[(j-1)*last_process_index
    + i] = S_t[j,i]
  else beta[(j-1)*last_process_index
    + i] = 0
  endif
);
```

3) Final trace vector:
   - the vector γ holds non-zero indices of β,

```
forall(i in gamma_indices)(
  if gamma[i] > 0 then
    beta[gamma[i]] != 0
  else beta[gamma[i]] == 0
  endif
);
```

- all the elements of γ are different except zero,

```
alldifferent_except_0(gamma);
```

- all the elements following the last non-zero element of γ are equal to zero,

```
forall(i in gamma_indices)(
  if i > last_gamma_index then
    gamma[i] == 0
  else gamma[i] != 0
  endif
);
```

- for each pair of tasks in γ if the pair is in the same row of matrix S_t then these task should be ordered in the same way as in S_t.

```
forall(i in gamma_indices, j in
  gamma_indices)(
  if i != j /\ gamma[i] != 0 /\
    gamma[j] != 0 /\
    same_block(gamma[i], gamma[j])
    then
    if i > j then
      gamma[i] > gamma[j]
    else
      gamma[i] < gamma[j]
    endif
  endif
);
```

In order to run the MiniZinc solver two files are needed:

- the model file *trace_id.mzn* which contains definitions of decision variables, predicates and constraints,
- the data file *subgraphs.dzn* where activity names, their maximum number of executions and subgraph adjacency matrices are defined.

For the workflow trace generation the search goal should be set for constraint satisfaction by using the statement `solve satisfy`.

The analyzed example model contains 6 tasks and 3 subgraphs, then $p = 6$ and $q = 3$. Formula 4 presents an example subgraph trace matrix S_t for subgraphs shown in Figure 8. Creation of vector β consists in merging all the subgraph traces (see Formula 5). Indices of β are used to generate trace vector γ (see Formula 6).

$$S_t = \begin{bmatrix} A & B & 0 & 0 & 0 & 0 \\ D & 0 & 0 & 0 & 0 & 0 \\ E & F & 0 & 0 & 0 & 0 \end{bmatrix} \tag{4}$$

$$\beta = [A\ B\ 0\ 0\ 0\ 0\ D\ 0\ 0\ 0\ 0\ 0\ E\ F\ 0\ 0\ 0\ 0] \tag{5}$$

$$\gamma = [13\ 7\ 1\ 2\ 14\ 0] \tag{6}$$

The resulting trace is an ordered set (see Formula 1) determined by non-zero elements of β whose indices are ordered by values of γ. Its value for the running example represented by the BPMN model in Figure 7 and trace matrix S_t defined by Formula 4 is shown in Formula 7.

$$\sigma = \{E, D, A, B, F\} \tag{7}$$

In order to generate all the admissible task sequences the solver should be set to print all solutions. Execution of the model results in a sufficiently complete log of a SESE process block. If a process contains multiple token split blocks then all of them should be handled separately.

VIII. Log-Based Verification of Process Models

Several metrics were proposed to analyze results of process discovery algorithms, namely: replay fitness, simplicity, precision, and generalization [47]. Since we tend to compare two sufficiently complete workflow logs without analyzing the graphical layout of the generated model, the following quality measures have been considered and adopted for the purpose of log comparison:

- model fitness – the percentage of traces from the original log which were generated based on the discovered model,
- execution precision – the percentage of generated workflow traces that are allowed in the original log.

It is worth noting that values for both metrics should be calculated in order to validate the resulting model. To illustrate this problem, let us analyze the example shown in Figure 6. Its original complete log can be easily determined analytically:

$$\begin{aligned} W_C = \{&\{A, B, C\}, \{B, A, C\}, \\ &\{A, B, C, D\}, \{B, A, C, D\}\}. \end{aligned} \tag{8}$$

Now let us assume that this log was used to discover a BPMN model whose traces were then generated using the constraint-based approach. The synthetic log W_S was determined as follows:

$$W_S = \{\{A, B, C, D\}, \{B, A, C, D\}, \{A, C, B, D\}\}. \tag{9}$$

Traces where activity D does not occur were not present in W_S. Thus, only half of the original traces are reproduced by the model which results in a model fitness equal to 50%. On the other hand, trace $\{A, C, B, D\}$ is not an element of W_C. In this case the execution precision will be equal to 66,67%, as only two synthetic traces out of three can be found in the original workflow log.

The application of the proposed method to the example process model presented in Figure 4 resulted in generation of 11820 distinct workflow traces. Table I presents results of a log-based verification performed for the example BPMN model.

Table I
Evaluation of the example BPMN model.

Parameter	Value
Number of original traces	36
Number of synthetic traces	11820
Traces not generated	0
Model fitness	100%
Synthetic traces not included in the log	11784
Execution precision	0.03%

The results show that the discovered process model is characterized by low execution precision (0.03%). It means that the selected process mining algorithm has a tendency to generalize, i.e. it allows for much more behavior than included in the original workflow log. Therefore, the next step of the verification process should be to check if the synthetic traces not included in the original log can be allowed in the real process. If not, then the choice of the process mining algorithm should be reconsidered in order to provide more accurate process representations.

IX. Conclusions

In the paper, we presented a novel constraint-based algorithm which results in generation of a sufficiently complete workflow log for a given business process model. The proposed approach may serve as an additional tool to verify BPMN diagrams generated using process mining techniques. Comparison of the real execution log with a synthetic one helps to choose the most suitable discovery algorithm for the analyzed process or gives clues to the user how the model can be enhanced manually.

As future works, we plan to develop an automated tool for a comparison of two workflow logs which will be able to identify flaws occurring as a result of process discovery. Such a solution could be also used as a decision support system that, based on a re-created log, provides advice to process designers which mining algorithm to use.

3rd International Workshop on Language Technologies and Applications

DEVELOPMENT of new technologies and various intelligent systems creates new possibilities for information processing. Natural Language Processing (NLP) addresses problems of automated understanding, processing, evaluation and generation of natural human languages. LTA workshop provides a venue for discussion and presenting innovative research in NLP domain, but not restricted, to: computational and mathematical modeling, analysis and processing of any forms (spoken, handwritten or text) of human language, interactions via Virtual Reality and Augmented Reality, Computational Intelligence models and applications but also other various applications in decision support systems. We welcome papers covering innovative applications and practical usage of theoretical aspects. The LTA workshop will provide an opportunity for researchers and professionals to discuss present and future challenges as well as potential collaboration for future progress in the field.

TOPICS

The submitted papers shall cover research and developments in all NLP aspects, such as (however this list is not exhaustive):

- Computational Intelligence methods applied to language & text processing
- text analysis
- language networks
- text classification
- language networks, resources and corpora
- document clustering
- various forms of text recognition
- machine translation
- intelligent text-to-speech (TTS) and speech-to-text (STT) methods
- authorship identification and verification
- author profiling
- plagiarism detection
- sentiment analysis
- NLP applications in education
- knowledge extraction and retrieval from text and natural language structures
- multi-modal and natural language interfaces
- innovative language-oriented applications and tools
- interactions models and applications via Virtual Reality and Augmented Reality
- NLP for text analysis in forensic linguistics and cybersecurity

***Abstract*—This work explores the connection between language, personality, and influence in a social media network. It clusters users based on two types of features: account activity features and stream content (word) features and compares the usefulness of these different types of features in categorizing users according to their influence and leadership potential in the network. Results of clustering using different sets of features are examined to answer questions about distribution of Twitter users from the influence perspective. These results are compared against distributions of personality traits obtained from previous research on personality types and established assessment tools that measure leadership aptitude and style. Experiments with different clustering algorithms are described and their performance and cluster outputs are reported.**

I. Introduction

This work pursues the research question of how language, personality, and influence are connected. We use Twitter data to analyze users from the perspective of influence. For the purpose of this analysis, we use both user account data and content data to cluster users in different categories according to their leadership or influence abilities. We refer to features extracted from each type of data above as "activity" (or account) features and "word" (or language) features, respectively. We also compare the different types of features in their usefulness for modeling and predicting influence. The underlying reference model is DISC [1], [2]: a behavioral assessment tool that measures different personality traits including leadership aptitude and style. It was first proposed by psychologist William Marston in 1928 and later developed by industrial psychologist Walter Clarke. DISC is a widely used personality assessment tool that is based on studies in various fields and involves surveying a large number of people from different backgrounds, professions, and personalities [3], [4]. A significant portion of this assessment tool is based on the use of language; hence, motivating its use for extracting features to identify influence in tweets. We use this specific tool as a reference for identifying different personality traits associated with DISC categories and focus on the categories of leaders and influential people.

This kind of profiling has many important applications. It can be used to identify points of influence in a large social network. This is of especial interest in places where social media is used as an alternative means to exercise influence or express opinions otherwise not represented in main stream media. For commercial purposes, companies may need to identify influential users to provide them a product or a service so they may recommend it to their followers. This is essentially linked to the "activity shaping" problem in social networks. This kind of analysis can also be used to answer important questions about social media networks such as the similarity in behavioral distribution to patterns/distributions found in larger populations. In addition to answering questions about social media, this kind of analysis can help understand and better model the dynamics of influence, trust, and information propagation. Other applications include targeted advertisement and personalized interface design.

This project is on one hand exploratory work aimed at examining the nature of Twitter data in terms of whether typical DISC distribution patterns can be found in Twitter and whether content/word features are as useful in predicting influence as account/activity features. On the other hand, this work can be viewed as a first step towards automating the task of DISC profiling in social media networks.

II. Background and Related Work

In recent years, a line of research connecting natural language processing and social media analysis has emerged. Several related studies focused on various aspects of personality and interaction including prediction of social relationships and tie strength [5], [6], prediction of Big Five personality traits [7], and prediction of anti-social traits [8]. *Influence* which is an important aspect of personality has been studied using language features or account activity features but has not been explored, to our knowledge, in social media analysis using and contrasting both types of features.

While previous work focused on personality models based mostly on the Big Five personality traits [7], [5], we use DISC model in this work to explore the relationship between language and influence. DISC is an assessment tool that has been developed for different personality analysis purposes including testing leadership aptitude and

style [1], [2]. It basically distributes the population in a space of two dimensions that roughly correspond to 1) people-oriented vs. task-oriented and 2) outgoing/active/fast-paced vs. reserved/reflective/moderately-paced as shown in Figure 1 on page 3. Different variants of the test focus on different aspects of the classification depending on which dimension is more relevant to the problem and its domain. According to DISC studies focusing on leadership aptitude, only 4% of the population falls in the two extremes of leadership aptitude and at most 2% are natural leaders who have strong leadership qualities regardless of training and environment. The majority of the population is found in between not deviating much from the mean in a distribution that resembles a bell curve. The DISC model has been used in different studies for different purposes such as improving team performance through behavioral assessment profiling [9], identifying behavioral factors of individuals in high managerial ranks [3], and even studying the influence of personality style on performance of students in educational settings [4]. In this work we focus on using DISC to answer questions about categorization of Twitter users according to leadership aptitude and style and compare empirical findings to expected distribution based on domain knowledge. We also explore whether language features are as useful as action features (e.g.,#followers, #following,#retweets, etc.) in modeling and predicting influence. We first discover clusters based on user account features and word features separately and then examine whether we obtain similar or different results. We compare the usefulness of each type of features for coming up with clusters that resemble DISC categories and decide whether "actions speak louder than words," "words speak louder than actions," or whether they convey the same information in this context. This also allows us to see differences between the influence aspect of personality and other aspects that are accurately predictable using linguistic content as shown in previous work [7], [8], [6], [5].

III. Data and Feature Engineering

Next we describe the dataset, the different features computed, the motivation and method for feature selection and numerical scaling of features.

A. Data

In this work, we use a subset of Twitter obtained and published in previous work on social user profiling for inferring home locations [10]. The dataset contains network data for 3 million users (profile/account data) and 147 thousand tweet streams. There are about 78 thousand users for which we have both account data and tweet streams.

B. Feature Engineering

We consider two types of features: account (action) features and language content (word) features. Account features include the number of followers, number of friends (following), ratio of the previous two numbers, number of tweets, retweets, and favorite (liked) tweets. The last two are used as an indication of tweet popularity/impact as tweets that tend to be retweeted and liked frequently have more influence and propagate further. In addition to these features that are almost available with the data and required little computation, we also compute the page rank of a user as another account feature. The page rank of a user A is given by the formula:

$$PageRank(A) = 1 - d + d \sum_{i=1}^{n} \frac{PageRank(i)}{L(i)}$$

where n is the number of A followers, $L(i)$ is the number of i's followers and d is the damping factor[1]. Table 1 lists all account (action) features. Note that these features are not all independent. We experiment with different functions and subsets of features for clustering users.

The other type of features is language/content features. These features are based on a bag of words language model in which words are either grouped or treated as individual features. Several linguistic content categorization systems exist including Linguistic Inquiry Word Count (LIWC) system that is commonly used for personality analysis [8], [12], [5], DISC categories which are based on grouping words according to DISC categories: Dominance, Influence/Inducement, Submission, and Compliance, and finally broad categorization of most frequent words into linguistic categories such as function words, common verbs, and pronouns and semantic categories such as social processes, emotions, and work-related words. Both normalized frequencies and tf-idf were used in different experiments to explore the effect of relative weighting in this clustering task.

1) Extracting Content Features: Since this work is exploratory in nature, different sets of word features were used. In one set, words are grouped into categories and one frequency counter is maintained for each category, another set was formed by splitting words into separate features (frequency counter for each word), a third set was formed by including words describing different categories in the DISC assessment, and another variant of the word features was based not on counts but tf-idf scores. The set in which words were split as individual features resulted in very sparse representation of some features so we used the grouped version of the word features (as done in linguistic analysis of most related work). The tweet stream was preprocessed before computing the features. The text was converted to lower case, irrelevant punctuation and other markers were removed, and constant keywords were ignored. However, we did not perform stemming on the tweet stream; weighing the computational cost and information gain we decided that counting variants of the surface word sharing the same stem was not computationally expensive and often important to differentiate.

2) Extracting and Scaling Account/Activity Features: Most action features were readily available in the data. User profiles include the number of followers, friends, retweets, and favorite (liked) tweets. However, in addition to normalizing these

[1]We use the commonly assumed value of 0.85 [11].

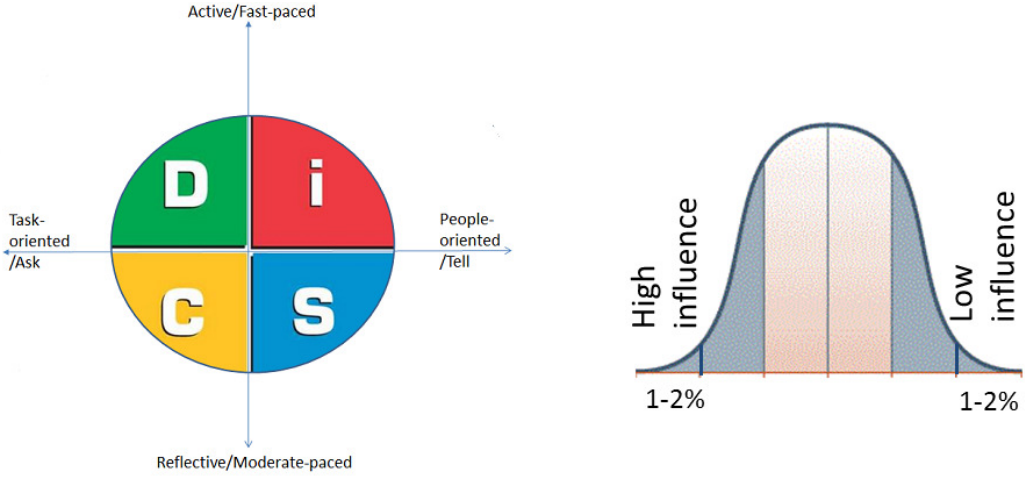

Fig. 1. DISC categories and distribution

activity features	word features
# followers A	LIWC
# following B	DISC
ratio A/B	LIWC + DISC
# tweets	tf-idf of LIWC
# retweets	tf-idf of DISC
# hashtags	tf-idf of LIWC + DISC
# likes	individual words variant of above
pageRank	grouped words variant of above

TABLE I
ACCOUNT ACTIVITY FEATURES AND CONTENT/WORD FEATURES

counts and creating features based on simple functions of these counts (ratios for example), we computed a "pageRank" feature which captures deeper influence in the network than simply the number of followers or the ratio between followers and friends. Interestingly, results show that the pageRank follows a power-law distribution; i.e., there are very few users with high pageRank and there is a long tail of users with small pageRank, while the number of followers have a smoother distribution.

Analyzing user account data, we noticed a wide range of values with a long tail for several key features. This called for scaling of features before feeding the values into clustering algorithms, otherwise the algorithms may yield unexpected results or convergence behavior due to the skewed distribution. The following account statistics are obtained from three million user accounts (3123283 Twitter user profiles). Table 2 shows that the data varies in a wide range with a very long tail across all features. This long tail phenomenon has to be addressed before clustering. Therefore, all features are scaled by the median of the feature set except the *likes* count feature (because its median is 0) which is scaled by 10 times the mean of that count.

3) Feature Selection: Since the number of combined features is very large, Principle Component Analysis (PCA) was done to produce a lower number of linearly uncorrelated features that are most informative. The total number of features exceeds 500, since not all features may be informative and a large number of features may slow the convergence of clustering, we used PCA to represent these hundreds of features in a few eigen components not exceeding 15. Indeed, dimensionality is reduced with PCA and clustering was performed on the projected feature space produced by PCA.

IV. METHOD

Section 2 detailed the different feature types and different linguistic categorizations for word features (LIWC, DISC, individual, grouped). This section presents the clustering algorithms and different experimental settings created from various combinations of feature types and clustering algorithms.

A. Empirical Support for Hypothesis

One of the main questions in this work is whether language and influence are related. We describe an experiment conducted to test the hypothesis that language and influence are related before running clustering algorithms. In this experiment, users were ranked according to each action feature (#followers, #following, etc.), resulting in n different rankings/lists (where n = #action features), then the top 5% of users in each list were extracted, the pair-wise intersection of user lists (i.e., intersection of top 5% users according to each pair of features) was obtained, and finally the union of resulting sets was taken.

Feature	min	max	mean	median	sum
# FRIENDS	0	695509.0	719.4	218	2246906359.0
# FOLLOWERS	0	11060753.0	1348.48	136.0	4211702993
# TWEETS	0	982934.0	2319.71	272.0	7245121544.0
# LIKES	0	3200.0	27.41	0.0	85628538.0

TABLE II
ACCOUNT DATA STATISTICS

The final set contained the top 5% users according to action features. Initially, the experiment was designed to simply take the intersection of all n lists and regard that intersection as the top 5% influential users according to action features but that intersection was almost empty[2] which suggests that these features were not redundant and that each feature targets a different "action" and therefore possibly different kinds of users. The other option was to simply union all top 5% users obtained from rankings by different features but that set may contain users that are not as influential as those who are ranked highly by more than one feature. Taking the pair-wise intersection and then taking the union of all resulting sets is a balanced option in between. The 5% lowest rank users were sampled following a similar procedure.
We then examined the language use for these two sets of users that are on different extremes according to action features. A clearly different use of language across all linguistic categories is observed. The variation is measured in differences in (normalized) frequencies of words across categories as shown in Figure 2. One observation is that the top 5% users tend to use more words (i.e., express themselves more) and that the ratio between the two sets of users varies across categories from double to more by a third or less. This supports the intuition that language and influence are related. The following section describes the clustering experiments conducted to further examine this hypothesis and answer other questions about influence distribution in Twitter.

B. Clustering

Clustering was done using three different clustering algorithms: k-means, EM, and spectral clustering. In each experiment users were clustered according to word features and account features, separately. The resulting sets of clusters are examined for similarity and overlap. The idea is that if we cluster using action features and cluster using word features separately and then find that the resulting clusters are similar and overlap then we can infer that these different sets of features (actions and words) model the same phenomenon: influence, and that although they are different in nature they are strongly related as they can make similar predictions about the same phenomenon. Algorithm 1 on page 4 is high-level description of the clustering and analysis steps.

k-means: We experimented with different values of k. Based on the problem domain, however, we selected 4 as it reflects the number of main categories in DISC. Although k-means is suitable in settings where the data is expected to be separable, we noticed that clusters we obtained are dense around the mean with far fewer points spread further. So even with k-means we were able to obtain clusters that were clearly distinct.

[2]The intersection of all top 5% lists included only 6 users from the original list of 78 thousand users.

```

EM: Since EM is suitable for soft clustering where clusters are expected to overlap, we clustered the users using EM on mixture-of-Gaussian models. This was motivated by the large number of data points ($>$ 78K users) calling for the applicability of the central limit theorem as a reasonable assumption and more significantly that the overall distribution of influence resembles a normal distribution as depicted in II on page 3.

Spectral: We also applied spectral clustering to see if it confirms results of other clustering algorithms or behaves differently. Spectral clustering is further motivated by its applicability in settings where clusters may overlap. We noticed that spectral clustering does not scale with a large dataset. To successfully apply spectral clustering, k-means was first run to reduce the dimensionality of the data and then spectral clustering was run on the dimension-reduced dataset. Different values of k ranging from 700 to 50 were tried, spectral clustering scaled only to the smallest dataset; i.e., the maximally reduced set with 50 means.
In the following section, we present results and compare the performance of clustering algorithms.

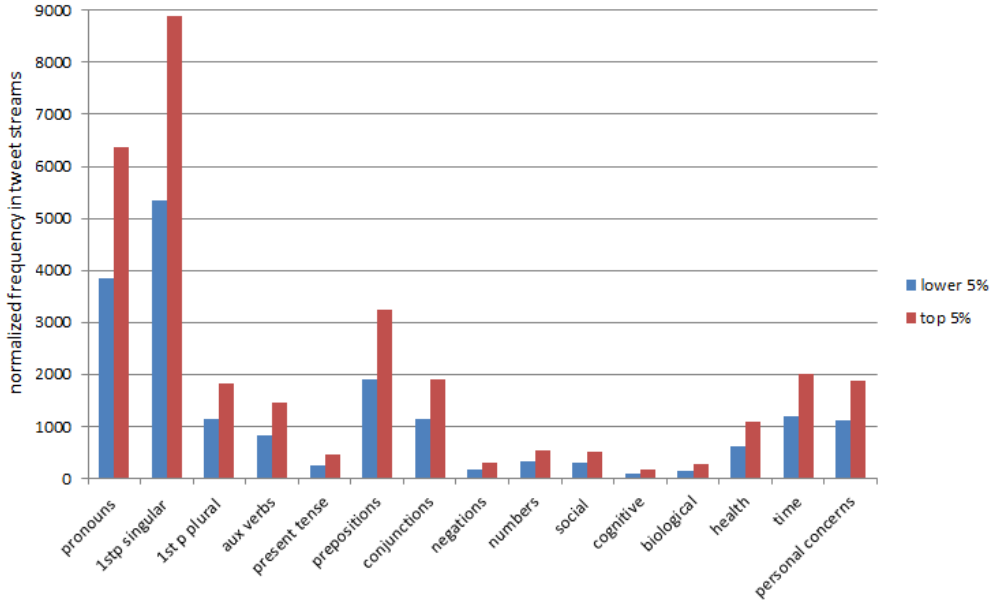

Fig. 2. language use in different groups of users

V. Results

A. Comparison of Different Clustering Algorithms

Table 3 summarizes differences in performance and output of clustering algorithms. The runtime reported is based on running the algorithms on the largest data set of profiles (> 2.5 million users). The runtime for spectral clustering includes the runtime of running k-means with k=50 first and then running spectral clustering on the result.

B. Cluster Overlap Results

Clusters based on action features and those based on word features are examined for overlap. Overlap between two clusters is measured in the number of users they have in common. The idea is that if action-based clustering and word-based clustering result in respective clusters that overlap; i.e., have many users in common, we conclude that action features and word features can mirror each other in making similar predictions and therefore are related. Figure V-B shows overlap patterns for clustering using different sets of features. A diagonal means that overlap is observed in all four clusters. A partial diagonal means that overlap is observed only in some subset of clusters. We present the plots that represent common patterns across algorithms and discuss these findings in the analysis section.

VI. Analysis and Discussion of Results

The following are observations from the experimental results along with analysis for each result.

1) Clustering based on account features and on word features show that the sizes of clusters produced closely match the typical size of population categories according to DISC with two small clusters representing the extremes on influence abilities and two large (possibly overlapping) clusters representing most of the population. In fact, all clustering combinations almost always produce a skewed distribution of cluster sizes which matches the typical distribution of individuals according to the theory of influence and leadership. It is also observed that the distribution is more skewed when word features are used to cluster. We've attempted further analysis on the word content of these clusters in order to draw reliable conclusions about the nature of these clusters. This is discussed in cluster identification section below.
2) Similarity was found between clusters obtained using word features from different linguistic content categorization systems. More specifically, adding DISC word categories to LIWC does not significantly change clusters obtained from LIWC word categories. This shows that the latter is a comprehensive categorization that subsumes DISC categories. However, clustering based on DISC categorization of linguistic content results in better alignment with clusters obtained from action features. This agrees with the claim that DISC is designed to specifically target the influence aspect of personality.
3) Similar clusters are obtained from account features in original spaces and PCA projection space. This result is not surprising due to the small number of action features that even when projected using PCA result in principle components that are very similar to the original representation.
4) More importantly, a clear overlap is observed between clusters based on action features and clusters based on word features.

	run-time	scalability with		cluster sizes
		# features	# data points	
4-means	1m 1s	✓	✓	12,19,27,42(%)
EM	5m 3s	✓	✓	6,13,36,45(%)
Spectral	42m 44s	✗	✗	6,18,35,41(%)

TABLE III
COMPARISON OF DIFFERENT CLUSTERING ALGORITHMS

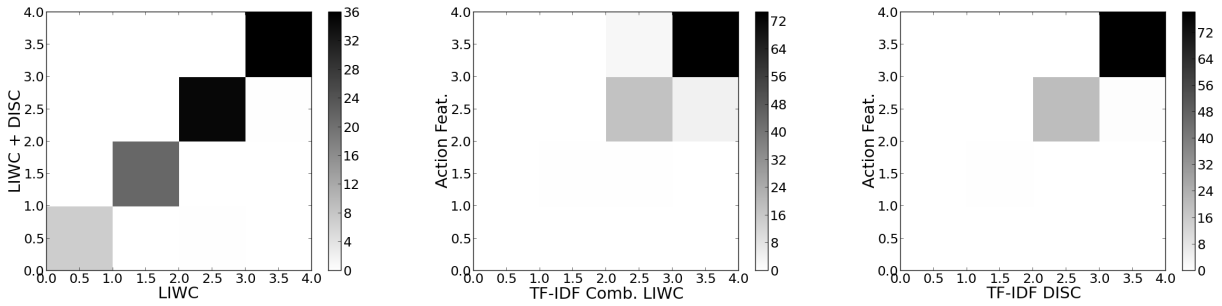

Fig. 3. Overlap between clusters obtained using different feature sets

5) Different clustering algorithms produce different clusters for both action and word features yet EM and spectral clustering results are closer to each other. This shows that each algorithm handles the data differently leading to different clusters. However, the overall relative sizes of clusters and their densities are very similar. We suspect that each of these algorithms is best at modeling a specific aspect of the intricate phenomenon of influence for example: degree of influence vs. style of influence.

VII. CLUSTER IDENTIFICATION

The objective of cluster identification is to label instances in clusters according to influence categories. In the initial experiments, our analysis was not limited to the sizes of clusters. We examined the word content for clusters based on user account (activity) features. The analysis was to see if a mapping exists between clusters obtained from account activity features and those obtained from word features. Although the use of language shows commonalities among clusters, there are variations in the word patterns from cluster to cluster suggesting some differences in the use of language across clusters obtained from account/action features only. There are at least two clusters that seem more similar and two that seem to exhibit different use of words. This agrees with the distribution of cluster sizes with two small clusters (different use of language) and two overlapping clusters (similar use of language).

We also checked membership of the top 5% users sampled according to action features to see if they belong to the same word-based cluster which we can use to identify the cluster of most influential users. These users were distributed across all clusters.

We sampled tweet streams of users from each cluster (closest to the centroids in k-means) and examined the content of

Fig. 4. visualization of language content of sample streams: small cluster vs. large cluster

the small vs. large clusters that we expect are the influential and ordinary clusters, respectively. Indeed, the sample from the small cluster streams shows that the discussions and topics were about work, strategy, marketing, and topics that are in general very different from those found in the other sample which are mostly related to personal concerns and daily activities as depicted in Figure 4 on page 6. This shows that the small clusters, as expected from background knowledge on typical influence distribution, correspond to influence extremes. The limitations of these samples should be taken into consideration, however, as these samples are small and streams are noisy.

A. Challenges and Remarks

Data Representation and Sparsity: Coming up with useful informative features require revisiting domain specific algorithms and implementing them. For example, pageRank features. Four different versions of word features and different grouping combinations and linguistic models were used. We tried running the clustering algorithms using all combinations

but some resulted in sparse representation of the data so PCA and clustering algorithms could not be run. Although this was useful for feature selection (eliminate features leading to sparsity), it was counter-intuitive as some of these features were carefully selected based on domain knowledge (i.e., relevance to DISC).

Dimensionality: With the large number of user account and stream content features, both feature extraction and data clustering require significant computation power and memory. Most of the experiments were run on a dedicated server yet some algorithms had excessively long run times or crashed due to memory errors. We attempted different clustering algorithms including DBSCAN (for density-based clustering) and spectral clustering which was useful in understanding scalability limitations of different clustering algorithms and possible approaches to address these limitations like preprocessing using k-means prior to spectral clustering. Moreover, we attempted to cluster in different spaces: original feature space and feature space from PCA. Running in original feature space required considerably more computational time and power so clustering was mostly done on the transformed feature space.

Unsupervised learning of latent parameters: With no labels and no explicit correspondence between "influence" and language in the noisy data present in social media, the problem of identifying users with leadership potential is a challenging one. Using a latent variable model such as LDA or a combination of semi-supervised and active learning methods may be useful in moving from clustering to classification and realizing the goal of automated leadership profiling in online communities.

VIII. Conclusion

The overlap between clusters obtained from word features and those obtained from action features suggests the usefulness of both types of features in predicting influence. This answers the main research question posed in this work and shows, based on empirical evidence, that language and influence are connected. It is important to contrast results obtained from these two different sources of information especially with the more recent phenomena of bought followers and likes that can render account (non-content) features less reliable. Our experiments show that using different systems for analyzing the language content of Twitter can lead to variations in results and that DISC seems to be the most appropriate tool for studying influence. The influence distribution found in this sample of Twitter resembles that obtained from large population statistics. It is highly skewed and shows two minority categories that are clearly separated and two larger overlapping categories. Manual labeling of sampled instances from different clusters shows different use of language and agrees with theoretical and empirical results suggesting that influential users are a minority.

Appendix: Supplemental Material

k-means is typically used in cases where clusters are expected to be separable. However, the following figures are provided to illustrate that even when applying k-means to cluster

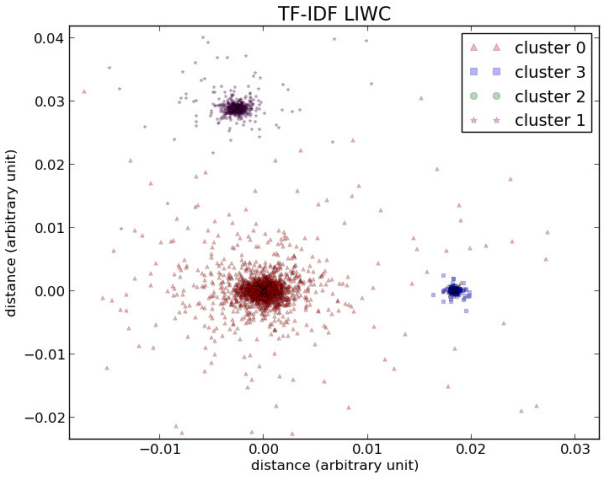

Fig. 5. Visualization of of k-means clusters based on tf-idf LIWC word features

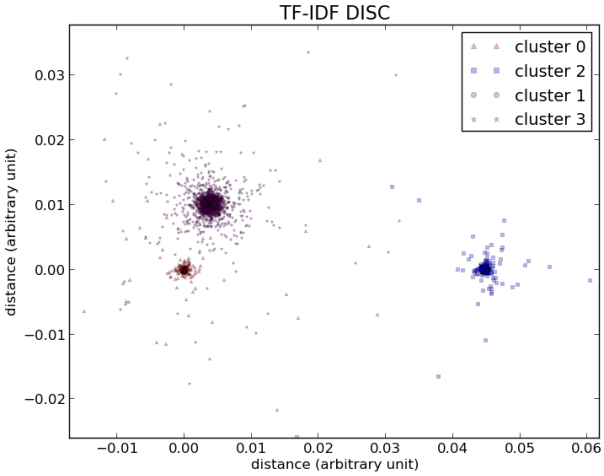

Fig. 6. Visualization of k-means clusters based on tf-idf DISC word features

users according to language features that are expected to result in some overlaps, we get clusters that are dense around the mean and clearly distinct. Since the data is multidimensional, a special distance function was designed to compute the distance between clusters and present their relative sizes and distances from each other in 2D. The two selected visualizations are for clusters obtained from tf-idf features on LIWC and DISC linguistic categorizations. The graphs show only three clusters because in one case the fourth cluster is too small to be seen relative to the other three clusters and in the other the fourth cluster is at a large distance from the other three clusters making it not possible to fit all four clusters in one reasonably scaled image.

***Abstract*—The paper concerns the design and implementation of a search engine for mathematical expressions given by the user in a convenient form of natural language or visual queries. Proper presentation and transcription of the mathematical notation is substantial for further processing and the adequate choice of the word distance measure for string comparison is an important issue as well. Within this project a complete solution for acquiring and processing the mathematical query and a searching algorithm is elaborated. We present results of exemplary search queries obtained for different types of input data format with application of two different word distance measures and discuss briefly the observed properties.**

I. Introduction

THE mathematical notation is an example of a visual language, which uses images for communication. A visual language consists of a set of planar diagrams representing expressions which are defined to be correct, and in which the syntax and semantics are determined by the mutual geometric relations between particular symbols.

The mathematical notation intended for machine processing may be transcribed in many different formats. The most popular ones are LaTeX, a dedicated document preparation system widely used for publication of scientific content, and MathML dedicated to Web applications. Both of these formats have their origins in text description languages, TeX and HTML/XML, respectively, and are designed to be open. Other solutions are used mainly in Desktop Publishing (DTP) and usually allow exporting to and importing from the above mentioned universal formats. We also mention a special format for mathematical Braille dialect, used by visually impaired people.

Independently of the chosen document description language, automation of mathematical notation processing requires transcription of the common planar visual language notation into a sequential notation used in programming languages. Hence all structural information on the mathematical formula, encoded in the geometric mutual relations between symbols, must be transcribed to the notation, in which the semantics of the given expression is incorporated solely in the sequencing of symbols possibly grouped by brackets (the significant dissimilarity of the Reverse Polish Notation to the natural mathematical notation excludes its application in most of the areas, especially for educational purposes). Such approach enables preparation of documents containing arbitrary complex mathematical expressions, while on the other hand it provides poor capabilities for searching or indexing of mathematical content.

The goal of the presented work was to develop a novel tool for searching for mathematical expressions based on queries containing parts of original or similar formulae, which are preferably given in a natural language.

II. Processing mathematical notation for semantic search

The problem of expressing the mathematical symbolic notation in the natural language has drawn interest of many researchers in different aspects within the scope of didactics of mathematics. A particular interest in this issue is observed in terms of assistance for the disabled people. A thorough survey on the English transcription of mathematical content can be found in [1], while some considerations on the ambiguity of certain notation rules are elaborated in [2], [3], [4], [5]. Various examples of algorithms implementing verbalization of mathematical content can be found in [6], [7], [8], [9], [10] and an algorithm designed to meet the needs of visually impaired is presented in [11]. Other results concern the problem of searching the mathematical expressions (see [12], [13], [14], [15], [16]) and some indexing algorithms for efficient search are elaborated in [17], [18], [19], [20], [21]. The automatization of content categorization is discussed in [22], methods for correctness validation are presented in [23], and certain search algorithms by means of natural language queries are elaborated in [24], [25], [26] and [27].

The verbalization of mathematics provided by math-to-speech engine used in our experiments allows the use of different dialects and national versions. There are English, Polish simplified/natural and full transcriptions available at the moment. The main difference between these versions is the level of details and abbreviations introduced to shorten the output and make it sound more or less similar to the actual verbalization done by human readers.

To build the query in an artificial description language with the use of complex notation and the set of non-familiar commands the user must have extensive technical experience. This is very unlikely for the majority of students at different levels of education. Moreover, translating the query into the special language distracts the user's attention from the actual search object.

There is also the additional challenge – to construct the query with the use of some characteristics of the searched mathematical expression, for example the presence of the particular key symbol as root or integral sign. This is important because the user very seldom remembers exactly the whole equation, rather reminds only some fragments, the general layout or is able to prompt the field of mathematics.

Summarizing, the important issue while searching for the mathematical expression in the database containing the collection of equations is the construction of the query. Is can be done with the use of common document description languages, but it requires complex lexical knowledge and complicates queries based on the fragmentary information and simplifications due to imperfections of human memory.

The verbalization of the mathematical notation stored in the database can help to solve problems mentioned above. There is a possibility to compare the spoken version of the equation with the query given in natural language with the use of the methods, tools and measures for approximate string matching. This way the accuracy of the semantic search for mathematical notation should significantly increase.

Given a query expression, the search algorithm follows the steps:

1) Converting the query expression entered in the Formula Editor into one of three formats: LaTeX, natural English, natural Polish
2) Comparison of the transcribed query with the existing database records by means of one of the text similarity measures: normalized Levenstein distance, and (weighted) cosine similarity measure.
3) Visual presentation of the list of 20 best matches (according to the chosen comparison measure results)

The Levenshtein distance $D_{Le}(a,b)$ is the measure of difference between text strings a and b of possibly different length, calculated as the minimum number of single-char edit operations, required to change one string (a) into another (b) [28], where operation categories are: insertions, deletions and replacements weighed equally 1. The normalized Levenshtein distance $D_{LeN}(a,b)$ additionally places the resulting values in the range 0 – 100%

$$D_{LeN}(a,b) = 100 \times \frac{D_{Le}}{\max\left(|a|,|b|\right)}$$

where $|s|$ is number of characters in string s.

Another useful text comparison measure is the (weighted) cosine similarity measure. Two strings are first transformed into numerical vectors $v = [v_1, ..., v_n]$ and $w = [w_1, ..., w_n]$ with coordinates being the counts of instances of a given key word in the string, and then the cosine of the angle between v and w is calculated by means of the standard dot product of the two vectors:

$$\cos\angle(v,w) = \frac{v \circ w}{|v| \cdot |w|} = \frac{\sum_{i=1}^{n} v_i \cdot w_i}{\sqrt{\sum_{i=1}^{n} v_i^2} \cdot \sqrt{\sum_{i=1}^{n} w_i^2}}.$$

Values close to 1 are interpreted for high similarity of the vectors, while values close to 0 indicate big differences in v and w. Additionally, by introducing weights in the cosine similarity measure, one can choose symbols that should have stronger or weaker impact on the comparison. For instance, since brackets are typically used only for ordering the expression and do not introduce their own meaning, one should pay less attention to them while comparing formulae. In our examples the following weights have been assigned to certain basic types of mathematical expressions: roots 30, fractions: 30; integral: 30; sums: 30; components: 15; products: 30; factors: 15; limits: 30; parentheses and brackets: 5; powers, including squares and cubes: 20. These weights have been chosen experimentally as ones appearing the most suitable for effective comparison.

In the case of comparison based on the verbalization (word transcription) of the formulae, an initial step of conversion to the spoken language is performed and the transcripts are stored in a database. In the conversion process the macrodefinitions formulated in an interpretable script language Lua are used. A model is loaded from the database to the inner engine, which stores the tree of objects corresponding to each element of the processed formula. To increase the efficiency of the comparison all database records are pre-processed and saved in an additional data structure of type in-memory-table. As the processing time of a formula consisting of tens of symbols is ca 50–100ms for typical PC unit, the initial pre-processing step significantly increases the performance of the presented algorithm.

III. Experimental results

The proposed algorithm has been implemented and tested for the quality of search, interpreted as the similarity of the original formula to the obtained results. The performance measure of the search algorithm was defined as the position of the original formula on the list of search results. The experimental queries were formulated in all accepted data formats:

1) the inner data format of the Equation wizard ("Edytor wzorów") application, based on LaTeX language,
2) the natural English transcription/verbalization,
3) the natural Polish transcription/verbalization.

With respect to the details of the content and possible application areas the following three categories of test queries were distinguished:

(C1) the query and original expressions differ in single symbols (correction),
(C2) the query was a part of the original expression (autocompletion),
(C3) the query expression contains few symbols, specific to the original expression (search).

Each test query was introduced to the search engine in two ways: by means of a visual editor and by entering the respective natural language key words. The performance of our search algorithm was then compared for the different

TABLE I
TOTAL SUCCESS RATE OF SEARCH WITH RESPECT TO FORMATS OF COMPARED DATA, QUERY INPUT (VISUAL / KEY WORDS), AND THE MEASURE USED FOR STRING COMPARISON.

Data format	Measure	Visual query	Key words query
Inner	Levenstein	66.6%	0%
	Cosine	66.6%	17%
English	Levenstein	83.3%	100%
	Cosine	100%	50%
Polish	Levenstein	100%	83.3%
	Cosine	100%	33.3%

data formats, within each category of queries and the input modes. The test consisted of two parts. Firstly, the queries were executed on a general database of mathematical expressions, containing various formulae from different branches of mathematics. Some of the database records were totally irrelevant to the queries. We present the obtained results in Table II, column GD.

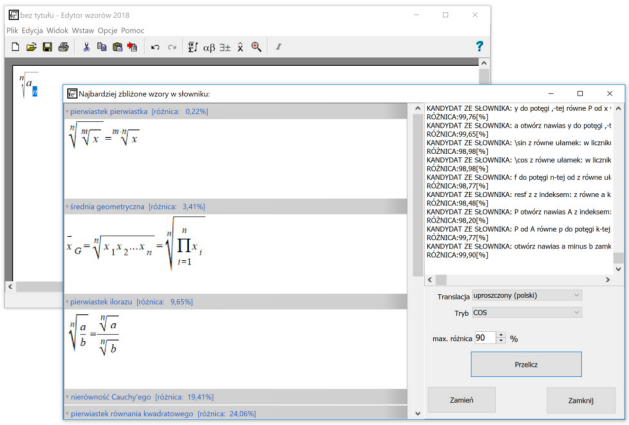

Fig. 1. The user interface of the Equation wizard („Edytor wzorów") test application with the results of the visual query.

For the second part of the test a specialized database was used in order to reveal possible weaknesses of the search algorithm or text similarity measures used for comparison. The test database consisted of 20 different formulae all containing quadratic subexpressions and having elements identical with the original formula. The column SD in Table II presents the search results for three different queries referring to the original formula $(a+b)^2 = a^2+2ab+b^2$ in different settings.

In order to compare the performance of the search algorithm for different settings, the total success rate has been calculated. The total success rate is defined to be the percentage of correctly found expressions, where correctly found means that the desired expression was among the first five entries on the list of search results. A summary of these rates is presented in Table I. The main observations are the following. The queries in lingual data formats provide the required expressions at average rate of more than 81%, while the success rate of queries processed from inner format is twice lower (around 37%). A less significant difference is observed when comparing the similarity measures used by the search algorithm - the Levenstein measure success rate is around 72%, while for cosine measure it is around 61%. However, if one looks into positioning of the queried formula, the advantage of Levenstein measure becomes more evident. Finally, the observed success rate of visual queries is significantly higher than for key word queries – nearly a half (47%) of key word queries provided desired outcome, while 86% of the visual queries appeared successful.

A few further results, presenting the overall performance issues of the proposed algorithm on a general database are given in Table III.

IV. CONCLUSIONS

The results of the experiments with the developed interactive application give the basis for the research of an efficient mathematical search engine. Both the search with the description languages as LaTeX as well as usage of verbalized text fragments was possible and accurate, especially while processing relatively not much different equations. Therefore, the proposed method is suitable for automatic or semi-automatic, supervised correction of documents containing complex mathematical notation.

On the other hand, the search for the given equation on a partial information basis, i.e. the excerpt of the formula or unordered sequence of symbols or keywords, has been also successful in many cases. Thanks to developed solution such an approximate matching is convenient and does not require any extra technical knowledge from the user, since the system accepts queries in natural language. The introduction of the advanced translator for the verbalization of the mathematical notation, taking into account the complexity of the subexpressions, dialect and national languages helped to increase the quality of text comparisons and thus the efficiency of the search.

The performed tests revealed also some general tendencies in the results obtained for different kinds of queries when compared by means of different similarity measures. The Levenstein measure seems more suitable for queries that differ slightly from the origin and therefore it could be applied for corrections. On the other hand, the cosine measure appeared to provide better matching for shorter queries, being parts of the original formula, and hence its area of application would preferably be searching or autocompletion.

One of the main directions for future experiments in this area could be the introduction of more flexible queries, possibly with the notation for logical operators as AND, OR and NOT, which could increase the accuracy of the search.

***Abstract*—In this paper we suggest a novel systematization of Information Retrieval and Natural Language Processing problems. Using this rather general description of problems we are able to discuss and proof the equivalence of some problems. We provide reformulations of well-known problems like Named Entity Recognition using our novel description and discuss further research and the expected outcome. We will discuss the relation of two problems, cluster labeling and search query finding. With these results we are able to provide a novel optimization approach to both problems. This novel systematization approach provides a yet unknown view generating new classes of problems in NLP. It brings application and algorithmic approaches together and offers a better description with concepts of theoretical computer science.**

I. Introduction

A LOT of research in the last decades focused on the computational perspective of information retrieval and improving clusterings, partitions, search queries and document decomposing with and without feedback. Several authors like Manning et al. [1] or Clarc et al. [2] give an overview about the algorithmic part of computational linguistics and NLP. Applied researchers try to answer questions similar to "What was the question?", "What is the best description of this set of documents?", "How can we compare this and that clustering?". We realized that there are several names for the same or at least similar problems and approaches. For example Hagen et al. [3] tried to find search queries for a given set of documents and used it as a cluster labeling approach. This seems somehow obvious, as well as some other equivalent problems might also sound obvious. But nevertheless, we think a formal description and proof is necessary.

During our literature search and evaluation of several algorithms for query optimization and clustering, we realized that a formal Schema would ease the task. For finding and grouping This we propose such a schema within this work. We claim every NLP problem can be described using a five-tuple. To proof our theory a discussion on several problems and the proof of equivalent problems will follow. This novel systematic approach has a different perspective focusing on the computational view on this research area. We hope this early research will lead to a valuable discussion and more research on the theoretical and algorithmic fundamentals of natural language processing.

In table I we list some prominent NLP and IR probleme in our proposed five tuple with a corresponding description. The details of the tuple are introduced and discussed in the following chapters. However the connection between the problems can already be seen within this table.

TABLE I: Example formulations of information extraction problems as five-tuple. The first element describes the domain set, the second the domain subset of interest. The third element is a description function f. We either note this function or the image set of this function. The last entries are a feasible similarity or error measure and a reference standard. These problems are introduced in sections III and IV.

Problem Formulation	Problem Description
$\mathbb{D}\|R\|\mathbf{X}\|err\|R$	Generating of optimal Search Queries
$\mathbb{D}\|R\|\mathbf{X}\|err\|R$	Generating of optimal Cluster Labels
$\mathbb{S}\|\emptyset\|\boldsymbol{f}\|e\|\{\mathbb{S}\times[0,1]\}$	Named Entity Recognition
$\mathbb{D}\|R\|\mathbf{L}\|sim\|\emptyset$	Text summarization
$\mathbb{D}\|R\|\mathbf{K}\|sim\|\emptyset$	Keyword identification
$\mathbb{D}\|R\|\mathbf{C}\|sim\|\emptyset$	Document Clustering in $C=\{1,...,n\}$ cluster.
$\mathbb{D}\|R\|\mathbb{D}^{\mathbb{D}}\|sim\|\emptyset$	Relation Extraction
$\mathbb{D}\|R\|\mathbb{D}\|sim\|R$	Document Subset Finding Problem
$\mathbb{D}\|R\|\mathbf{G}\|sim\|\emptyset$	Parse tree

II. Notation

We want to introduce our problem description approach using a five-tuple. Therefore we define a domainset $\mathbb{D}$ and subset $R\subseteq\mathbb{D}$, a description set $\mathbb{X}$ and a description function $f:\mathbb{D}\rightarrow\mathbb{X}$, an evaluation function $e:\mathbb{E}\rightarrow[0,1]$ and a reference standard E. Hence NLP problems can be given as:

$$p=\mathbb{D}|R|f:\mathbb{D}\rightarrow\mathbb{X}|e:\mathbb{E}\rightarrow[0,1]|E \tag{1}$$

At first we have to introduce and describe the notation and sets. Some examples and applications will be provided within the next sections. For an illustration of sets and functions we refer to figure 1.

A. Domain Set

Let $\mathbb{D}$ be a finite *domain set* containing all instances of a Probleme, e.g documents, text data, speech or any other semantic content. A definition is $\mathbb{D}=\{d_1,...,d_n\}$ where d_i is a vector of documents or semantic data. We may see a textual

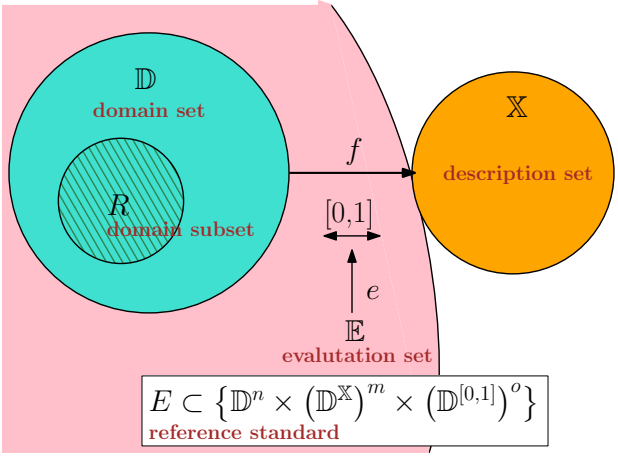

Fig. 1: Illustration of sets in equation 1. If not feasible, these sets or functions can be set to $\emptyset$ or id. The cut between $\mathbb{X}$ and the other sets is not necessarily empty.

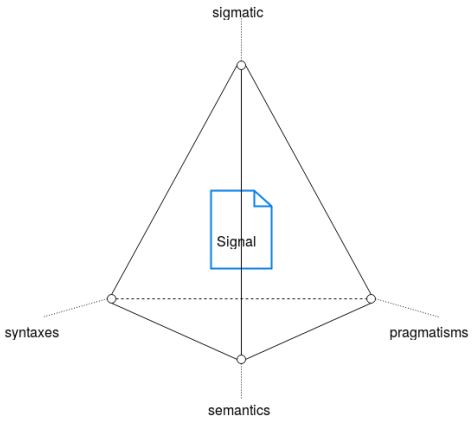

Fig. 2: Illustration of an SDA. All four properties, (a) Sigmatics (identification) (b) Pragmatics (what is being represented) (c) Semantics (what is being represented) and (d) Syntax (how is the signal constructed), are wrapped around the digital asset to provide more meta-data. All five elements for the semantic digital asset which. Multiple SDAs connect if they share at least one of these elements.

document d as a vector containing n meta data as well as full text etc., describing a document as follows

$$d_i = \begin{pmatrix} d_i^1 \\ d_i^2 \\ d_i^3 \\ \vdots \\ d_i^{n_i} \end{pmatrix} = \begin{pmatrix} \text{title} \\ \text{authors} \\ \text{fulltext} \\ \vdots \\ \text{NE} \end{pmatrix}$$

Here $\mathbb{D} = L^{\mathfrak{n}}$ with $\mathfrak{n} = \max_i n_i$ is the vector space of $\dim(\mathbb{D}) = \mathfrak{n}$ data fields of a natural language L. We may also store binary data within this vector. For a better generalization we can set $\mathbb{D} = \mathcal{P}(\mathbb{S})$ as the vector space of semantic digital assets. Here $\mathcal{P}$ denotes the power set. In this case a document d is a list $d = \{s_1, ..., s_n\}$ of semantic digital assets (SDA) $s_i \in \mathbb{S}$. These SDAs are an optimal carrier for meta-data or annotations.

A semantic digital asset can be defined as "an asset that exists only as a numeric encoding expressed in binary form" [4]. This definition includes text, images, sound files, tables, and so on. In a nutshell we can conclude that "digital assets include any electronically stored information" [5]. In addition some meta data is included. Thus we can describe a SDA as a variation of the information tetrahedron introduced in [6] where four semiotic properties are wrapped around each signal. These semiotic properties are (a) Sigmatics (b) Pragmatics (c) Semantics and (d) Syntax, see figure 2. As described by Hodapp et al. in [7] SDAs are highly flexible and can be easily connected. The hierarchy is connected into annotations. Applications can be found in [7] and [8].

Since it is of crucial importance, we will discuss the hierarchical connection in a nutshell, but refer to [7] for further information. Let a and b be defined with Sigmatics *sentence:S153:1322066041* and *sentence:S153:1322066041* – the first one with the Pragmatics *sentence* and the second one *Mus_musculus*. Here, the first SDA contains the sentence in natural language, for example "Spontaneous antepartal RhD alloimmunization" whereas the signal of the second one contains the named entity information *{"begin": 24,"end": 27,"attr": "original","ref": "MM137098:Rhd"}*. Thus it is not really necessary to store explicit relations between SDAs, since they are implicitly given in the structure of SDAs.

B. Domain Subset

To find a proper problem description, we can either focus on the complete domain set $\mathbb{D}$ or a subset $R \subseteq \mathbb{D}$ This can either be a manually created subset or created by semi-automatic tools. One can imagine the result of a search query.

In addition, we allow a ranking of elements in R in the intervall $[0, 1]$ of real numbers. Then $R = R' \times [0, 1]$ with $R' \subseteq \mathbb{D}$.

C. Description Function

If necessary, we may also add a *description function* f for documents or subsets of $\mathbb{D}$. Given a description set $\mathbb{X}$, this function can have several forms, in general denoted by $f : \mathbb{D} \to \mathbb{X}$. In our short notation we can either note the function f or the set $\mathbb{X}$ if we need to focus on this set. If both information are needed, we can write $f, \mathbb{X}$.

If we want to map elements in R to a meta data subset of a document $d \in \mathbb{D}$ like publishers, authors etc. f has the form $f : \mathbb{D} \to D$ with $\dim(D) \leq \dim(\mathbb{D})$ and $f(d_i) = f_i^j$. This may also be a combination of vector entries.

A description function may also return several discrete values, for example *true* or *false*. In this case f is given by $f : \mathbb{D} \to N \subset \mathbb{N}$. If we want to describe concepts from a terminology T, f is given by $f : \mathbb{D} \to T$. The function may also return words σ^* from a language L which leads to $f : \mathbb{D} \to \Sigma^*$. Here Σ^* denotes the set of all words (or strings)

over a given alphabet or language. We can even consider a subset from the language which leads to $f : \mathbb{D} \to L$. If we do not need a description function we can simply set $f = \text{id}$ to the identity function. As we can see the cut between $\mathbb{X}$ and the other sets is not necessarily empty.

In some cases it is useful to assume that $\mathbb{X} = f(\mathbb{D})$ and thus q as a surjective mapping. It follows that f has a right inverse q with $f \circ q = \text{id}_{\mathbb{X}}$. This function is necessary to model some problems. Usually we cannot assume that f is also an injective mapping: A description set $x \in \mathbb{X}$ may have more than one origin in $\mathbb{D}$.

Considering an element $\mu \in \mathbb{X}$ and $\mathbb{X}$ as the description set of a search engine, R can be explicitly set as $E = q(\mu)$ with the right inverse of f. Here q denotes the search function with $q : \mathbb{X} \to \mathbb{D}$.

D. Evaluation Function

For several problems we need an *evaluation function* $e : \mathbb{E} \to [0, 1]$ which is either a similarity measure sim, an error measure err or a weight $weight$. If it is not applicable, we may use the identity function id. The set $\mathbb{E}$ must be set according to our optimisation goal. If we optimise $\mathbb{D}$, for example by adding new documents or additional information, $\mathbb{E} = \mathbb{D} \times \mathbb{D}$. The same holds, if we want to find an optimal subset $R \subset \mathbb{D}$.

If we want to optimise our description function f, we must use the function space $\mathbb{D}^{\mathbb{X}} = \mathbb{E}$. An evaluation of the reference standard will be even more complex, see below. Then $\mathbb{E} = E$ applies.

E. Reference Standard

Usually the evaluation process cannot be done without an external criterion. In this cases we can add a *reference standard* or *evaluation set*

$$E \subset \left\{ \mathbb{D}^n \times \left(\mathbb{D}^{\mathbb{X}}\right)^m \times \left(\mathbb{D}^{[0,1]}\right)^o \right\}$$

to optimize our result. We either have one single subset of $\mathbb{D}$, or two subsets – a positive and a negative reference standard. We may also have a ranked list of subsets of $\mathbb{D}$. A description function in the function space $\mathbb{D}^{\mathbb{X}}$ or n of them could also be set as a reference standard, as well as one or o evaluation functions out of the function space $\mathbb{D}^{[0,1]}$. This is sometimes denoted as one or many *gold standards*. This can be very complex, but usually problems only need one of these sets.

If not feasible or unused, we may also set $E = \emptyset$.

F. Problem Description

Natural Language Processing problems can thus be described by a five-tuple. We can denote them by a combination p of

$$p = \mathbb{D}|R|f : \mathbb{D} \to \mathbb{X}|e : \mathbb{E} \to [0, 1]|E$$

with a domain set $\mathbb{D}$, a domain subset R, a description set $\mathbb{X}$ and a description function f as well as an evaluation function e evaluating on the set $\mathbb{E}$ according to the reference standard E. We usually have four parameters given and want to obtain an optimal solution for the fifth. The optima result with respect to the problem will be denoted in bold letters. We can add an additional index for ambiguous notations.

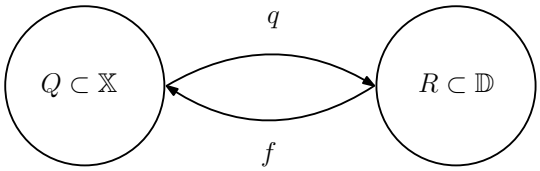
If we have an optimal algorithm we only need one computation step. If we have a heuristic returning approximate values, we may use the output of the first iteration as an input for the next iteration. We will discuss, that similar approaches usually only differ with respect to the chosen set $\mathbb{X}$.

III. Search Queries and Cluster Labels

A. Generating and optimisation of Search Queries

In this paper we use a very generic definition of search engines and search queries. A search engine is a function $q : \mathbb{X} \to \mathbb{D}$ which outputs a set of documents or any other content of the domain set if the input is a subset of a description set $\mathbb{X}$ which we cal search query.

The problem of generating search queries usually has a domain set $\mathbb{D}$ restricted by the database of the search engine. The return value of our problem is a search query $\mu \in \mathbb{X}$ so that $q(\mu) = R$. Thus R is the subset of documents for which we want to create a search query. We have a mapping from



one element in $\mathbb{X}$ to a subset of $\mathbb{D}$. q is thus the right inverse of the description function f and $f \circ q = \text{id}_{\mathbb{X}}$. Not only does f have to be surjective, but we also have to assume that even q is surjective. Every document in the target set $\mathbb{D}$ should be a target of some search query.

It is very easy to see that this is usually not given in reality: Assume q is a websearch, $\mathbb{X}$ the web search description and $\mathbb{D}$ the set of all web pages available. Some of them may not be indexed due to restrictions made to the robots crawling and indexing the web. We can sail around this by restricting $\mathbb{D}$ to $q(\mathbb{X})$. Then f should be the right inverse of q with $q \circ f = \text{id}_{\mathbb{D}}$.

We can also see, that $\forall d \in \mathbb{D}$ several $\mu_1, ..., \mu_n \in \mathbb{X}$ exists with $d \in q(\mu_i)$ – neither q nor f are injective mappings. If we want to find the optimal μ we need to define some sort of metric on elements in $\mathbb{X}$. This can be very complex. If we assume, that we have a terminology T and a simple algebra with $\vee$ and $\wedge$, we can simplify $\mathbb{X} = \mathcal{P}(T, \vee, \wedge)$ and take the length of $\mu \in \mathbb{X}$ as a metric. But if all documents have a unique index stored in $\mathbb{X}$ the shortest search query might consist of a concatenation of these indexes listing all documents in R.

Thus, the simplest evaluation function $e : \mathbb{D} \to [0, 1]$ is set by

$$err_1(d_i, d_j) = \begin{cases} 1 & i \neq j, f(d_i) \neq f(d_j), d_i, d_j \in R \\ 1 & i \neq j, f(d_i) = f(d_j), d_i \text{ or } d_j \in R \\ 0 & \text{else} \end{cases}$$

If f, the description function with the image set $\mathbb{X}$, does not map two documents in R to the same element, which is the

search query $\mu \in \mathbb{X}$, we count an error. Same happens, if another document not in R is mapped to R. Thus we want to find a description function f so that $f(R) = \mu \in \mathbb{X}$ with $q(\mu) = R$. It follows that the problem is given by

$$p = \mathbb{D}|R|\mathbf{X}|err_1|R$$

This is the simplest formulation of the stated problem. As discussed, it can be more complex. We have not defined a proper quality measure for search queries $\mu \in \mathbb{X}$. In addition, the space $\mathbb{X}$ may be very complex and it is not clear, if it is – like $\mathbb{D}$ – a discrete space with a proper metric. In addition, although f is a surjective mapping and q can be set to be surjective, it is left open, if one of these mapping might also be injective.

B. Generating and optimisation of Cluster Labels

A clustering is usually done on a domain set $\mathbb{D}$ and leads to several clusters $C_1, ..., C_n$, $n \in \mathbb{N}$. If $\mathbb{D} = \mathcal{P}(\mathbb{S})$, these clusters are explicitly coded in the set $\mathbb{D}$. Finding cluster labels is the task of assigning a subset of a description set $\mathbb{X}$ with the description function $f : \mathbb{D} \to \mathbb{X}$ to a cluster $R \in \{C_1, ..., C_n\}$. We might consider an evaluation function measuring the distance between the description between two documents in R, $|f(d_i) - f(d_j)|$. But we need to assume a proper metric on $\mathbb{X}$ to do so. This leads to very complex questions. For example: What is a proper metric on a space of boolean algebra? The easiest evaluation function is thus given by

$$err_2(d_i, d_j) = \begin{cases} 1 & i \neq j, f(d_i) \neq f(d_j), d_i, d_j \in R \\ 1 & i \neq j, f(d_i) = f(d_j), d_i \text{ or } d_j \in R \\ 0 & \text{else} \end{cases}$$

Here we define that every two documents in R must share the same cluster labels. This cluster label has to be unique to this cluster. The reference standard can also be set to R. Thus the problem of generating and optimisation of cluster labels is given by

$$p = \mathbb{D}|R|\mathbf{X}|err_2|R$$

where the resulting label set is the image $f(R) \subset X$. Depending on the choice of X this either leads to a set of metadata, terms, sentences or any subset of natural language. Again, this problem can be very complex.

C. Search Queries and Cluster Labels are closely connected

In our introduction we already discussed, that Hagen et al. found out that both problems are similar, see [3]. It is easy to proof that given the same domain set $\mathbb{D}$, image set $\mathbf{X}$ of the description function and the same evaluation function both problems are equivalent. Thus, they are closely connected.

Lemma III.1. *Let $\mathbb{X}$ be a description image set. For every solution f of $p_1 = \mathbb{D}|R|\mathbf{X}|err_1|R$ this is also an optimal solution of $p_2 = \mathbb{D}|R|\mathbf{X}|err_2|R$.*

Proof. This follows directly, since $err_1 = err_2$. □

Same follows directly for the inverse:

Lemma III.2. *Let X be a description image set. For every solution f of $p_2 = \mathbb{D}|R|\mathbf{X}|err_2|R$ this is also an optimal solution of $p_1 = \mathbb{D}|R|\mathbf{X}|err_1|R$.*

Thus both problems are equivalent if we consider the same domain set $\mathbb{D}$, image set X of the description function and the same evaluation function. We can conclude that we can use the same or similar heuristics for solving both problems. Usually a search query language is not used for representing cluster labels. But since query languages and natural languages are not only highly connected but merge more and more (see [9] or [10]) we follow that in future both problems will be even more connected. We will now discuss a small example.

D. Example

We will do a generation and optimization of cluster labels with a similar approach to Borkowski et al. [11], Kanavos et al. [12] and Demner et al. [13]. All of them use a taxonomy of categories like Medical Subhect Headings (MeSH, see https://www.nlm.nih.gov/mesh/) and process the documents using tfidf-method. We will use SCAIView, see [14] or https://www.scaiview.com), an information retrieval system for knowledge discovery for a similar approach. SCAIView was used in many recent research projects, for example regarding neurodegenerative diseases [15], brain imaging features [16] and other theoretic research like document clustering, see [17]. The advantage is, that SCAIView already provides us with Named Entities for MeSH but also other ontological representing biomedical entities. Thus we get a better coverage of text with named entities.

Our domain set $\mathbb{D}$ is MEDLINE data, and R a subsets of MEDLINE data. MEDLINE (Medical Literature Analysis and Retrieval System Online) is a bibliographic database maintained by the National Center for Biotechnology Information and covers a large number of scientific publications from medicine, psychology, and the health system. For the clustering use case, we study MEDLINE abstracts and associated metadata that are processed by ProMiner, a named entity recognition system, see [18], and indexed by the semantic information retrieval platform SCAIView.

Our goal is, to find a unique representation of R in $\mathbb{X}$. Let $f(d) = \mu$ for all $d \in R$. We have to define the description set $\mathbb{X}$.

Borkowski et al. [11] processed a ranked list of categories with their weights. We will follow Kanavos et al. [12] and use all ontologies available at SCAIView. To make our approach easier, we will limit our image set $\mathbb{X}$. Let $\mathbb{X}$ be the SCAIView search query set limited to NE.

R is the document set retrieved by a list of pubmed identifiers. In our example, we have R as the result of a list of 38 PMIDs. $\mathbb{D}$ is the set of all documents in SCAIView databse. Querying the Lucene backend we find a list of 654 NE $N = n_1, ..., n_{654}$ and the documents containing them, which we donate by $l(n_i)$. The list $n_i : l(n_i)$ has the form

```
CHEBI:36929 : [38]
MESH:E05.598.500 : [9, 11, 18, 36]
ENTREZGENE:3630 : [29, 37]
MESH:C10.597.742 : [9]
ENTREZGENE:387244 : [34]
MESH:C10.597.622 : [14]
MESH:F03.900.675.400 : [12]
MGI:96543 : [6, 15, 29, 32, 33]
CHEBI:6271 : [26]
...
```

We will now use a novel set covering approach. Following [12] the labels for distinct subsets can be seen as potential candidates for cluster labels. For example we can cover r with n terms:

```
 1   ;MESH:F01.700.039
 1   ;MESH:C10.597.606.057
 1   ;SWISSPROT:HUMAN
 1   ;MESH:D059445
 1   ;MESH:C23.888.592.604.039
 2   ;CHEBI:36929   ;MESH:F01.700.039
 2   ;CHEBI:36929   ;MESH:C10.597.606.057
...
```

If we use sim_1 as an evaluation measure, we are nearly done. But we might get more documents in $\mathbb{D}$ by querying these labels.

We can now construct a hierarchical tree using the logical operators *and* and *or* in $\mathbb{X}$. We will do this by considering a graph $G = (V, E)$ with nodes $V = N$, in our example $V = \{n_1, ..., n_{654}\}$. We add weighted edges between two nodes n_i, n_j if $l(n_j) \subset l(n_i)$. The weight is set to zero if $\nexists n_k \in N$ such that $l(n_j) \subset l(n_k) \subset l(n_i)$. Otherwise we set the weight $w(n_i, n_j)$ to the largest number $\mathfrak{w}$ so that $\mathfrak{w}$ elements in N exist with $l(n_j) \subset l(n_1) \subset ... \subset l(n_{\mathfrak{w}}) \subset l(n_i)$. Thus the weight is zero if the document set is a direct subset of the other document set. Otherwise, it is the largest number of subsets that lie in between. Finding the minimum spanning tree(s) in this graph G and connecting all nodes with `AND` and the `OR` of their child nodes lead to the solution μ:

```
MESH:F01.700.039
AND MESH:C10.597.606.057
AND SWISSPROT:HUMAN
AND MESH:D059445
AND MESH:C23.888.592.604.039
AND (
  MESH:E05.598.500 AND (MGI:95574 OR MESH:C10
      .597.742)
  OR ENTREZGENE:3630 AND (MGI:96542 OR MESH:C19
      .246.300)
  OR
  ...)
```

The description function f is a heuristic finding one spanning tree on G with the named entities covering the domain subset R.

This is both: a correct solution of clustering labeling of R on $\mathbb{X}$ obtained by f as well as a possible solution of a search query so that $q(\mu) = R$.

As we can see, even this simple approach needs a complex heuristic. Although finding minimum spanning trees is usually in $\mathcal{FP}$, we can construct more complex examples that are $\mathcal{NP}$-complete. It would be very beneficial to find problems that are in $\mathcal{P}$.

This approach can now very easily be transferred into natural language, although a very complex boolean algebra might not be very helpful to human readers. This leads to another problem we already discussed: How is the space $\mathbb{X}$ defined? Is it a metric space? Is q an injective mapping? This reformulation of both problems is very helpful to discuss and proof the complexity and the real underlying problems and to find more suitable heuristics and algorithms. But it also leads to new questions and problems.

IV. More information extraction problems

Information extraction problems can be transferred into $p = \mathbb{D}|R|\mathbb{X}|sim|\emptyset$ with a result information description image set $\mathbb{X}$ for R. Here f is a function that extracts some information out of a document d: This may be natural language $f : \mathbb{D} \to L$ or another subset of $\mathbb{D}$ or a mapping to ontologies or terminologies.

We will discuss some examples and point out the benefits of our new approach.

A. Named Entity Recognition

Named Entity Recognition (NER) was initial proposed as the task to identify names, location and temporal constructs in text [19]. Over the decades this initial definition expanded to detect arbitrary concepts, defined as things of thought [20]. Different Algorithms developed and adapted to NER over time from simple gazetters [21] over rule based engines [18] and probabilistic context-free grammar [22] to Conditional Random Field [23] and neuronal networks [24]. No matter on how the algorithm solves the problem in the end it needs to link a sequence of character to one or many concepts. Therefor a model, a function, is constructed that encode how this should happen. This model is either generated by manual labour or my machine learning approaches or mixtures in between.

The evaluation of NER applications is often done by comparing an obtained result to a reference (gold) standard [25]. For this comparison a function $e : \{\mathbb{S} \times [0, 1]\} \times \{\mathbb{S} \times [0, 1]\} \to \{0, 1\}$ is needed that assesses if a Named Entity (NE), a Concept, is correctly detected or not. Based on the discrete values of the function Precision, Recall and a F-score are computed and are used as a performance indicator [25]. For the definition of e we assume that the target set of the description function, performing the NER, matches the definition of a reference standard. This allows to use a result of a description function a as a reference for a different function.

As initial mentioned NER is the task to link a sequence of character to concepts. Subsequent the description function looks like $f : \Sigma^* \to Concept$. If we assume a Concept is encoded as an SDA the function is a mapping from a sequence of character to SDAs. We also encode sequences of characters as SDAs so the function can be refined as $f : \mathbb{S} \to \mathbb{S}$. To also encode the uncertainty of such a mapping the final function is $f : \mathbb{S} \to \{\mathbb{S} \times [0, 1]\}$. To fit into the proposed schema, the

function needs to map from a document $\mathbb{D}$, thus we define $\mathbb{D} = \mathcal{P}(\mathbb{S})$ and $f : \mathbb{D} \to \{\mathbb{S} \times [0, 1]\}$

We transferred the application $p = \mathbb{D}|\emptyset|f|\emptyset|\emptyset$ and evaluation $p = \mathbb{D}|\emptyset|f|e|\{\mathbb{S}\times[0, 1]\}$ phase of NER into the initial proposed five-tuple. Likewise we can decode a learning phase, therefore we define a training set $T = \{\mathbb{S}^1 \times [0, 1]\}, \mathbb{S}^1 \subset \mathbb{D}$. The function f than can be learned resp. optimized by using the training set T and the evaluation function e. Subsequent a learning phase is expressed as $p = \mathbb{D}|T|\mathbf{f}|e|\emptyset$. Combing all three phases the initial proposed five tuple is constructed:

$$p = \mathbb{D}|T|\mathbf{f}|e|\{\mathbb{S} \times [0, 1]\}$$

We like to illustrate this with a gazatter based approach. We choose gazetter as an example because it is simple to understand and it eases discussion about extending to more advanced methods. Assume we have a gazetter, a list, with n Concepts $g = g_1, g_2, ..., g_n$. Each Concept $g_i = \{g_{i1}, g_{i2}, g_{im_i}\}$ is a set of alternative names (pairwise disjoint), where g_{i1} is the Representative. The description function f maps SDAs that encode sequences of character to a SDA that encode the Representative of a Concept. For a simple gazetter the function could look like the function below where an exact string match [26] between the character sequence and an alternative name is required.

$$f(n) = \begin{cases} \{S(g_{11}), 1\} & \text{if } \exists g_{1j} = n, 1 \leq j \leq m_1 \\ \{S(g_{21}), 1\} & \text{if } \exists g_{2j} = n, 1 \leq j \leq m_2 \\ \vdots & \vdots \\ \{S(g_{n1}), 1\} & \text{if } \exists g_{nj} = n, 1 \leq j \leq m_n \end{cases}$$

This function can be extend to a fuzzy string matching [27]. The fuzziness can be encoded via a normalized edit distance [27] in the second argument. Orthogonal an extension on the used data is possible. The function could work on Token , Stems or Lemmas [25] instead of character sequences. This requires a preprocessing of the gazetter as well as a transformation of SDA. Or alternatively a minor refinement of the tuple, switching from character SDAs to e.g. Token SDAs. However this is possible within the proposed five tuple and shows the generality of our systematization. The same transformation approach can be used to directly incorporate various machine learning methods, like [23], [24], [22]. The SDA, of the training set can be decoded into a better suited feature representation for the used method and the results can also be transformed into SDAs. Alternatively the method could directly use SDA as features.

As it can be see the systematization is a common base for various methods. Various methods can be transferred into this tuple representation by a transforming the data from and into an SDA. This shows the strength and flexibility of SDAs and the proposed tuple.

B. Text summarization

Text summarization is the task of assigning a short summary in natural language L to a document $d \in \mathbb{D}$. Thus our description set $\mathbb{X} = L$ and the complete problem has the form

$$p = \mathbb{D}|R|\mathbf{L}|sim|\emptyset$$

with a result information description $f(R)$ for R. Here f is a function that extracts some information in form of language out of a document d: $f : \mathbb{D} \to L$. Once again we have to ask how our evaluation function sim works. Is sim just the vector distance in a vector-space representation of L? If we limit L to a list of terms, a terminology or ontology summarising the document, this might be suitable. But considering the context of text might be more helpful. We can find several examples in literature: Demner et al. [13], who generated extractive summaries for abstracts of documents in MEDLINE. Barzilay et al. [28] did use lexical chains, without considering the semantic interpretation. Gong et al. [29] rather explicitly considered the semantic of the texts.

Thus all these approaches differ in the definition of the domain set $\mathbb{D}$. It may contain a simple list of texts or abstracts, but it may as well contain semantic digital assets $\mathbb{S}$ considering the semantics and context. In addition the description function is another criterion for distinction. We may add them as additional index to $\mathbb{X}$. This leads to $p = \mathbb{D}|R|\mathbf{L}_{lexical\_chains}|sim|\emptyset$ for [28] or $p = \mathbb{S}|R|\mathbf{L}_{semantics}|sim|\emptyset$ for [29].

This novel problem description provides a helpful framework for sorting the approaches found in literature.

C. Relation Extraction

The task of extracting relational facts – or relations – from a text is the combination of two or multiple entities in a computable format. This is usually either done by manual curation (see [30]) or by supervised or unsupervised learning (see [31] or [32]). Relation extraction is widely used in biomedical research, biology or toxicology to handle the growth of publications and data available. In addition it is used in medical research, see [33]. After relation extraction computable networks are created, see [32].

Let $\mathbb{D} = \mathcal{P}(\mathbb{S})$ be a set of documents denoted by SDAs. Our description set contains all relations between SDAs. Thus it is the set of all functions from SDAs to SDAs: $\mathbb{X} = \mathbb{D}^{\mathbb{D}}$. In addition we need a similarity measure that maps relations from documents to SDA terms:

$$sim : \mathbb{X} \to [0, 1]$$

Then doing Relation Extraction is the task of finding an optimal description function

$$f : \mathbb{D} \to \mathbb{X}$$

that either maps SDAs for sentences to one or more relations between SDAs or to 0 if a SDA has no NE. Thus we find

$$p = \mathbb{D}|R|\mathbb{D}^{\mathbb{D}}|sim|\emptyset$$

A lot of question have to be left open: How can we define f according to the solutions found in literature? Could $\mathbb{X}$ be reduced to a subset without loosing information? Once again a systematization of approaches found in literature could be made, although this will be part of future work.

V. Discussion and further research

We proposed a novel formal schema for information retrieval and natural language processing problems and reformulated several well-known problems. Our schema is helpful to sort NLP-problems according to their underlying and inherent structure and to identify the complex parts to solve the problem.

Discussing the equivalence between cluster labelling and finding search query we proofed that they are – obviously – equivalent if they share the same description set and the same evaluation function. This directly leads to the conclusion, that most NLP-problems have a core problem that can be solved with distinct heuristics and algorithms. Finding an evaluation function and a description set is not a core problem of computer science, but deeply related to linguistics and applied computer science. Our new approach will help to group problems and foster synergies for optimization and offer a better description with terms of theoretical computer science. Here we already reduced a simplified search query problem to a graph problem.

We left several open questions. Further research has to be done with focus on time and space complexity – what is the computational complexity in these natural language problems? Here the integration of formal language theory will be the next step. Also unsupervised and supervised learning can be expressed with our novel approach, more research has to be done regarding this. In addition, our paper is based on text data. But we can also express binary data such as speech and images in $\mathbb{D}$.

In this paper we could only discuss some early work on the preliminaries and provide a few short examples. We hope that the impact of our schema is a better categorization of NLP-problems and a better communication between application and theoretical informatics, leading to more efficient algorithms and heuristics.

A neural framework for online recognition of handwritten Kanji characters

Małgorzata Grębowiec, Jarosław Protasiewicz
National Information Processing Institute, Warsaw, Poland

***Abstract*—The aim of this study is to propose an efficient and fast framework for recognition of Kanji characters working in a real-time during their writing. Previous research on online recognition of handwritten characters used a large dataset containing samples of characters written by many writers. Our study presents a solution that achieves fine results, using a small dataset containing a single sample for each Kanji character from only one writer. The proposed system analyses and classifies the stroke types appearing in a Kanji and then recognises it. For this purpose, we utilise a Convolutional Neural Network and a hierarchical dictionary containing Kanji definitions. Moreover, we compare the histograms of Kanjis to solve the problem of distinguishing character having the same number of strokes of the same type, but arranged in a different position in relation to each other. The proposed framework was validated experimentally on online handwritten Kanjis by beginners and advanced learners. Achieved accuracy up to 89% indicates that it may be a valuable solution for learning Kanji by beginners.**

I. Introduction

KANJI, along with the syllabic kana - hiragana and katakana, belong to the Japanese writing system. They are adopted logographic Chinese characters and literally mean "Han characters" (漢字). The number of Kanji characters is vast and amounts to over 500,000 [1]. However, in order to understand Japanese newspapers and books, it is usually enough to know 2,136 of *jouyou kanji* from the official list of Kanji determined by the Ministry of Education of Japan in 2010.

A large number of Kanji characters and a complex structure could require a lot of time to learn them. One of the solutions that may help the students in that may be an intelligent application. Its main idea is that it analyses online Kanji characters when a student is writing them stroke by stroke. The analysis relies on checking the correctness of the drawn characters or suggesting their meaning. To make this possible, such a system has to recognize the handwritten Kanjis online.

There are several approaches to this issue. Early solutions for online recognition of handwritten Kanji presented in [2] emphasize the similarity of the sequence of pen movements to the problem of speech recognition. Due to this similarity, they utilised a Hidden Markov Model (HMM) for a sub-stroke of Kanji and built a hierarchical dictionary defining the characters' structure. For further improvement of the recognition accuracy, [3] used pen pressure to propose writer-independent handwriting recognition. The further studies of [4], [5] have expanded this solution, taking into account the relative position of the strokes in Kanji. Study of [6] also is based on HMM recognition for structured character pattern representation.

We have to underline that the approaches mentioned above deal very well with the issue of Kanji recognition. However, some improvements may be required to gain better efficiency, especially when considering a solution that is able to work in real-time. One of the above approaches refers to a hierarchical dictionary containing definitions of Kanji characters. Creating such a dictionary required manual preparation of rules that could contain errors, and it was a time-consuming task. Further work on its construction could include automatic generation of rules that would be helpful in adding new definitions to the dictionary. Current research assumes that strokes in Kanji characters are drawn in the correct order, considering that the errors could occur while writing a character. Thus, new studies should include this problem to develop algorithms that are less sensitive to strokes order.

Having in mind these two problems, namely (i) the definition dictionary of Kanji characters and (ii) sensitivity of algorithms to strokes order, we propose a neural framework for online recognition of handwritten Kanji characters. More specifically, the main objectives of this study are as follows:

1) To propose a framework for online recognition of handwritten Kanji characters utilising convolutional neural networks, which are currently one of the state-of-the-art approaches in image recognition.
2) To automatically generate a dictionary containing definition of Kanji characters, which simple construction allows to easily supplement it with new definitions and its further development.
3) To assess the effectiveness of proposed solutions by experiments carried out using own implementation of the framework.

The novelty of our research is based on the implementation of a framework that allows to suggest Kanji characters in real time. The user can draw a character from the first stroke to the last and the system returns a sorted list of proposed Kanji characters after each line drawn. The results returned by the system are sorted by a measure of similarity between the character being drawn and the characters contained in the Kanji dictionary. This makes it possible to find the target character even before finishing the drawing of all the strokes.

The remainder of this paper is as follows. Section II introduces the problem to solve and presents the proposed framework for Kanji recognition. Next, Section III validates

the framework performance with illustrative examples. Finally, the findings are concluded, and references are provided.

II. KANJI RECOGNITION FRAMEWORK

In this section, we define the problem of online recognition of handwritten Kanji characters, and we propose and describe the framework that solves the indicated issue.

A. Problem definition

Let us assume that a single Kanji character, K consists of n strokes:

$$K = \{s_1, ..., s_i, ..., s_n\}. \quad (1)$$

Information about the number of strokes which compose a character is not sufficient to recognise the Kanji correctly. For a given stroke s_i, it is required to specify its type s_t, order s_o in which it appears in the sign K, and its position s_p in relation to other strokes:

$$s_i = (s_t, s_o, s_p) \quad (2)$$

The examples illustrating the described problem are the signs 犬 (dog) and 太 (fat) . Each of them consists of four lines. There are many more signs that are built by using the same number of strokes. Additional information about the strokes type is also not sufficient to indicate correctly the character. Although they have the same number of dashes, and they are of the same type written in the same order, the last short slashing line is in a different position in each of these Kanjis. Therefore, information about the placement of each stroke in a character is an issue that must be considered.

The task is to recognise the character, K during writing its strokes s_i, $i = 1, ..., n$, including their parameters s_t, s_o, s_p.

B. Framework overview

The simplified construction of our framework that tries to solve the above task is presented in Figure 1.

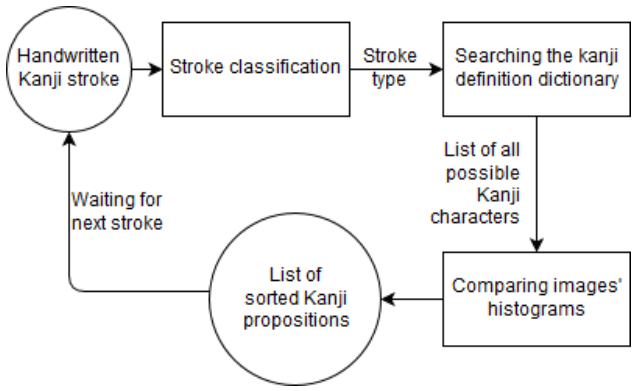

Figure 1. Overview of the framework for online recognition handwritten Kanji characters.

In the first step, after receiving the first handwritten stroke, the system saves it to a PNG file and tries to classify it to a proper type. The classification of the stroke type is done by a convolutional neural network. Having classified the stroke type, the system searches the Kanji definitions dictionary. This dictionary covers definitions of all Kanjis from our dataset. The result of that is a list of all Kanjis that start with the previously classified type. Since the list of such possible characters is extensive, in the next step, the system tries to sort them by the most likely ones. For this purpose, we compare the histograms of Kanjis' images returned by the dictionary with the image containing the handwritten strokes. Based on these comparisons, the list of Kanjis is sorted by the most similar to the drawn character. When the next stroke appears, the whole process is repeated from the beginning as described above by keeping the order of drawing lines. Finally, a sorted list of the proposed Kanji characters is returned.

Detailed implementation of individual modules are presented in the following subchapters.

C. Classification method

We utilise a Convolutional Neural Network (CNN) to classify Kanji strokes. The CNN contains several layers processing signals feed-forward. In the input layer ($INPUT$), neurons are arranged in three dimensions (width, height, depth) to process pictures. They are transferred through the set of hidden layers which are of three types, namely: (i) a convolutional layer ($CONV$), (ii) a pooling layer ($POOL$), and (iii) a fully-connected layer (FC) with an ReLU activation function. These layers produce class scores z. The architecture of the networks can be simplified as follows:

$$\begin{array}{c} INPUT \rightarrow (CONV * N \rightarrow POOL) * M \rightarrow \\ FC * K \rightarrow softmax \end{array}, \quad (3)$$

where the asterisk, $*$ indicates repetition N, M, K times respectively. In the final layer, $softmax$ the vector of class scores, z returned from the last fully-connected layer are integrated using the following softmax function:

$$\sigma(z)_j = \frac{e^{z_j}}{\sum_{k=1}^{K} e^{z_k}}. \quad (4)$$

D. Kanji dictionary

The Kanji dictionary is constructed from the definitions of 7,365 Kanjis appearing in the dataset of files describing the characters. We extract all strokes from each file that maintain information about the appearance order of strokes. The dictionary is based on a tree structure, in which the number of trees is determined by the number of stroke types. The first stroke in the character determines the selection of trees to which its definition will be saved. Each subsequent stroke forms the next node in this tree. Only unique stroke types can exist at the same depth of the tree. An example of Kanji definitions is presented in Figure 2.

E. Histogram comparison

The list of suggested Kanjis returned by the dictionary may be extensive. Moreover, they are not sorted according to the similarity to the character under examination. To solve this problem, we decided to use the comparison of histograms as the similarity measure of images.

A histogram is the graphical representation of the tonal distribution in a digital image. To compare two histograms (H_1,H_2), we choose Chi-Square as a distance measure $d(H_1, H_2)$ which evaluates how well both histograms match:

$$d(H_1, H_2) = \sum_I \frac{(H_1(I)) - H_2(I))^2}{H_1(I)} \quad (5)$$

The smaller the distance between histograms is, the more similar they are. By calculating the distance between the image containing drawn lines and the images representing Kanjis returned by the list, we can sort the Kanji list according to their similarity to the tested image.

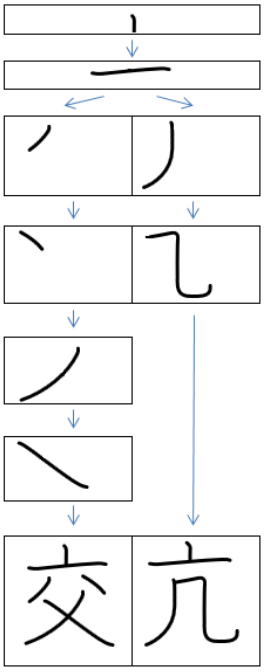

Figure 2. An example of Kanji definitions stored in the dictionary. The straight vertical stroke at the top is the root of a tree. Each subsequent stroke is added to the dictionary as a new node. If a stroke duplicates on a given depth of the tree, it is not added again to the tree.

III. Experiments

In this section, we (i) characterise the dataset for experiments, (ii) evaluate various configurations of the CNN network classifying the stroke types, and (iii) test online recognition of Kanjis written out by two groups of testers.

A. Dataset

The experiments are based on the KanjiVG database, which contains descriptions of Kanji, hiragana, and katakana. In this study, we use only Kanji, namely the version, kanjivg-r20160426 containing 7,365 characters. Each of them is described as an SVG file, which is a universal format of two-dimensional vector graphics. Essential information in this database is the order of strokes from which a particular Kanji character is constructed. Each stroke type is labelled by an identifier. Figure 3 shows 26 stroke types available the database, and samples size for each type. Unfortunately, the distribution of strokes over their types is unequal.

B. Parameters of the Convolutional Neural Network

To select an optimal classifier of Kanji strokes, we decided to test three configurations of a CNN. They are based on the architectures proposed by [7], [8] and our pre-experiments. Table I depicts the architectures in detail, namely CNN1, CNN2, and CNN3. Each of them contains several convolutional layers followed by an activation layer and a max-pooling layer. Next, there are up to three fully-connected layers in which the final result is calculated by a softmax classifier.

Table I
CONFIGURATIONS OF CNN WHICH WHERE EVALUATED. EACH COLUMN CORRESPONDS TO A LAYER OF THE NETWORK, E.G. CONV3-32 STANDS FOR THE CONVOLUTIONAL LAYER WITH KERNEL 3X3 AND 32 FILTERS, FC-1024 STANDS FOR THE FULLY CONNECTED LAYER WITH SIZE 1024.

	maxpool	maxpool
		conv3-512
		maxpool
FC-256	FC-1024	
FC-n classes		
softmax		

An input layer holds the raw normalised pixel values of an image with the the size of $108x108$ pixels with one colour channel. All convolution layers compute by using the kernel with the size of $3x3$ with the stride equal to 1. The number of filters varies from 32 to 512. All max-pooling layers utilise kernels with the size of $2x2$ with the stride of two downsamples. The fully-connected layers are the size of 256 or 1024 outputs. However, the last fully-connected layer has the same number of outputs as the number of classes. It is followed by the softmax classifier. Each of fully-connected and convolution layers contains a ReLU non-linear layer with a dropout equal to 0.5 [9].

All the networks were trained by using the Adam optimiser with the parameters equal to $\beta_1 = 0.9$, $\beta_2 = 0.999$, ϵ= 10^{-8} and the learning rate equal to 10^{-4} [10]. The weights were initialised by the Glorot uniform initializer, which is also called the Xavier uniform initializer [11]. The size of mini-batch of 16 was performed. For training, we use 80 of all samples in dataset, 20% for validation at each epoch, and an untrained 20% of examples were used for testing. The models were implemented by using the Keres interface.

C. Stroke classification

The first set of experiments involved the selection of an optimal model for Kanji strokes classification to their types. The results of experiments are covered in Table II, which includes typical classification quality indicators such as by accuracy, precision, recall, and F1-score.

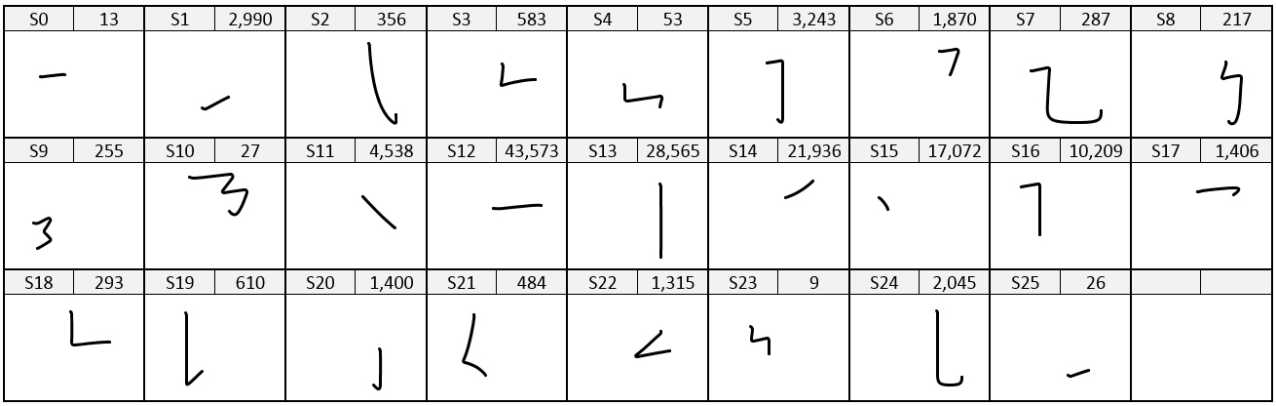

Figure 3. Kanji stroke types available in the KanjiVG database, and distribution of stroke examples over the stroke types.

We implemented and tested three network architecture configurations, namely CNN1, CNN2, and CNN3, which are described in Subsection III-B. We also used a callback function for monitoring the training process. It works as follows: if the loss function does not improve in two epochs, the process is interrupted, and the algorithm does not execute the next epoch. The results of these experiments are covered in the section, "Configuration selection" in Table II. A simple construction of the Kanji character strokes suggested starting from a simple architecture of the convolution neural network (CNN1). However, we decided to increase the number of network parameters by adding more layers, in order to see if this would improve the classification results. Subsequent attempts to deepen the network (CNN2, CNN3) did not bring any improvement. Moreover, the additional complexity of the network configuration adversely affected the network learning time. Comparing the obtained results, we decided to use the CNN1 network in the succeeding experiments.

Initially, the only element of data preprocessing was normalisation to the range of (0,1). Additionally, we utilised a ZCA (Zero Components Analysis) whitening transformation of the input images. It is a linear algebra operation that reduces redundancies in the matrix of pixel images. The operation is intended to better highlight structures and features in images for the learning algorithm. However, in our case, the improvements were insignificant (see the results in the section, "Additional ZCA whitening transformation" in Table II). Thus, we decided to skip this technique not to increase the complexity of the algorithm.

Due to the relatively small number of samples in the case of some types of strokes, e.g. S0, S4, S10, S23, we tried to extend the dataset by more samples. Unfortunately, the image augmentation techniques may not produce the expected results. This is due to the characteristic construction of Kanji characters, in which even a slight rotation of the image could change a stroke type. A good example highlighting this problem is the case of S11 and S12. Turning the stroke S11 in too high angle to the left can cause it to become too similar to the stroke S12. A similar case appears in the pair of strokes S0 and S1. These concerns have been confirmed in the research. Setting the rotation range parameter to 20 degrees degraded the results compared to the original dataset (see the results in the section, "Sensitivity to rotation" in Table II).

Looking at the shape of 26 classes, we noticed that several pairs of strokes are very similar in regard to each other. We combined the most similar stroke types by reducing the number of classes from 26 to 12. Table III presents the stroke types that we decided to merge into new classes. This approach allowed to achieve the best results in comparison to all previous experiments (see the results in the section, "Classes reduction" in Table II).

Table II
RESULTS OF THE EXPERIMENTS INVOLVING THE SELECTION OF AN OPTIMAL MODEL FOR KANJI STROKES CLASSIFICATION TO THEIR TYPES.

Architecture	Image augmentation	Accuracy	Precision	Recall	F1-score
Configuration selection					
CNN1	- normalization	96,14	96,14	96,14	96,11
CNN2	- normalization	95,79	96,23	95,25	95.72

LISTING OF THE NEW MERGED CLASSES.

S0	S1	S2	S3	S4	S5	S6	S7	S8	S9	S10	S11
S0 S12 S17	S1 S14 S25	S2	S3 S18	S4 S8 S23	S5 S6 S16	S7	S9 S10	S11 S15	S13 S19 S20	S21 S22	S24

D. Kanji recognition

The second set of experiments involved Kanji characters recognition in real-time during their writing by an individual. In order to perform these tests, we have created a simple web interface. It contains a space, in which a user can draw Kanji by using a mouse cursor. The real-time tests involved two groups of individuals, namely (i) ten people who have never studied Japanese before, (ii) one expert familiar with Japanese

language and Japanese calligraphy. Each tester had to draw 100 randomly selected Kanji characters. Prior to that, each non-expert individual had performed a small tutorial, which instructed how to write ten Kanjis.

During the tests, especially with non-expert group, we encountered two problems. The first issue resulted from unfamiliarity of Kanji structure by testers. Some individuals were not able to notice differences between some strokes, because they were so similar in regard to the others. The second issue was of technical nature. Our tests were carried out on a laptop with a mouse device. Testers complained about the shape of the mouse device, because it was too small and uncomfortable to use. It affected the quality of drawn lines. Users could not draw in the way that they wanted to. We were suggested that it would be more convenient to do tests on a tablet with a pen device.

It has to be noted that we assumed that a target Kanji was correctly identified if the following conditions had been met:

1) The target character had to appear in the first five characters proposed by the system.
2) A tester had only two attempts to draw the mark; any subsequent attempts were not taken into account.

In spite of the problems mentioned above, we managed to obtain the following results. 79% of the drawn Kanji characters by the non-experts were correctly recognised by the system. For the expert's drawings, the system recognised correctly 89% of characters. The detailed results showing the number of correctly recognised Kanjis are in Table IV.

Table IV
THE NUMBER OF CORRECTLY RECOGNISED KANJIS IN RESPECT TO A POSITION ON WHICH THEY WERE PROPOSED BY THE SYSTEM (IT PROPOSES FIVE THE MOST LIKELY KANJI CHARACTERS).

Group of testers	Position					Sum
	1st	2nd	3rd	4th	5th	
Non-experts	43	18	7	5	6	79%
Expert	78	9	1	1	0	89%

In both groups, the correctly recognised character was, in most cases, in the first position of the suggested Kanjis. In only one case for the non-expert group, the correctly identified Kanji was farther than the fifth position. In other cases, the type of stroke was incorrectly classified so that the Kanji could not be recognised. The most frequent mistakes occurred between lines S0 and S1 and S9 and S1. An imprecisely drawn line caused an incorrect classification. Due to this, searching of a dictionary with the definitions of Kanji did not bring the expected result. Another encountered problem, which also affected the results, consisted of incorrectly marked strokes in the KanjiVG database. We had found that some of the characters in our sets for testers had a stroke marked as S8, when it should be marked as S1.

IV. CONCLUSIONS

In the study, we presented and implemented a complete framework that recognises Kanji characters in a real-time, based on successively drawn strokes. In comparison to the previous works, our solution did not assume writing characters in cursive. For this reason, the comparison of prior results with those achieved by us is not entirely reliable. However, we were able to find out that even the characters written by a group that has never before had contact with the Japanese writing system can be correctly recognised by the system. Another advantage of our solution is the uncomplicated construction of the system, as well as an automatically generated dictionary definition of Kanji, which can be easily expanded with new meanings. The problems encountered during the tests included the incorrect classification of strokes, which in the training set were present in a small amount. In order to improve the quality of CNN classification, it would be necessary to expand the collection in the least numerous classes. One of the limitations mentioned in earlier studies was the problem of writing strokes in the wrong order. This will be the subject of our further research.

***Abstract*—Automatic extraction of synonymous collocation pairs from text corpora is a challenging task of NLP. In order to search collocations of similar meaning in English texts, we use logical-algebraic equations. These equations combine grammatical and semantic characteristics of words of substantive, attributive and verbal collocations types. With Stanford POS tagger and Stanford Universal Dependencies parser, we identify the grammatical characteristics of words. We exploit WordNet synsets to pick synonymous words of collocations. The potential synonymous word combinations found are checked for compliance with grammatical and semantic characteristics of the proposed logical-linguistic equations. Our dataset includes more than half a million Wikipedia articles from a few portals. The experiment shows that the more frequent synonymous collocations occur in texts, the more related topics of the texts might be. The precision of synonymous collocations search in our experiment has achieved the results close to other studies like ours.**

I. Introduction

OVER the last few years, there has been an upsurge of interest in the research which focuses on ways to the retrieval and identification of semantic similarity for textual elements of various levels (words, collocations, and short text fragments). One of the main reasons for this is the expansion of the boundaries of the use of semantically similar texts fragments in various natural language processing applications. Nowadays, words similarity can be processed in Information retrieval systems, Question answering systems, Natural language generation systems, Plagiarism detection systems, Automatic essay grading systems and some others. The second reason for the growth of interest in the identification of a semantic similar element in texts is that on social media billions of small text messages are made public every day, each of which is comprised of approximately thirty words. Whereas very popular traditional algorithms, such as, for example Tf-idf used to compare texts, often fail in very short texts [1]. For this reason, sometimes semantic algorithms and techniques are more needed than statistical ones.

Now there exist enough studies concerning the problems related to the search of words with similar meaning. We could divide all the existing approaches into two groups. The first group of studies is based on the relations of the concepts in a thesaurus. The second group of methods for computing word similarity is based on the appliance of distributional models of meaning.

Measuring the semantic similarity between sentences or collocations is a more challenging task than searching words with similar meaning. Since the task of deciding whether two sentences or two collocations express a similar or identical meaning requires a deep understanding of the meaning of the text fragment. Increasingly, this task is being integrated into the common challenges of the paraphrases [2].

II. Related work

The most explored level of text similarity for the different languages is the level of words. There are a lot of different approaches and methods of computing words similarity. Some of them use thesaurus relations of hyponyms or hypernyms to compute word similarity; the others use distributional similarity of words in a corpus.

However, automatic synonymous collocation pairs extraction from corpora is the more challenging task of NLP. As the task involves two simultaneous operations. The first operation is the collocations extraction from a corpus and the second one is the acquisition of their synonymous pairs.

Wu and Zhou [3] suggested a method that firstly gets candidates of synonymous collocation pairs based on a monolingual corpus and then selects the appropriate pairs of the candidates using their translations in a second language. Pasca and Dienes

This work was supported by the Committee of Science of the Ministry of Education and Science of the Republic of Kazakhstan

[4] offered to utilize the alignment of two sentences fragments in order to retrieve small phrases with the same meaning. Barzilay and McKeown [5] like [3] built upon the methodology developed in Machine Translation. They presented an unsupervised learning algorithm for identification of similar phrases from a corpus of multiple English translations of the same source text.

Increasingly, the task of the synonymous collocation pairs extraction is being integrated into the common challenge of the paraphrases, which is interpreted as the search of the various textual realizations of the same meaning. Typically, n-gram models [2], annotated corpora and bilingual parallel corpora [6], [7] are used for paraphrases in such studies. Han et al. [8] and Kenter [9] are some of the most recent studies that concern determining the semantic similarity between short fragments of texts. Han et al. [8] combined lexical similarity features, Latent Semantic Analysis (LSA) similarity using WordNet knowledge, alignment algorithm and support vector regression model and n-gram models in order to establish the semantic text similarity. Kenter performed semantic matching between words in two short texts and used the matched terms to create a saliency-weighted semantic network [9].

In our study, we propose using logical equations in order to search collocations of similar meaning in English texts. These equations are based on conjunctions of morphological and semantic characteristics of the words that constitute the collocations. In order to correctly identify the grammatical characteristics, we exploit Stanford POS tagger and Stanford Universal Dependencies (UD) parser[1]. Additionally, in order to pick synonymous words which constitute the collocation we use WordNet synsets[2].

In order to evaluate our approach, we use Wikipedia articles from a few projects. Traditionally, articles of Wikipedia cover various subjects. However, depending on a topic and language versions, Wikipedia community has different numbers of experienced authors or experts [10]. Such groups of users often work together within some subject area of Wikipedia project. Articles related to the projects can have a specific writing style and quality standards, which are defined by the user community of these projects. Therefore, we can expect there is a lot of synonyms and synonymous collocations in texts related to similar topic.

III. Logical-Linguistic Model

According to previous studies [11], [12], the proposed logical and linguistic model formalizes semantically similar elements of a text by means of grammatical and semantic characteristics of words in collocations.

The semantic-grammatical characteristics determine the role of words in substantive, attributive and verbal collocations. Defining a set of grammatical and semantic characteristics of collocation words, we use two subject variables a^i and c^i. In substantive, attributive and verbal collocations, a set of possible semantic and grammatical characteristics for the main collocation word is defined by the predicate *P(x)*, for the dependent collocation word it is defined by the predicate *P(y)*.

The two-place predicate *P(x,y)* describes a binary relation which is a subset of the Cartesian product of $P(x) \wedge P(y)$ and so determines a correlation of semantic and grammatical information of collocation words *x* and *y*:

$$\begin{aligned} P(x,y) = {} & y^{NObjAtt} x^{NSubAg} \vee (x^{NObjOfAg} \vee \\ & x^{NObjOfAtt} \vee x^{NObjOfPac} \vee x^{NObjOfAdr} \vee \\ & x^{NObjOfIns} \vee x^{NObjOfM}) y^{NObjAtt} \vee \\ & x^{VTr} y^{NObjPac} \vee y^{AAtt} (x^{NSubAg} \vee \\ & x^{NObjAtt} \vee x^{NObjPac} \vee x^{NObjAdr} \vee \\ & x^{NObjIns} \vee x^{NObjM}) \vee x^{NSubAg} y^{APr} \end{aligned} \tag{1}$$

Using the algebra of finite predicates, we define the value of the predicate of semantic equivalence for three main types of collocations:

$$\begin{aligned} & \gamma(x_1, y_1, x_2, y_2) = (x_1^{NSubOfAg} \vee x_1^{NSubAg}) \wedge \\ & y_1^{NObjAtt} (x_2^{NSubOfAg} \vee x_2^{NSubAg}) y_2^{NObjAtt} \vee \\ & x_1^{VTr} y_1^{NObjPac} x_2^{VTr} y_2^{NObjPac} \vee x_1^{NSubAg} \wedge \\ & (y_1^{AAtt} \vee y_1^{APr}) x_2^{NSubAg} (y_2^{AAtt} \vee y_2^{APr}) \end{aligned} \tag{2}$$

IV. The Stages of Our Methodology

In order to show the correctness of our synonymous collocations extraction model we have used methodology that comprises a few steps. Fig. 1 shows the structural scheme of the methodology, which includes POS-tagging phase, Stanford UD parser and exploitation of the lexical database WordNet.

In the first phase, we employ POS-tagging and UD parser to define the grammatical and semantic characteristics of words in sentences.

The main reason to use UD parser is that its treebanks is centrally organized around notions of subject, object, clausal complement, noun determiner, noun modifier, etc. [13]. Therefore the syntactic relations which connect words of a sentence to each other can express some semantic content.

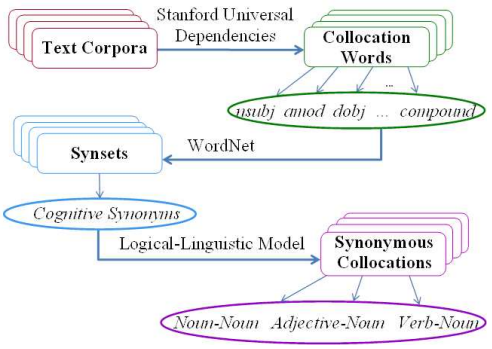

Fig. 1. The structural scheme of our experiment methodology

[1]http://universaldependencies.org/

[2]http://www.nltk.org/_modules/nltk/stem/wordnet.html

We took six types of syntactic relations tags *(compound, nmod, nmod:possobj, obj (dobj), amod* and *nsubj*) from a fixed inventory of UD grammatical relations to denote directed relations between two nouns, a verb and a noun, a noun and an adjective.

Grammatical and semantic characteristics realized through the syntactic relations tags correspond to the variables value in the two-place predicate of equation (2).

Next phase, we use WordNet in order to obtain synonyms of words connected with these types of the syntactical relations. For each collocation (substantive, attributive and verbal), synonyms are searched in WordNet synsets.

If a synonymous word is found, conformity of grammatical and semantic characteristics of a collocation and a potential synonymous word combination is being checked using the proposed logical-linguistic model.

Table I shows the examples of identified synonymous collocations in *Art* and *Biography* Wikipedia portals.

V. Source data and experimental results

Our dataset includes more than half a million articles (502 274) from Wikipedia belonged four thematic projects related to two portals. We focused on projects and portals of Wikipedia because they constitute a huge corpus of texts, which are combined by a common subject, and, at the same time, these texts are written by various authors and, consequently, may contain a lot of different synonyms.

In our studies, we choose two of the biggest portals: *Art* and *Biography*. Each portal can consist of different Wikiprojects. For our experiments, we choose four Wikiprojects (two projects from each selected Wikipedia portals)[3].

In order to estimate our synonymous collocations extraction model, we focus on three approaches. In the first approach, we identify synonymous collocations in any Wikiproject. In the second approach, we identify synonymous collocations in two different projects of the same portal. In the third of our experiments, we identify synonymous collocations in two different projects of two different portals. Our hypothesis is that two projects of the same portal may have the higher number of synonymous collocations than two projects that belong to different portals. The hypothesis is based on an idea that synonyms are occurring more often in related topics texts.

[3]List of the articles of each Wikiproject was extracted in April 2018 https://tools.wmflabs.org/enwp10/cgi-bin/list2.fcgi

Based on the Corpus Linguistics approaches [14], in order to have the opportunity to compare the synonyms occurrence frequency in the Wikiprojects of different sizes, we normalized the frequencies per ten thousand words. Additionally, we devoted attention to synonymous collocations distribution by three types.

Tables II - IV show relative frequencies of synonymous collocations that occur in four different Wikiproject, two different projects of the same portal and two different projects of two different portals, respectively.

TABLE II
Relative frequencies of synonymous collocations that occur in the Wikiproject

Wikiproject	The relative frequency of synonymous collocations		
	Substantive	Attributive	Verbal
Album	214.4	144.8	12.9
Film	277.5	281.7	10.9
Politics and government	200.9	175.4	3.5
Science and academia	280.2	210.4	210.4 4.6

TABLE III
Relative frequencies of synonymous collocations that occur in two different projects of two different portals

Wiki-projects / portal	The relative frequency of synonymous collocations		
	Substantive	Attributive	Verbal
Album – Film / Art	199.3	166.3	5.9
Politics and government - Science and academia /Biography	200.8	162.5	3.9

The results of Tables II - III show that the number of synonymous collocations in articles belonging to one Wikiproject is more than the number of synonymous collocations in articles belonging to two different Wikiprojects.

The results of Tables III - IV show that the number of synonymous collocations in articles belonging to the one portal is more than the number of synonymous collocations in articles belonging to two different portals. The articles of one project are closer to one subject than the articles of two different projects.

However, Wikiprojects can also have similar fields of knowledge. Due to it, articles from different projects of the same portal might have enough synonymous collocations.

TABLE I
The Examples of synonymous collocations extracted from Art and Biography portals

Collocations	Syntactic relation tags	Synonymous collocations	Syntactic relation tags	Collocation types
history of land	nmod:of	nation's story	nmod:poss	Substantive
soul power	compound	ability of person	nmod:of	Substantive
spectacular progression	amod	outstanding advance	amod	Attributive
restoration is incompetent	nsubj:cop	restitution is incapable	nsubj:cop	Attributive
qualify place	dobj	modify position	dobj	Verbal
preserve fire	dobj	maintain flame	dobj	Verbal

TABLE IV
RELATIVE FREQUENCIES OF SYNONYMOUS COLLOCATIONS THAT OCCUR IN TWO DIFFERENT PROJECTS OF THE SAME PORTAL

Wiki-projects (portal)	The relative frequency of synonymous collocations		
	Substantive	Attributive	Verbal
Album (Art)–Politics and government (Biography)	128.7	117.2	2.8
Album (Art)–Science and academia (Biography)	172.5	144.4	3.8

VI. EVALUATION RESULTS AND CONCLUSIONS

In our experiments, we use precision to assess the validity of our approach. The main reason why we could not evaluate recall of experiment results that we did not have a training corpus with correctly identified synonymous collocations.

In order to obtain the number of correctly found semantically similar collocations, we use an expert opinion. About 1000 synonymous pairs of collocations were randomly extracted from each list of three types of collocations and presented for judgment. The purpose of the evaluation was to obtain judgments on how synonymous collocations found in the texts were similar in meaning. The experts were asked to compare the similarity of meaning of the collocation pairs on the scale of from 0 to 2. The experts needed to assess the pair of collocations as 2 if these collocations had not any semantic similarity, as 1 if the pair of collocations had some semantic similarity and as 0 if they obviously found it difficult to answer.

Table V shows the values of the average precision of our approach calculated for three types of collocations.

TABLE V
THE CALCULATION OF AVERAGE PRECISION OF OUR APPROACH FOR THREE TYPES OF COLLOCATIONS

Type of collocations	Average precision
Substantive	0.781
Attributive	0.644
Verbal	0.627

Such precision is close to results of the other studies [4], [5]. In our opinion, the reason why the data show relatively low results is mistakes of the POS tagging and UD-parser.

In the future research we intend to broaden the scope of the study on semantic equivalence. In particular, there is a need for calculating the recall of our experiment and extending the approach to some other languages. Multilingualism of Wikipedia on the one hand, and the independence of each language version of this encyclopedia on the other, give the opportunity to create models that can help to identify content with the highest quality [15]. Therefore, presented approach can be used to define new metrics for the tasks of the quality texts assessment.

ACKNOWLEDGMENT

This research is supported by the Committee of Science of the Ministry of Education and Science of the Republic of Kazakhstan (project No. AP05131073 – Methods, models of retrieval and analyses of criminal contained information in semi-structured and unstructured textual arrays).

Email: johannes.linden@miun.se, stefan.forsstrom@miun.se, tingting.zhang@miun.se

***Abstract*—News companies have a need to automate and make the process of writing about popular and new events more effective. Current technologies involve robotic programs that fill in values in templates and website listeners that notify editors when changes are made so that the editor can read up on the source change on the actual website. Editors can provide news faster and better if directly provided with abstracts of the external sources and categorical meta-data that supports what the text is about. In this article, the focus is on the importance of evaluating critical parameter modifications of the four classification algorithms Decisiontree, Randomforest, Multi Layer perceptron and Long-Short-Term-Memory in a combination with the paragraph vector algorithms Distributed Memory and Distributed Bag of Words, with an aim to categorise news articles. The result shows that Decisiontree and Multi Layer perceptron are stable within a short interval, while Randomforest is more dependent on the parameters best split and number of trees. The most accurate model is Long-Short-Term-Memory model that achieves an accuracy of 71%.**

I. Introuction

THERE are several approaches to extracting the key points of non-formatted text to be able to retell the most important information to the reader. A common problem is the over all descriptive word of the text, such as this text is about Kultural arts. In this article we will call this information a category. Other problems involve retrieving shorter summaries of text documents and computing other meta data describing the text content. The purpose is to make the text more available to readers/writers, and from there link the text the appropriate audience by for example personalization and document search algorithms.

Swedish journalists categorize their news articles manually. It is a time-consuming task and yields inconsistent results. A previous study by Oscar Hjelmstedt and Mats Sellfors shows that journalists needs to take advantage of algorithms that can manage news content to get a better understanding of how they work and move on from old habits of news paper press that are very different from digital media [1]. In the future, news will to a greater extent be written by using deep learning algorithms to write news faster and at a lower cost [1]. It is therefore important that the journalists have an understanding and know how to work with the new working conditions. Hence, this research seeks to answer the following research questions:

1) Will a combination of classification and paragraph vector algorithms improve the results of the categorizations?
2) To which extent and which combinations of classification and paragraph vector algorithms shows the best accuracy for new articles?

In this article, the focus will be the paragraph vectors distributed memory and distributed bag of words as described by Mikolov et al. [2]. As an additional layer of algorithms we categorize the paragraph vector using the standard data mining algorithms: decision tree, random forest and multi layer perceptron. A comparison between the result of our work and other categorization algorithms like Fasttext and Lai Siwei et al.'s classification algorithm will be presented and the f-score metric will be evaluated [3], [4].

A. Outline

This article will first go through some related work that already have been done in the research field. Secondly a approach/models description about the algorithms used and how they are combined in the experiments conducted described in the next section. The scores that are based on the model evaluation experiments are then presented in the result section, followed by the discussion and conclusions of the project. Finally suggestions for future work are presented.

II. Related Work

In the field of text categorization, there is already existing research that should be considered. Facebook announced their own categorization algorithm called fasttext a few years ago, which shows good performance in speed [3]. In a matter of seconds, a trained fasttext model is ready to categorize texts in comparison to other algorithms like Gensim with the same dataset setup this is fast, there by the name. The reason for the speed increase is most likely their n-gram implementation that mainly introduces good results for the syntactical parts of the text, but weakens the semantic parts. The fasttext algorithm gets a way with less computational complexities and still performing well on syntactic problems [4]. In this article

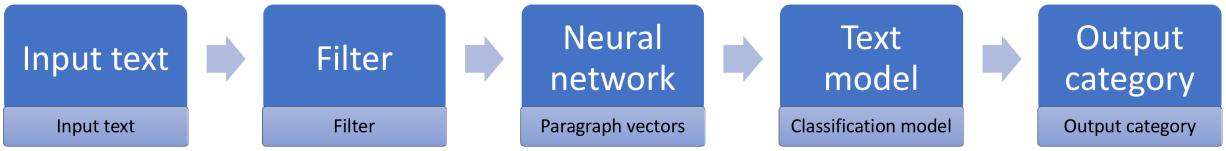

Fig. 1. An overview of the approach and model

several steps to categorize the text are performed. An LSTM classification algorithm using a multi-timescale approach to prolong the long-term memory in the network is proposed by Liu et al [5]. Liu uses English data sources with question-answer and binary data.

Standford University conducts research in the field of natural language processing, which includes text categorization of Twitter feeds. They consider a large number of Twitter posts and categorizes the posts into positive and negative. They also consider emoticons noisy labels. Although they are showing good results they categorize the posts of two categories and emoticons are quite unstable facit. The Standford work is in line with this article in that it too uses predefined categories for training, but positive and negative categories are more abstract which implies human error is greater. [6]

A completely different approach to text categorization is term association, associates certain rules and patterns of the text with certain categories. This approach relies on the pruning phase of the model, since a lot of fake rules will emerge from a large dataset. Therefore Maria-Luiza Antonie and Osmar R. Zaïane [7] came up with three pruning rules that reduce the amount of rules and increases the accuracy of the model in 2002. The paper shows that an association model for categorization can be both accurate and fast.

The algorithms used when dealing with natural language processing are commonly also used in image processing. For example a paper about practical study of network image based classification by Dabrowski, Marek et al uses a convolutional network to categorize images which can be compared to a very deep convolutional network approach to character based language classification by Conneau Alexis et al [8], [9]. These algorithms depending on the dataset takes often long time to converege given the initial weights the time of the result could vary between different training runs Polap, Dawid et al shows one method to use multi-threaded learning with a multi-core solution to achieve faster training time [10].

Google released a data source platform called GDELT that stores a lot of news metadata from all over the world. The system has the computer power to store and monitor world news on the internet from certain news sources, new events as well as events reaching as far back in time as 1979. Over 200 million events are recorded from over 240 countries and available for live requests. In 2013, a comparison between the GDELT and ICEWS was made that compared the popularity and scale of the two data sources. [11], [12]

Other competitive algorithms that provide a document vector for a given text are LDA algorithms and text ranking algorithms. In an article by Thanda et al. [13] they compare the different algorithms in a systematic matter to find relations between math queries.

III. Approach and Model

We propose a four step model that predicts categories of arbitrary text paragraphs. See Figure 1 for an overview of our implementation. The input in Figure 1 is the algorithm parameters θ and a single document D, which is interpreted as a sequence of words $w_1, w_2, \cdots, w_n$. The output of the model is a set of category probabilities $c_1, c_2, \cdots, c_i, \cdots, c_m$ where

$$c_i = P\left(\text{ith category}|D, \theta\right) \approx P\left(\text{ith category}|D\right) \quad (1)$$

. Before the actual training, the data is filtered from text paragraphs that only consists of a link to another article and that does not represent any categorical value. The combination of step three and four is the machine learning part, which will answer the research questions. The algorithms used are described in the following sections.

A. Input Text

The input of the proposed algorithm is an unstructured sequence of words forming a text paragraph. The text should be in Swedish and can be of any length. Although in this article the tested the text sizes have a length between 5 to 600 words.

B. Input Filter

Before the text can serve as the input to the model the text needs to be filtered to remove special characters. Exclamation marks and question marks are replaced by full stops. Commas, references and document links are removed. The purpose of the filter layer is to make the paragraph uniform, so that the model can be processed with as few exceptions as possible. In this step, one scenario was to filter on verbs and nouns to make the input data more precise to the point and thus describe the category using narrow information without noise words. To filter on these words a part-of-speech tagger was used.

Part-of-speech taggers (POS-tagger) are used to extract the sentence structure in the form of a dependency tree and the cooresponding word's tags [14]. A tag indicates if the word is a verb, noun, preposition or any other type. The dependency tree has a root word node and child words that directly relates to the parent word, an example is shown in Algorithm III-B. Google released a POS-tagger called SyntaxNet with state-of-the-art performance, and one year later announced an

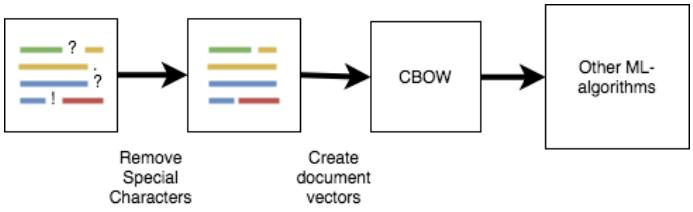

Fig. 2. The input vector of the algorithms: decision tree, random forest and multi layer perception is generated as shown above. It applies the filter layer conditions, and by using a CBOW algorithm directly on the document it produces the document vectors that can be categorized with the classification algorithms.

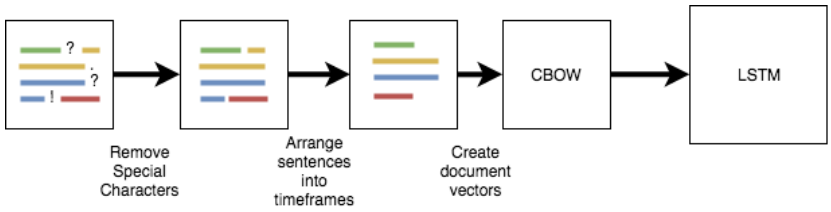

Fig. 3. The input vector of the LSTM algorithm is shown above. It first applies the filter layer conditions, then divides the document into sentences to be used as input data for the CBOW algorithm that produces the document vectors.

improved version [15], [16]. In the experiments in this article SyntaxNet is used with a Swedish training set (also called a treebank). Out of the resources mentioned in Nilson et al, we selected a treebank made by Jan Einarsson's project, which is well documented [17], [18], [19]. In the experiments we will try to select only nouns and verbs to predict a category.

Algorithm 1 A part-of-speech example sentence parsed by SyntaxNet.

Input sentence: I found a website to post AI tutorials .
Parsed dependency tree:

```
found VBD ROOT
+– I PRP nsubj
+– website NN dobj
|   +– a DT det
|   +– post VB infmod
|       +– to TO aux
|       +– tutorials NNS dobj
|           +– AI NNP nn
+– . . punct
```

C. Paragraph Vectors

The third step in Figure 1 is a neural network model that is constructed and trained to predict paragraph vectors when given the text form in the input or filter step. The paragraph vectors are unique vectors that describe the relation between the words in the document and a likely word to appear with them [2]. Computing the cosine similarity between two paragraph vectors yields a positive value when the documents are sharing similar contexts, a value close to zero when no relation could be found, and a negative number when a relation with opposite meaning [2]. With this knowledge, it is common to carry out paragraph operations such as you could for word vectors, for example Equation 2 [2].

$$king - man + woman = queen \tag{2}$$

The paragraph vectors do have context awareness, and are therefore believed to contain information about what makes a document category. The paragraph vectors are computed using the PV-DM algorithm which is an extension of the known word2vec algorithm bag of words (WV-BOW) [20].

The PV-DM algorithm tries to map all word vectors in a paragraph to a unique vector. The unique vector and the word vectors are averaged into the hidden layer h in our implementation. The rest of PV-DM algorithm follows the continuous bag of words (CBOW) algorithm [4], [21]. The unique paragraph vector can be considered an additional word in the context of a CBOW network. The idea of this extra vector is to have a form of memory about the topic of the paragraph, which explains the name PV-DM. The training of a PV-DM uses stochastic gradient descent [22] and neural network back-propagation by calculating the derivate of the vector from the next layer and applying it to compute the previous layer vector.

In our experiments, the PV-DBOW paragraph algorithm is implemented by the distributed memory vector concatenated with the distributed bag of words vector described by Mikolov et al [2].

D. Text Model

When a paragraph representation has been established it is time to go to step four: the categorization step. Therefore, we continue with the assumption that the paragraph vectors are properly and uniquely defined with good paragraph relationships in the previous step. The categorization algorithms we propose in these experiments are decision trees, random forest, multi layer perception and long-short term memory (LSTM).

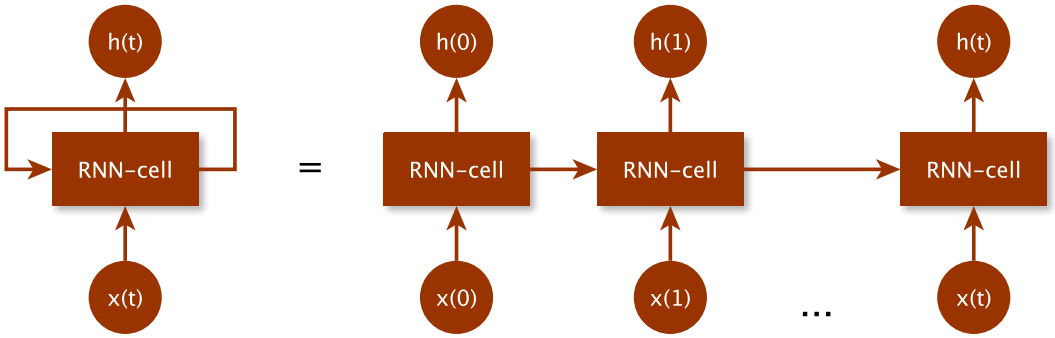

Fig. 4. A recurrent neural network cell. The cell to the left is the general notation of the hidden layer in an RNN model. The right unfolded version is the representative of the RNN with a short-term length of t.

Each algorithm has its own parameters that will be evaluated in the experiments. The input of the categorization step is the paragraph representation of the text. The output is the category belonging probabilities for each considered category described in Equation 1.

For the machine learning algorithms decision tree, random forest, multi layer perception are using the document vector from doc2vec CBOW algorithm was used directly as input, as shown in Figure 2. For the LSTM model, the time parameter was used to separate the paragraph into sentences, and then calling the CBOW algorithm in each sentence input into each LSTM time-slot as shown in Figure 3.

LSTM networks are based on recurrent neural network techniques. A recurrent neural network (RNN) is constructed like a neural network with an input, hidden layers and a output layer. The size of the input and output layer depends on the objective of training. The RNN-cell can be visualised as shown in Figure 4. The activation function of an RNN is usually the $tanh$ function. For each iteration, the model is trained by backpropagation through the network. The purpose of RNN is to have a short-term memory that remembers previous neurons. One of the first and simple constructions of RNN is the recurrent neural network language Model (RNN-LM). The hidden layer of an RNN-LM algorithm remembers the neurons one time-step back in the training history. [23]

Today, there are different variations of RNNs depending on the goal of the model. Andrej Karpathy summarises the different networks that are used into different mappings. One-to-one mapping is the original algorithm, for example the RNN-LM algorithm. One-to-many mapping when there is one input and several RNNs connecting to several outputs. This mapping can, for example be, used for image prediction with one image and several words that predict the image. Many-to-one mapping is where there are several inputs mapping to one output, this mapping can for example be used for classification. Many-to-many mapping is what Karpathy describes as two different mappings: one mapping that maps to an equal number of input and output RNNs (N-N), and another mapping that maps to a different number of inputs and outputs (N-M). The N-N mapping can, for example, be used to predict video sequences over time, while N-M mapping can be used for translation problems. [24]

LSTM networks are a special case of RNN that solve a fatal problem in the original RNN. The long-term problem that LSTM solves is introduced in RNN where the gradient descent exponentially diverges to infinity or converges to zero. On an ordinary RNN, the most simple solution that is used is to clamp the value between zero to one, but that still leaves the convergence to zero problem. The way LSTM networks work is to introduce three sigmoid layers and certain gates that only let parts of the information through to compensate for the vanishing gradient. The first sigmoid layer determines what information that is important from the previous LSTM-cell, the second sigmoid layer determines what information is important from the $tanh$ layer in the current cell and the third sigmoid layer determines what information will be passed to the next LSTM-cell. The gates that open or close based on the input from the previous LSTM-cell either remove or add information to a cell state that is also passed through to the next LSTM-cell. The third sigmoid layer extracts a piece of information from the cell state to the output value. [25], [26]

E. Output Category

As mentioned in the beginning of this chapter, the output layer interprets the output of the classification model and determines the number of categories, the probability of the prediction, and finally returns the category probabilities of the given text paragraph. The output category probabilities are normalized such that the highest probability of a category is one and the lowest one is zero according to Equation 3.

$$\frac{value - min(value)}{max(value) - min(value)} \tag{3}$$

IV. Evaluation and Experiments

This section presents the experiments conducted in the evaluation of the model. The dataset that we will train the models on consists of Swedish texts from the MittMedia article

TABLE I
THE PARAMETERS USED TO TRAIN THE CLASSIFIER MODELS. THERE ARE 2848 TRAINED MODELS IN TOTAL, E.G. EACH COMBINATION OF THE PARAMETERS FOR EACH ALGORITHM.

Algorithm	Parameter	Values
MLP	Dimensionality of the feature vectors	100x1, 100x2, 100x3, 100x4, 100x5 and 100x6
	Activation function	Identity, Logistic sigmoid, tanh and relu
	Solver function	LBFGS, SGD and Adam optimizer
	L2 penalty	0.005, 0.010, 0.015, 0.020
Decisiontree	Criterion	Gini and Entropy
	Max features	20%, 40%, 60%, 80% and 100% of the training data
	Max depth	10, 20, 30 and 40
	Minimum sample split	2, 4, 6 and 8
	Minimum leaf samples	2 and 4
Randomforest	Criterion	Gini and Entropy
	Max depth	10, 20, 30 and 40
	Minimum sample split	2, 4, 6 and 8
	Minimum leaf samples	2 and 4
	Number of trees	5, 10, 15, 20 and 25
	Features count for best split	2, 4, 8, 10, auto, $\sqrt{\text{number of features}}$, $\log_2$ (number of features)
LSTM	No of hidden layers	2, 3, 4
	LSTM neurons	10, 32, 50
	LSTM Timesteps	10, 20, 40
	Filter	Stop words, non-nouns and non-verbs
	Training epochs	2, 5, 15

database, including metadata. The metadata for categorization contains tags and categories that are attached to each training instance. Each instance can have more than one category. When the article was written, the categories were attached manually by the editors. During the experiments 5 to 30 categories were used to train, test and validate the models. The implementation of the experiments where made in Python. A tensorflow model was constructed for each model [27].

The data-instances are not always valid, therefore a prepossessing step is necessary to filter outlier texts. The dataset was divided into three groups to train, test and validate. First, one large filtered set was fetched from the database. The training and testing groups were separated into 60% training (5597 articles) and 40% testing (8396 articles) data after filtering of invalid outliers. Next a new non-seen filtered data-set was fetched and used for the validation group.

A. Experiment Settings

The following pre-processing was done before starting the actual training. The dataset used was filtered due to some odd outliers. The outliers are the result of different guidelines from the company Mittmedia, at different times, such as links to other articles or dynamically loading content. The restrictions were removed by ignoring the instance body content shorter than 10 words. If the instance body content contained more than 10 words, there were still outliers and unusable document-instances. The unusable instances sometimes contained JavaScript code that loaded contents from another URI onto the page dynamically when loading the page. Since these instances from the database are usually displayed in a web browser, this was not a problem. However, when the instances were directly fetched to the algorithm, the JavaScript content had to be removed.

In the experiments, the parameters of the classification algorithms consisted of all combinations of values for each algorithm as shown in Table I. The document count and categories were also changed independently of the algorithm parameters to evaluate impact on the result. For a full report on the results for the document and categories variation we recommend that you read the full report [20]. The F_1-score measurement were used to compare, validate and test the models. The measurement was developed in 1992 and gives an objective result of the harmonic mean between the precision and recall with equal weights [28].

The categories used for the experiment are labelled in Swedish: Blåljus, Ekonomi, Kultur, Nöje, Släkt och familj and Sport. The categories could be roughly translated as Accidents, Economy, Culture, Entertainment, Family and Sport, respectively. Accidents are texts about car chases, fires, injuries and so on. Economy is about financial issues such as business deals, the stock market and so on. Culture is mostly about art, museum or movie premiers, the nobelprice and so on. Entertainment is similar to Culture, as also this category potentially could include movie reviews, popular events, and other fun activities in the society. It is a fine line what would be defined as Culture and what is defined as Entertainment and different editors could have slightly overlapping definitions. Family is about newborns, the royal family, or family activities. The Sport category covers all kinds of sports, such as tennis, hockey, horse riding and so on. A majority of news

TABLE II
CONFUSION MATRIX OF THE CBOW AND LSTM COMBINED PREDICTIONS OF THE NEWS ARTICLE DATASET

Real \ Predicted	Accidents	Economy	Culture	Entertainment	Family	Sport	
Accidents	536	35	3	2	18	6	600
Economy	1	465	39	4	38	2	600
Culture	50	30	426	35	106	2	600
Entertainment	15	33	200	272	62	18	600
Family	14	25	112	29	413	7	600
Sport	14	17	10	25	81	453	600
	632	605	790	367	718	488	3600

TABLE III
CONFUSION MATRIX OF THE SINGLE LSTM-NETWORK PREDICTIONS OF THE NEWS ARTICLE DATASET

Real \ Predicted	Accidents	Economy	Culture	Entertainment	Family	Sport	
Accidents	287	51	16	27	46	173	600
Economy	154	287	27	34	57	41	600
Culture	32	100	262	13	121	72	600
Entertainment	92	128	106	139	58	77	600
Family	85	70	62	41	242	100	600
Sport	148	20	13	50	90	279	600
	798	656	486	304	614	742	3600

are written for the Sport category. Therefore it is important that we consider equal amount of text documents for each category so that the model isn't biased to, for example the Sport category.

TABLE IV
ACCURACY OF THE EVALUATED MODELS

Algorithm	Test Score	Validation Score
LSTM	0.74	0.71
LSTM (without CBOW)	0.42	0.37
MLP	0.31	0.14
Decision Tree	0.10	0.05
Random forest	0.08	0.03

The best model will be selected and evaluated without the CBOW vectors but, instead, word identifiers are used to verify that the combination is better than the algorithm alone. For objective fairness, the settings of the additional evaluated model will be the same as the best performing model.

B. Results

The test and validation measurements of each model are presented in Table IV. Only the best performing models are selected and presented in Table IV for each algorithm. The neural network is consistently performing well with a test F-score of about 0.31 and validation score of 0.22. The decision-tree classifier performs with a validation score of 0.05. The F-score of randomforest validation is 0.03. The LSTM network is currently superior to the other algorithms with a test score of 0.74 and validation score of 0.71. The confusion matrix of the combined CBOW and LSTM model show that the categories Culture and Entertainment are frequently mixed up by the algorithm, it is where the majority of miss-predictions occur, see Table II. In Table III the LSTM is compared with indicies as input, which shows that there is a larger uncertainty in this data.

Since the LSTM model performed best out of the the selected models, the additional model was trained using only the LSTM model with the same settings and unique IDs as input data. The additional model was performing with a validation score of 0.37 and thus we can confirm the research question that will investigate the combination of paragraph vectors and classification algorithm.

By running the model with different initial conditions we can evaluate the be model that had highest score value with a statistical approach. This way we check the reliability of the model in case it will be retrained at some point.

C. Discussion

The confusion matrix in Table III indicates that articles within one category are potentially difficult to distinguish from another category's texts. For example, the categories Entertainment, Family and Culture have some prediction overlaps. Most predictions are correct for all categories, which means that there are at least a few articles that characterize each category. Comparing LSTM with CBOW and the network without CBOW yields that the combination has significantly better performance. The reason is likely to have something to do with the vocabulary size, which is many times larger than the dataset that we are using, and thus not all words are present in the training data. This means that it is more difficult for LSTM without CBOW to predict correct categories.

Filtering away all words except nouns and verbs performed poorly compared to using all words in the document as input. The reason could be because the document vector also captures some information about how the text is structured and how the words are used in conjunction with each other. For example, which words tend to be used together, thus more frequent the word in a certain category the easier it is to predict. The time and network sizes did not significantly change the outcome, the score was slightly better using a larger value with any or both parameters. MLP is a good candidate if speed is a concern, although not near as good as fasttexts' performance. Random forest is slightly better than the decisiontree algorithm, but in general they perform similarly.

V. Conclusion

In this article we proposed a combination of classification algorithms and paragraph vector algorithms to improve the results of categorization problems. We aimed to find out if the combination of classification and paragraph vector algorithms improves the categorization, which we found to be true. We also investigated how the algorithm performed on news articles and to what extent it can be used. From the trained categorization models a probability score can be estimated for each available category that can be predicted. Based on the probabilities, a number of categories can be suggested to the editors in the system that, for example, has a probability higher than a certain threshold. The LSTM model is perfoming best in combination with the word vectors when predicting the categories. Based on the confusion matrix we can see that it is not overfitted. It can be concluded that a combination of LSTM and CBOW (classification and paragraph vector) algorithms perform better together (score of 0.71) than using only a classification algorithm such as LSTM (score of 0.37). Although the combination is not enough for the other evaluated algorithms: decisiontree, random forest and MLP with the combined CBOW algorithm achieve better result than a LSTM network with word IDs as input.

Future work for this project could be to extend the domain to other domains outside of the journalists that has a certain way of writing texts, such as common word choices and spelling standards. Although the proposed model should work in any other domain, further exploration has to be made to confirm. A recommended next step is to compare the model with the results of Liu et al, to make this possible we need to look into what data that model is evaluated on and see if we can apply the CBOW combined LSTM model using that data instead.

***Abstract*—The gameplay in the augmented or virtual reality is based on the use of external equipment such as glasses/telephones and possibly the use of additional sensors or controllers. In both cases, the interaction involves pressing the keys on the phone or controller. An interesting aspect is the control of objects created in a virtual way using voice commands. In this paper, we propose a solution to manipulate objects in the augmented reality using player's voice. The user can move the object using pre-programmed commands. The solution is based on speech processing and artificial neural networks. The technique has been tested and the results presented and discussed.**

I. Introduction

AUGMENTED, merged or virtual realities are leading technological and research directions in the field of human machine interaction, image processing, games and many more. The rapid development of technology is visible through numerous achievements in these areas. The last examples are getting rid of mobile phones for extended goggles with motion controllers that allow not only to much more interaction, but a much longer immersion (the goggles do not overheat as fast as smartphones). Not only virtual reality, but augmented one is widely used. It is especially used in games, learning or even medicine what is visible in the effects of scientific work of scientists from around the world.

The biggest commercial achievement of these technologies was the mobile application for catching virtual monsters in 2016, i.e. *Pokemon GO*. The game based on searching and catching was based on a combination of reality (using a camera and GPS locator in smartphones) with 3D models that caused young people to leave the houses for fresh air and cross the streets. To this day, game is considered as a good change in the gaming industry when it comes to long time spent in front of the computer [1]. These types of applications not only have a good effect on health, but also make it possible to meet new people and cooperate [2]. Support for augmented reality is performed using a certain application with access to the camera. It is a kind of human–machine interaction [3], [4].

The transition from augmented to virtual reality is quite smooth. It is only necessary to turn off the camera and set up goggles to be able to move into a fully artificially created world. Studies on immersion are dispelled in increasing the feeling of detachment from the environment [5]. Enabling and capturing movements is quite a significant problem. However, it is gradually solved, as shown by the authors of [6], where the virtual keyboard was presented. Health problems such as stress or focusing too close to the display are constantly analyzed so that in the future everyone can safely and fully immerse into virtual world [7]. Nowadays, important issue is Internet of Things and its impact on our life [8], [9]. Similar, this technology and methods can be applied to different problems like some of geological [10], [11].

An important aspect is also research in the field of voice analysis and processing. In [12] deep learning was used to quickly detect the accent for English language. Again in [13], the authors focused on recognizing emotions on the basis of voice samples using classical processing and classification techniques. Moreover, the techniques of voice processing recorded in the sound file to the text version using artificial intelligence methods are presented and widely described in terms of numerous applications in practice [14].

In this paper, we focus on introducing a voice to this type of technology. Selected, recent developments in the signal processing field can be viewed in [15], [16]. My proposition is based on the analysis of the voice and its transformation into a text command that can be realized in an augmented/virtual reality.

II. Voice Controller

The voice controller operates on the basis of downloading a sound sample, its processing, classification and processing of the output decision. Described controller is based on converting a speech signal into its graphical form, cutting and classifying it, and then transferring information to an application supporting augmented or virtual reality.

A. Voice processing

The sound analysis is quite problematic for several reasons. The pronounced sound has the continuous form, by saving it in bit form, it simplifies the signal and is still incapable to analyze. Let $s(n) = (s_0, s_1, s_2, \ldots, s_{N-1})$ is a signal in discrete form. Unfortunately, this number sequence is still not possible to be analyzed. To remedy this, use a selected transformation such as Fourier defined as follows

$$S_k = \sum_{n=0}^{N-1} s_n \exp\left(-\frac{2\pi i n k}{N}\right) \quad 0 \leq k \leq N-1, \qquad (1)$$

where $S_k \in \mathbb{C}$ is a discrete value in $(S_0, S_1, S_2, \ldots, S_{N-1})$. For the purpose of machine calculations, in practice the above

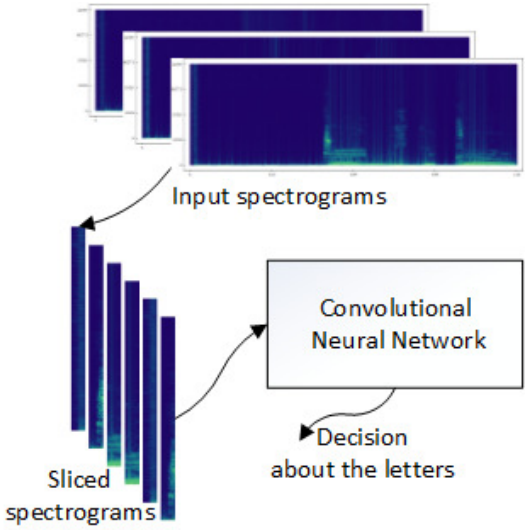

Fig. 1: Model of the proposed technique of converting the voice to the text.

equation is not used, and its recursive form called Fast Fourier Transform is used. It is defined as follows

$$\begin{aligned} S_k &= \sum_{n=0}^{N-1} s_n \exp\left(-\frac{2i\pi nk}{N}\right) \\ &= \sum_{m=0}^{N/2-1} s_{2m} \exp\left(-\frac{2i\pi km}{N/2}\right) \\ &+ \exp\left(-\frac{2i\pi k}{N}\right) \sum_{m=0}^{N/2-1} s_{2m+1} \exp\left(-\frac{2i\pi km}{N/2}\right). \end{aligned} \tag{2}$$

It is possible to present a sound sample with the help of an image so-called spectrogram. It is a flattened three-dimensional graph that is spanned on two axes – time and frequency. The flattened dimension is the intensity, which is depicted by the shadow of a given color. The formula for that is defined as

$$spectrogram\{s(t)\}(t,f) \equiv |S(t,f)|^2, \tag{3}$$

where $S(\cdot)$ is a short-time Fourier transform understood as

$$S(m,f) = \sum_{n=-\infty}^{\infty} s[n]w[n-m]\exp(-jfn), \tag{4}$$

where $s[n]$ is a signal in discrete form, $w(\cdot)$ is a window function like sine window described as

$$w(n) = \sin\left(\frac{\pi n}{N-1}\right) \tag{5}$$

B. Convolutional Neural Network

Convolutional neural network are an example of neural structures adapted to receive graphic images in the input [17]. The idea of operation this type of classifier is based on the cells in the primary cortex. The network structure is composed of three types of layers. First type is convolution layer where some feature are extracted from input image. In practice, some filter ω is applied to the image (for instance blur or sharpening defined as a matrix of 3×3 with step size S). Output from this layer is an image called feature map. The second type of layer is pooling, which reduces the size of the incoming image by calculation the mean, maximum or minimum value in a given neighborhood area. The third type is called fully connected and the architecture of these is similar to classical neural network structure. Each pixel returned from the last layer is considered as a single neuron which form the input layer. Then, hidden and one output layers are created.

These type of structure can be trained using backforward propagation algorithm [18], [19]. Let me introduce some designation – $f(\cdot)$ as an error function, output value from neuron at position (i,j) in l layer as $\frac{\partial f}{\partial y_{ij}^l}$. The error at the end of the network is known and marked as $\frac{\partial f}{\partial y_{ij}^l}$. Algorithm is based on chain rule what is understood as sharing weight with one another can be defined as

$$\frac{\partial f}{\partial \omega_{ab}} = \sum_{i=0}^{N-m}\sum_{j=0}^{N-m} \frac{\partial f}{\partial x_{ij}^l}\frac{\partial x_{ij}^l}{\partial \omega_{ab}} = \sum_{i=0}^{N-m}\sum_{j=0}^{N-m} \frac{\partial f}{\partial x_{ij}^l} y_{(i+1)(j+b)}^{l-1}. \tag{6}$$

Using above equation, error $\frac{\partial f}{\partial x_{ij}^l}$ can be calculated as

$$\frac{\partial f}{\partial x_{ij}^l} = \frac{\partial f}{\partial y_{ij}^l}\frac{\partial y_{ij}^l}{\partial x_{ij}^l} = \frac{\partial f}{\partial y_{ij}^l}\frac{\partial\left(\sigma(x_{ij}^l)\right)}{\partial x_{ij}^l} = \frac{\partial f}{\partial y_{ij}^l}\sigma'(x_{ij}^l), \tag{7}$$

where $\sigma(x)$ is activation function in classic reasoning. Having defined a formula for an error on the current layer, it is necessary to define formula for an error in earlier layers. Note that the gradient for the convolutional layer can be determine as

$$\begin{aligned} \frac{\partial f}{\partial y_{ij}^{l-1}} &= \sum_{a=0}^{m-1}\sum_{b=0}^{m-1} \frac{\partial f}{\partial x_{(i-a)(j-b)}^l}\frac{\partial x_{(i-a)(j-b)}^l}{\partial y_{ij}^{l-1}} = \\ &\sum_{a=0}^{m-1}\sum_{b=0}^{m-1} \frac{\partial f}{\partial x_{(i-a)(j-b)}^l}\omega_{ab}, \end{aligned} \tag{8}$$

and this equation can be used to define error as

$$\frac{\partial x_{(i-a)(j-b)}^l}{\partial y_{ij}^{l-1}} = \omega_{ab}. \tag{9}$$

It worth to note, that algorithm does not work for pooling layer which are skipped during training process.

C. Proposed technique for object manipulation in augmented reality

The built-in microphone on smartphone or tablet can record the sound in real time. Assume that the obtained audio will be saved every 2 seconds, it is possible to represent such a sample as spectrogram that will be cut every 0.5 seconds (these values are chosen in an empirical way). As a result, four graphics will be obtained, which will be subjected to training

and classification through a convolutional neural network (classical 5x5 filters were used – Gaussian blur and emboss). A schematic model is presented in Fig. 1.

This action allows to classify the analyzed spectrogram in order to change the sound into a text form. The text is simple in order to pass the parameter to the program, and more accurately enables the voice manipulation of the object placed in the augmented reality.

TABLE I: Values of statistical coefficients.

	0.1	0.01	0.001	0.0001
Γ	0.435	0.575	0.755	0.835
Λ	0.362	0.560	0.756	0.832
Ψ	0.221	0.388	0.608	0.713
Υ	0.416	0.581	0.752	0.845
Φ	0.447	0.570	0.758	0.825

III. Experiments

In order to test the proposed speech processing techniques and object manipulation, a simple model was created and placed on the screen of smartphone. The classifier was trained with 150 samples (75 per command) which were arranged in a random manner in the ratio of 70 : 30 (learn:test samples). The classifier was trained to obtain an error of 0.1, 0.01, 0.001 and 0.0001. The correctness of classification with respect to the error has been presented in Fig. 2-5. The best results were achieved for the smallest error, screenshots from application where these proposition was implemented are shown in Fig. 6. These results allow to calculate some statistical coefficient like accuracy Γ, Dice's coefficient Λ, overlap Ψ, sensitivity Υ, specificity Φ and calculated values of these parameters are presented in Tab. I. It shows that the accuracy increases very fast, which is a good indicator. Other values also increase, such as sensitivity, which means the probability of indicating that this is a mistaken command among all erroneous commands. Again, the coefficient of specificity points to value of incorrect samples that had a negative result.

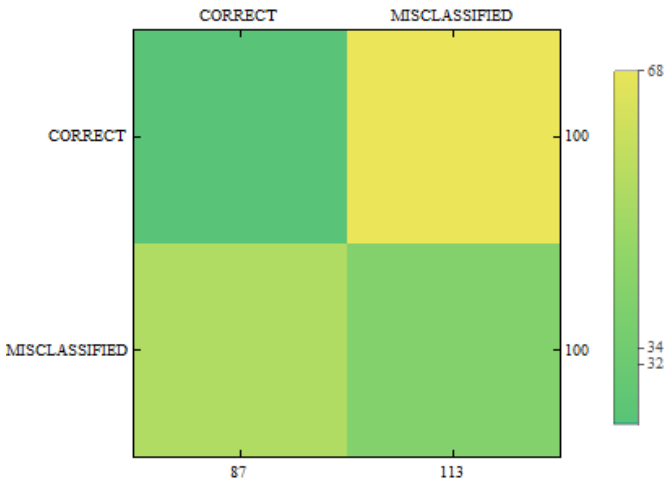

Fig. 2: Accuracy in relation to obtained error 0.1.

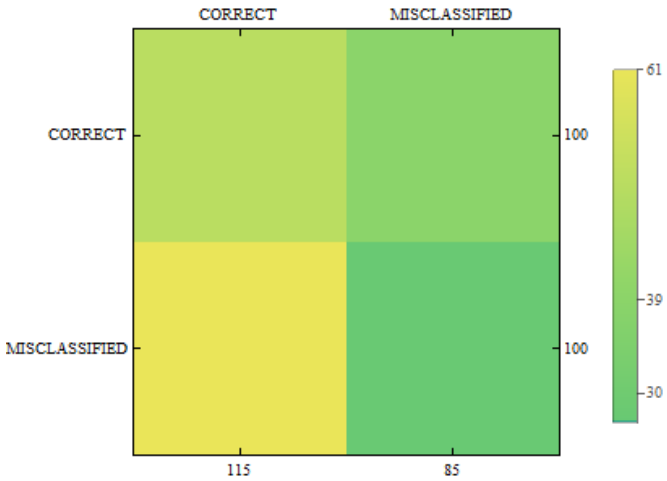

Fig. 3: Accuracy in relation to obtained error 0.01.

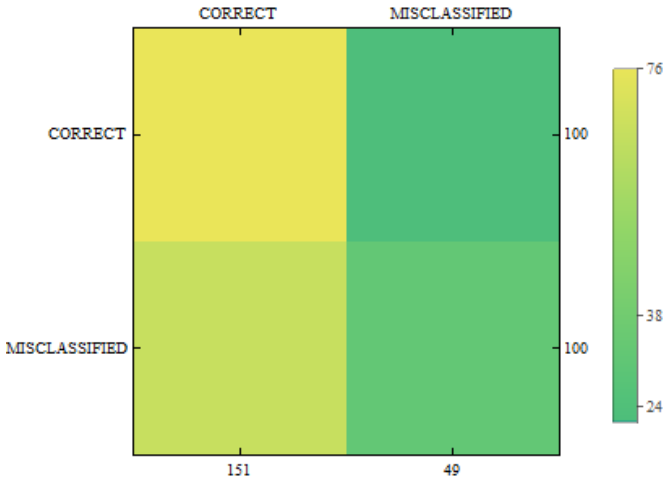

Fig. 4: Accuracy in relation to obtained error 0.001.

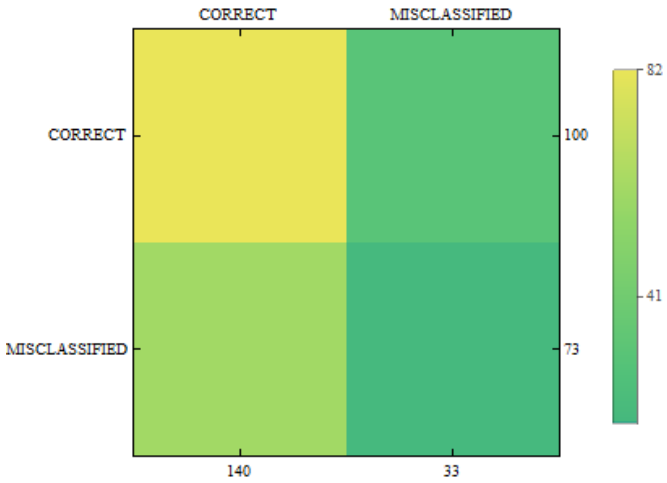

Fig. 5: Accuracy in relation to obtained error 0.0001.

IV. Conclusion

The proposed solution can diversify, and above all, improve user interaction with artificially created objects. This type of solution is the first approach to this type of activity. The obtained results indicate a high potential, however, the proposed technique has several parameters that should have been taken into account. Particularly problematic is saving audio sample every few seconds, loading processing as well the length of sliced elements from spectrograms.

In this paper, two simple commands such us *UP* and *DOWN* were tested. The trained classifier allowed to correct manipulation of the object. The effectiveness of this model indicates the high flexibility of use in games like *Pokemon Go*, which can increase the playability and refresh the classic operation of augmented reality technology. In my future work, we plan to focus on improving these issues as well as improving the classifier's operation on longer text commands.

***Abstract*—Automatic detection of abnormal behaviour of computer network users is a desirable and hard to achieve feature. We show that convolutional neural networks can classify users in local computer networks based on features of web pages which were requested by a user (e.g. URL address, URL category, the day of week or time when the web page was visited). We demonstrate our approach on data collected from a firewall over an eight-month period. This network traffic meta-data allowed to achieve satisfactory classification accuracy on unseen, future network traffic data.**

I. Introduction

FOR the past twenty years, the Internet and its utilisation have grown at an explosive rate. Moreover, for several years computer network users have been using various devices, not only personal computers. We also have to manage with many appliances being constantly online and small Internet of Things devices. Efficient computer network intrusion detection and user profiling are substantial for providing computer system security. Along with the proliferation of online devices, we witness more sophisticated security threats. It is possible to enumerate many ways to harm networks, starting from password weakness. Malicious software can be illicitly installed on devices inside the network to cause harm, steal information or to perform large tasks. Another source of weakness can be Bring Your Own Device schemes, where such devices can be infected outside the infrastructure. At last, social engineering can be used to acquire access to the corporate resources and data.

Each network user leaves traces, some of them are generated directly by the user, e.g. on social networks, others are closely related to the computer network mechanisms. Thanks to network traffic-filtering devices, network administrators nowadays have an enormous amount of data related to network traffic at their disposal. One of the ways to ensure security is to block traffic based on the categorisation of websites. Edge devices (e.g. firewalls or routers with firewall function) verify requested URLs based on the global URL databases and their category ultimately deciding whether a user can access a given page. An example of such devices and reputation databases can be PaloAlto with the Brightcloud database. In order to increase the security, high-end firewalls, simultaneously to filtering, log all the traffic passing through them, storing it, e.g. in relational databases, SYSLOG systems, etc. Thus, network operators can verify the actions of individual users. Log analysis is a crucial element of the network security diagnosis. Usually, the log content is analysed after the fact of an attack or a possible error. Registration of logs is also one of the basic requirements of the right to conduct telecommunications activities. It is mandatory for Internet providers to record who and when visited or shared network resources. Depending on the authentication methods used in a given network and the class of security devices, logs contain information from a very general level, e.g. user IP address, time of the event (of page visit), the address of the requested page up to the user's name.

In [1] the authors rely on the classification of users with all data stored in network logs. The aim was to identify users for the purposes of forensic applications. A compelling argument about why to identify users using data from network traffic and not using the IP addresses assigned to them is that people use mobile devices more often and identify less and less with one, single network. They do not limit the data, as in our case, to the URLs themselves. They use the meta-data of the traffic. However, that base only includes 46 users. The disadvantage of the system that uses all the data can be its performance. Using only URLs, we have fewer data to process, which contributes to the higher efficiency of our system. Events can also be detected by distributed MapReduce approaches [2]. The authors of [3] used a logger on each computer, which additionally logged applications, mouse movements, how were the keys pressed. The error was only 7.1 per cent for 21 users. However, the disadvantage of the method is the interference in the user's system and continuous logging of its behaviour in the system. We expect that artificial neural networks can improve the results on the problem presented in the paper [4][5][6]. A promising approach can be using space-time features [7]. A comprehensive surveys are presented in [8] and [9]. As we faced the challenge of processing a significant amount of data, it would be beneficial in the future to utilise some big data processing methods [10].

In the paper we use convolutional neural networks [11], [12] to classify computer network users based on URL requested by their devices.

II. Computer Network Data

This article is based on data collected from a WAN network infrastructure, which is used by residents of four districts in Poland, as well as network users who are employees of the local government offices and their organisational units,

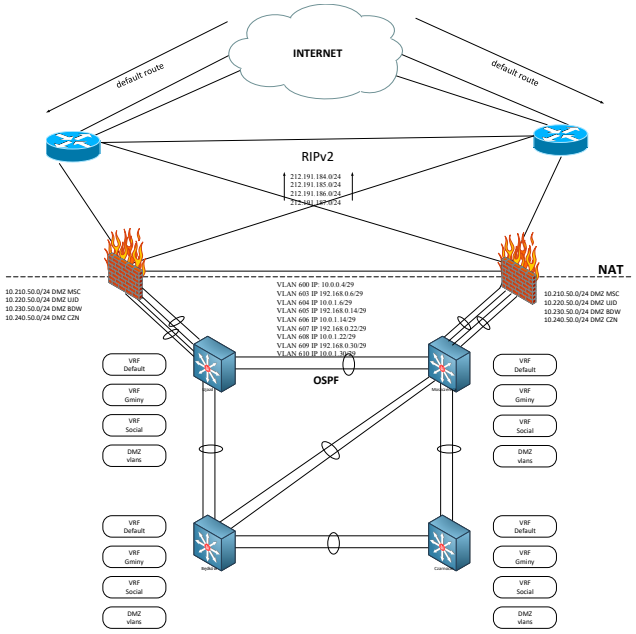

Fig. 1. Schema of the network infrastructure used in the paper to collect traffic data. The Internet is accessed by two routers, and the local network is protected by firewalls.

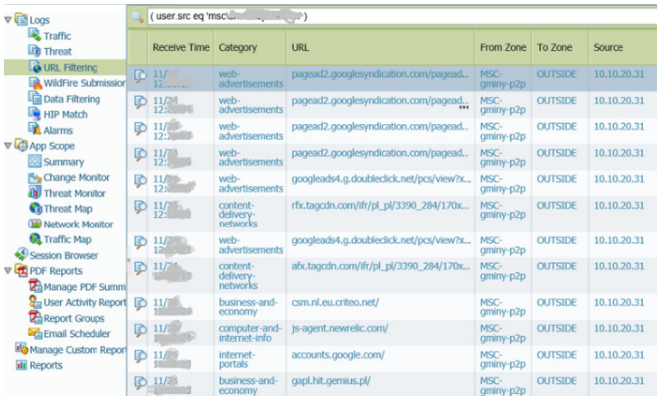

Fig. 2. Part of the network log used to create the training data.

e.g. schools, hospitals, etc. Internet access to the analysed network is done with the help of two CISCO ASR edge routers that route packets using RIP version 2. A cluster of PaloAlto devices working in an active-active mode takes care of the network security. The network is routed by the Open Shortest Path First (OSPF) algorithm with virtual routing and forwarding (VRF). In each of the four districts, there is one CISCO core switch. The network is shown in Fig. 1. In the analysed network infrastructure, users are authenticated using accounts in Active Directory services. A RADIUS service is configured for users using the wireless network. PaloAlto devices integrate with the list of accounts contained in domain controllers, thanks to which each user's network traffic is logged using its Active Directory name. The data was acquired in the form of logs from the MS SQL database, then sorted

Fig. 3. Example of a part of the input image created from a set URLs.

by user names, by the dates when they were recorded, and by the name of the URL address. Sorting by date is designed to reflect the order of websites that were visited. We do not operate on exact dates in this case. It is important to note that additional sorting by name is important. It happened that between two identical URLs registered at exactly the same time a foreign address was requested by another program of that user. If the two URLs next to each other were the same, only one was left. This treatment had a big influence on the results and was able to improve the results.

III. Experiments

A URL is an address that allows locating a website on the Internet. The user encounters it mainly when using a web browser. However, the computer network logs we work on in the paper also contain URLs that have been used by programs running in the background such as antiviruses, system updates, etc. Each user's computer uses different applications and at a different time, which allows to even better distinguish them. As we have observed in our data, certain addresses can be typed in a characteristic way for a given person, e.g. www.google.pl, google.com, www.google.com are three different URLs from our point of view but referring to the same site.

We were inspired here by Zhang et al [12] to present text data in the form of a one-hot vector at the character level. The dictionary consisted of 70 characters:

```
abcdefghijklmnopqrstuvwxvyz_0123456789
-;.!?:/\|#$%&ˆ'+=<>()[],"'|^
```

From URL sequences, we created sessions consisted of 8 to 300 URL addresses. The session in the paper is a set of user's URLs where the interval between requests does not exceed 30 minutes. We choose 300 as the maximal value because it was the longest session in the data where there was no 30-minute break.

URLs are concatenated into one string (string), with one URL maximum being 45 characters long. We did not assume a minimum URL length. There was no such need in the collected data. If one URL next to the other was exactly the same, then only one remained. In our experiments, we were only interested in transitions between addresses. The maximum pessimistic length of the training vector is therefore 300 * 45 characters = 13,500.

After creating the input sequences, because only a few vectors had a length of 13,500, we truncated all the sessions to 8014, which allowed to speed up the learning of the network.

The data were collected from June 2017 till February 2018, where the last ten days of February 2018 were used as testing data. The data we collected allowed to divide it into 36,937 sessions, with 1,684,704 for training data, and 9,208 sessions

with 788,086 URLs for testing data. The testing dataset was created from the last data in the aforementioned period, thus the testing was performed on the future, unseen URLs. Table I presents top IP numbers present in the training data.

We built convolutional networks [11], [12] and trained them with the backpropagation algorithm [13]. To improve the accuracy we added the linear embedding layer [14] that was also trained from the data. The first network (CNN1), shown in Fig. 4 obtained 33% classification accuracy. It had 32-output linear embedding layer, convolution, max pooling and finally three-layer full-connected network with 62 outputs. The second network (CNN2) is shown in Fig. 5 and obtained 27% classification accuracy. It had the same structure and the only difference was adding additional two input channels encoding time of the week (work days vs. weekends). It allowed improving the accuracy. The next experiment was performed with the same structure with increased the number of outputs in the linear embedding layer to 42 (Fig. 5). It reduced slightly the classification error to 26%. The network training is shown in Figures 7-9.

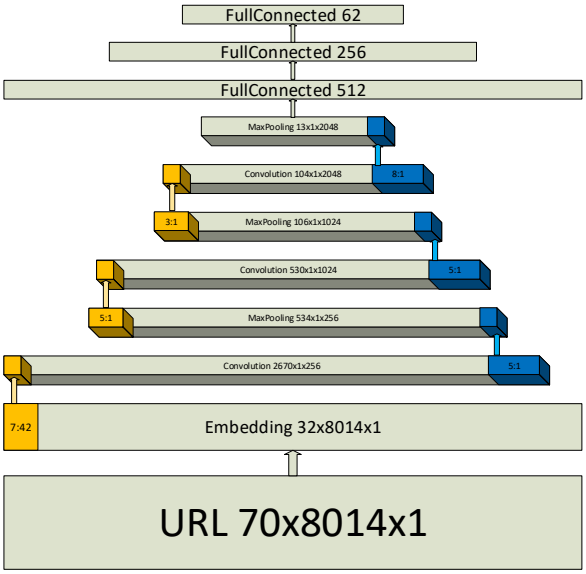

Fig. 4. Convolutional network architecture (CNN1) with 32-output embedding layer without work day information.

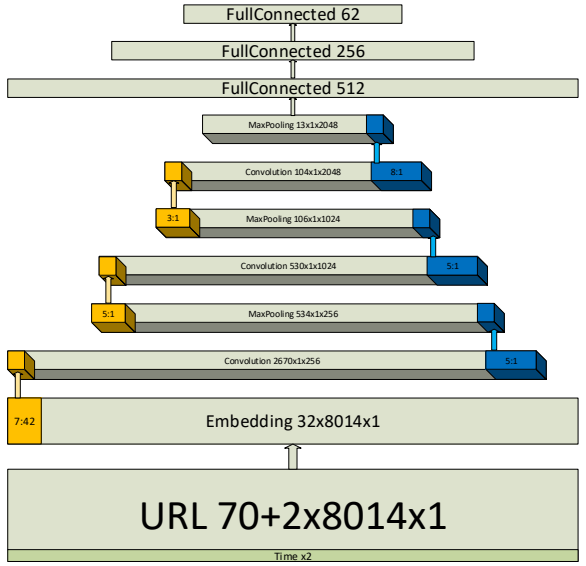

Fig. 5. Convolutional network architecture (CNN2) with 32-output embedding layer with work day information encoded in two last characters.

IV. CONCLUSION

In this article, we proposed a method to classify computer network users based on URLs they have visited. To this end, we encoded URLs as one-hot vectors and presented them as inputs to convolutional neural networks. The obtained results show that the use of additional input data channels with information on users' work days (working days or weekends) resulted in improvement of profiling quality by over 6%. Also, very good effects brought the addition of the embedding layer in the structure of the convolution network. However, increasing the size of this layer does not significantly improve the quality of classification results. The limitation of the presented method is, of course, limited possibility to accurately detect users solely basing on the requested URLs.

***Abstract* — Methodology of Constructing and Analyzing the Hierarchical structure of the Contextually-Oriented Corpora was developed. The methodology contains the following steps: Contextual Component of the Corpora's Structure Building; Text Analysis of the Contextually-Oriented Hierarchical Corpus. Main contribution of this study is the following: hierarchical structure of the Corpus provides advanced possibilities for identification of the Morphological and Structural features of texts of different tonalities; Contextual, Morphological and Structural specificity of texts with tonality, originally assigned by the authors, has significant differences; exist the certain thought and writing style Templates, under the influence of which the formation of texts of various tonalities takes place. As basic features of such templates for the texts of the two basic (positive/negative) tonalities could be used: Contextual Structure, Morphological Types, Emotional Features, Writing Style and Vocabulary Richness. For verification of the proposed methodology, a case study of Polish-language film reviews Dataset was used.**

INTRODUCTION

In recent years the sentiment analysis has been one of the hottest research areas in natural language processing [1]. The challenges to the researchers are both theoretical aspects, such as the objective laws of the sentiment expressions in the natural language, and the practical aspects, for example, the analysis of consumer opinions and reviews [2].

There are two main approaches to the sentiment analysis [3]: *lexicon-based* and *machine learning*. The first of them determines the text sentiment by means of individual words polarity in the text. The latter considers the task of sentiment analysis as the problem of text categorization. Both approaches require high quality sentiment lexicons: even in the text categorization methods the word weights are often proportional to word polarity and strength.

There are many studies on the problem of Sentiment Lexicons creation. They generally use three main approaches [4]: manual approach, dictionary-based approach, and corpus-based approach. In the manual approach the sentiment lexicons are constructed by human annotators. In the dictionary-based approach the sentiment lexicons are created with the help of the universal dictionaries and thesauri, e. g., WordNet [5].

In the corpus-based approach the sentiment lexicons are built based on the analysis of text corpora. Also, the various hybrid combinations of these approaches are used. Though the problem of Sentiment Lexicon creation is very important, little attention is paid to the evaluation of the quality and in-depth analysis of the generated lexicons, especially for Polish language.

Main direction of this research is to design the methodology for constructing and analyzing the Hierarchical Corpora, which allows improving the quality of the algorithms for the Sentiment Lexicon building by offering the additional tools for determining the tonality based on the availability of data about the semantic properties of the text. As the main research tool, text mining methods and algorithms will be used.

THEORETICAL BACKGROUND

Under the notion of texts mining we understand the application of methods of texts computer analysis and presentation in order to achieve the quality, which corresponds to the "manual" processing for further usage in various tasks and applications. One of the actual tasks of automatic texts mining is their clustering (definition of groups of the similar documents). More and more often statistical topical methods are being applied [6].

The topics are presented as discrete distributions on a number of words, and the documents – as discrete distribution on a number of topics [6]. Topical methods perform a "non-precise" clustering of words and documents, which means that a word or a document can be referred to a few topics with different probabilities simultaneously. The synonyms with higher probability will appear in the same topics since they are frequently used in the same documents. At the same time, the homonyms (words different in meaning, but similar in writing) will be placed in different topics because they are used in different contexts [7].

A. Preprocessing Procedure

Topical methods, as a rule, apply the method of a "bag-of-words", where each document is considered as a set of words not connected to each other. Before the topics are defined, the text is preprocessed – its Graphematic and Morphologic

This work was not supported by any organization

analysis is conducted with the objective to define the initial form of words and their meanings in the speech context.

Graphematic Analysis

To start the preprocessing procedure of a text it is necessary to divide the original unstructured text into sentences and words. At first sight, it is a very simple task, but it has its own specificities and plays an important role in the further analysis of a text.

Graphematic analysis includes:

– division of the original text into elements (words, separators);

– elimination of non-text elements (tags, meta-information);

– extraction and formalization of non-standard elements: structural elements: headlines, paragraphs, notes; numbers, dates, complexes of letters and numbers; names, patronymics, surnames; extraction of e-mail addresses;

– extraction of files' names;

– extraction of sustained phrases, words that are not used separately from each other.

In English sources, we can meet the definition of tokenization, which, by its content, is similar to the graphematic analysis. Tokenization – is a process of dividing the text stream into tokens: words, collocations and sentences [8]. Thus, the graphematic analysis is the initial analysis of an unstructured text, presented as a chain of symbols in any coding, elaborating information, which is necessary for further text processing.

There are almost no tools specializing exceptionally on graphematic analysis. Basically, graphematic is included into integrated packages of text analysis: NLTK, Stanford CoreNLP, Apache NLP, AOT, MBSP etc. The function of division into tokens is also included into programs of text markup, for instance into the part-of-speech taggers.

Morphologic Analysis

Morphologic analysis provides definition of the normal form, from which the word-form was created, and of the set of parameters, assigned to this word-form [9].

Stemming has been the most widely applied morphological technique for information retrieval. With stemming, the searcher does not need to worry about the correct truncation point of search keys. Stemming also reduces the total number of distinct index entries. With short queries and short documents, a derivational stemmer is most useful, but with longer ones the derivational stemmer brings in more non-relevant documents. Stemming increases search key ambiguity. Stemming may, however, is a non-optimal approach to the clustering of documents in agglutinative languages. Firstly, stemmers do not conflate compounds whenever the first components do not match exactly. Secondly, they are unable to split compounds, which typically have the head-modifier structure and the headword is the last and more important component for clustering [10]. The most widely-spread algorithm of stemming is the Porter's algorithm. Except for that algorithm there exists the Lancaster's algorithm (for English language) and the algorithms, working by the principle of a "snowball" (snowball stemmers) for other languages.

Lemmatization is another normalization technique: for each inflected word form in a document or request, its basic form, the lemma, is identified. The benefits of lemmatization are the same as in stemming. In addition, when basic word forms are used, the searcher may match an exact search key to an exact index key. Such accuracy is not possible with truncated, ambiguous stems. Homographic word forms cause ambiguity (and precision) problems – this may also occur with inflectional word forms [11]. Another problem is that words cannot be lemmatized, because the lemmatizer's dictionary does not contain them.

B. Vector Space Models of the Semantic Relations Analysis

The method of processing words in a machine-readable natural language, as a rule, is based on the vector-space method of data description (Vector Space Model) [12], suggested by [13]. Within the framework of the method each word in a document has its particular weight. Thus, each document is presented as a vector and its dimension is equal to the total number of words in the document.

Similarity of a document and a topic is evaluated as a scalar product of a few information vectors. The weight of separate words (terms) can be calculated both applying the absolute frequency of a term appearing in the text and the relative (normalized) frequency:

$$F_{w_i} = TF \times IDF = tf(w,t) \cdot \frac{\log_{10} D}{df} \qquad (1)$$

$tf(w,t)$ – relative frequency of the w-th term occurrence in document t:

$$tf(w,t) = \frac{k(w,t)}{df} \qquad (2)$$

$k(w,L_t)$ – the number of w-th term occurrences in the document t; df – the number of documents in the collection that contain the w-th term; D – total number of documents in the collection.

Then, for solving the problem of finding the similarity of documents (terms) from the point of view of the relation to the same topic, the different metric can be applied, for example:

– *Euclid's* measure:

$$dist_{t_i} = \sqrt{\sum_{i=1}^{m} (x_i - y_i)^2}\,, \qquad (3)$$

where x – vector of the document, y – point of reference words vector;

– *Cosine* of the edge between the vectors:

$$dist_{t_i} = \cos\theta = \frac{x \cdot y}{\|x\| \cdot \|y\|}, \qquad (4)$$

where $x \cdot y$ – scalar product of the vectors, $\|x\|$ and $\|y\|$ – quota of the vectors, which are calculated by the formulas:

$$\|x\| = \sqrt{\sum_{i=1i}^{n} x_i^2}\ ,\ \|y\| = \sqrt{\sum_{i=1i}^{n} y_i^2} \qquad (5)$$

A further algorithm is to divide the source data into groups corresponding to the events, as well as in determining whether a text document describes a set of any topic. The main idea of the solution is the use of clustering algorithms [14] (e.g., k-means method, etc.). It is assumed that each cluster contains documents that describe an event.

Latent Semantic Analysis (LSA) is a Discriminant theory and method for extracting context-dependent word meanings by statistical processing of large sets of text data [15-17]. It uses the "bag-of-words" for modelling, begins with transforming text corpora into term-document frequency matrices, reduces the high dimensional term spaces of textual data to a user-defined number of dimensions by singular value decomposition (SVD), produces: weighted term lists for each concept or topic; concept or topic content weights for each document; outputs that can be used to compute document relationship measures [18].

According to the theorem on singular decomposition, any real rectangular matrix can be decomposed into a product of three matrices:

$$X_{t\times d} \approx X_{K_{t\times d}} = U_{K_{t\times d}} \Sigma_{K_{t\times d}} \left(V_{K_{t\times d}}\right)^T \qquad (6)$$

where $\Sigma_{K_{t\times d}} \left(V_{K_{t\times d}}\right)^T$ – represents terms in *k-d* latent space; $U_{K_{t\times d}} \Sigma_{K_{t\times d}}$ – represents documents in *k-d* latent space; $U_{K_{t\times d}}$, $V_{K_{t\times d}}$ – retain term–topic, document–topic relations for top *k* topics.

But, as [19, 20] proved, there are three *limitations* to apply LSA: documents having the same writing style; each document being centered on a single topic; a word having a high probability of belonging to one topic but low probability of belonging to other topics. The limitations of LSA is based on orthogonal characteristics of dimension factors as well as on the fact, that probabilities for each topic and the document distributed uniformly, which does not correspond to the actual characteristics of the collections of documents [13, 21, 22]. That is why, LSA tends to prevents multiple occurrences of a word in different topics and thus LSA cannot be used effectively to resolve polysemy issues.

C. Probabilistic Topic Models

To get rid of the above-mentioned disadvantages the probability LSA is conducted, based on the multinomial distribution – in particular, on the algorithm of Latent Dirichlet Allocation (LDA) [23, 24]. The *probabilistic topic modelling* – a set of algorithms to analyze the words in large sets of documents and from the retrieve the threads that connect into topics [25, 26]. In this case document is regarded as a set of words, the order of which does not matter. For each document to determine the distribution $\boldsymbol{\theta_d}$ of its words on topics, that probability for each topic meets it herein. This topic is presented in the form of distributions $\boldsymbol{\varphi_t}$ of words from a fixed vocabulary, i.e. each word included in the subject with a certain probability

The next text mining technique that was developed to improve upon LSA was the Probabilistic topic modeling techniques. Probabilistic topic modeling is a set of algorithms that allow analyzing words in textual corpora and extract from them topics, links between topics [23, 24, 27]. Latent Dirichlet Allocation (LDA) is a generative model that explains the results of observations using implicit groups, which allows one to explain why some parts of the data are similar. It was proposed by David Blei [23, 24] and it uses a Bayesian model that treats each document as a mixture of latent underlying topics, where each topic is modeled as a mixture of word probabilities from a vocabulary.

The algorithm of the method is the following: Each document is generated independently: randomly select for document its distribution on topics θ_d for each document's word; randomly select a topic from the distribution θ_d, obtained in the first step; randomly select a word from the distribution of words in the chosen topic φ_k (distribution of words in the topic *k*). In the classical model of LDA, the number of topics is initially fixed and specifies the explicit parameter *k*. In the process of assigning the topics to documents usually LDA uses the maximal from possible (not always very high) level of probability of documents belonging to the topic.

According to [28] – words in a topic from LDA (as an extended LDA method) are more closely related than words in a topic from LSA. For polysemy, words in a topic from LDA can appear in other topics simultaneously: topics are Dirichlet multinomial random variables, each word is generated by a single topic, and different words may be generated from different topics. The *limitation* of LDA is that there is no probability distribution model at the level of documents. Thus, the larger the number of documents, the larger the LDA model.

METHODOLOGY FOR CONSTRUCTING AND ANALYZING THE HIERARCHICAL CORPORA

A. Novelty and Motivation

The *purpose* of this research is development of the methodology of constructing and analyzing the *Hierarchical Corpora* intended for subsequent use in the creation of the Sentiment Lexicon using text mining tools.

In this research the following scientific research questions (RQ) were raised:

RQ: *Using what methods and algorithms it is possible to increase the quality of the formation of the Corpus intended for the analysis of text tonality*?

RQ_1: *Does creation of the Contextual Structure of the Corpus provides advanced possibilities for identification of the morphological and tonal specifics of analyzed texts?*

RQ_2: *Does the preliminary Morphological and Structural analysis of the Corpus allow to reveal specific characteristics of Corpus content in the light of improving the quality of texts Sentiment recognition?*

For finding the answers for these questions, the following assumptions (A) were formulated:

A1: Taking into account the specificity of the chosen case study [16, 17, 29], assume that each paragraph could be interpreted as a topically completed textual component (TCTC).

A2. Classified texts are characterized by their initially known subjective (author's) evaluations of their tonality.

On the basis of the research questions and assumptions, the following scientific hypotheses (H) were formulated:

H1. *Contextual structure of the certain type of texts writing does not depend on its tonality, initially assigned to it by the author.*

H2. *Morphological structure of the certain type of texts writing does not depend on its tonality, initially assigned to it by the author.*

H3. *Writing style of certain type of texts does not depend on the tonality, initially assigned to it by the author.*

H4. *Vocabulary richness of certain type of texts does not depend on the tonality, initially assigned to it by the author.*

As a *case study* for testing the basic workability and proposed Methodology quality, the Polish-language Film Reviews Dataset was used.

B. Contextual Component of the Corpora's Contextually-Oriented Hierarchical Structure Building

At the first stage of the methodology development, the authors take into account specificity of the chosen case study and the results of previous research results [29]. These results suggest the possibility of building the Hierarchical structure of the Contextually-Oriented Corpus (COHC) via application of the Discriminant and Probabilistic Methods of the Latent Dirichlet Allocation (LDA) and Latent Semantic Relations Analysis (LSA) [28, 30]. In our case COHC is the two-point (Positive/Negative Classes) structure of the sets of paragraphs, semantically close to Topics, identified as the main Contextual Framework of the analyzed initial Dataset. The process of Hierarchical structure of COHC *Building* involves the following stages (figure 1):

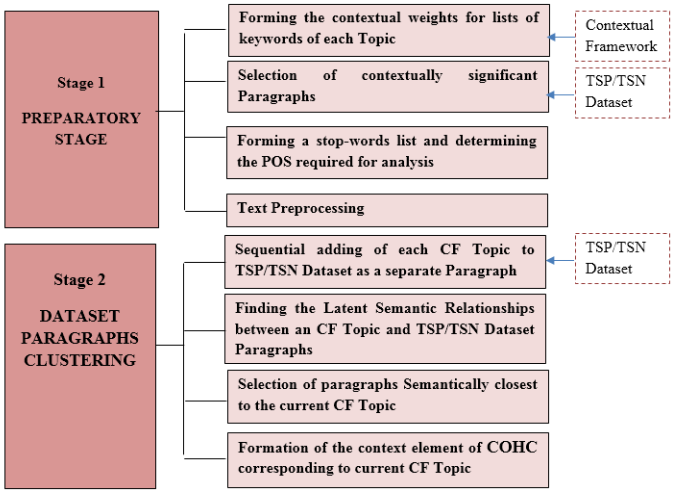

Fig 1. Steps of the Corpora's Contextually-Oriented Hierarchical Structure Building

Formation and analysis of the Contextual components of the COHC are based on the following concepts:

Concept A. Obtaining an adequate sentiment description of positive and negative texts tonality is possible only via formation of the Corpus on the basis of Truly Subjectively Positive (TSP, the subjective evaluation by reviewes is more than 8 points) and Truly Subjectively Negative (TSN, the subjective evaluation is less than 4 points) Dataset.

Concept B. As a Contextual Framework (CF) for COHC building the hierarchical structure of Topics (with list of keywords) for TSP and TSN dataset are used. Applied methods for CF creating – combination of LSA and LDA methods [16, 17, 28].

Concept C. As a quantitative measure of the degree of influence of each keyword from the CF Topics on the process of COHC building the contextual keyword weights (CKW) are used. Applied methods for CKW creation – combination of LSA and LDA methods, measure – the probability of occurrence of each word in the topic [16, 17, 28].

Concept D. As a tool for determining the belonging of each paragraph to a CF topic, the LSA is used [16, 17, 28].

Concept E. As a TCTC a paragraph of at least 100 characters should be used. The possibility to determine the topic of such paragraph with sufficient accuracy is experimentally proved [16, 17, 28].

C. Text Analysis of the Contextually-Oriented Hierarchical Corpus

The process of Text Analysis of COHC involves the following steps (figure 2).

Step 1. Morphological Analysis of the Contextually-Oriented Hierarchical Corpus

The purpose of this first stage is to conduct the COHC analysis and create the Hierarchical Morphological Framework (HMF) for each element of each COHC level.

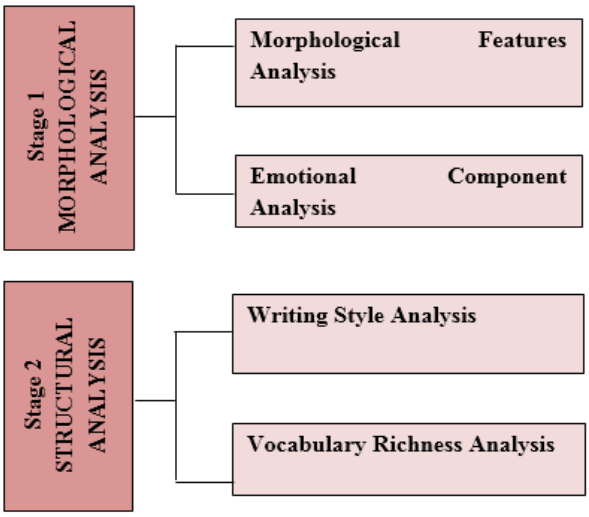

Fig 2. Steps of the Text Analysis of Contextually-Oriented Hierarchical Corpus

The objective of creating this HMF is to accumulate the Hierarchy of specific morphological types and emotional

features of the COHC texts to identify their differences depending on: the text tonality, initially assigned to it by the author, and belonging to a particular CF Topic. As main indicators to carry out this stage of analysis, the measures with following interpretations are proposed:

– the part of speech (POS) distribution for each COHC Element (*M1*) – determining the authors morphological types of the expression of positive or negative judgments;

– the percentage of new (unique) words in each COHC Element (*M2*) – characterizing the emotional component specificity of positive or negative judgments expression.

Step 2. Structural Analysis of the Contextually-Oriented Hierarchical Corpus

The purpose of this first stage is to conduct the COHC analysis and create the Hierarchical Structural Framework (HSF) for each COHC element of each level. The objective of creating this HSF is to accumulate the Hierarchy of specific writing styles and vocabulary richness features of the COHC texts to identify their differences depending on: the text tonality, initially assigned to it by the author, and belonging to a particular CF Topic. As main indicators to carry out this stage of analysis, the measures with following interpretations are proposed:

– the specificity of first Zipf's "rank-frequency" law for each element of each COHC level (*M3*), determining the authors *writing styles* of the expression of positive or negative judgments and classically characterized by a constant value of C as the ratio [31, 32]:

$$C = F*R, \quad (7)$$

where: F – frequency of occurrence of a term in the text; R – Rank of the word (the most commonly used word gets rank 1, the next – 2, etc.); C – constant;

– the specificity of the second Zipf's "quantity-frequency" law for each element of each COHC level (*M4*), determining the authors *vocabulary richness* of the expression of positive or negative judgments [5,6].

CASE STUDY RESULTS AND DISCUSSION

For testing and evaluating the adequacy of the author's Methodology realization, as a *case study* were used the training samples: 3000 Polish-language films reviews (1500 TSP and 1500 TSN) from the filmweb.pl.

All words/terms of film reviews in this paper will be presented in English language. The experimental part of all steps of author's Algorithm *was* technically realized in Python 3.4.1.

D. Contextual Component of the Corpora's Contextually-Oriented Hierarchical Structure Building

In the process of implementing this stage, about 30% of contextually insignificant paragraphs, and about 20% of paragraphs, for which topic could not be identified, were separated.

The quality indicator – recall rate as the ratio of the number of topically recognized paragraphs (probability of belonging the paragraph of topic >0,7) to the total number of paragraphs – is within 90-95% (table I).

As a method of evaluating the quality of probabilistic topic models the calculation of *Perplexity* index on the test data set [2-4] is used. In information theory, perplexity is a measurement of how well a probability model predicts a sample. A low perplexity indicates that the probability distribution is good for predicting the sample.

TABLE I.
STRUCTURE OF THE CONTEXTUAL SUMMARY

Corpora Samples	Number of paragraphs	Number of CF topics	Average Number of topics in Document	Average Number of terms in	Average Perplexity Value
TSP	10239	36730.0	5.1	5.7	1 182 169
TSN	10934	41015.0	4.2	6.1	1 342 155

As a result, the following structure of the two-level two-point *Contextually-Oriented Hierarchical Corpora of Polish-Language Film Reviews* [29] was obtained (tables II- III).

TABLE II.
CONTEXTUAL STRUCTURE OF THE SUBJECTIVELY POSITIVE (SP) ELEMENTS OF THE COHC OF POLISH-LANGUAGE FILM REVIEWS

Element of 1st level CF l	Element of 2nd level CF	% of paragraphs
"Hero"	Actor / Play	24%
	History / Film	43%
	Picture / Scene	30%
	Director / Creator	3%
"Director"	Film / Director	30%
	Scene / Story	10%
	Style	6%
	Creator / Author	54%
"Script"	Film / Director	8%
	Story / Hero	58%
	Author / Creator	13%
	Role / Actors	21%
"Plot"	Film / Effects	5%
	Portrait / Image	31%
	Director / Production	24%
	Script / History	40%
"Spectator"	Hero / Fan	40%
	Film / Aspects	20%
	Role / Formulation	16%
	Scene / Director	24%

TABLE III.
CONTEXTUAL STRUCTURE OF THE SUBJECTIVELY NEGATIVE (SN) ELEMENTS OF THE COHC OF POLISH-LANGUAGE FILM REVIEWS

Element of 1st level CF	Element of 2nd level CF	% of paragraphs
"Hero"	Action / History	49%
	Director / Cinema	21%
	Scene / Actor	31%
"Actor"	Hero / Image	24%
	Role / Scene	58%
	Script / History	18%
"Creator"	Hero / Scene	23%
	Film / Script	60%
	Picture / Actor	18%
"Plot"	Story / Hero	39%
	Director / Image	18%
	Creator / Film	43%

The results obtained at this stage of the experiment indicate that the tonality, initially assigned by the authors specificity of texts with Persuasive writing type, affects the Contextual Structure of the analyzed content. As can be seen from the tables II-III, the Contextual Structure of Subjectively Positive and Subjectively Negative elements of COHC differs both in content and in the variety (amount) of topics covered in the texts (H2 is rejected).

E. Text Analysis of the Contextually-Oriented Hierarchical Corpus

Step 1. Morphological Analysis of the Contextually-Oriented Hierarchical Corpus

As a result of the specific morphological types and emotional features of the COHC texts identification, the following initial statistics were obtained (Table IV)

TABLE IV.
FREQUENCY CHARACTERISTICS OF THE PARTS OF SPEECH DISTRIBUTION IN SP / SN HIERARCHICAL CORPORA'S ELEMENTS

Negative Hierarchical Corpora's Elements				**Positive Hierarchical Corpora's Elements**			
Morphological Types (M1)		**Emotional Features (M2)**		**Morphological Types (M1)**		**Emotional Features (M2)**	
% of adjectives	**Frequency**	**% of Unique adjectives**	**Frequency**	**% of adjectives**	**Frequency**	**% of Unique adjectives**	**Frequency**
18,09003	1	46	1	12.50	2	38	1
19,61974	1	53.5	2	15.02	0	50.4	2
21,14945	4	61	3	17.55	0	62.8	2
22,67915	9	68.5	4	20.07	0	75.2	9
More	1	More	6	22.59	12	87.6	6
				More	11	More	5
% of nouns	**Frequency**	**% of Unique nouns**	**Frequency**	**% of nouns**	**Frequency**	**% of Unique nouns**	**Frequency**
0.906111	1	38	1	52.88136	1	31	1
15.52333	0	46.5	2	56.16872	5	42.6	1
30.14056	0	55	5	59.45609	12	54.2	3
44.75778	0	63.5	4	62.74345	4	65.8	8
More	15	More	4	66.03082	1	77.4	7
				More	2	More	5
% of verbs	**Frequency**	**% Unique verbs**	**Frequency**	**% verbs**	**Frequency**	**% of Unique verbs**	**Frequency**
20.02801	1	51	1	13.43874	1	43	1
21.01446	4	60.75	2	15.22556	0	54.4	1
22.00092	6	70.5	3	17.01239	2	65.8	1
22.98737	2	80.25	6	18.79922	3	77.2	4
More	3	More	4	20.58605	5	88.6	9
				More	14	More	9

In table IV the "% of part of speech" is the border of % of these types of words in the whole number of words in particular Corpora's Element; "Frequency" – the number of COHC elements in which this "% of part of speech" occurs.

The results of comparative analysis of differences in the part of speech distribution and percentage of new words in the different COHC elements could be interpreted in the following way:

1. The law distribution of adjectives in the positive and negative COHC *Elements* indicates that:

– % of adjectives used in *positive* elements of the Hierarchical Corpora is slightly higher than this percentage in *negative* Elements.

This result can be interpreted as the presence of a general tendency to make reviews more intonational in expressing positive emotions;

– % of new (unique) adjectives used in positive elements of the Hierarchical Corpora is significantly higher (by 20%) compared to this indicator in negative Elements.

Thus, the need and realization of the emotional component of the authors' positive judgments through the use of different adjectives (characteristics) is much higher than in the expression of negative emotions.

2. The distribution of nouns in the positive and negative COHC Elements indicates that:

– % of the nouns, used in positive Hierarchical Corpora's Elements, obeys the classical normal distribution law and indicates the average weightiness of the judgments expressed. Negative judgments are characterized by extremes – either many, or very few nouns;

– % of new (unique) nouns used in positive Hierarchical Corpora's Elements is higher (about 10%) compared to this indicator in negative reviews.

Since the nouns primarily serve to ascertain the facts, the existence of objects (entities, etc.), on the whole these facts can indicate that negative judgments are more based on emotions rather than facts.

3. The distribution law of verbs in the positive and negative COHC Elements indicates that:

– % of verbs used in *positive* elements of the Hierarchical Corpora is insignificant, and even lower than this percentage in *negative* Elements.

This can be interpreted as the desire of reviewers to characterize the actions that caused the particular emotions, in a greater degree;

– % of new (unique) verbs used in *positive* elements of the Hierarchical Corpora is higher (about 10%) compared to this indicator in negative reviews.

This again testifies to a more creative approach to writing reviews by authors of positive reviews.

In general, these facts may indicate that the expression of negative emotions is characterized by greater stinginess of emotional coloring (from the point of view of linguistic evaluation).

When generalizing the results obtained at this stage of the experiment, it can be argued that the tonality, initially assigned by the authors specificity of texts with Persuasive writing type, affects the Morphological Structure of the analyzed content. As it can be seen from table V, the Morphological Structure of Subjectively Positive and Subjectively Negative elements of COHC differs both in the morphological types and emotional features (H2 is rejected).

TABLE V.
MORPHOLOGICAL TYPES AND EMOTIONAL FEATURES IN SP / SN HIERARCHICAL CORPORA'S ELEMENTS

Part of speech	SP Elements		SN Elements	
	M1	M2	M1	M2
Adjectives	High	High	High	High
Nouns	Average	High	Polar	High and Average
Verbs	High	High	Average	Average

Step 2. Structural Analysis of the Contextually-Oriented Hierarchical Corpus

a) First Zipf's "Rank-Frequency" Law

As a result of comparative analysis of writing styles of the expression of positive or negative judgments, the following types of internal structure of the COHC Elements from the point of view of the specific of the Rank-Frequency distribution (*writing styles*) of the words usage were identified:

– the *Classical* structure of the COHC Elements, in which the proportion of terms with a high frequency of usage (in the authors' algorithm it is intended to remove the often-used and not load-bearing stop-words of the Polish language at the stage of preprocessing) account for no more than 0.25% of all terms (C≈0.06-0.07);

– the *Medium normalized* structure of the COHC Elements, in which terms with a high frequency of use account for about 10% of all terms (C≈0.02-0.05);

TABLE VI.
THE RANK-FREQUENCY DISTRIBUTION STRUCTURE OF THE 1ST LEVEL OF HIERARCHICAL CORPORA'S ELEMENTS

Element of 1st level CF	Classical				Medium normalized				Non-standard			
	All POS	Adjective	Nouns	Verbs	All POS	Adjective	Nouns	Verbs	All POS	Adjective	Nouns	Verbs
Positive Hierarchical Corpora's Elements												
"Hero"	18.75%	12.50%	25.00%		6.25%	6.25%		18.75%	6.25%			6.25%
"Spectator"					18.75%	6.25%	25.00%		6.25%	18.75%		25.00%
"Script"	25.00%	12.50%	25.00%					12.50%		12.50%		12.50%
"Director"	12.50%		6.25%		6.25%	12.50%	12.50%	12.50%	6.25%	12.50%	6.25%	12.50%
"Plot"	6.25%		6.25%		12.50%	6.25%	12.50%	6.25%	6.25%	18.75%	6.25%	18.75%
Negative Hierarchical Corpora's Elements												
"Hero"	25.00%		25.00%	8.33%		25.00%		16.67%				
"Actor"	16.67%		25.00%		8.33%	16.67%		8.33%		8.33%		16.67%
"Creator"	25.00%		25.00%			25.00%		16.67%				8.33%
"Plot"	16.67%		16.67%		8.33%	25.00%	8.33%					25.00%

– the *non-standard* COHC Elements structure, in which about 90% of terms have a frequency of use no more than 1 time (C≈0.03-0.04).

Characteristics of Rank-Frequency distribution, obtained during this stage of experiment for the 1st level of COHC, are presented in table VI.

Interpretation of these results as a characteristic of specific Writing Style, could be the following:

– negative reviews are characterized by a small part of opinions, expressed with the help of unique words. And the most non-standard from the point of view of the use of unique words and the brevity of presentation are the paragraphs characterizing the topic Plot of the film with the help verbs.

Adjectives used in negative reviews mainly refer to the second type of Hierarchical Corpora structure, which can be interpreted as a fairly high percentage of frequently repeated definitions (terms).

The predominant type of COHC Elements structure are standard reviews, in which the most commonly used words account for 0.25% of all COHC Element vocabulary;

– structure of the *positive* part of the COHC is fairly uniform – all the texts represented in it are equally structured. However, from the point of view of distinctive features, it is necessary to note the percentage of non-standard (unique) adjectives.

The structure of the COHC that characterizes the Spectator is especially different – in this part of the COHC there is no standard Corpora Elements structure, and there is a high percentage of both repeating and unique verbs.

Generalizing the results obtained at this stage of the experiment (table VII) it again can be argued that the tonality, initially assigned by the authors specificity of texts, affects the Writing Style of the analyzed content (H3 is rejected).

TABLE VII.
WRITING STYLES STRUCTURE OF THE HIERARCHICAL CORPORA OF POLISH-LANGUAGE FILM REVIEWS

Writing Style (M3)	SP Hierarchical Corpora's Element	SN Hierarchical Corpora's Element
Classical	30.00%	45.83%
Medium normalized	35.00%	39.58%
Non-standard	35.00%	14.58%

b) Second Zipf's "Quantity-Frequency" Law

As a result of the experiments, the initial statistics, which describes the specificity of second Zipf's "quantity-frequency" law for Polish-Language Film Reviews COHC were obtained.

The basic coefficients for the analysis were the coefficients of the approximation in the equation for the second Zipf's law:

$$y = a + \frac{b}{x} \qquad (8),$$

where, a – determining the average frequency of occurrence of most part of the terms in the COHC Element; b – determining the average speed of appearance of new words in the text – the *Vocabulary Richness* (M4) of text's author.

The *lower* the value of the coefficient b, the higher the richness of the vocabulary of the COHC Element, since the curve of the dependence of the occurrence frequency of each word in the number of these words decreases more quickly, accordingly a smaller number of terms appears frequently (that is, the same words are used more often).

In order to ensure the adequate comparability of the conducted studies results, the corrected (taking into account the number of unique words in the COHC Element) coefficients of equations a and b were used.

The characteristics of Quantity-Frequency distribution (Zipf's law coefficients), obtained during this stage of experiment, are presented in the figures 3-4.

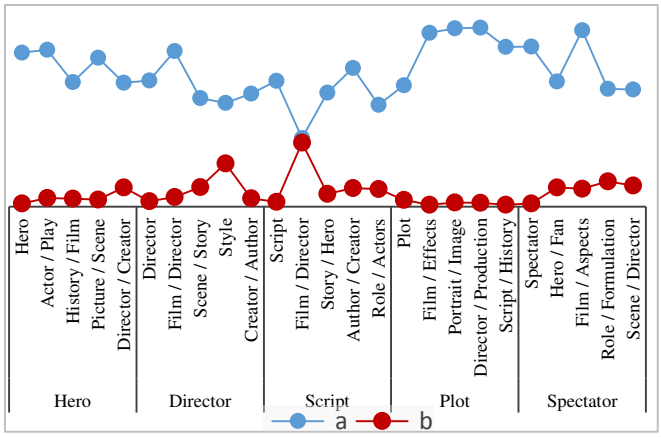

Fig 3. Second Zipf's law coefficients for Positive Hierarchical Corpora's Elements

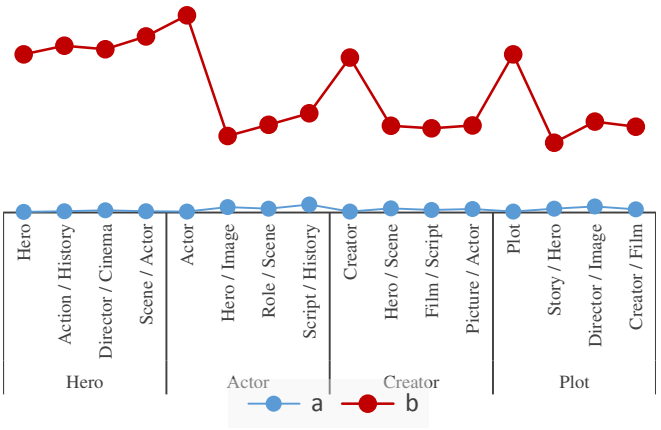

Fig 4. Second Zipf's law coefficients for Negative Hierarchical Corpora's Elements

Based on the obtained data, the comparative analysis of the specificity of second Zipf's "quantity-frequency" law coefficients distribution of the Positive and Negative Elements of Polish-Language Film Reviews COHC was carried out (table VIII), where "Frequency" – the number of COHC elements in which such value of coefficients occurs:

TABLE VIII.
STRUCTURE OF THE SECOND ZIPF'S LAW COEFFICIENTS DISTRIBUTION (M4)

Positive COHC Elements				Negative COHC Elements			
Coefficient a	Frequency	Coefficient b	Frequency	Coefficient a	Frequency	Coefficient b	Frequency
0.016	3	0.004	22	0.001	9	0.029	9
0.022	12	0.007	2	0.001	5	0.041	0
0.028	10	0.010	1	0.002	2	0.052	7

Interpretation of the specificity of Polish-Language Film Reviews COHC from the point of view of the vocabulary richness of the expression of positive or negative judgments (table VIII) could be the following:

– *positive* reviews are characterized by an initially high (in comparison with negative) values of the corrected coefficient ***a*** (a≈0.010-0.027), which indicates a high average level of frequency of most part of the terms in the COHC Element. At the same time, this part of the case is characterized by relatively low values of the corrected coefficient ***b*** (b≈0.0003-0.0009), on the one hand, testifying to a sufficiently rich (in comparison with negative reviews) vocabulary of the text. That is, in general, positive reviews characterized by a greater proportion of terms that are used *uniformly often* throughout the text. This, in turn, may indicate a rather *highly semantic structured opinion*, expressed in a carefully and balanced manner;

– the *negative* reviews are characterized by sufficiently low (in comparison with positive) values of the corrected coefficient ***a*** (a≈0.0002-0.0021), which indicates a lower (i.e., more unique) average level of frequency of most part of the terms in the COHC Element. In this case, this part of the COHC is characterized by sufficiently high values of the

corrected coefficient ***b*** (b≈0.0183-0.0517), which may indicate that in the expression of the main negative emotions, authors use the same words quite often, and the rest of the words are used *randomly*, depending on the context of the film or the specific expression of the author's thoughts. This, in turn, can testify to the *average level of semantic structure of the opinion*, expressed more spontaneously and under the influence of emotions.

Generalizing the results obtained at this stage of the experiment (table IX) it again can be argued that the tonality, initially assigned by the authors specificity of texts, affects the Vocabulary Richness of the analyzed content (H4 is rejected).

TABLE IX.
VOCABULARY RICHNESS STRUCTURE OF THE HIERARCHICAL CORPORA OF POLISH-LANGUAGE FILM REVIEWS

Vocabulary Richness (M4)	**SP COHC Element**	**SN COHC Element**
Average frequency of words occurrence	High	Low
Average speed of new words appearance	Low	Polar
Vocabulary Richness	Sufficiently High	Random
Semantic Structuredness	Highly Semantic Structured	Medium Semantically Structured

CONCLUSIONS

In this paper, authors present the methodology of constructing and analyzing the *Hierarchical Corpora* for the Purpose of Further Forming and Training the Sentiment Lexicon. The main contribution of the paper and the authors' study is finding the answers to the main research questions:

1. The hierarchical structure of the Corpus allows for more flexible and clear identification of the Morphological and Structural features of texts of different tonalities and contexts, originally assigned by the authors.

These differences should contribute to improving the quality of algorithms development for the Sentiment Lexicon creation, allowing the introduction of additional tools for determining the tonality based on the availability of data about semantic properties of the text being studied.

2. The Contextual, Morphological and Structural specificity of texts that have a tone, originally assigned by the authors, has significant differences. The basic features of the Sentiment Patterns for the texts of the two basic tonalities, which were obtained, are the following (table X):

Table X.
SENTIMENT PATTERNS OF THE TEXTS WITH THE DIFFERENT TONALITY

Features	**Subjectively Positive Texts**	**Subjectively Negative Texts**
Contextual Structure	Wide	Moderate
Morphological Types	More Adjectives and Verbs	More Adjectives and Partly Verbs
Emotional Features	Very Emotional	Restrained Emotionally
Writing Style	Colorful	Monochrome
Vocabulary Richness	Structured and rich	Medium Structured and Random

The frameworks obtained by the authors testify to the existence of certain thought and style templates, under the influence of which the formation of texts of various sentiments takes place.

ACKNOWLEDGEMENTS

The research results, presented in the paper, are partly supported by the Polish National Centre for Research and Development (NCBiR) under Grant No. PBS3/B3/35/2015, the project "Structuring and classification of Internet contents with the prediction of its dynamics".

***Abstract*—In recent years, deep learning has shown promising results when used in the field of natural language processing (NLP). Neural networks (NNs) such as convolutional neural networks (CNNs) and recurrent neural networks (RNNs) have been used for various NLP tasks including sentiment analysis, information retrieval, and document classification. In this paper, we the present the Supreme Court Classifier (SCC), a system that applies these methods to the problem of document classification of legal court opinions. We compare methods using traditional machine learning with recent NN-based methods. We also present a CNN used with pre-trained word vectors which shows improvements over the state-of-the-art applied to our dataset. We train and evaluate our system using the Washington University School of Law Supreme Court Database (SCDB). Our best system (word2vec + CNN) achieves 72.4% accuracy when classifying the court decisions into 15 broad SCDB categories and 31.9% accuracy when classifying among 279 finer-grained SCDB categories.**

I. Introduction

Legal court opinions are lawful statements written by a judge providing the justification and legal reasoning for a court ruling. This paper describes an automated document classification model implemented as our Supreme Court Classifier (SCC) system. In theory, SCC could make obsolete many time-consuming manual tasks requiring legal experts. A legal expert would need to read hundreds or thousands of documents in order to place opinions into subject categories, whereas an automatic system like SCC could do this with little or no human effort.[1]

Some document classification efforts, particularly, those using unsupervised approaches, evaluate output based on human evaluation of automatically derived categories. However, when automatic document classification is based on human-defined categories, the results are, arguably, more "natural." Evaluation tends to be more straightforward with human-annotated classifications because it is usually easy for a human being to tell whether or not a document belongs to a human-defined category. In contrast, this determination is harder to make with purely unsupervised methods (e.g., topic modeling [1]), unless a manual component is added. For example, aligning automatically defined categories with some set of human categories will produce clearer results. Human-defined categories have names and notional definitions such as *Criminal Procedures*, *Civil Rights*, and *Federal Taxation* [2].

In contrast, automatically classified categories are usually defined as sets of keywords or other more oblique definitions using words in the corpus. For instance, the case *Roe v. Wade*, 410 U.S. 113 (1973)[2], may fit into a class labeled by a set of keywords like *abortion, reproduction, medical, ...* Although these words describe the case, they do not correctly encapsulate the legal significance of the case. Roe v. Wade would be classified under the *Privacy* legal issue and the *abortion: including contraceptives* sub-issue [2]. Unfortunately, it may be difficult for a human to decide what the boundaries of the classes are defined by these keyword sets. On the other hand, it may be possible to align the output of unsupervised classification with a manual set of categories. In fact, we do this for our baseline system that uses latent Dirichlet allocation (LDA) to model documents and then a logistic regression (LR) [3] model to align the results with the manual categories (see Section IV-A).

While categories can be extracted in many ways, we believe that some sort of human validation is preferable. Moreover, the legal domain often requires documents to be aligned with human-defined legal categories for a majority of legal tasks. For this reason, we have implemented a system that uses pre-defined document categories (from human evaluators) to train a model for classifying legal texts. Specifically, SCC automatically classifies legal opinions from cases seen by the Supreme Court of the United States (SCOTUS), manually classified into topics as part of the Supreme Court Database (SCDB) by Washington University School of Law [2]. Henceforth, we will refer to these as the SCDB categories. The SCDB categories are defined in Section III-A.

Our work systematically tests the application of a variety of machine learning (ML) techniques to automate semantic classification of SCOTUS legal opinions. Our most successful systems are based on neural networks (NNs). NNs are used to solve a variety of natural language processing (NLP) tasks because of their ability to extract relevant information from

[1]SCC can be downloaded from https://github.com/samir1/web_of_law_scotus_classification/ under an Apache 2.0 license (https://www.apache.org/licenses/LICENSE-2.0). In addition to computer code, the repository includes our training/development/test split of the SCDB data, ensuring that our results are both reproducible and comparable to future work.

[2]Roe v. Wade is a supreme court case that is famous in the United States for causing abortion to become legal.

text without having to specify features for any particular domain [4]. We examine two common NN architectures: the convolutional neural network (CNN) [5] and the recurrent neural network (RNN) [6], much like the medical text classification experiments using CNNs conducted by Hughes et al. [7]. Initially used for classifying images, variations of the original CNN architecture are used for NLP tasks [8]. Two main variations of the RNN, long short-term memory (LSTM) [9] and gated recurrent unit (GRU) [10], have recent successful results in their application to sequence modeling [11], [12].

We compare a series of different CNN and RNN architectures to documents represented by word embeddings. We show that our CNN performs better with the legal corpus than the other models implemented. SCC uses neural networks to select one of the SCDB categories for each supreme court case in our validation corpus.

In this paper, we use CNNs and RNNs to classify legal documents with minimal pre-processing, in contrast to other machine learning approaches (e.g., support vector machines) that require manually specifying features for classification or manually determining key words [13]. Any additional pre-processing that could potentially improve performance requires manual editing since each document contains slightly different formatting resulting from OCR errors from scans of printed documents. We measure the efficacy of NN classification techniques applied to our corpus and show that our CNN outperforms RNNs for legal text classification based on SCDB categories (see Table I in Section V). In order to apply our classification models to text, we first represent each word in our corpus as a word embedding (vector representations of words were generated using an unsupervised learning method from Mikolov et al. [14]). We use the publicly available pre-trained word vectors trained on about 100 billion words from part of the Google News dataset.[3] We use 300-dimensional word2vec vectors trained using the skip-gram architecture with negative sampling by Mikolov et al. [14]. We map each word to a word vector and use neural network classifiers on the dataset. Additionally, we present results from using two other word embedding models, fastText [15] and GloVe [16], with our CNN (our best system). We describe the neural neural network models in Section IV and results in Table I.

II. Related Work

We have found a relatively small body of previous work about automatic text classification of legal documents. For example, support vector machines (SVMs) have been used to classify legal documents like legal docket entries [17] and to classify non-English legal texts [4]. Although our work also examines the application of machine learning to a corpus written in the legal context, we focus on classifying SCOTUS legal opinions without significant pre-processing. For example, the Nallapati and Manning [17] system includes several steps of pre-processing before using an SVM to classify documents with human-selected features and labels. We explore more recent automated document classification techniques that do not rely on significant pre-processing and human interaction. Moreover, we present a comparison of different machine learning techniques in order to determine methods with the highest performance for our task.

Our work on SCC is similar to the approach of Wood et al. [1] for classifying medical summaries in that we model our corpus using LDA and classify with pre-defined labels (see Section IV-A). In that study, an initial topic model was derived from some training documents. Then the topic model was modified with pre-labeled data in order to classify the new data. Likewise, we use a combination of LDA and pre-labeled legal opinions to create our baseline classification system. We compare the results of our NN-based classification results to our application of LDA and an LR classification.

Domain-specific automated document classification has been applied to several fields, including electronic medical records. Hughes et al. [7] use convolutional neural networks to detect features for sentence-level classification of medical texts, resulting in a much smaller input compared to our experiments. Unlike SCC, in which we feed an entire document into a neural network, the Hughes et al. [7] model classifies texts by first transposing each document into a matrix of sentences with fixed lengths. Their model also differs from ours in that their model is essentially two sets of two stacked convolutional layers followed by a pooling layer, whereas our model does not have any consecutive convolutional layers. Additionally, one of our experiments (following Hughes et al. [7]) tests the effectiveness of using doc2vec embeddings with an LR model as the classifier. Similarly, Weng et al. [18] use medical texts as the subject of their classification task, although they use a different neural network architecture to classify health documents. Weng et al. [18] apply a complex combination of CNN and RNN architectures to clinical note text classification; their model is summarized by three convolutional and pooling layers followed by a bidirectional LSTM [18]. Moreover, Yin et al. [19] present a comparison of different neural network architectures used to complete a variety of NLP tasks. Such tasks include sentiment analysis, document classification, and part-of-speech tagging. In their text classification experiment, Yin et al. [19] use a pre-labeled set of 10,717 sentences evenly distributed over 19 labels, compared to our unevenly distributed dataset, in which a third of the categories have under one hundred examples and four classes have over 1,000 documents. In contrast, our experiments aim to solve the specific problem of document classification applied to legal texts. Moreover, Kim [20] describes a general CNN used to classify sentences with word2vec word embeddings. Similar to the model we propose, Kim's model also includes three convolutional and pooling layers. We optimize hyperparameters and experiment with a combination of different convolutional, pooling, and dropout layers. We compare applications of the Kim [20] and Hughes et al. [7] models to our legal corpus. We ultimately obtain improved results by using the customized CNN on the SCOTUS legal opinion corpus.

[3]https://code.google.com/archive/p/word2vec/

III. Experimental Setup

A. Dataset

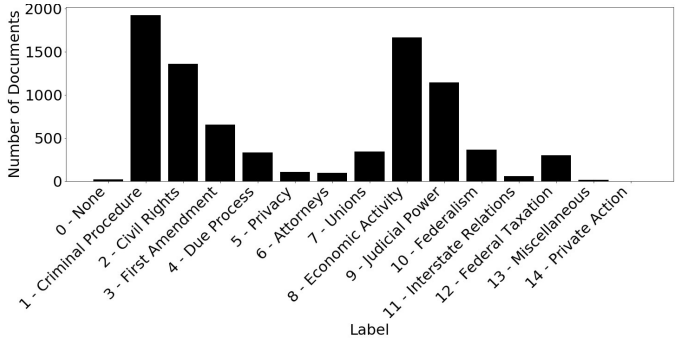

Fig. 1: 15 legal issues

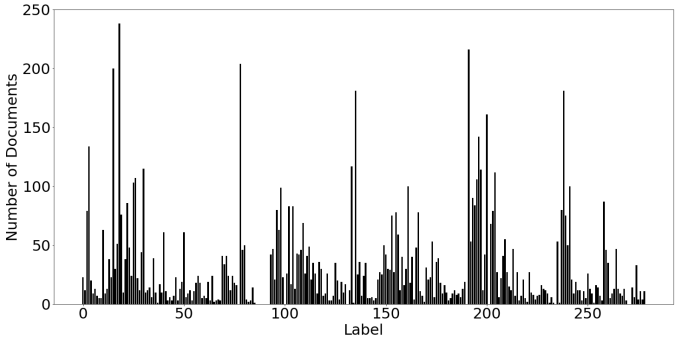

Fig. 2: 279 subtopics

We train and test our system on the manually-categorized SCOTUS legal opinion (Supreme Court Database or SCDB) corpus, from Washington University School of Law [2]. The dataset consists of 8419 US Supreme Court court opinions from "modern" cases (1946-2016), organized into 15 legal categories (Figure 1), which are further divided into 279 subtopics (Figure 2). We chose the modern dataset because both court opinions and pre-defined labels were available through the textacy Python package.[4] Textacy provides a formatted version of modern cases from FindLaw's US Supreme Court legal opinions database. The 8419 documents were randomly divided into training, validation, and test sets with a 80%/10%/10% split. Although the SCDB labels also covered "legacy" cases (1791-1945), FindLaw's database only reliably provided case text from the "modern" era of US law.

B. Initial Processing

Our system first removes (as noise) special characters that refer to footnotes. We also removed a number of characters used in formatting the original printed document. Next, each word in the corpus was mapped to a word2vec vector before being fed into a neural network for classification.

[4]http://textacy.readthedocs.io/en/latest/_modules/textacy/datasets/supreme_court.html

IV. Methods

A. LDA + Logistic Regression

Before the widespread use of neural networks for NLP tasks, probabilistic methods like LDA [21], [22], were used as a standard for a variety of NLP tasks including text classification. We use LDA as a baseline to compare the results of the NN-based classification models. Our process involves using LDA to represent each of the heavily pre-processed legal documents as a series of latent feature vectors. LDA is most commonly used to generate a collection of latent topics for a corpus, and then calculate the probability of a document belonging to a topic. We use the Gensim[5] library to create and train the LDA model. We classify vectors from the implementation of this model using LR.

The LDA Bayesian probabilistic model is an unsupervised machine learning method used to organize documents through topic modeling. In this model, each document is represented as a probability distribution over latent topics. These topics are derived from the assumption that the document's words themselves, modeled as a term frequency-inverse document frequency (tf-idf) matrix, with words represented using the bag-of-words (BoW) model, are distributed over latent topics as defined by the distribution of words in the corpus.[6]

After latent feature vectors are generated to describe each of the documents, we apply an LR to classify the documents into 15 legal issues and 279 legal subtopics. As in Wood et al. [1], we use a combination of LDA and pre-defined labels with corresponding documents to create our baseline classification system.

B. Doc2vec + Logistic Regression

Our first method of document classification using deep learning involves a higher-level application of word2vec. As described in [23], paragraph vectors, often referred to as doc2vec or document vectors, can be used to map semantic meaning from a variable-length document to a fixed-size vector. As in the word2vec learning method, a word is predicted by its neighboring words. The significant difference between the Distributed Memory Model of Paragraph Vectors and other similar learning techniques is that an additional paragraph token (treated like an additional word in the document) is used when learning the paragraph vector. Next, we classify the documents into both 15 and 279 classes using a logistic regression.

C. Bag-of-Words + Support Vector Machine

As another baseline, we represent documents using the BoW model and apply an SVM using Scikit-learn's SVM package[7] with default parameters. We chose SVM as a baseline because it is one of the highest performing traditional ML methods,

[5]https://radimrehurek.com/gensim/

[6]In order to find the ideal number of topics for the LDA-based classification, we conducted the experiment with different numbers of topics ranging from 100 to 600 in steps of 100 and and chose 300 topics because there was not a noticeable improvement in performance with more than 300 topics.

[7]http://scikit-learn.org/stable/modules/generated/sklearn.svm.SVC.html

used for lots of different tasks. Similarly, Kim [20] also uses an SVM benchmark.

D. Word2vec + CNN

For our neural network classification approach, we designed a multi-layer model similar to the one described by Kim [20], but with additional layers and modified hyperparameters.

Our model first creates an embedding layer using pre-trained word2vec word embeddings, and then creates a matrix of documents represented by 300-dimensional word embeddings. We include three sets of the following: a dropout of 0.25, a convolution layer of 128 filters with a filter size of 5, and max pooling layer with a pooling size of 5. We also add a dense layer consisting of 128 units between two dropouts of 0.5 to prevent overfitting. The last layer is a dense layer with size equal to the number of labels for the test (15 or 279).

E. Other Embeddings

In addition to using word2vec embeddings with the CNN, we conduct the same experiments with two other pre-trained word embeddings: fastText vectors[8] from Facebook AI Research (FAIR) [15] and GloVe vectors[9] from Pennington et al. [16]. The pre-trained 300-dimensional fastText vectors are trained on Wikipedia using the skip-gram model described in Bojanowski et al. [15]. The pre-trained 300-dimensional GloVe vectors are trained on Wikipedia and the Gigaword 5 dataset using GloVe model [16].

We use the publicly available pre-trained word vectors trained on about 100 billion words from part of the Google News dataset.[10] We use 300-dimensional word2vec vectors trained using the skip-gram architecture with negative sampling by Mikolov et al. [14].

F. Word2vec + LSTM

One of the RNN-based networks we used to classify our legal corpus is the LSTM, which is defined by these equations:

$$\mathbf{i}_t = \sigma(\mathbf{x}_t\mathbf{U}^i + \mathbf{h}_{t-1}\mathbf{W}^i + \mathbf{b}_i) \quad (1)$$

$$\mathbf{f}_t = \sigma(\mathbf{x}_t\mathbf{U}^f + \mathbf{h}_{t-1}\mathbf{W}^f + \mathbf{b}_f) \quad (2)$$

$$\mathbf{o}_t = \sigma(\mathbf{x}_t\mathbf{U}^o + \mathbf{h}_{t-1}\mathbf{W}^o + \mathbf{b}_o) \quad (3)$$

$$\mathbf{c}_t = \mathbf{f}_t \circ \mathbf{c}_{t-1} + \mathbf{i}_t \circ \tanh(\mathbf{x}_t\mathbf{U}^c + \mathbf{h}_{t-1}\mathbf{W}^c + \mathbf{b}_c) \quad (4)$$

$$\mathbf{h}_t = \mathbf{o}_t \circ \tanh(\mathbf{c}_t) \quad (5)$$

In this model, $\mathbf{x}_t$ represents an input x at time t. The three gates of the LSTM are the input gate $\mathbf{i}_t$, forget gate $\mathbf{f}_t$ and output gate $\mathbf{o}_t$. $\mathbf{c}_t$ is the memory cell state. $\mathbf{h}_t$ is the hidden state. The input weights are defined by $\mathbf{W}$, recurrent weights by $\mathbf{U}$, and bias by $\mathbf{b}$.

Our implementation of the LSTM consisted of the embedding layer formed with pre-trained word2vec vectors, an LSTM layer consisting of 128 units, and a dropout of 0.5 to prevent overfitting. Lastly, we had a dense layer representing the number of labels for the experiment.

G. Word2vec + GRU

Our last experiment involves the memory-enhanced GRU [10], a variation of the RNN. The GRU is described by the following equations:

$$\mathbf{z} = \sigma(\mathbf{x}_t\mathbf{U}^z + \mathbf{h}_{t-1}\mathbf{W}^z) \quad (6)$$

$$\mathbf{r} = \sigma(\mathbf{x}_t\mathbf{U}^r + \mathbf{h}_{t-1}\mathbf{W}^r) \quad (7)$$

$$\mathbf{s}_t = tanh(\mathbf{x}_t\mathbf{U}^s + (\mathbf{h}_{t-1} \circ r)\mathbf{W}^s) \quad (8)$$

$$\mathbf{h}_t = (1 - \mathbf{z}) \circ \mathbf{s}_t + \mathbf{z} \circ \mathbf{h}_{t-1} \quad (9)$$

where $\mathbf{x}_t$ represents an input vector x at time t, $\mathbf{r}$ is the reset gate, and $\mathbf{z}$ is the update gate. The input weights are defined by $\mathbf{W}$ and recurrent weights by $\mathbf{U}$.

As with our CNN and LSTM models, our application of the GRU begins with a word2vec embedding layer. Next, we include a GRU layer of size 128 and a dropout of 0.5 before the final dense layer for classification.

H. Hyperparameters and Regularization

In our experiments, we tested our model with a series of different hyperparameters and found that our best NN systems use 128 units for the RNNs and 128 filters for each of the convolutional layers in the CNN. For both these settings, we tried values of 32, 64, 128 and 256 and 128 gave the best results. Basically, the 128 gave better results than the lower settings and it turned out that the 256 setting could not be run effectively when training with an Nvidia GPU. It seems that additional GPU memory would be required (or a more efficient algorithm) to use 256 units. It is probable that 128 is simply the largest (power of 2) setting that is practical to use given the available equipment. This seems to be supported by the fact that many other NN systems (e.g. Kim [20]) use a value around 100.

Additionally, each of the models are regularized with a dropout [24], which works by "dropping out" a proportion p of hidden units during training. We found that a dropout of 0.5 before the final dense layer and batch size of 32 worked best for the LSTM, GRU, and CNN. We also found that the Adam optimizer [25] worked best for both the for CNN and RNN networks.

V. Results

Our goal is to determine the best method for applying automated document classification to legal texts with the hopes of facilitating legal experts in their classification of court documents. Our experiments look not only at comparing existing networks, but also at developing our own superior network. As shown in Figure I, our CNN model achieves the

[8]https://github.com/facebookresearch/fastText/blob/master/pretrained-vectors.md

[9]https://nlp.stanford.edu/projects/glove/

[10]https://code.google.com/archive/p/word2vec/

highest accuracy, both for the 15-label and 279-label tasks (72.4% and 31.9% accuracies, respectively). We present an analysis of our results.

TABLE I: Classification Accuracy Results on the Test Set

Model	15 labels	279 labels
Word2vec + CNN	**72.4**	**31.9**
fastText + CNN	67.3	25.1
GloVe + CNN	67.1	17.7
Word2vec + GRU	68.6	14.5
Word2vec + LSTM	43.8	6.5
Word2vec + CNN (Kim [20])	65.9	14.7
Word2vec + CNN (Hughes et al. [7])	54.7	19.8
LDA + LogR [21]	40.3	13.4
Doc2vec + LogR [23]	54.1	28.6
BoW + SVM	64.0	30.5

The accuracy results of correctly classifying documents with our CNN, LSTM, and GRU models compared to other classification methods. Our CNN best overcomes the problem of an uneven distribution of classes, as shown in Figures 1 and 2.

The relation between frequency and f-measure for the test set.

Tables II and III show the CNN's (our best system) performance on individual classes. Although the details are slightly different (e.g., a different number of documents for each category), the relative scores are about the same. We now do a more detailed analysis on the development set results, rather than the test set because we do not want to examine the test results too closely and bias our future work. It is clear that the model's accuracy tends to be higher for the most frequent categories. Categories 1, 2, 3, 8 and 9, all of which are labels on more than 50 documents, mostly have f-measures of over 70%, with one outlier at 56%. It is difficult to generalize about the least frequent categories (frequency < 10), including labels 0, 5, 6, 11, 13 and 14, as there is too little data to analyze. Some of these have f-measures of 0 or near 0, and on average, they do much worse than the high-frequency categories. This is expected since the high-frequency categories have more training data and thus provide more evidence for the model to build on. Thus, as expected, cases with correct labels of 1, 2, 3, 8 and 9 tend to be classified correctly and the categories with little to no training data (0, 5, 6, 11, 13, 14) are most often misclassified.

On the other hand, category labels 4, 7, 10, and 12 each have a similar moderate number of test documents (around 30 documents), but have very different results: the model achieves relatively high results for labels 7 and 12 and relatively poor results for 4 and 10. Thus it would seem that the results for labels 4, 7, 10 and 12 cannot be explained purely on the basis of frequency. Figure 3 is a confusion matrix for our CNN results on the development/validation set. We observe some patterns which may help us understand these results. For labels 7 and 12, where the model performs well, the correct category clearly dominates–no other category is marked for more than 4 documents. However, the poorly performing categories, each have a second (or third) dominant category in addition to the correct one. Label 4 (*Due Process*) is applied to 10 true *Due Process* cases and incorrectly classifies 7 as *Civil Rights* cases, 6 as *Economic Activity* cases and 4 as *Criminal Procedure* cases and another 3 miscellaneous erroneous labels. To the extent that a case may be given multiple classifications (*Due Process* and *Civil Rights*) or (*Due Process* and *Economic Activity*), these errors are understandable and may even reflect a defect in the experiment–perhaps cases should have multiple classifications and the one classification per case assumption is unrealistic. Similarly, label 10 (*Federalism*) is applied 14 times correctly to *Federalism* cases and 11 times incorrectly to *Economic Activity* cases (and rarely to other categories). It is expected that some federalist issues (issues about the power of the federal government) will overlap with economic issues. So these may also be understandable errors.

We now attempt to better understand these errors, focusing our error analysis on *Federalism* classification. We examine three samples from our development set, each sample consisted of four cases. We look at 4 cases that are correctly classified by our CNN as *Federalism* cases (True_Fed); 4 cases that were correctly classified as *Economic Activity* cases (True_Eco); and 4 *Federalism* cases that our system misclassified as *Economic Activity* cases (False_Fed). We compare the False_Fed cases to both True_Fed and True_Eco. Our goal is to understand the sort of factors that might cause a human or a machine learning algorithm to mis-classify the False_Fed

documents.

The True_Fed cases include *Testa et al. v. Katt*; *Bethlehem Steel Co. et al. v. New York State Labor Relations Board*; *Rice et al. v. Santa Fe Elevator Corp. et al.*; and *Rice et al. v. Board of Trade of the City of Chicago*. These all involved the interaction of state and federal authorities and laws, including questions of whether a state authority should be compelled to enforce a federal law or whether a state agency/law takes precedence over a federal agency/law.

The 4 True_Eco cases included *Halliburton Oil Well Cementing Co. v. Walker et al.*; *Champlin Refining Co. v. United States et al.*; *United States v. Howard P. Foley Co., Inc.*; and *Richfield Oil Corp. v. State Board of Equalization*. The Halliburton case is a patent dispute. The Foley case is about the government's liability in a contract dispute. The Champlin case examines whether the Interstate Commerce Commission, a federal entity, could require information from an oil refining company operating across several states. While similar to the True_Fed cases in some ways, there is no conflict between a state and a federal authority. The Richfield case is a dispute about whether a state sales tax applies to a sale to a foreign government. This seems similar to Federalist concerns, but there is no conflict between a state and federal authority. Rather the concern is whether or not a state sales tax effects a possibly-foreign transaction.

The False_Fed cases include *Phillips Chemical Co. v. Dumas Independent School District*; *Panhandle Eastern Pipe Line Co. v. Michigan Public Service Commission et al.*; *Wyeth v. Diana Levine*; and *North Dakota v. United States*. These cases all involve financial transactions, state authorities and federal authorities. The topics covered includes: the legitimacy of state taxes on federal land leased to a company; state regulation of alcohol and other goods procured for sale on a federal military base; liability of a drug company (in state civil court) for damages from harm by their drug, even though the FDA, a federal agency, granted them clearance for the drug; and whether the sale of natural gas was subject to state regulation, in spite of a federal law licensing the sale. While some of these issues seem to include federal/state authority conflicts, those conflicts are not as clearly articulated as in the True_Fed cases. So it is clear how experienced annotators may be able to consistently distinguish the *Federalism* and *Economic Activity* classes. However, we would imagine that inexperienced annotators may have trouble.[11] Similarly, machine learning may require more evidence (more documents) to correctly classify these cases.

The sparsity and imbalanced classes of the dataset presented itself as the most challenging obstacle for training the neural networks. For instance, nearly three fourths of all documents fell under 4 of the 15 legal area categories (*Criminal Procedure*, *Civil Rights*, *Economic Activity*, and *Judicial Power*). Not only was there not an even distribution of documents over each of the labels, many of the classes had little to no training data. Furthermore, our input sequence length was several

[11] We would expect lower inter-annotator agreement on these sort of cases.

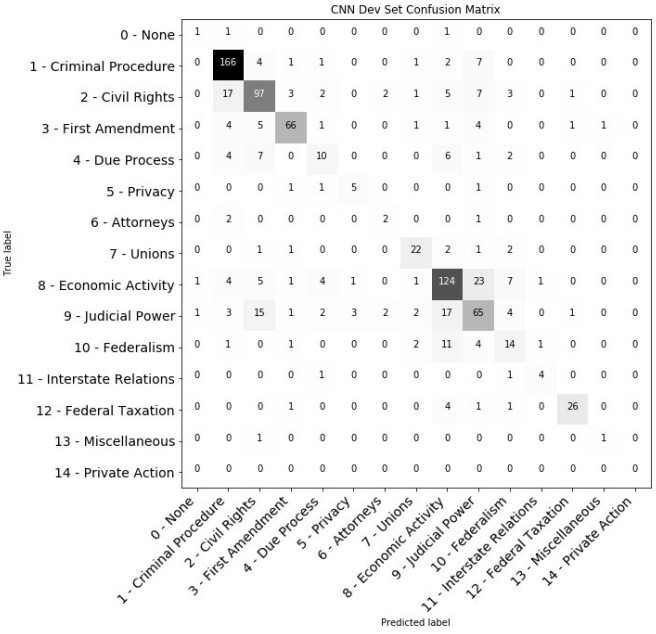

Fig. 3: Confusion Matrix for CNN Development Corpus

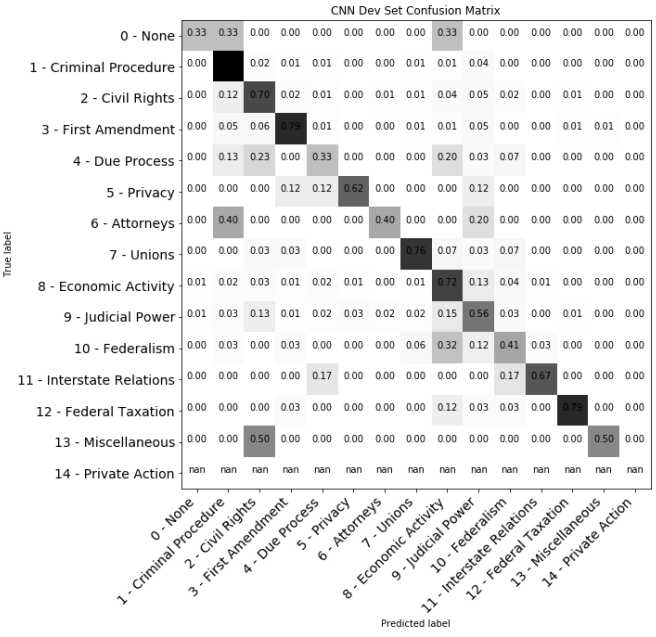

Fig. 4: Normalized Confusion Matrix for CNN Development Corpus

orders of magnitude larger than the inputs in experiments conducted by Kim [20] and Hughes et al. [7].

Due to adjustments we made for the dataset and configuration changes (see Section IV), our CNN performs better than other CNN models (see Table I). The adjusted parameters include dropouts to account for overfitting that occurs earlier in training and the addition of extra layers.

After generating a model for each of our NN-based tests, we use them for our entire corpus and analyze the documents that are misclassified in order to find patterns in the way each of NN architectures complete the classification task. Figure 5 shows a combination of the normalized confusion matrices resulting from classifying our entire corpus with our CNN and the simple RNN models, and each of the true label rows describe the fraction of documents classified per predicted label. As in Figure 5, the CNN performs the best for each of the categories, not just the top four labels (although a small number of errors made by the CNN were with documents from these classes). Unlike our CNN, the classifications from the GRU (our second best system) are more scattered. Figure 5 shows some of labels the GRU most frequently misclassifies. In contrast to the CNN and LSTM, the GRU tends to significantly mis-classify documents from both frequent and infrequent categories, as in the frequent category of *Criminal Procedure* and the uncommon category of *First Amendment*. The GRU also does not classify entire categories correctly, whereas the CNN had high classification accuracy for every category. For example, the GRU mis-classifies every legal opinion in the categories: *Interstate Relations*, *Miscellaneous*, and *Private Action*. Additionally, there was no single label L, such that our GRU system correctly classified more documents in class L than our CNN system.

It seems that the relatively low frequencies of some of the categories is more of a challenge to some of the learning algorithms than others. In particular, CNN and GRU appear to be somewhat more resilient to this effect, than LSTM, as evidence by the merged confusion matrices shown in Figure 5. The LSTM incorrectly classified a majority of the documents to one of the two most frequent labels (*Criminal Procedure* and *Economic Activity*), as shown in Figure 5. Despite categorizing almost all of the documents to only two legal issues, the LSTM did not have a higher accuracy for those two labels. In fact, the LSTM did worse than our LDA baseline system (see Table I). This was somewhat surprising considering that LSTMs often perform similarly to GRUs for a given task. We plan to investigate this further in future research, possibly trying additional models.

As in Chung et al. [11], we test the performance of LSTMs and GRUs. While we apply these models to categorizing legal text, their application was music transcription. Our results show that the structure of the simpler GRU leads to greater accuracy compared to the LSTM when classifying a relatively small number of documents over a large number of labels. The GRU performs better than the LSTM with document-length sequences. The LSTM tends to remember the wrong information needed for the classification because of the small

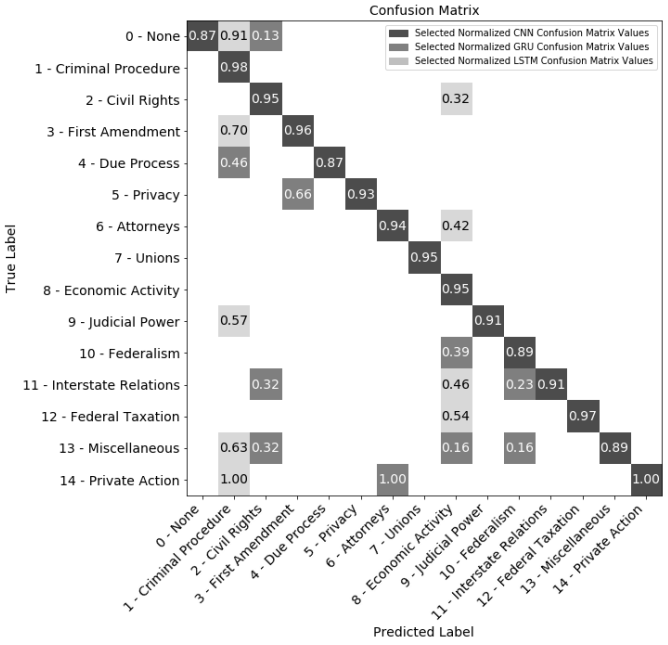

Fig. 5: Merged Confusion Matrix for CNN, GRU, and LSTM

size of the dataset.

Our results also show that the simple BoW+SVM model performs very well for both classification tasks. As Nallapati and Manning [17] mention, "the SVM assigns high weights to many spurious features owing to their strong correlation with the class" [17, p. 442]. In other words, even very infrequent words that have very high correlations with certain classes would help the SVM associate certain words with uncommon classes. This aspect of the SVM seems to explain why the SVM performed well with the 279-label classification task (nearly as well as the best system), in which only a few documents define each category.

In our results, the word2vec model out-performs the simpler bag-of-words model. With more statistical information, the classifiers find common features and patterns to describe categories with higher accuracy. The positive results from our experiment in which we apply an LR to paragraph vectors (doc2vec) show how well the embeddings capture the meaning of the documents (refer to Table I).

The simple GRU network has promising results compared to the CNNs because the GRU is designed to handle long sequences. While a word may carry a large weight in most contexts, the GRU allows for a word's weight to diminish based on specific examples. Yin et al. [19] shows that the accuracy of the CNN decreases as sequence length increases and eventually falls under the accuracy of the GRU. Since our experiments involve inputting entire documents instead of sentences, sequence lengths are orders of magnitude larger than than those used in the experiments conducted by Yin et al. [19], Kim [20], and Hughes et al. [7].

VI. Conclusion and Future Work

In this paper, we find the best method for automated legal document classification is the SCC system that uses a CNN (72.4% accuracy for 15 general categories and 31.9% accuracy for the 279 more specific categories). On the other hand, the GRU architecture shows promising results compared to our tuned CNN (nearly as high for the 15 category task). We believe that a tuned GRU-based network can potentially complete the task with higher accuracy.

The SCC system uses word embeddings from a general domain (Google News). It is possible that embeddings from the legal domain would improve results. Accordingly, we plan to compile a much larger corpus of US legal opinions from appellate and local courts in order to generate domain-specific word embeddings for our model. We will conduct experiments using these embeddings instead of the Google News embeddings used for the results reported here, or possibly in addition.

In future work, we plan to investigate the reasons behind the substantial difference between the performance of the LSTM and GRU. Moreover, we believe that an application of transfer learning as shown in [26] could be used to train classifiers for more specific topics and different subdomains of the legal field.

11th International Symposium on Multimedia Applications and Processing

SOFTWARE Engineering Department, Faculty of Automation, Computers and Electronics, University of Craiova, Romania "Multimedia Applications Development" Research Centre

Background and Goals

Multimedia information has become ubiquitous on the web, creating new challenges for indexing, access, search and retrieval. Recent advances in pervasive computers, networks, telecommunications, and information technology, along with the proliferation of multimedia mobile devices—such as laptops, iPods, personal digital assistants (PDA), and cellular telephones—have stimulated the development of intelligent pervasive multimedia applications. These key technologies are creating a multimedia revolution that will have significant impact across a wide spectrum of consumer, business, healthcare, educational and governmental domains. Yet many challenges remain, especially when it comes to efficiently indexing, mining, querying, searching, retrieving, displaying and interacting with multimedia data.

The Multimedia—Processing and Applications 2018 (MMAP 2018) Symposium addresses several themes related to theory and practice within multimedia domain. The enormous interest in multimedia from many activity areas (medicine, entertainment, education) led researchers and industry to make a continuous effort to create new, innovative multimedia algorithms and applications.

As a result the conference goal is to bring together researchers, engineers, developers and practitioners in order to communicate their newest and original contributions. The key objective of the MMAP conference is to gather results from academia and industry partners working in all subfields of multimedia: content design, development, authoring and evaluation, systems/tools oriented research and development. We are also interested in looking at service architectures, protocols, and standards for multimedia communications—including middleware—along with the related security issues, such as secure multimedia information sharing. Finally, we encourage submissions describing work on novel applications that exploit the unique set of advantages offered by multimedia computing techniques, including home-networked entertainment and games. However, innovative contributions that don't exactly fit into these areas will also be considered because they might be of benefit to conference attendees.

Call for Papers

MMAP 2017 is a major forum for researchers and practitioners from academia, industry, and government to present, discuss, and exchange ideas that address real-world problems with real-world solutions.

The MMAP 2016 Symposium welcomes submissions of original papers concerning all aspects of multimedia domain ranging from concepts and theoretical developments to advanced technologies and innovative applications. MMAP 2016 invites original previously unpublished contributions that are not submitted concurrently to a journal or another conference. Papers acceptance and publication will be judged based on their relevance to the symposium theme, clarity of presentation, originality and accuracy of results and proposed solutions.

Topics

- Audio, Image and Video Processing
- Animation, Virtual Reality, 3D and Stereo Imaging
- Big Data Science and Multimedia Systems
- Cloud Computing and Multimedia Applications
- Machine Learning, Information Retrieval in Multimedia Applications
- Data Mining, Warehousing and Knowledge Extractio
- Multimedia File Systems and Databases: Indexing, Recognition and Retrieval
- Multimedia in Internet and Web Based Systems
- E-Learning, E-Commerce and E-Society Applications
- Human Computer Interaction and Interfaces in Multimedia Applications
- Multimedia in Medical Applications and Computational biology
- Entertainment, Personalized Systems and Games
- Security in Multimedia Applications: Authentication and Watermarking
- Distributed Multimedia Systems
- Network and Operating System Support for Multimedia
- Mobile Network Architecture and Fuzzy Logic Systems
- Intelligent Multimedia Network Applications
- Future Trends in Computing System Technologies and Applications
- Trends in Processing Multimedia Information
- Multimedia Ontology and Perception for Multimedia Users

BEST PAPER AWARD

A best paper award will be made for work of high quality presented at the MMAP Symposium. The technical committee in conjunction with the organizing/steering committee will decide on the qualifying papers. Award comprises a certificate for the authors and will be announced on time of conference.

STEERING COMMITTEE

- **Amy Neustein, Boston University,** USA, Editor of Speech Technology
- **Lakhmi C. Jain, University of South Australia and University of Canberra,** Australia
- **Zurada, Jacek,** University of Louisville, United States
- **Ioannis Pitas, University of Thessaloniki,** Greece
- **Costin Badica, University of Craiova,** Romania
- **Borko Furht, Florida Atlantic University,** USA
- **Harald Kosch, University of Passau,** Germany
- **Vladimir Uskov, Bradley University,** USA

***Abstract*—This paper presents a novel immersive Virtual Reality platform, named ARGO3D, tailored for improving research and teaching activities in Earth Sciences. The platform facilitates the exploration of geological environments and the assessment of geo-hazards, allowing reaching key sites of interest (some of them impossible to be reached in person) and thus to take measurements and collect data as it can be done in the real field. The target audience of ARGO3D encompasses students, teachers and early career scientists, as well as civil planning organisations and non-academics. The overall workflow for real ambient reconstruction, processing and rendering of the virtual ambient is presented, as well as a detailed description of the VR software tools and hardware devices employed.**

I. Introduction

DUE TO technological advances in instruments and detectors over the last two decades, there has been a true explosion in both the amount and the complexity of scientific data, an exponential trend that will continue at ever increasing rate in the coming years. The concept of Big Data - defined not only as datasets too large to be processed with today's tools and methods but also (and perhaps more importantly) as datasets too complex to be effectively dealt with - permeates our world. Over the last decade, hundreds of thousands measurements involving complex 3D datasets of geological structures of the active seismic zones have been collected. The development of new instruments results in increasingly high resolution images and datasets, e.g. from Unmanned Aerial Vehicle (UAV) surveys. These data offer unique opportunities to build long term capacity for geo-hazard maps and studies never realised so far.

Virtual reality (VR) allows to generate virtual environments which gives the feeling of being elsewhere, within a real place. It can be considered as an advanced form of human-computer interface that allows to interact with a realistic virtual environment generated using interactive software and hardware.

The "Virtual Reality", starting from the 60's, has evolved in different manners becoming more and more similar to the real world. Nowadays, two different kinds of VR can be identified: non-immersive and immersive. The former is a desktop-based environment that can simulate places in the real or imagined worlds [11]; the latter takes the idea even further by giving the perception of being physically present in the non-physical world. The non-immersive VR can be based on a standard computer (using e.g. mouse, keyboard or joysticks), whereas the immersive VR is still evolving as the needed devices are becoming more user friendly and economically accessible.

In the past, there was a major difficulty about using VR equipment such as a helmet with goggles, while now new devices are being developed to make usability better for the user. VR is based on three basic principles: Immersion, Interaction, and User involvement with the environment. It offers a very high potential in education [5], [1], industry [13], research [3] and scientific collaboration [10], [8] by making the learning experience more motivating and engaging, and facilitating the investigation of complex scenarios. Up to now, the use of immersive VR in research, educational games and scientific dissemination has been limited due to the high price of the devices and their non user-friendly usability. At the moment, new virtual reality headsets like the commercial *Oculus Rift*™ or smartphone headsets (e.g. Samsung Gear VR), make it possible to access immersive VR in lots of research, educational and dissemination contexts.

This paper presents the first platform for immersive VR in Earth Sciences, here named ARGO3D (Augmented and virtual reality for geology and geophysics - http://argo3d.unimib.it/). Our immersive VR platform facilitates the survey of geological environments and related geo-hazards assessment; the target audience regards early career scientists, civil planning organisations, as well as academic (e.g. students and teachers) and non academic people. Virtual 3D visualization and navigation allows players to fully explore areas of interest for geo-hazards (e.g. the crater of an active volcano), and, thanks to the data collected (and observations) by virtual exploration, to better define and interpret the geological phenomena affecting the selected site. Thus, players will be able to reach more holistic and comprehensive concepts, as the main specific features

This work is supported by MIUR Accordo di programma ACPR15T4_00098

will be viewed from many different scales and perspectives. Moreover, students exhibit conceptual difficulty in interpreting various 2D diagrams and photos, showing 3D phenomena and geological site. Incorporating 3D visualizations into teaching earth related sciences can help the students in learning activities thanks to a wider spatial perspective and thinking, and may help them in improving their spatial ability.

II. Scientific Background

The use of virtual and augmented reality is a novel and extremely innovative method of 3D immersive approach for research and teaching activities in Earth Sciences. Marine and terrestrial environments will be brought directly into laboratories and classrooms giving the researchers and students the feeling of playing a videogame, instead they are exploring real geological key sites. Geological environments are rendered by means of the Structure from Motion (SfM) Photogrammetry technique. 3D scenarios are derived from UAVs regarding terrestrial environments and from submersibles (ROV) for marine environments, with exceptionally high-detailed images.

The ARGO3D platform is tailored with three main purposes: overcoming problems in research, as well as increasing the quality of training and outreaching activities in Earth and Environmental Sciences.

Regarding the research activity, the best way to study geo-hazards in terrestrial and submarine environments (such as landslides, volcanic eruptions, erosion, floods and recent surface seismic ruptures) is to examine rock outcrops and key sites directly in the field. Due to logistic conditions, this activity is often complicated or even impossible: for example, it is not achievable to directly explore the crater of an active volcano due to toxic gases and high temperatures whereas some peculiar geological spots are too far to be reached on foot or by car. Furthermore, very high vertical outcrops are difficult to be analysed in all their spatial extension.

Virtual reality represents a new way to bypass these problems, giving to the researcher the possibility to easily reach key sites of interest and thus to take measurements and collect data, as it can be done in the field. ARGO3D will allow both students and teachers to analyse environments and processes that would be impossible to observe in person.

In regard to the training and outreach activity, teachers will lead the students into virtually-reconstructed 'hard to reach' environments, explaining them the best ways to enjoy the activity and the geological meaning of the different features that appear on the screen. The development of useful teaching and training tools will allow each student to explore in real time virtually-reconstructed 3D environments, to take pictures of significant geological features, to collect basic geological data, as well as to virtually fly above the area and to export features to a GIS environment for further analysis. At the same time, the other students/people will have a chance to observe, just like in a 3D cinema/movie, how their colleagues navigate and interact with the environment. These tools will improve the students observation and field mapping skills, and their knowledge and understanding of areas subjected to natural hazards.

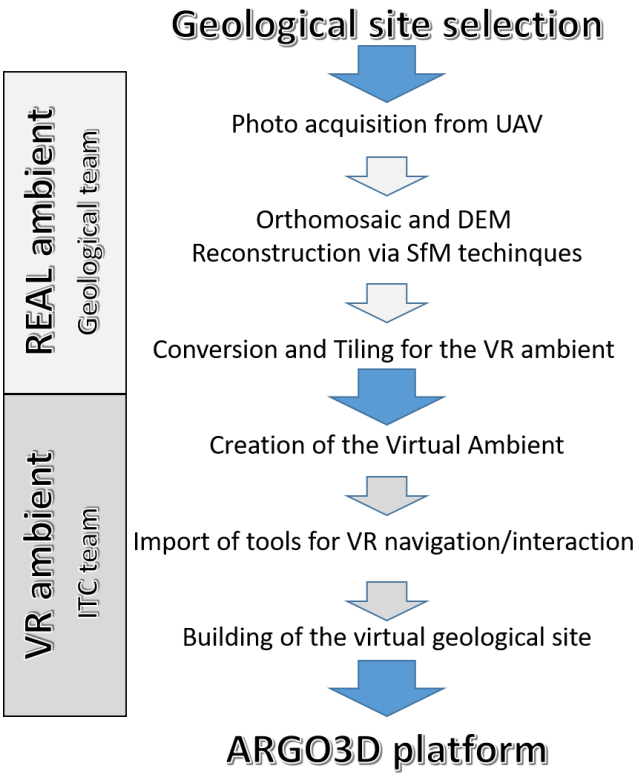

Fig. 1. General workflow describing the main steps involved for performing geological site reconstruction, processing and rendering from the real ambient into the VR ambient.

III. Data Collection and Processing

The overall workflow describing the main steps involved for performing geological site reconstruction, processing and rendering from the real ambient into the VR ambient is shown in Figure 1. Two teams are currently working closely to virtualize the geological sites of interests: geologists and ITC specialists. Geologists are in charge of performing the first three steps that are described in this section.

The input files for the creation of 3D reconstructed environments (in terms of terrain and texture) have been generated thanks to the Structure from Motion algorithms (SfM) applied to Unmanned Aerial Vehicle (UAV or drone)-captured images (e.g. [4]). Such approach involves three main processes (see the first three steps of Figure 1): i) acquisition of a set of images collected in order to cover the selected geological site (with an overlap greater than 60%); ii) processing of these images through a SfM software that leads to the creation of a orthomosaic and a digital elevation model (DEM) as final products; iii) conversion and tiling of the orthomosaic and DEM in a format compatible with Unity.

For the image acquisition we used a quadcopter, DJI Phantom 4 (Fig. 2A), one of the most used and versatile UAVs. They have been collected along a defined flight path (50 m of

altitude) in order to cover the whole selected geological key site with an overlap of 90% (Fig. 2B). In order to accurately georeference the resulting model, in addition to the GPS photo location from the drone, real-world coordinates of, at least, four Ground Control Points (GCPs) have been established within the surveyed area (e.g. [7]; [14]; [15]).

Regarding the SfM processing, UAV-captured photos have been processed with the use of Agisoft PhotoScan [1], a SfM software. The SfM technique allowed to identify matching features in different images, collected along a defined fly path, and combine them to create a sparse and dense cloud (Fig. 2B), a mesh, an orthomosaic and a DEM (Fig. 2C-D) (further details in [12] and [15]). Our model is made of 20722 x 20722 pixels, with a corresponding pixel size of 0.02 m (20 mm), the areal extension in an E-W and N-S direction is equal to 414.44 m. Both the orthomosaic and DEM are in GeoTiff file format.

GeoTIFF file format is widely used for raster imagery and aerial photography since it contains georeferencing information, necessary to establish the exact spatial reference of the file, such as the datum and UTM zone; in our case, we used WGS84 datum and the UTM zone is 28N. The DEM results as a GeoTiff with each pixel associated with altitude value of the real ambient (Fig. 2D), whereas the resulting orthomosaic is composed by pixels each representing the RGB color of the real ambient (Fig. 2C). Both of them have been exported with the same areal extension and pixel size (20 mm/pixel); NULL values in the DEM and orthomosaic have been filled by interpolation (Fig. 2D) and RGB pixel colour from satellite images (50 cm/pixel - image from Worldview-2 sensor, Catalogue ID 1030050051F92D00) (Fig. 2C), respectively.

In order to work as input file for Unity, the DEM must be converted in gray scale 16 bit RAW file (which is a format compatible with most image and landscape editors) with minimum value corresponding to 0 and maximum value to 65536, corresponding to a range of 14.029 m in the real world. Due to the high resolution, in terms of pixel size, of our model, we chose to implement this conversion considering altitude and areal extension of the model in mm. After that, we produced tiles of 512x512 pixels (required to support mobile devices) for the orthomosaic (Fig. 2E) and 513x513 pixels for the RAW file representing the DEM (Fig. 2F). The additional bit along x and y represents an overlap for a better merging of the tiles in Unity environment. In case of the selected key site, it results in 41x41 tiles, already flipped/rotated for the best import in Unity, each one with an extension of 10240x10240 mm.

Each tile is finally associated with a descriptive text file, which adds information about the real environment depicted in the data previously mentioned. The essential information these files must contain are: longitude ("XWorldLimits" keyword contains leftmost one and rightmost one for the current tile), latitude ("YWorldLimits" keyword contains lowest one and highest one for the current tile) and elevation ("MinAlt" keyword is the minimum and "MaxAlt" keyword is the maximum for the current tile). These text files are formatted as JSON strings, used to calculate the position of the player in the real world coordinates.

An example of metadata (Fig. 2D) is provided below:

```
{
"XWorldLimits": [406161.706, 406576.186],
"YWorldLimits": [7316243.990, 7316658.430
    ],
"MaxAlt": 291.108,
"MinAlt": 277.079
}
```

IV. ARGO3D PLATFORM

A. General Description

In order to experience the software properly, the player must wear the VR headset and hold the input peripherals before running the application. At this stage, he also must sit in front of the motion sensor, so that all the startup settings, like default position of the user and peripherals in real world space, are completed.

When the virtual environment is loaded, the user can move and rotate his head to look at the computer-generated objects around himself. As said by Palmer Luckey in [2], there are various infrared lights on the headset, that are used by the sensor to track the position and rotation of the user. When he moves his head, the software rotates the internal camera in order to simulate an immersive well-rounded vision of the environment.

To navigate in the scene, the player can use left hand "Thumbstick" placed on one of the provided input peripherals. These inputs are one for each hand, so multiple functionality are available for various scenarios, such as changing view and velocity through the scene (see subsection IV-B). These must be in the range of sensor placed in front of the peripherals, in order to be localized and rendered in the virtual scene.

B. Use Cases

The player has currently three possible modes to navigate in the scene, called "Walk Mode", "Flight Mode" and "Drone Mode" (Fig. 3). He can switch between these modes in every moment.

When the user is in "Walk Mode" (Fig. 3A) he behaves like a moving rigid body, so he's subject to gravity and can navigate the scene stick to the ground, or doing little jumps, thus experiencing the scene in realistic and immersive way. He can walk in a certain direction and look around thanks to the VR tools and, also, regulate his height with two special keys. This is the default mode, the one the user is in at the beginning.

In "Flight Mode" (Fig. 3B) the user can watch details that can't be observed or reached otherwise, and, at the same time, has a clear view from above of the entire scene. In

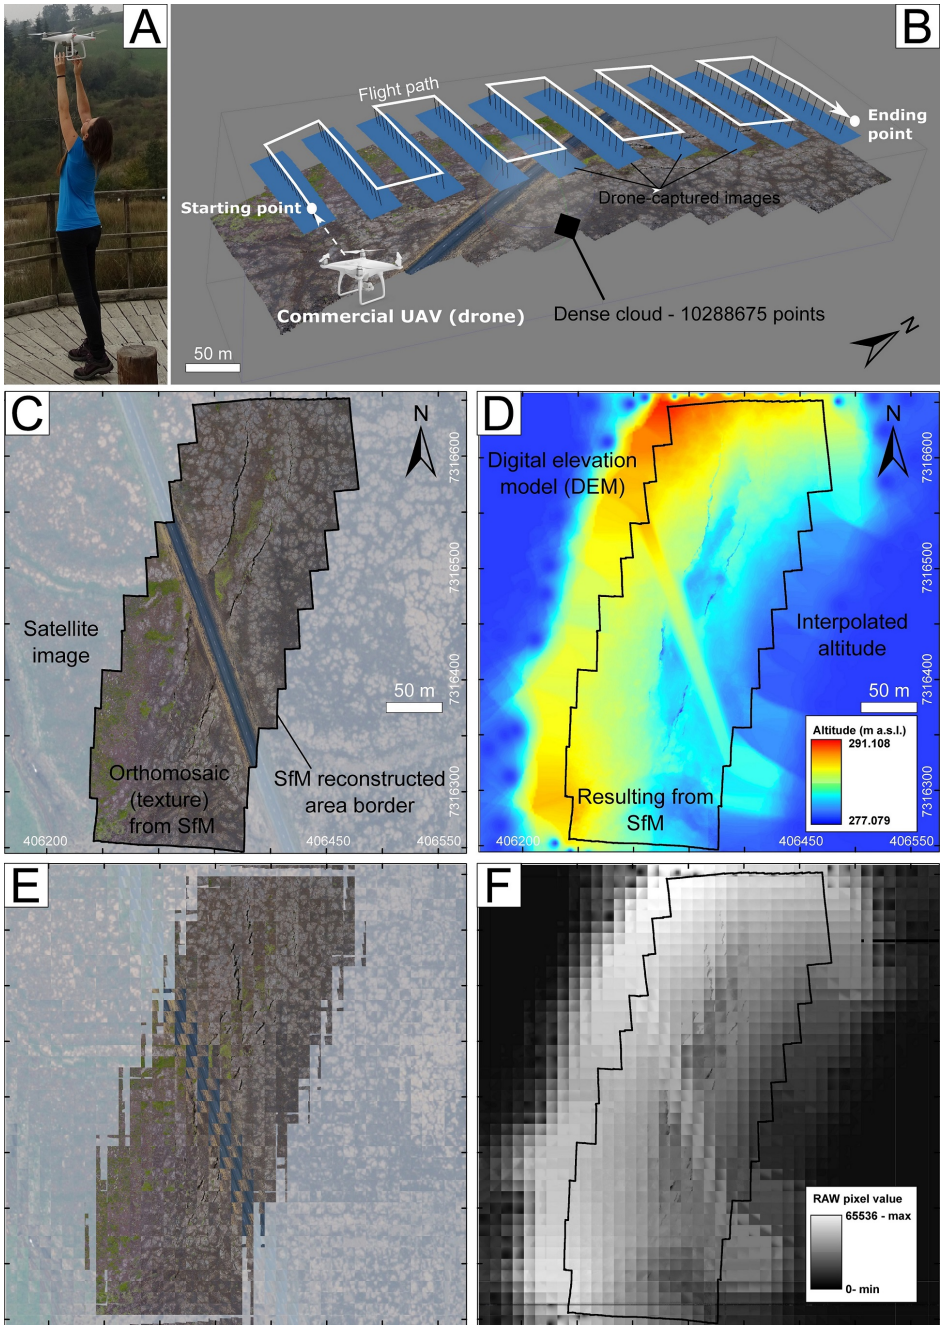

Fig. 2. Main steps involved in 3D reconstruction and processing for the input of the ARGO3D VR platform. (A) UAV (DJI Phantom 4) used for photo collection, person for scale. (B) 3D representation of the flight path, drone-captured photos (with location and orientation) and the dense cloud (resulting from SfM approach). (C) Orthomosaic resulting from the SfM processing (within the black border) characterized by the high resolution of 0.02 m/pixel. Outside the black border, pixels are from high-resolution satellite image (50 cm/pixel - image from Worldview-2 sensor, Catalogue ID 1030050051F92D00). The whole area is scaled at the best pixel resolution (0.02 m/pixel). (D) DEM resulting from SfM processing (within the black border) characterized by the high resolution of 0.02 m/pixel. Outside the black border, DEM values result from IDW interpolation. The whole DEM is scaled at the best pixel resolution (0.02 m/pixel). (E) Tiled texture and DEM (F) ready to be imported in Unity. The tiled texture is in JPG format, DEM values have been converted in Grayscale 16 bit RAW format.

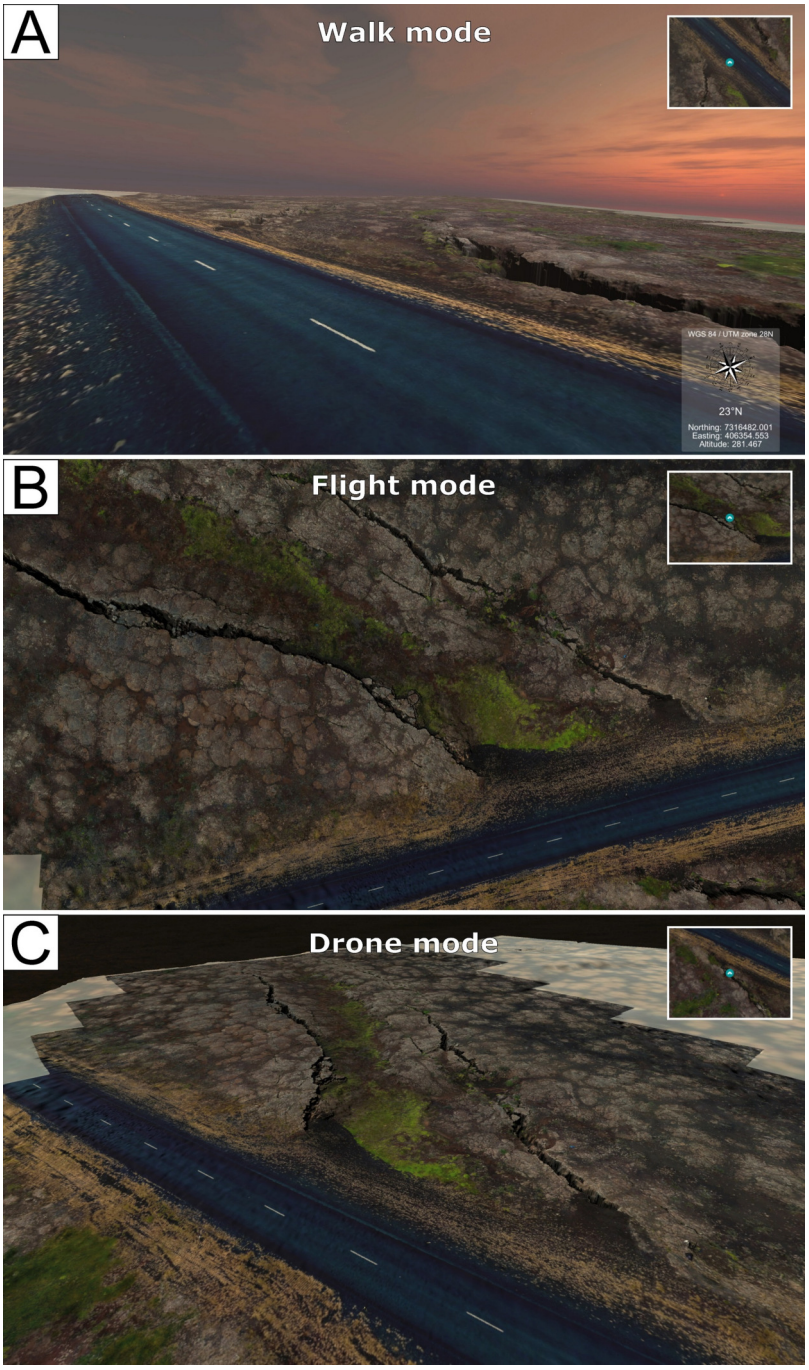

Fig. 3. Three modes of exploration are available in the immersive-VR ARGO3D platform: (A) Walk (B) Flight and (C) Drone mode. Inset in the upper right corner represents location of the player within the VR ambient (blue circle); in the lower right corner, GPS data are reported, they regard easting and northing (in UTM format), altitude (m), as well as the compass and the azimuth of where the player is looking. Road for scale.

this mode, he relocates from the ground position to a certain ground clearance, and moves parallel to the ground as he's flying. The view is oriented orthogonally to the terrain, as the user can look at it from above, experiencing the whole comprehension of the scene. Two special keys allow to get closer or further from the ground, in a range of given values of ground clearance (this to avoid the user to be disoriented being too near to the ground or too far from it). When the user leaves "Flight" mode, it is relocated to the same position he currently was but near to the ground. The subsequent ground clearance depends on the mode the user is switching to: if on "Walk Mode", he finds himself standing on the ground; on the contrary, if on "Drone Mode" he's at the minimum height allowed by this mode.

In "Drone Mode" (Fig. 3C) the user has both the ability to move free in the scene and to not be subjected to gravity. The aim of this mode is to make the user feel like he's a radio-controlled drone, so he can fly on peaks and move to a certain ground clearance, but without the constraint of being forced to look in only one direction. If he tries to get too close to the ground he feels something like an elastic barrier that prevents him from crashing on the ground and relocate him at the correct height. In this mode the user is faster than in the others. A special feature allows him to aim at a point of the scene with tracked controller and rapidly move up to that point by pressing a trigger button. This was meant to be a quick way to reach certain locations far from the user.

In every mode it is visible to the user a GUI that shows useful information: a map in which it is possible to seek user position in the scene (view from above); below the map is located text with real world coordinates (northing and easting) and real world altitude, relative to his position in every moment; below this text there's a compass with azimuth of where the player is looking.

C. Technologies

1) Hardware technologies: The tool on which Virtual Reality is implemented is Oculus Rift (Fig. 4). The Oculus Rift headset uses an OLED panel for each eye, each having a pixel resolution of 1080x1200. The high refresh rate, global refresh and low persistence allow the user to experience none of the motion blurring or judder that is experienced on a regular monitor. It uses lenses with a wide field of view. The separation of the lenses is adjustable by a dial on the bottom of the device, in order to accommodate a wide range of interpupillary distances. The same pair of lenses are used for all users, however there are multiple facial interfaces so that the user's eyes can be positioned at a different distance. This also allows for users wearing glasses to use the Rift, as well as users with widely varying facial shapes.

The Rift has full 6 degrees of freedom rotational and positional tracking. This tracking is performed by Oculus's Constellation used to track the position of the user's head as well as other VR devices, consisting of external infrared tracking sensors that optically track specially designed VR devices.

Fig. 4. Player using the Oculus Rift (VR headset) and the input peripherals.

The constellation sensor comes with a stand of a desk lamp form factor, but has standard screw holes and can be detached from this stand and mounted anywhere appropriate to the user. The Rift, or any other device being tracked by the system, is fitted with a series of precisely positioned infrared LEDs under or above the surface, set to blink in a specific pattern. By knowing the configuration of the LEDs on the objects and their pattern, the system can determine the precise position of the device with sub-millimeter accuracy and near-zero latency.

The Oculus Rift's motion controller system is known as Oculus Touch. It consists of a pair of handheld units, one for each hand, each containing an analog stick, three buttons, and two triggers. The controllers are fully tracked in 3D space by the Constellation system, so they may be represented in the virtual environment, and each controller features a system for detecting finger gestures the user may make while holding them.

2) Software tools: To develop all the scenes and to test the experience it's been chosen Unity3D v. 2017. Unity is composed of a set of windows to control various parts of the scene and development, such as the Scene Window, where it's possible to locate the assets as they'll be seen in the final version of the software, the Game Window, where it's possible to test the runtime behaviour of the software while editing it, and the Hierarchy, where the developer is able to keep track of all the active asset in the scene.

Every asset has a component that describes it. The essential one is the "Transform" component, which describes position, rotation and scale of the object in the scene. If an object is visible he must have a "Renderer" component, which can be a 2D or 3D Renderer, depending on purpose and design. Other important components are "Collider", which calculates where

there's been a collision between objects and collects information about it, "Rigidbody", which simulates the behaviour of an object subject to kinematic and dynamic laws.

When a script, which implements an object-oriented paradigm, is created, it is attached to the object as a component. It's responsible of computation of data, but also of controlling and coordinating components, in order to obtain aimed behaviour in the scene.

V. Related Works

VR has been extensively used in geosciences. In this section we give an overview of some interesting recent use cases exploiting VR technologies.

Kinsland and Borst in [9] have presented the utility of 3D virtual reality systems in the interpretation of various 3D geologic/geophysical datasets. They have more than 10 years experience mainly exploiting large tiled display systems. In their studies they have identified some reasons that can lead to low utilization of the investigated systems for geological studies, i.e.: geologists would like to use their own desks to access other data useful for interpretation, they would require support from computer specialists, they experience motion sickness. Therefore, in the design of our ARGO3D platform we have tried to minimize these issues by improving the software usability and portability to common desktops with head mounted device and mobile devices.

Cerfontaine et al in [2] presented the workflow used to create immersive visualizations and spatial interaction for geophysical data with head mounted devices. They have used Unreal Engine 4 as VR tool for developing the platform to perform simple scene navigation (more interaction mechanisms are foreseen as future works). For the ARGO3D platform it was decided to use a different game engine and editor: Unity 3D 2017. This game engine was best-suited for our development, because the complexity of scripts and the weight of the computation is quite proportional to the amount of asset and functionality of the software. This is different from other game editors, which need more work and computational power to reach initial acceptable performances. Unity supports the object-oriented programming language C#, that is more modular, so it is possible to define different functionalities in different period of development, more simple and structured, so very easy to read and understand; C# also has very good performance compared to his simplicity. Unity is much more documented on the web, so it's been easy to tackle most of the problems.

Finally, the authors in [6] discuss how VR technology could support geohazard research. In our project, we are further expanding the investigation of the application of VR for geo-hazards' assessment, by implementing the ARGO3D platform.

VI. Conclusions

We presented the first results of our innovative research centered on experimenting and implementing a new approach designed to use the immersive VR for geo-hazards' assessment. Such research results in a platform, here named ARGO3D, that contains several ad-hoc tools, and will be soon available on http://argo3d.unimib.it/. Applications comprise both research and teaching activities in Earth Sciences, the target audience spans from academic to non-academic people. ARGO3D is designed to facilitate communicating geological environments and hazards to students, early career scientists, civil planning organizations and citizens.

We described the overall workflow for real ambient reconstruction, processing and rendering of the virtual ambient, the VR tools and hardware devices employed.

Our approach is aimed at giving the possibility of navigating into a 3D geological environment, where it is possible to observe in detail and measure objects of interest for Earth Sciences and geo-hazards in particular. This approach allows to re-create in laboratory real geological settings in order to share data and study key sites of interest at any time. Moreover, this allows to investigate also sites which are logistically difficult to reach in the field, or dangerous as, for example, active volcanic areas.

***Abstract*—To implement efficient computer vision mechanisms, efficient image clustering methods are important. The paper elaborates a clustering method based on particle swarm optimization (PSO) which provides automatic establishment of clustering parameters. The developed PSO based clustering method was tested on 860 images for a car vision system and its results and contribution to the pattern recognition quality improvement were assessed in comparison with fuzzy C-means and k-means. The results do not differ significantly, but distinction in average time of work for these methods was noted. The PSO clustering method is faster than k-means and slower than fuzzy C-means. However, fuzzy C-means method does not guarantee correct results during the further analysis, so the PSO clustering method can be more efficient for implementation in computer vision systems.**

I. Introduction

COMPUTER vision is one of the most prospective fields in different spheres of life [1-4]. It is a wide area of theoretical materials and technical methods connected with object detection, object tracking and object classification. It can be embedded in devices in order to automate their working processes and make them perform pattern recognition tasks.

To provide the correct work of pattern recognition, it is necessary to elaborate efficient methods of image processing; and clustering is one of them. However, many existing clustering methods depend on manual tuning and do not guarantee accurate results in case of visual information distortion.

Usage of machine vision is one of the most important challenge of automatization in different spheres of social life. Authors study implementation of machine vision for autonomous vehicles. Main tasks of such research are defining of other road users (autonomous cars), recognition of road infrastructure and road marking [5-7].

Most of the existing solutions are particular – it seems necessary to make some adjustments to use such solutions in other conditions. Some of the approaches for organizing machine vision need a lot of computing power.

The paper is dedicated to the ways of pattern recognition quality improvement. Relevance of the proposed paper to the computer vision area can be explained by the fact that computer vision can be embedded in cars, drones and used in order to automate such process as road traffic and space monitoring. It is vital to provide a correct work of computer vision, because its errors can have fatal consequences: victims and damages.

In order to avoid such consequences, the authors state the purpose to elaborate efficient methods of image processing. Among them it is possible to call segmentation and clustering. However, they do not guarantee accurate results in case of visual information distortion or high noise level. The reason is in the need for manual tuning of these methods.

The authors of the paper tried to develop a clustering method based on the particle swarm optimization (PSO) that sets parameters automatically. This method also includes *k*-means clustering method, which is intended to group pixels into predetermined number of clusters by calculating the minimum value of distance function. Relative to the PSO, the particle group motion (pixel-by-pixel passage through the image) and search for the best solution for the entire swarm (search for pixel with a maximum average intensity value in a certain region) are used.

In comparison with the original *k*-means method, the need of cluster amount predetermining by user is eliminated, and apart from the operation of distance function minimization the operation of color function minimization is added. An object in an image (or a part of an object) is characterized with relative color uniformity, i.e. if the distance function for pixels *a* and *b* that belong to one object tends to minimum, their color function also tends to minimum. In this paper experiments with non-spoiled images are represented in order to prove preparedness of this method for implementing in process of work with distorted visual information.

Further structure of this paper is as follows. Section 2 provides the overview of the relevant works and sets the theoretical background. Section 3 considers the research task statement and the suggested clustering method based on particle swarm optimization. Section 4 demonstrates the experimental results. Conclusions and future research directions are outlined in section 5.

II. Related Work and Theoretical Background

One of the main purposes in the area of computer vision is the error percentage reduction in the pattern recognition. In this paper the pattern recognition error is a situation when the needed object in the image either is not detected or is detected incorrectly. The pattern recognition process consists in three basic stages:

- filtering and image preparation for the analysis; the image preparation includes image compression, selection of needed regions, ridding of noise;
- logical processing of filtering results, which is responsible for object detection in the filtered image;
- decision-making based on the results of the logical processing, which implies classification of the detected objects.

Image segmentation [8] is related to the ways of increasing the accuracy of recognition. It is a process of dividing a digital image into a set of its constituent regions in order to select objects and their boundaries. As there is no general solution for the image segmentation task, different methods and algorithms were created, which are oriented to the determined categories of images. Depending on the category of the image, its priority properties and then the ways of grouping them are chosen.

The methods listed below can serve as examples:

- active contour method [9] (deformation of original image contours to the boundaries of the specified objects);
- topological alignment method (matching two consecutive frames in the image stream);
- watershed method [10] (establishment of boundary watersheds between different segments according to the determined rule).

As for semantic part [11-13] of the visual information, the following kinds of image segmentation can be distinguished:

- semantic segmentation based on the use of Fully Convolutional Networks (pixel-to-pixel mapping without prior allocation of specific areas);
- weakly supervised semantic segmentation (with use of bounding frames and special labels on the images);
- region-based semantic segmentation (region allocation based on predetermined grouping rules).

One of the segmentation methods is clustering. Image clustering is a division of pixels into several non-intersecting groups (clusters) in such a way that pixels from the same group have similar features, meanwhile the features of pixels from different groups vary significantly from each other.

Clustering task statement:

1) There are: X – a set, which consists of N objects; C – a set, which consists of M identifiers, such as number, name or label; the distance function between objects $d(x,x')$, where x and x' are two objects in the image. The distance function is represented in (1):

$$d(x;x') = \sqrt{(x-x')^2} \tag{1}$$

2) It is necessary to divide the set of objects X into M non-intersecting subsets (clusters) in such a way that each cluster was represented as an aggregate of objects from the set X, whose distance function values d are closed to each other. In addition, the following conditions must be fulfilled:
   - each cluster is assigned a cluster identifier C_j; $j \in [1; M]$ (number, name, label);
   - each object x_i; $i \in [1; N]$ can belong to one and only one cluster.

There are plenty of different clustering methods. Some of the most spread examples of these methods are k-means and fuzzy C-means. The idea of the k-means algorithm is to minimize the distance between objects in the clusters. The algorithm stops working when the further minimization becomes impossible.

The main step of the k-means algorithm:

1) At the beginning of the algorithm the quantity of clusters is set and then, according to the determined rule, centroids are allocated (centers of mass of clusters). The minimizing function is represented in (2):

$$J = \sum_{i=1}^{N}\sum_{k=1}^{M} d(x_i, c_k) \tag{2}$$

   where X – a set of clustering objects, $x_i \in X$ a clustering object, $i \in [1; N]$, C – a set of clusters, $c_k \in C$ – centroid, $k \in [1; M]$, M – an amount of clusters, N – an amount of objects, d – a value of distance function between object and centroid.
2) Each object correlates with the determined cluster by calculating the value of the distance function between this object and each center of mass and then selecting the least one among the calculated values. After that the centers of mass of clusters are recalculated, as in (3):

$$c_j = \frac{(\sum_{t=1}^{T}(x_t))}{T} \tag{3}$$

   where $x_t \in C_j$; $t \in [1; T]$; T – an amount of objects in the cluster C_j; j – a cluster number, $j \in [1; M]$; M – an amount of clusters.
3) If $c_j = c_j - 1$, it means that object clustering is completed, otherwise it is necessary to return to the second step and recalculate centroids again.

Fuzzy C-means algorithm is based on the fuzzy logic, i.e. on the assumptions that each clustering object from the set X, which consists of N objects to some extent belongs to a particular cluster from the set of clusters C.

The main step of the fuzzy C-means algorithm:

1) As input values, there are: M – an amount of clusters, $1 < m < \infty$ – a measure of accuracy, $0 < \varepsilon < 1$ – a criterion of the end, $U_0 = u_{ij}(x_i; c_j)$: $x_i \in X$; $c_j \in C$ –

a weighting matrix of belonging of the clustering object $x_i \in X$; $i \in [1; N]$; to the cluster $C_j \in C$; $j \in [1; M]$; $0 < u_{ij} < 1$:

The minimizing function is shown in (4):

$$J = \sum_{i=1}^{N} \sum_{k=1}^{M} u_{ij}^{m} \cdot d(x_i, c_k) \quad (4)$$

2) Then the centroids are calculated, as in (5):

$$c_j = \frac{(\sum_{i=1}^{N} u_{ij}^{m} \cdot x_i)}{\sum_{i=1}^{N} u_{ij}^{m}} \quad (5)$$

3) After this the weights are recalculated, as in (6):

$$u_{ij} = \frac{1}{\sum_{k=1}^{M} \left(\frac{d(c_j, x_i)}{d(c_k, x_i)} \right)^{\frac{2}{m-1}}}$$

4) The next step is to compare $|U_k - U_{k-1}|$ with the value of ε. In case the first value is less than the second one, the algorithm is finished, otherwise it is necessary to return to the step 2 and recalculate the centroids.

III. Clustering Method Based on Particle Swarm Optimization

The algorithms mentioned above have quite substantial drawbacks, such as:

- sensitivity to outliers (values that are allocated from the total sample);
- need for the user to specify the amount of clusters beforehand;
- presence of some uncertainty degree in the threshold parameter definition;
- uncertainty of actions with objects that possess the properties of two different clusters simultaneously;
- need for the user to specify clustering parameters.

Due to shortcomings of clustering algorithms represented by authors, there is such a situation when the clustering task can be solved incorrectly, namely: for the clustering objects $x_i \in X$; $i \in [1; N]$ and the clusters $C_j \in C$; $j \in [1; M]$ with the centroids c_j $\exists t \neq j$ $g_{xi} \neq g_{ct}$; $g_{xi} = g_{cj}$; $x_i \in C_t$; $x_i \notin C_j$; where g_{xi} – a label of belonging of the i^{th} object to the cluster, g_{cj} – a label of belonging of the centroid to the j^{th} cluster.

In this way, authors of this paper have the following research task: it is necessary to find such centroids c_j for the $C_j \in C$ that $\forall x_i \in X$ $\exists! C_j$ $g_{xi} = g_{cj}$; $x_i \in C_j$; $g_{xi} \notin g_{ca}$; $x_i \notin C_a$; $g_{xi} \neq g_{cb}$; $x_i \notin C_b$; $a \in [1; j-1]$; $b \in [j+1; M]$.

To solve this pattern recognition quality improvement task, it is essential to exclude the user's direct participation in the process of specifying the amount of clusters and rule (or set of rules) during the initial centroid allocation.

Methods providing automated image segmentation and clustering were proposed in many scientific works. In the [14] processing of image segments for fruit peel defects detection was proposed. The source image is divided into segments, which are given as an input to Adaptive Artificial Neural Network (AANN). The image processing is automated, because AANN adapts to each input and its features.

Segmentation based on color maps was developed in the article [15]. Its authors in the research rely on four-color labeling theorem. They improved the existed four-color labeling method, which used random initial distribution and developed heuristic four-color labeling. This iterative algorithm generates more reasonable color maps with a global view of the whole image and provides better results in case of images with clutters and complicated structures.

In the paper [16] image clustering is used in order to provide automated retinal screening. In the described method heuristic based clustering is included. Initial centers are allocated according to measures defining statistical distribution of data is incorporated in the proposed methodology.

Another effective clustering method was proposed for heterogeneous disease expression data [17]. Recursive K-means spectral clustering method (ReKS) was developed, which was found to be superior to the hierarchical clustering method and much faster than *k*-means.

In the work [18] a novel data clustering algorithm was elaborated. It is based on heuristic rules, which are built according to *k*-nearest chain, and give an opportunity to get rid of the need in specifying the number of clusters. K-Nearest Neighbors Chain (KNNC) serves as basis for proposing two heuristic rules to find initial clusters and their proper amount. The first heuristic rule reflects the degree of separation of clusters and the second rule determines the inner compactness of a cluster.

In order to resolve the issue of arbitrary choices on clustering parameters, authors decided to use some elements of particle swarm [19] optimization.

Particle swarm optimization [20] method consists in the following steps:

1) There is a swarm of S particles, and each of them is assigned a coordinate $x_i \in \boldsymbol{R_n}$ and a velocity $v_i \in \boldsymbol{R_n}$; f: $\boldsymbol{R_n} \rightarrow$ R is an objective function that needs to be minimized; p_i – the best known position of the i^{th} particle (in the context of solving the given optimization problem); g – the best known state of the entire swarm.
2) For each particle $s_i \in S$; $i \in [1; S]$ it is needed to:
   - generate an initial position using a random vector in the range from r_{min} to r_{max} these values are lower and upper boundaries of the search-space, respectively;
   - assign to the best known position of particle p_i its initial value x_i;

- in case $f(p_i) < f(g)$, there is a necessity to update the value from g to p_i;
- generate velocity value of the particle v_i, which belongs to the interval from $-(r_{max} - r_{min})$ to $(r_{max} - r_{min})$.

3) It is required to repeat the following sequencing for each i^{th} particle until the predetermined stopping criterion is fulfilled:
   - generate random vectors r_p and r_g, which have a range of admissible values in the interval between 0 and 1;
   - update the velocity value of the particle, as in (7):

$$v_i = w \cdot v_i + \varphi_p \cdot r_p \times (p_i - x_i) + \varphi_g \cdot r_g \times (g - x_i) \quad (7)$$

   where × is a vector product operation, w; φ_p; φ_g – are the parameters specified by user;
   - change the particle position according to (8):

$$x_i = x_i + v_i \quad (8)$$

   - compare the values of $f(x_i)$ and $f(p_i)$; if the first value is less than the second one, it is needful to update the best known position of the particle from p_i to x_i and then in case $f(p_i) < f(g)$; it is necessary to change the value of the parameter g to the value of the parameter p_i;
4) As a result of the operations above, the parameter g will contain the best solution.

For pattern recognition quality improvement the authors of the paper developed a clustering method which combines some elements from particle swarm optimization (numerical optimization method) and from k-means algorithm (cluster analysis method). From each method such operations were selected that do not require random parameter settings and do not take into account user's subjective opinion (user has just an observing role). In this clustering method all the parameter calculation will happen automatically, and the user no longer needs to generate manually any input values.

It is necessary to normalize the source image before using the developed algorithm. Normalization allows making an image insensitive to the light changes, ridding it of unnecessary noise.

It is achieved by dividing the RGB vector components of each pixel by the length of this vector, as in (9):

$$(r', g', b') = \left(\frac{r}{\sqrt{r^2 + g^2 + b^2}}, \frac{g}{\sqrt{r^2 + g^2 + b^2}}, \frac{b}{\sqrt{r^2 + g^2 + b^2}} \right) \quad (9)$$

where r, g, b are the initial values of pixel's RGB vector; r', g', b' are the normalized values of pixel's RGB vector.

The algorithm of the developed clustering method consists in the following procedures:

1) Rounding W' pixels horizontally and H' pixels vertically to the nearest values of W and H, respectively, which are multiple of 10.
2) Sequential selection of 10 by 10 regions (clusters) in the image and search for a pixel with a maximum average intensity value in each region – these pixels will be centers of mass c_j; $j \in [1; W \cdot H / 100]$ (in case there are more than one pixel with a maximum average intensity value in the region, it is possible to choose any of them). The formula of pixel's average intensity calculation is represented in (10):

$$I_{av} = \frac{(r' + g' + b')}{3} \quad (10)$$

   where r', g', b' are the normalized values of pixel's RGB vector.
3) Comparison of the rounded average intensity values for elements with maximum average intensity values from neighboring regions. It was found empirically by authors that the most effective rounding is to two decimal places. If the rounded average intensity values are equal to each other, two neighboring clusters are combined into one. In the new cluster the centroid is the pixel with a maximum average intensity value. It is necessary to repeat this step until there are M clusters c_j; $j \in [1; M]$ with the pairwise distinct rounded average intensity values of the centers of mass.
4) Calculation of two parameters for each pixel x_i; $i \in [1; W \cdot H]$ relative to each centroid: distance function d and so-called color function f. The color function is represented in (11):

$$f(x_i, c_j) = \sqrt{(r'_{xi} - r'_{cj})^2 + (g'_{xi} - g'_{cj})^2 + (b'_{xi} - b'_{cj})^2} \quad (11)$$

   where r'_{xi}; g'_{xi}; b'_{xi} are the normalized [19] values of RGB vector of the pixel x_i; c_j is the centroid of the cluster C_j; r'_{cj}; g'_{cj}; b'_{cj} are the normalized values of RGB vector of the centroid c_j.
5) Then for the pixel x_i it is necessary to find a centroid c_a, $a \in [1; M]$ relative to which the square root of distance function value will be minimum and a centroid c_b; $b \in [1; M]$ relative to which the value of color function value will be minimum. After that the following differences need to be calculated, as it is represented in (12) and (13):

$$d_{diff} = | d(x_i, c_a) - d(x_i, c_b) | \quad (12)$$

$$f_{diff} = | f(x_i, c_a) - f(x_i, c_b) | \quad (13)$$

6) The function, whose difference was less, is chosen as a priority function (in case d_{diff} equals f_{diff}, the distance function obtains a priority, because pixels that are closer to each other more likely belong to the same object than the ones that have similar colors). The allocation of pixels to clusters is realized according to the priority function, i.e. the pixel x_i will be assigned to a cluster, if the priority function value

between this pixel and this cluster's centroid is minimal.

7) Ridding the image of noise:
For this purpose the authors chose non-local means method. It is illustrated in (14):

$$u(p)=\frac{1}{C(p)}\int_{\Omega} v(q), f(p,q)dq \quad (14)$$

where *u(p)* is the filtered intensity value of pixel color component at point *p*, *v(q)* is the unfiltered intensity value of pixel color component at point *q*; *f(p; q)* – weighting function, *C(p)* – normalizing factor.
As the weighting function Gaussian function is used, it is shown in (15):

$$f(p,q)=e^{\frac{-|B(q)-B(p)|^2}{h^2}} \quad (15)$$

where *h* is the filter parameter (in general, for RGB color images *h* = 3), *B(p)* is the local average intensity value of color components of pixels around the point *p*, *B(q)* is the local average intensity value of color components of pixels around the point *q*.
Normalizing factor *C(p)* is calculated, as in (16):

$$C(p)=\int_{\Omega} f(p,q)dq \quad (16)$$

The developed clustering method uses the following elements borrowed from the particle swarm optimization method: particle group motion (pixel-by-pixel passage through the image), search for the best solution for the entire swarm (search for pixel with a maximum average intensity value in a certain region).

At the same time the main differences from the original algorithm are the next points: each particle has a fixed velocity value which excludes the necessity of its manual recalculating by user, initial particle parameters are not specified randomly.

As for the *k*-means cluster analysis method [21], its next aspects were improved: the need of cluster amount predetermining by the user was eliminated, apart from distance function minimization an operation of color function minimization was added, which gave an opportunity to increase the probability that pixels will be assigned to clusters correctly.

IV. Experiments

To check the effectiveness of the clustering method based on particle swarm optimization 860 test images of cars and 860 images of road signs were picked and normalized [22].

For this purpose the mixture of manual photos, images provided by Stanford University laboratory and images from Russian Traffic Sign Dataset (both datasets are publicly available) was used. Authors have analyzed existing pictures with some samples with ideal results of clustering and figure recognition.

Fig. 1 and Fig. 2 outline examples from this set of test images.

The normalization [23] results of these source images are showed in Fig. 3 and Fig. 4.

Fig. 5 and Fig. 6 depict the work results of the clustering method based on particle swarm optimization.

One of the shortcomings of the developed method is that optimal rounding of the average intensity value for cluster combining empirically established by the authors is not universal.

It may provoke two opposite situations:

1) there are extra clusters in the output image, especially in the places of glare;
2) in the output image several different objects are merged into one cluster.

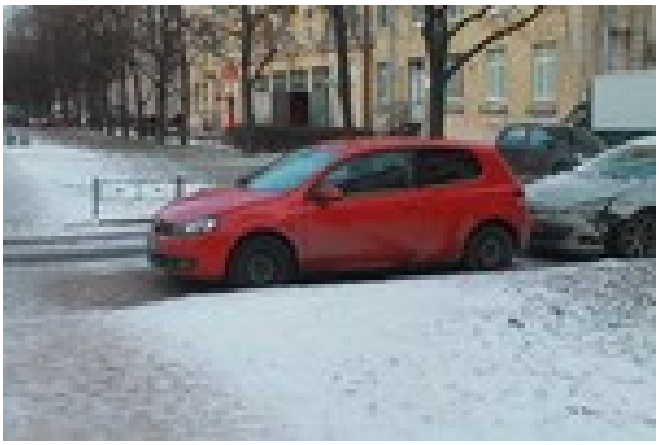

Fig. 1. Source image of a car

Fig 2. Source image of a road sign

Fig. 3. Normalized image of the car

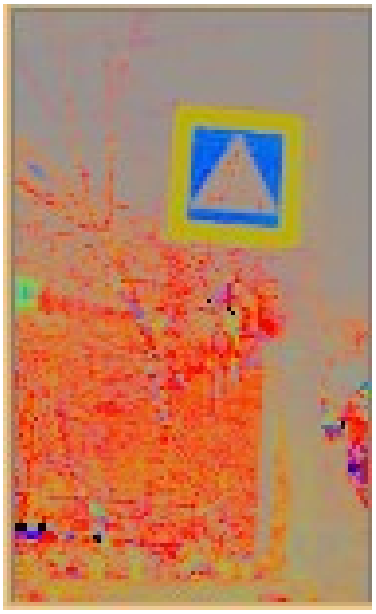

Fig. 4. Normalized image of the road sign

Fig. 5. Clustered image of the car (PSO clustering method)

The examples of work of the clustering method based on the PSO with reduced number of decimal places (1 decimal place) in the rounded average intensity value are represented in Fig. 7 and Fig. 8. All the objects were combined into one.

Thus, the image in Fig.7 seems to be one-colored – the proposed approach can find only one color, so, it seems impossible to recognize any figure on the picture.

Fig. 6. Clustered image of the road sign (PSO clustering method)

Fig. 7. Example of clustering quality worsening because of reduced number of decimal places in the rounded average intensity value (car image)

The examples of work of the clustering method based on the PSO with increased number of decimal places (3 decimal places) in the rounded average intensity value are represented in Fig. 9 and Fig. 10. In the given image there are extra detected regions: piece of land, parts of sky, building.

Also, this method depends on the input image size: the more the number of the analyzed pixels, the greater is risk that more clusters will be detected, and due to this the time of work will be enlarged. This causes the necessity of proportional reducing the source image size or increasing the initial cluster size.

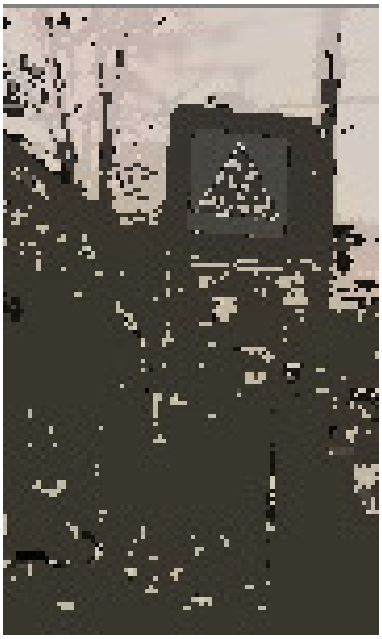

Fig. 8. Example of clustering quality worsening
because of reduced number of decimal places
in the rounded average intensity value (road sign image)

Fig. 9. Example of clustering quality worsening
because of increased number
of decimal places in the rounded average intensity value (car image)

The example of work of the clustering method based on the PSO with increased number of resultant cluster quantity due to absence of preliminary image size reduction is represented in Fig. 6. The size of the source image of the road sign is 500 × 250. It is notable that in the resultant image many extra clusters were detected that during further analysis can provoke different issues.

To perform clustering, the authors reduced proportionally the image size. Currently the size of reduced image needs to be established empirically. Particularly, for the images represented in this paper the maximum size of 150 pixels wide and tall was chosen.

Thus, the developed clustering method currently is suitable for small images, which are not overloaded with details and excessive amount of glares.

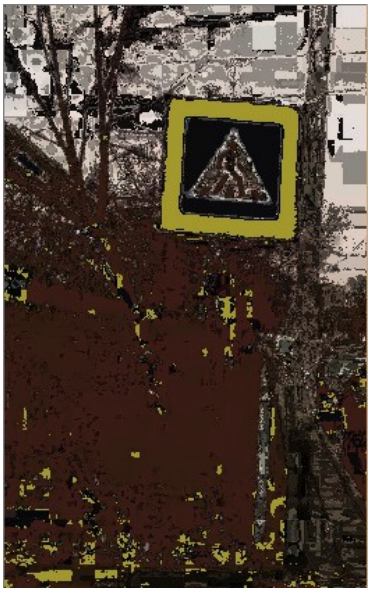

Fig. 10. Example of clustering quality worsening
because of increased number of decimal places
in the rounded average intensity value (road sign image)

To improve the effectiveness of this method, it is planned to disclose dependencies between image features (pixel quantity, histogram of gradients) and such aspects as: number of decimal places in rounded average intensity value, initial cluster size.

To perform comparison, apart from the clustering method based on the PSO, the test images were clustered by the fuzzy *C*-means and the *k*-means (as an input value, the number of clusters obtained in the PSO clustering method was used; maximum iteration quantity – 3). The average working time of mentioned clustering methods are represented in Table 1.

TABLE I. COMPARISON TABLE OF TIME OF WORK
FOR PSO, FUZZY C-MEANS AND K-MEANS CLUSTERING METHODS

PSO	Fuzzy *C*-means	*k*-means
1.69	0.0013	35.98

Fig. 13 and Fig. 14 represent the worked results of *k*-means clustering method. Fig. 11 and Fig. 12 show the working results of the fuzzy *C*-means clustering method.

With *k*-means and fuzzy C-means clustering methods it became possible to separate objects from background. However, the algorithm proposed by the authors marks details more legibly.

To illuminate influence of the represented clustering methods on the pattern recognition quality the authors implemented Haar [23] cascade classifier on the given example to detect the car. It is possible to see the results in Fig. 15-20.

PSO and *k*-means clustering methods contributed to obtaining correct results: region with the car was entirely detected. Fuzzy *C*-means algorithm despite its high speed does not guarantee accurate recognition.

Fig. 11. Clustered image of the car
by fuzzy *C*-means clustering method (car image)

Fig. 12. Clustered image of the car
by fuzzy *C*-means clustering method (road sign image)

Fig. 13. Clustered image of the car by *k*-means clustering method
(car image)

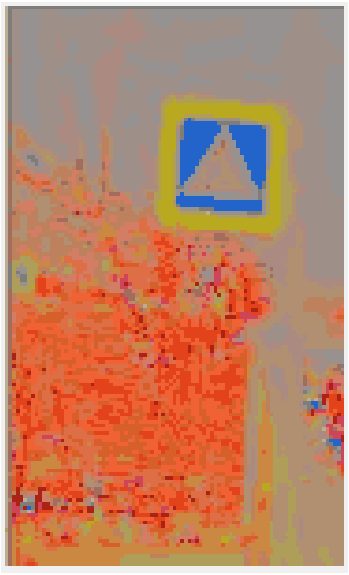

Fig. 14. Clustered image of the car
by *k*-means clustering method (road sign image)

Fig. 15. The result of classifying (PSO clustered image of car)

Fig. 17. The result of classifying (fuzzy *C*-means clustered image of car)

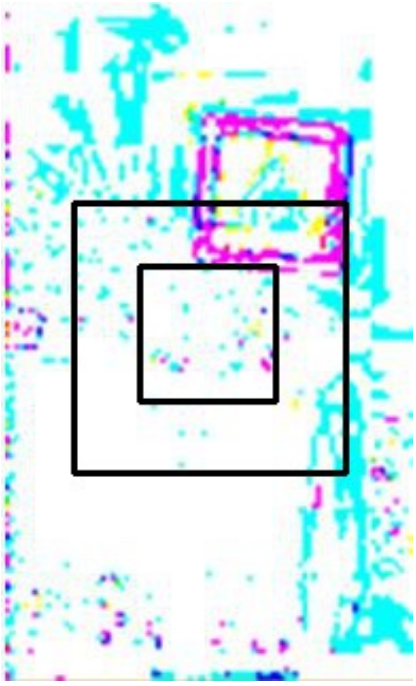

Fig. 18. The result of classifying
(fuzzy *C*-means clustered image of road sign)

Fig. 19. The result of classifying (*k*-means clustered image of car)

Comparing PSO and k-means, the second one is slower because of using several iterations.

Reducing iteration number can have a negative impact on clustering quality. PSO determines clusters during the first two steps without the risk of worsening results.

(*k*-means clustered image of road sign)

V. Conclusion

The paper proposed and investigated the clustering method based on particle swarm optimization. The developed method was tested for a car vision system and its results and contribution to the pattern recognition quality improvement were evaluated.

The experiments demonstrated that the suggested clustering method is faster than the *k*-means, but it cedes in speed to the fuzzy *C*-means. However, it provides more accurate results. The advantages of the proposed method are as follows:

(1) use of particle swarm optimization helped to eliminate the necessity for user of cluster amount predetermining - one of the main reasons of incorrect clustering in the majority of cluster analysis methods;

(2) the authors liquidated the need for user of calculating and specifying threshold parameters; this need often led to a situation when one pixel could be assigned to several clusters at the same time which contradicts with the clustering task;

(3) there are rules that regulate grouping of objects, which possess the features of the different clusters; thanks to this the uncertainty in correlation of objects and clusters is minimized and, as a result, the pattern recognition error probability is reduced;

(4) clustering parameters are predetermined automatically and do not require user's intervention.

However, currently, this method has the following disadvantages: absence of clear dependencies between way of rounding the average intensity values and image features; absence of clear dependencies between size of initial cluster and image features.

In further research it is planned to liquidate the mentioned drawbacks of the developed clustering method, propose the ways of its improvement and to finalize the embedded vision prototype. Implementation of the proposed approach may be used for different cyber-physical systems. One of the most interesting sphere is autonomous cars.

Further research will be also aimed on modification of the proposed method and development of software for video streaming analysis for real-time systems. There are such systems for different physical models of autonomous vehicles [24]. Some of them are particular, it is necessary to rebuild algorithm for different conditions of environment, some of them work only with certain functions, required for correct movement of the cars [25-27].

In this case, authors will prepare the method not only for image recognition in usual cases, but also for fully automatic recognition in case of violations. Current results seem to be useful as the main approach for machine vision organization, but this approach should be improved with usage of different existing machine learning methods.

***Abstract*—Parallel programming is a field of science with a great potential nowadays due to the development of advanced computers architectures. Appropriate usage of this tool can be therefore highly beneficial in multimedia applications and significantly decreases the time of calculations.**

In this article, we analyze how the speed of calculations is influenced by the usage of parallel algorithms in image filtering processes. We present a method based on multithreading and the division of the image for rectangles. The filter is applied parallel on each part of the image. Results show that in some cases our proposition can bring over 90% benefit when compared to the classical approach.

***Index Terms*—parallel programming, image filtering, Laplacian, multithreading**

I. Introduction

PARALLEL programming is currently a dynamically growing field of computer science. Modern multicore processors enable a significant reduction of computation time. Proper use of computing power is an enormous challenge for programmers. A skillful preparation of parallel instructions that are to be carried out causes a lot of problems. However, benefits of parallel programming are obvious. Some multimedia applications require a huge amount of time - it is visible for instance in image processing. Filtering the images containing the several thousand pixels can take a lot of time, especially, when there is a substantial number of images to be filtered. Therefore an intelligent methods that improve image processing are very important.

It is clear that image filtering has a lot of applications. It is possible to improve the quality of photos with blur, noise or other undesirable effects. Moreover, sharpening the edges can be helpful in the objects detection. Parallel methods can be very useful in graphics processing and cloud computing directed to multithreading. High-quality images are also crucial in medicine in diagnosis of diseases (for instance in X-ray pictures). Therefore, capturing the details is very important. In this article we present multithreading in image filtering, and its impact on the whole process. Our approach is designed to equally distribute work among all the threads. The input image is divided into equal rectangles and each thread filters only the designated area. Therefore by the proposed algorithm we construct a method which uses all available cores. Depending on the number of CPU threads in the computer we can significantly decrease time of processing, reaching even 90% of improvement. It has a significant importance for HD multimedia systems where all the images and multimedia streams are very complex structures. Therefore our proposed method may reduce time and improve the efficiency of processing. For the research we have used an architecture with 32 CPU threads and 320 GB of memory.

The main part of this article is following: Section II describes some related works, Section III presents a theoretical background of the image filtering and three Laplacian filters applicated in the research. In Section IV it is shown a detailed description of the tested parallel method. Section V gives a results of measurements and Section VI contains conclusions and remarks after studies.

II. Related works

Very important application of multitasking is connected with data processing. In [1] it was shown how to parallelize fast sorting algorithm, while in [2] it was proposed a new more efficient parallel merge sort algorithm. These decrease computation time in large databases for instance in case of data analysis. In [3] an overview on intelligent systems for data retrieval was discussed. Graphics processing is frequent and very important topic of many publications. In [4] it was proposed a method how to more efficiently analyze the information from images for detection, and in [5] a segmentation of images based on graph analysis of the semantic image structure was presented. The image decomposition method which combines information from the infrared and visible images is presented in [6]. This method can be helpful for instance in target recognition. In [7] and [8] was presented a system for image data classification by the use of fast selection methods based on shapes comparisons. Authors in [9] propose a Weighted Guided Image Filtering algorithm (WGIF) which prevents so

called "halo artefacts" effect. In many cases combination of different data ensures more efficient analysis. Such approach in medical images is shown in [10]. The method intended for filter identification is presented in [11]. An interesting problem connected with underwater imaging is introduced in [12]. Authors in [13] show the Core algorithm designed for document's identification from images. It is compared with classical detectors like ORB, SIFT and SURF-BRISK. In our paper it will be shown a method which can speed up the calculations on images. A properly and quickly processed image streamlines further work. The presented method is intended for initial processing of the images.

III. Image filtering

A very common situation is that the analysis of the original image is difficult due to noise, blur or other factors. Furthermore, if the number of details is too large, a detection of the crucial parts of the image (for instance, the contours of presented objects) is impossible. Therefore it is necessary to pre-process the image. Further analysis will be easier thanks to such tools as the image filtering.

A. Theoretical background

One of the most popular color models is RGB model [14]. Each pixel consists of three components: R (red), G (green) and B (blue). They can be integers from the range $\{0, 1, ..., 255\}$. For instance $[0, 0, 0]$ represents black, $[255, 255, 255]$ determines white, $[255, 255, 0]$ yellow, etc.

In this paper we assume that calculations will be performed by using the RGB model. Let $R_{n\times m}$ be a two-dimensional array with the values of pixels of a given image (n is the width of an image and m is the height of an image, $R[i, j]$ represents the position (i, j) on the image, $i \in \{1, ..., n\}$, $j \in \{1, ..., m\}$). The idea relies on modification of the image by moving the convolution mask over the pixels. The new values of three components R, G, B depend on the pixels in the nearest neighborhood of the calculated one. This process is illustrated in Fig. 1, by the example of 3×3 mask. The new value of the position (x, y) depends on 9 pixels. Of course, other sizes are also allowed.

The greater the mask, the larger number of pixels is taken into account during processing. The impact of each pixel is defined by the table of weights, called a filter. In our research, there were applied three types of convolution masks: 3×3, 5×5 and 9×9. The larger the filter is, the more details are lost [15]. During calculations on larger masks it is necessary to create an auxiliary image with borders filled with black pixels (the convolution masks exceeds the original one). This operation has an nonsignificant influence on the final image but it enables the filtering. The pattern for the new value of each component of the pixel located at position (i, j) in the case of 5×5 mask is as follows: [16]:

$$R'(i,j) = \frac{1}{M} \sum_{k=-2}^{2} \sum_{l=-2}^{2} w(k,l) \cdot R(i+k, j+l), \quad (1)$$

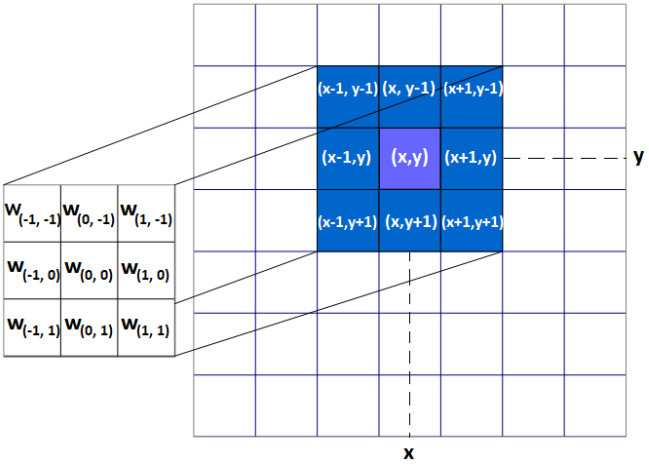

Fig. 1: The sample of using a 3×3 convolutional mask.

where M is the sum of all values in the array (the convolution mask), $w(k, l)$ is the weight of pixel located at position $(i + k, j + l)$ and $R(i + k, j + l)$ is the previous value of the pixel at given position. Sometimes M may be equal to 0. In that situation, the factor $\frac{1}{M}$ is omitted. Patterns for other convolution masks are created similarly.

Fig. 2: Illustration of the image split into 4 rectangles. (The original photo was taken by Jonathan Andreo, and is available at unsplash.com)

B. The applied filters

During further calculations, three Laplacian filters will be used (Fig. 3). [17]. Their main task is sharpening the edges of the objects and hence, loosing of irrelevant details. The picture which has been filtered, is presented in Fig. 4. It is possible to see how the Laplacian filters influence the original image. The edges are therefore definitely more visible than the rest of the image. This kind of filters facilitates the detection of shapes.

IV. Parallelization

Image filtering involves a lot of calculations. The larger the photo is, the greater the time of filtering is. In case of analyzing a large number of pictures, minimizing the computation time is

$$\begin{pmatrix} 0 & -1 & 0 \\ -1 & 4 & -1 \\ 0 & -1 & 0 \end{pmatrix}$$

(a) 3×3 Laplacian filter

$$\begin{pmatrix} -1 & -1 & -1 & -1 & -1 \\ -1 & -1 & -1 & -1 & -1 \\ -1 & -1 & 24 & -1 & -1 \\ -1 & -1 & -1 & -1 & -1 \\ -1 & -1 & -1 & -1 & -1 \end{pmatrix}$$

(b) 5×5 Laplacian filter

$$\begin{pmatrix} 0 & 1 & 1 & 2 & 2 & 2 & 1 & 1 & 0 \\ 1 & 2 & 4 & 5 & 5 & 5 & 4 & 2 & 1 \\ 1 & 4 & 5 & 3 & 0 & 3 & 5 & 4 & 1 \\ 2 & 5 & 3 & -12 & -24 & -12 & 3 & 5 & 2 \\ 2 & 5 & 0 & -24 & -40 & -24 & 0 & 5 & 2 \\ 2 & 5 & 3 & -12 & -24 & -12 & 3 & 5 & 2 \\ 1 & 4 & 5 & 3 & 0 & 3 & 5 & 4 & 1 \\ 1 & 2 & 4 & 5 & 5 & 5 & 4 & 2 & 1 \\ 0 & 1 & 1 & 2 & 2 & 2 & 1 & 1 & 0 \end{pmatrix}$$

(c) 9×9 Laplacian filter

Fig. 3: The presentation of Laplacian filters applied in the paper.

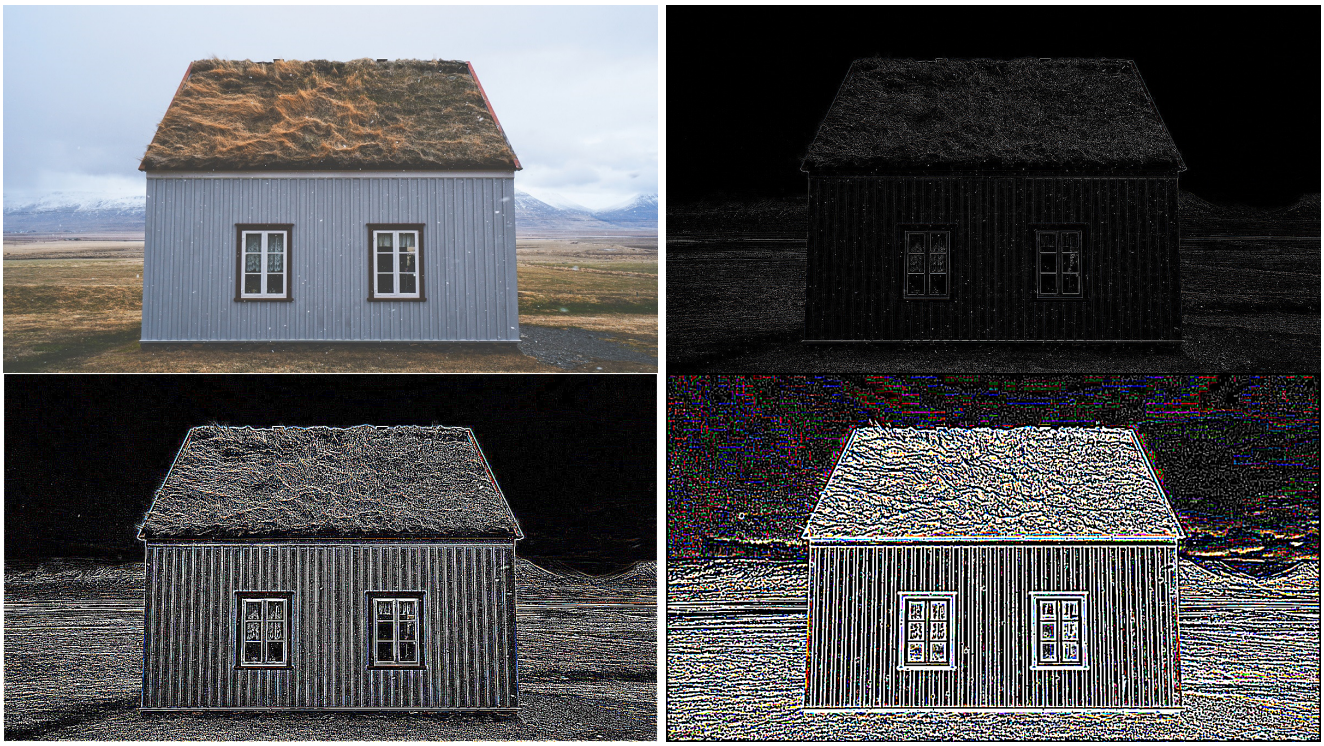

Fig. 4: The figure presents as follows: the original image and the image after 3×3 Laplacian filter (the first row) and images after 5×5 and 9×9 Laplacian filter (the second row). (The original photo was taken by Jonathan Andreo, and is available at unsplash.com)

crucial. The idea presented in this paper relies on moving the mask parallely over the image. The photo can be divided into t rectangles, where t is the number of threads (an exemplary division into 4 rectangles is presented in Fig. 2). Then each thread applies the filter to the allocated area and does not influence any other parts. Finally, all filtered fragments are combined into one image.

The only issue is to determine the way of assigning suitable areas for t threads. Each thread after running receives its own index (the numbering starts from zero). Let w be the width of the processed image (in pixels). Then the number of pixels per one thread is equal to $\lfloor \frac{w}{t} \rfloor$. The ceiling function is necessary because $\frac{w}{t}$ may not be an integer. In such a situation the last thread can have slightly more pixels to calculate. The Algorithm 1 presents the pseudocode of the proposed method.

V. Experimental results

As was said before, application of three Laplacian filters was tested. In all cases, 100 measurements were performed and the results were averaged. The investigated image is 1200 pixels wide and 676 pixels high. For each convolution mask the image was filtered by using 1, 2, 4, 8, 16 and 32 threads. The algorithm was implemented in C# language. The testing parallel architecture was Quad-Core AMD Opteron 8356 8p (32 CPU threads). Detailed results of experiments are presented in Tab. I and shown in Fig. 5 - 7. On all graphs the horizontal axis represents the number of threads and the vertical axis represents time.

TABLE I: Results of image filtering by using Laplacian filters (100 averaged measurements).

threads	average time (seconds)	percentage	standard deviation	average time (CPU ticks)	standard deviation

32	10.67084	7.53%	0.51039	23968946	1146444

Algorithm 1 Pseudocode of the parallel method of the image filtering.

Input: the image for filtering, the size of the image: width *w*, height *h*, the convolution mask, number of threads t
Calculate the number of pixels per one thread: $\lfloor \frac{w}{t} \rfloor$.
Create t threads.
for $i = 0$ to $t - 1$ **do**
  Set the range for the thread from $i \cdot \lfloor \frac{w}{t} \rfloor + 1$ to $i \cdot \lfloor \frac{w}{t} \rfloor + \lfloor \frac{w}{t} \rfloor$.
  if $i = t - 1$ **then**
    Set the range for $(t-1)$-th thread from $(t-1) \cdot \lfloor \frac{w}{t} \rfloor + 1$ to w.
  end if
  Filter the determined area according to the convolution mask.
end for
Merge all the parts into the one image.

It is possible to observe that even the division of the image into 2 rectangles speeds up significantly the calculations (53%-57% of the calculation time for one thread). In the case of the 9×9 convolution mask, the time was decreased from 141 to 75 seconds. Fig. 5 - 7 show a hyperbolic decline of the computing time. The differences between consecutive cases are getting smaller but still the most beneficial application is while using 32 threads (the maximum number of available CPU threads). The larger the convolution mask is, the more time can be saved thanks to multithreading (7-10 seconds in the case of the 3×3 mask, 22-42 seconds in the matter of the 5×5 mask and 66-131 seconds regarding to the 9×9 mask). As we have proposed multithreading method can be a very useful tool in speeding up the calculations.

VI. Conclusions and final remarks

The research has shown that proposed parallelization significantly decreases the time of calculations. The profit is best visible when all CPU threads are used. The larger the picture and the computation mask is, the more important reduction in time spent for calculations is visible. It is worth to mention that the time necessary to filter the image of a size 1200×676 pixels by using only one thread and the 9×9 convolution mask exceeds two minutes. It can be concluded that filtering larger image (for instance of a size 6000×6000 pixels or even higher) involves several minutes, especially in the case of large convolution masks, also bigger than 9×9. Striving for a significant reduction of the calculation time is essential.

The method can be further developed by examining other parallel algorithms or trying to process many images at the same time. In our future research we will also investigate this methodology in movie processing, since this application can be the most important for HD multimedia systems.

***Abstract*—A rehearsal environment for conducted orchestras via the public Internet requires a specialized server infrastructure, in order to provide minimal latencies between the musicians involved. In this document, we present a cloud computing concept for digital signal processing of audio and video data in realtime. Since 60 musicians and one conductor shall connect to the cloud, it is most important to distribute the signal processing and machine learning algorithms over multiple processing servers. The server infrastructure under investigation is built on top of an AVB network segment to be scalable and to maintain low latencies and jitter under heavy load. Latency and jitter are the most important properties of the realtime streams that are connected to the cloud, and are analyzed and discussed. The results have proven the proper design of the concept, but revealed the need for further optimization.**

I. Introduction

SOUNDJACK [1] is a realtime communication software that establishes up to five peer to peer connections via the public Internet. This software was designed from a musical point of view and first published in 2006 [2]. Playing live music via the public Internet is very sensitve to round trip as well as one-way latencies. Thus, the main goal of this application is the minimization of latencies and jitter, while limited by the speed of light. Participating musicians require some soft skills to tolerate the latencies none the less.

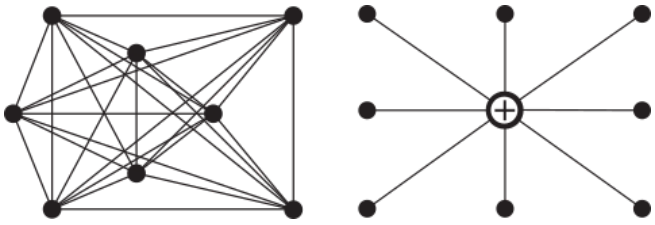

Figure 1. *Left: Peer to Peer Network Topology, Right: Star Network Topology*

A. Soundjack and fast-music

The goal of the research project fast-music is to develop a rehearsal environment for conducted orchesteras via the public Internet. Up to 60 musicians and one conductor, who are randomly distributed throughout Germany, shall be able to play together live. The central node represents the multimedia signal processing cloud under investigation, which ideally is located in Frankfurt on the Main. First investigations of round trip times suggest Frankfurt on the Main as the logical center of Germany.

Further fields of research are the transmission of Wavelet based low delay live video streams and motion capturing of the conductor. The latter shall be displayed on a holographic LED cube [3] that was developed by our project partner Symonics GmbH [4].

B. Motivation

The most important aspect for any further network and software design decision for the cloud concept is the application of digital signal processing algorithms to the audio and video streams. Examples for digital signal processing applications are audio error concealment due to UDP packetloss in the public Internet, based on a machine learning approach, or virtual room acoustics in the form of individual binaural rendered Ambisonics soundfields that simulate the musicians location inside an orchestra for a better immersion.

The second important requirement is the service time of Ethernet frames that are arriving on a serial network interface at the wide area network (WAN) side of the server cloud. In this document the network under investigation is the campus network of the university. Thus, Ethernet is also considered a WAN technology for the scope of this paper.

During the service time, no datagrams of any concurrent UDP streams can be received. Consequently any stream arriving on such a serial network interface experiences a latency, equal to accumulated latency of all streams arriving at this interface.

A scalable and extendable concept with multiple proxy servers that are connected to the same signal processing network segment is chosen over a single processing server. The Soundjack processing cloud has to be segmented accordingly. The approach that we chose is shown in fig. 2.

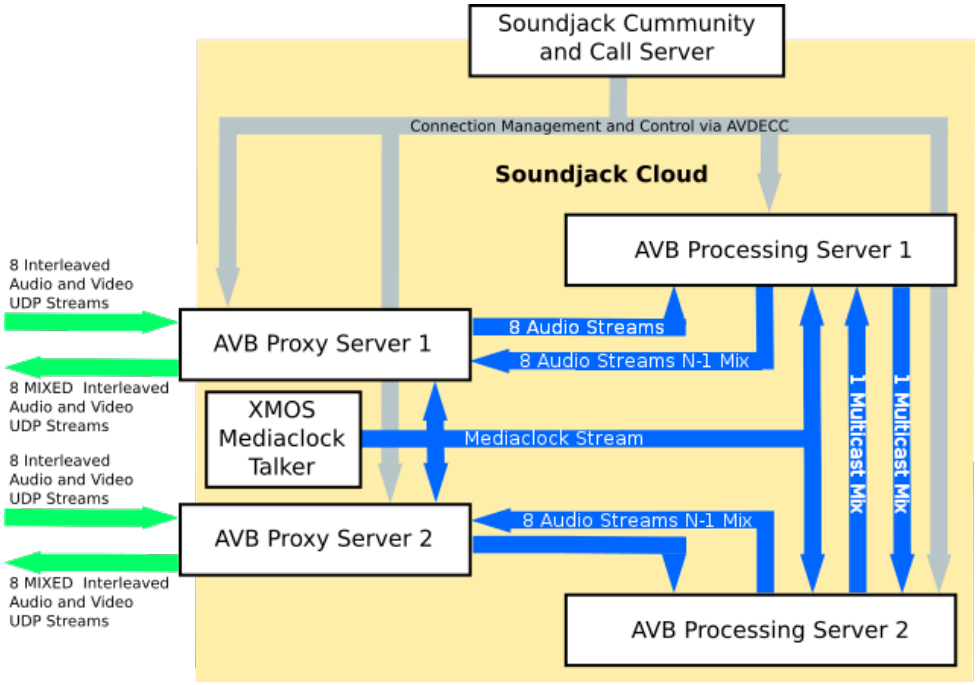

Figure 2. *Soundjack Realtime Processing Cloud Concept*

II. Soundjack Realtime Processing Cloud Concept

Audio Video Bridging / Time-Sensitive Networking (AVB/TSN) is a technology with the focus on audio and video streams in computer networks, that require realtime responsiveness. This technology is a set of IEEE 802.1 industry standards, which operate on OSI-Layer 2 [5]. These standards are:

- IEEE 802.1AS [6] - Timing and Synchronization for Time-Sensitive Applications in Bridged Local Area Networks
- IEEE 802.1Qat [7] - Virtual Bridged Local Area Networks - Amendment 14: Stream Reservation Protocol (SRP)
- IEEE 802.1Qav [8] - Virtual Bridged Local Area Networks - Amendment 12: Forwarding and Queueing Enhancements for Time-Sensitive Streams (FQTSS)
- IEEE 1722 [9] - IEEE Standard for Layer 2 Transport Protocol for Time-Sensitive Applications in Bridged Local Area Networks (AVTP)
- IEEE 1722.1 [10] - IEEE Standard for Device Discovery, Connection Management, and Control Protocol for IEEE 1722 Based Devices (AVDECC)

These AVB standards extend the IEEE 802.1 standard family with precise synchronization, resource reservation and bandwidth shaping. Lower latencies and jitter, the avoidance of packet bursts and bandwitdh shortage are addressed by these extensions, providing realtime responsiveness to a generic Ethernet computer network. These properties are used to ensure a constant bandwidth streaming with low latency and jitter inside the Soundjack realtime processing cloud. Thus, the Soundjack client streams can be processed inside the cloud, without interfering with each other.

AVB networks require special hardware for timestamping Ethernet frames with seperate transmission queues for each traffic class, i.e. AVB traffic with Stream Reservation (SR) classes A/B and generic Ethernet traffic. IEEE 802.1-2014 [11] defines the two distinct stream reservation (SR) classes A and B to differentiates audio and video traffic from other Ethernet traffic. SRP declares and registers resources on all switch ports along the path from the AVB talker to the AVB listener. This way, the resources to maintain an inter packet gap (IPG) of 125 μs (250 μs for SR class B) are reserved.

The two AVB server types required for the Soundjack cloud are an AVB proxy server and an AVB processing server. The AVB proxy and processing servers are each connected to the same AVB LAN segment. The media transport in this design should not exceed a round trip time of 4 ms, since AVB networks are constrained to a bounded one way latency of 2 ms [9, p. 14]. Additionally, each server is connected to a non-AVB LAN segment. The Soundjack community and call server is also connected to this generic network segment and handles the session management of the different user sessions on the Internet and of the respective AVB server sessions. Since IEEE 1722.1 AVDECC traffic is not necessarily time-sensitive, it is sufficient to use a non-AVB LAN segment for command and control purposes. The Soundjack community and call server also provides community services of Soundjack.

A. Mediaclock Server

All AVB servers subscribe to a mediaclock stream, which is supplied by an XMOS/Atterotech development board [12].

The mediaclock concept is based on the idea of the recovering from a clock stream, as it is proposed in [13].

B. Common AVB Server Software Architecture

To meet the requirements of an AVB server software, it is not sufficiant to write a multiprocessing and multithreading application in C. The hardware support for AVB requires a properly configured and optimized OS. The Linux kernel can be patched to operate in realtime mode [14], a Linux mainline kernel 4.8.6 was configured, patched with the corresponding realtime patch 4.8.6-rt5 and compiled.

The AVB talkers running on the system need to use hardware queues of the network interface to utilize the FQTSS mechanism for enqueueing AVTP packets. A detailed description of the software architecture of the two different server configurations can be found in [15].

C. AVB Proxy Server

In contrast to the public Internet where IP packets are forwarded on best effort, the Soundjack processing cloud provides a fully managed and controlled Ethernet network with AVB support. The traffic shaping property of AVB prevents the Soundjack cloud network from bursty traffic by means of a credit-based bandwidth shaper. The proxy server is used as a wave trap to break down large and erratic UDP datagrams into more and smaller, but constant AVTP packets. Thus, the stream packets can travel inside the Soundjack cloud network in a deterministic fashion, managed by the credit-based bandwidth shapers.

The AVB proxy server receives and transmits UDP streams from and to Soundjack Clients, that were assigned by the Soundjack session server. A maximum of eight streams is assigned to one AVB proxy server to keep the latency introduced by the service times low. The UDP streams received on the WAN interface are fragmented, because they need to be transmitted in the AVB LAN segment at another bitrate with a different payload. A UDP datagram of such a stream contains 256, 512 or 1024 Bytes of compressed or raw audio data. AVB implements its traffic shaping based on the idea of constant bitrate streaming. The resulting AVTP stream is sent from the AVB proxy server to the AVB processing server, which processes the eight streams and sends them back as AVTP with the same, but processed payload. Inside the Soundjack cloud a constant link capacity utilization per stream is of paramount importance to maintain the deterministic behavior of the AVB LAN segment. To achieve constant link capacity utilization, the payload of each UDP datagram needs to be properly fragmented into multiple AVTP packets. IEEE 802.1Qav [8, p. 44] requires an AVB talker to send an AVTP packet every $125\ \mu s$ for a class A stream and $250\ \mu s$ for a class B stream. This inter packet gap (IPG) is necessary to maintain a constant sample flow at 48kHz sample rate: $6/48\ kHz = 125\ \mu s$, and AVTP packet rate of $48\ kHz/6 = 8\ kHz$. A single stream may also contain multiple audio channles, thus an AVTP packet contains six samples per audio channel. Inside the Soundjack processing cloud however, all AVTP streams contain two channels - a stereo stream. The proxy server talker instances mix the possible eight, four and two channels down to (or one channel up to) two channels per received UDP datagram, which reduces the payload size for the AVTP stream. The return stream of the Soundjack cloud has always 64 samples per UDP datagram for two audio channels - a stereo mix. The stereo mix from the samples of the UDP datagrams needs to be distributed over multiple AVTP packets. Soundjack uses a sample rate of $48\ kHz$ exclusively and all channels are mixed down (or up) to two channels by the proxy server. The stereo mix channel count, the sample rate and the sample encoding determine the actual AVTP payload size of $48\ bytes$. Since AVTP packets arrive with the IPG of $\Delta t = 125\ \mu s$ at the proxy listener buffer, a constant latency is introduced by waiting for the correct amount of AVTP packets required to properly fill the UDP datagram.

Apart from the audio samples, the UDP stream also contains interleaved video data, which is described in [16].

D. AVB Processing Server

The AVB processing server receives the audio and video streams, originating at the clients as AVTP streams with a constant packet rate of $8\ kHz$. It provides signal processing facilities for audio and video processing.

The JACK [17] audio server is deployed as infrastructure for the audio signal processing stage. It is a professional and open source audio server to share sample accurate audio data between different applications. A large number of signal processing applications and algorithms are available for JACK.

As off now, an audio multicast mixing application, to mix all streams that are connected to the Soundjack cloud, is deployed. A detailed description can be found in [18]. Further signal processing application, as mentioned in the introduction, are still under development.

III. Evaluation

A first evaluation was done with a single UDP audio stream that enters the Soundjack cloud via the WAN network interface of the AVB proxy server in the campus network. The proxy server forwads the stream as AVTP stream to the AVB processing server. After processing the audio signals, the processing server returns the AVTP stream to the AVB proxy server, which in turn constructs an UDP stream to return to the Soundjack client. The latency was measured with a scope connected to the digital-analog and analog-digital converters of the Soundjack clients audio interface.

Furthermore, the arrival timestamps of the UDP send and return stream and the different AVTP streams have been captured with the packet analyzer Wireshark. The probability density function of the difference to the previous timestamp of the AVTP streams is the bounded IPG of $125\ \mu s$ defined by AVB. In the context of the UDP streams, this probability density function gives a measure for the audio quality of the stream - whether it has high or low jitter.

IV. Discussion

A generated sine wave with a frequency of 1 kHz was transported through the entire cloud and is late by 16 ms round trip time. At some point in time however, some buffer seems to underrun which could not be located yet. In this case, the latency of the return stream is stable at 316 ms round trip time.

Both, the send and the return stream, show the expected IPG for the tested payload sizes. The send stream maintains an IPG of 2.666 ms for 256 bytes (128mono samples/48 kHz) and the return stream maintains an IPG of 1.333 ms for 256 bytes (64stereo samples/48 kHz), respectivly.

An round trip time of 16 ms (8 ms end-to-end) for the Soundjack client streams, still violates the end-to-end delay limit of 2 ms formulated in [9, p. 14]. Additional latencies that are introduced by the networks and not compensated yet are for example some minimal portion of undeterministic network behavior by the campus network, buffer synchronization latencies, packet de- and fragmentation inside the cloud. On the audio processing side we have to consider drift of the JACK audio server, because it is not phase locked to the incoming mediaclock stream. When the mediaclock is very early and the audio interface hardware interrupt is very late in relation to each other, the drift between those two interfaces can lead to a worst case latency of $\Delta t_{max} = 1/48\ kHz = 20.833\ \mu s$. This latency is much less significant than the latencies introduced by the signal processing algorithms that shall be implemented. A measurement of the latency introduced by the multicast mixing application has still to be done.

V. Conclusions

The Soundjack cloud prototype is not fully tested yet, but the evaluations in this paper show the proper operation of the presented concept. Analysis has shown that the AVB requirements could be mostly fullfilled. Further sources for the remaining latency, besides the actual algorithmical latency of the digital signal processing involved, have to be exposed.

VI. Future Work

The software has to be further optimized to reliably meet the AVB constrains.
Furthermore, the AVB server software behavior requires evaluation under heavy load with up to eight possible streams. In parallel to the creation of this paper further signal processing applications have been developed which will be integrated into the streaming process. The jitter and latency behavior under heavy load with signal processing applications in place will be evaluated in the future. Those evaluations will mainly focus on the task scheduling precision in tems of meeting the calculated task deadlines with the EBF-CBS scheduler.

Signal processing and machine learning application are under development an might be ready to be tested prior to a deployment in the public internet.

As soon as the proper networking operations of the cloud are verified, measurements will be performed in the public Internet. We will then deploy the Soundjack cloud in Frankfurt on the Main and test in a real world environment. A comparison between an IPv4 and an IPv6 deployment will be done as well.

***Abstract*—In this paper a new Content Based Image Retrieval based on a sketch method was proposed. The main idea of the algorithm is based on decomposing an object into predefined set of shapes (primitives): line segments, polylines, polygons, arches, polyarches and arc-sided polygons. All primitives are stored as a graph in order to store the mutual relations between them. Graphs are stored in a tree-based structure which allows fast querying. As an improvement to the algorithm, a conversion to the HSL color space was proposed in order to detect primitives more accurately. Moreover, computing all line slopes in relation to the object oriented bounding box was also proposed. Additionally, in order to better detect objects present in images, the usage of Edge Boxes algorithm was proposed.**

I. Introduction

MULTIMEDIA databases are becoming more and more popular. Most often they store huge number of images which causes the need of effective storage, processing and query methods. This is becoming an important problem because they are used more often in everyday life, from searching for information in the internet to authorising, recognizing and monitoring systems. Moreover, most of social media portals stores images as the part of provided content or even are oriented only on providing images, thus they also need effective methods to manage and provide data to users.

There are many different methods in the area of image retrieval from multimedia databases. Most of the algorithms may be grouped into three categories: the Keywords Based Image Retrieval (KBIR) algorithms, the Content Based Image Retrieval (CBIR) algorithms and the Semantic Based Image Retrieval (SBIR) algorithms.

The KBIR algorithms use textual annotations in order to describe objects present in the image. Then, during the query they are compared with keywords typed by the user [1]. The CBIR algorithms use content present in the image in order to perform queries. Most often global statistical features are used (e.g. contrast, entropy [2] or a normalized histogram of colors [3]) or grouping similar pixels into regions in order to construct graphs which are then compared using e.g. Maximum Likelihood [4]. There are also methods which use sketches instead of images as a query(e.g. [5]). The SBIR algorithms tries to minimize the difference between the data present in the image and the information which can be deduced by a human [6], [7]. The text may be classified e.g. by one of the methods described int [8]. There are methods which use textual queries and graphical queries.

This paper presents a new Content Based Image Retrieval method from multimedia database which is based on querying by a sketch. The main idea of the algorithm is based on representation of objects using a set of predefined shapes, called primitives: line segments, arches, polylines, polygons, polyarches (a chain of connected arches) and arc sided polygons (a looped chain of connected arches). For each type of a primitive, there are defined attributes which describes them, e.g. a line slope for a line segment or an angle for an arc. The primitives may be extracted from images using proposed approach based on HSL color space segmentation. All primitives are connected into a graph which stores all relations between them. Graphs are stored in a tree-based database structure which gathers similar objects graphs in the same subtrees, but without fast tree height grow. In comparison to our previous works, in this paper we focused on improving the primitives extraction algorithm and the precision of the results. The proposed approach provides easy graphical queries for users, both using sketches drawn by themselves (without need of high drawing skills) and example images. All similar graphs are stored in congruent nodes, thus the querying is faster than in e.g. linear data structure. Also the structure allows performing queries in parallel which also improves the computation time.

The paper is organised as follows: the first section is an introduction. Next section presents the proposed object representation. The third section describes the shapes extraction algorithm with improvements and the fourth possible usages of Edge Boxes algorithm. The fifth section presents the experimental results. The next section is the summary and future research section. The last one section is a list of references used in this paper.

II. The object representation

During previous stages of our research, we found that most objects and images can be described using sketches. This method is very efficient, because there is no need of example image, but if existent, it can be processed in order to extract a sketch. Moreover, sketch representation of objects may be used when there is no full knowledge about searched matter, e.g. when only a front part of a car is known.

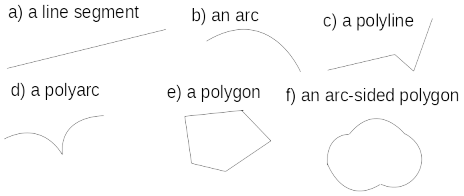

Fig. 1. The proposed primitives: a) a line segment, b) an arc, c) a polyline, d) a polyarc, e) a polygon, f) an arc-sided polygon

The sketch may be represented by an image (e.g. using black pixels as sketch edges [9]), an object outline (e.g. as in [5]) or, as proposed in our research, as a set of predefined shapes. The advantage of our approach is the simplicity to draw a sketch by users, ability to store additional information for each shape (e.g. information about material or color). The predefined, simple shapes are called primitives. During our research we noticed, that line segments (Fig. 1 a)) and arches (Fig. 1 b)) are suitable for describing a sketch of most objects. Moreover, during experiments, we realised that storing the information about connected segments and arches improves the efficiency of the algorithm. Thus, additional primitives are proposed:

- based on line segments: polylines (Fig. 1 c)) and polygons (Fig. 1 e))
- based on arches: polyarches (a chain of connected arches, Fig. 1 d)) and arc-sided polygons (a looped chain of connected arches, Fig. 1 f))

Since all primitives are based on line segments or arches, they are called base primitives, afterwards all primitives created using them are called complex primitives.

Each primitive is defined by its type and an attribute or set of attributes, which are defined as follows: a line segment attribute is its line slope, an arc attribute is its angle, a polyline and a polygon attributes are number of segments and their line slopes, a polyarc and an arc-sided polygon attributes are number of segments and their angles.

During our research we realised that not only the information about primitives is needed but also an information which shapes are connected. Thus, such an information is stored using a graph where nodes are used to store primitives and edges used to store connections between them. This approach is similar to graphs of regions in region-based CBIR algorithms. Moreover storing the information about mutual positions between connected primitives also improves the efficiency of the image retrieval from the multimedia database [10]. Therefore, for each connection, there is stored the information about positions using the geographical windrose (N, S, E and W directions). The example of the graph is shown in the Fig. 2.

Since an image may contain many objects, in order to clearly emphasize that they are separated in a graph, a structure called complex shape was introduced [10]. It may be used optionally or mandatory based on types of stored images in the multimedia database.

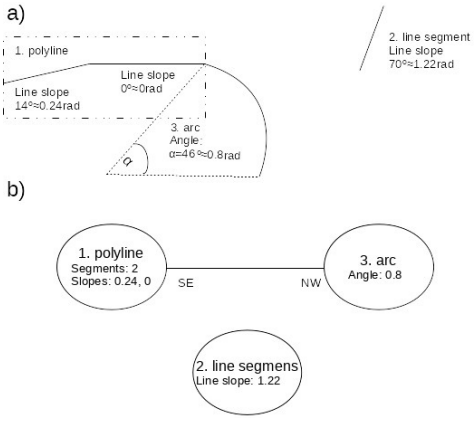

Fig. 2. The example of the graph which contains 3 primitives: a) primitives and their attributes (a polyline, an arc and a line segment), b) the graph: a polyline (1) and an arc (3) are connected, no. 3 lies on the right bottom (SE) of no. 1 and consequently no. 1 lies on the top left (NW) of no. 3; the node no. 2 does not have any connection

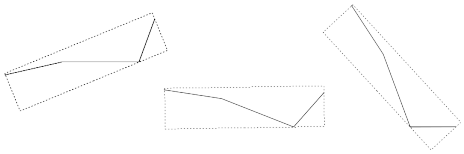

Fig. 3. The example polyline object with its Object Oriented Bounding Box (marked by dotted lines) in three different orientations.

In order to improve the algorithm resistance to different objects orientations, as an addition to the previous works, we propose to store primitives attributes in axis independent manner. During the stage of attributes values computing, line slopes may be computed in relation to the longest side of the Object Oriented Bounding Box built on top of the object. The example bounding box of a polyline is shown in the Fig. 3. Such an approach allows comparisons of differently oriented primitives which are strictly the same or very similar with high precision. Without such solution, there may be some problems with proper image retrieval from the database when users draw a sketch which is e.g. rotated in comparison with sketches stored in the database.

During previous experiments we found that storing the information about mutual positions of connected nodes highly improves the precision of the image retrieval algorithm results. Due to that fact, we propose to store the same information also for each pair of nodes (not only connected), similarly to coincidence matrix used in graphs. In this paper we test if such an approach improves the precision of the results.

III. The Image Shapes Extraction Algorithm Based on HSL Image Representation

In this paper we propose to enhance the shapes extraction algorithm in comparison with the previous version used in [1]. The main idea of the improvement is based on converting an image into a HSL color space. Due to the conversion three images are created: first with only hues present in the image,

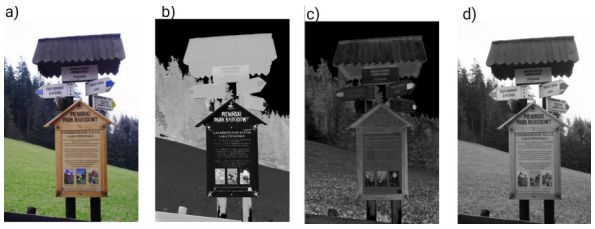

Fig. 4. The representation of image using HSL color space: a) initial image, b) hue channel, c) saturation channel, d) lightness channel which is most often the same as grayscale image representation.

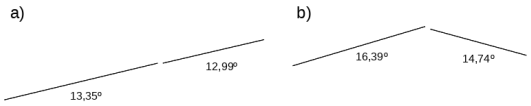

Fig. 5. The example of line segments merging with close endings: a) two segments with line slopes close to 13° which can be merged, b) two segments with completely different line slopes.

the second one with lightness information and the last one which stores saturations of different areas (the example image representation is shown in the Fig. 4). Thanks to that, the algorithm is able to detect line segments and arches with the same hue, the same lightness level and the same saturation.

Similarly to other objects detection algorithms, morphological operations should be performed on the image in order to remove unnecessary details or noise.

The first algorithm step is the detection of base primitives - line segments and arches. Firstly all line segments are detected in hue channel using Line Segment Detector algorithm. Next, for each channel thresholding with different values is performed in order to create uniform areas of similar pixels and reduce the slight differences on the same shapes. After that, line segment detection is performed again for each channel. Thanks to that more line segments are detected. Next all detected line segments are merged if possible, checking if they have the same line slope and connection of very near endings (Fig. 5). As a next step, all segments shorter than defined threshold are removed from the list. The algorithm is shown in the Alg. 1.

When all line segments are found, then the list is searched in order to find the candidates of arches. In order to find line segments which may construct an arc, we check if in the list there is a chain of connected line segments with length equal or greater than 3. Then, if a chain is found, angles between each segments are checked if they are equal or very similar. Moreover a test if their values are in the range $(0°, 180°)$ (Fig. 6) is performed. Additionally, lengths of segments are checked in order to detect if they are very similar. The arc detection algorithm is shown in the Alg. 2. In the practical implementation, the algorithm is assisted with Circular Hough Transform in order to improve the detection of circles.

The last shapes extraction algorithm step is the creation of more complex primitives defined as follows: polylines, polygons, polyarches and arc-sided polygons. Firstly all detected

Algorithm 1 Line segment detection algorithm

Ensure: img - the image which has to be processed, $lsList$ - list which stores line segments

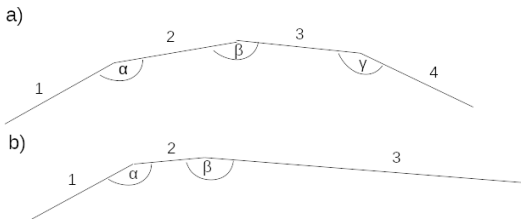

Fig. 6. Different chains of line segments a) a chain from which an arc may be created: segments lengths are very similar (1=146, 2=145, 3=146,8, 4=145,8) and angles α, β, γ are equal to 160° b) the chain from which an arc cannot be created: segments lengths are different (1=138,7, 2=85,4, 3=371) and angles are not equal or very close ($\alpha = 157°$, $\beta = 170°$)

line segments are processed and checked for chains. After chains detection, they are tested in order to detect looped chains from which polygons are created. Then, all others are transformed into polylines. Similarly, founded arches list is processed: firstly chains of arches are detected and then looped ones are transformed into arc-sided polygons and all others into polyarches.

IV. Shapes Extraction Improvement using Edge Boxes

The shapes extraction algorithm performance could be improved by a usage of object proposal algorithms. One of the

Algorithm 2 Arches detection algorithm

Ensure: $lsList$ - list which stores line segments; $chains$ - list of chains of line segments; $archesList$ - list which stores arches

end if

most suitable algorithm for our approach is the Edge Boxes [11]. It is based on the idea that when there are many contours enclosed by bounding box, there is a high likelihood that it contains an object. As an edge extractor a Structure Edge detector is used. All contours are examined using a sliding window approach. In order to improve the computation time, efficient data structures are used. The result of the algorithm is a set of bounding box objects proposals.

In this paper we propose two approaches using Edge Boxes:

- first - where shapes extraction is only performed for edges in the found bounding boxes
- second - where information about object bounding boxes is used as an assistance to the shapes extraction algorithm

The first approach highly decreases the number of shapes detection areas which should highly improve the computation time. Moreover, the primitives extracted from each bounding box should be stored in a one complex shape which should improve the query comparison time and precision.

The second approach detects primitives in the whole image area and then uses Edge Boxes proposals in order to strength the links between shapes in the same bounding box. This is performed by adding connections between unconnected nodes in a graph. Due to that fact, all shapes which are meant to be in a one object should be connected. Such an approach should also improve the precision of comparisons with graphs in the database but may decrease the computation time.

V. The database structure

The database structure is based on a tree which stores similar object's graphs in the same part of a subtree. Two types of tree nodes are defined:

- common graph nodes
- data nodes

The common graph nodes are used in order to store the common parts of graphs which are stored in its children. For example, if there are two children with a car and a bicycle graphs, as a common graph, wheels are used. The common graph nodes does not store any image information and are only used to check if a whole subtree should be tested or abandoned during the query.

The data nodes are used to store graphs of objects, images and metadatas connected with them. In order to reduce the height of the tree, all similar graphs are stored in the same node in a structure called a slice. A slice is a vector of very similar graphs where the first element is the most similar to the parent common node graph and the last one the least. There may be more than one slices in the data node in order to provide the ability to process queries in parallel.

The tree database structure and operations which may be performed (adding, deleting and querying graphs) were described more detailed in [1].

TABLE I
THE COMPARISON OF PRECISION AND RECALL RESULTS FOR BICYCLE IMAGES (NORMAL, ALIGNED TO THE X-AXIS AND SLIGHTLY ROTATED) FOR COMPUTING LINE SLOPES VALUES IN RELATION TO THE X-AXIS AND TO THE LONGEST SIDE OF THE OBJECT ORIENTED BOUNDING BOX (OOB).

object	TOP 10 precision		Recall	
	X-axis	OOB	X-axis	OOB
normal	0.5	0.9	0.26	0.63
rotated	0.3	0.7	0.16	0.42

VI. Experimental results

In order to examine the proposed approach, an experimental application was written in C++ language for database implementation and python language with Django, HTML and JavaScript for GUI. The database stores images of three types of objects: cars, bicycles and motorbikes.

Firstly the computation of primitives attributes in relation to the object oriented bounding boxes was examined. In order to compare the results, two commonly used coefficients were used:

$$precision = \frac{number\ of\ relevant\ results\ images}{total\ number\ of\ results\ images} \quad (1)$$

$$recall = \frac{number\ of\ relevant\ results\ images}{total\ number\ of\ relevant\ images\ in\ the\ database} \quad (2)$$

The experimental results are presented in the Table I. As can be seen, when line slopes values are computed in relation to the longest side of the object oriented bounding box, both precision and recall reach much higher values in comparison to the previous version where slopes are computed in relation to the X axis. It can be noted that even if there are used the same images but with rotations, there are still some differences in precision and recall values for them. This problem is caused i.e. by inaccuracies during shapes extraction stage and will be taken into consideration in the future research.

Another tests were performed in order to evaluate the usage of the additional information about mutual positions of all nodes during queries. The results are presented in the Table II. The experiments does not prove that adding such an

TABLE II
THE COMPARISON OF PRECISION AND RECALL RESULTS FOR BICYCLE IMAGES (NORMAL AND ROTATED) AND A CAR IMAGE FOR PREVIOUS ALGORITHM VERSION AND A VERSION WITH INFORMATION ABOUT MUTUAL POSITIONS OF ALL NODES IN THE GRAPH.

object	TOP 10 precision		Recall	
	previous	mutual positions	previous	mutual positions
bike normal	0.5	0.6	0.26	0.79
bike rotated	0.3	0.4	0.16	0.95
car	0.8	0.6	1	1

TABLE III
THE COMPARISON OF NUMBER OF DETECTED PRIMITIVES FOR PREVIOUS VERSION (RGB) AND VERSION WHICH USES HSL COLOR SPACE

primitive	bike		car		motor	
	RGB	HSL	RGB	HSL	RGB	HSL
line segments	24	36	73	54	64	71
arches	2	3	2	2	2	3
polylines	0	3	8	11	2	10

information improves the precision of the query results. For the bicycles images the precision values are only slightly higher, but for the car it is lower than in previous version. Moreover, the computation time was much longer. Contrary, for bicycle images, the recall values are much higher than in previous version. Due to that fact, the usage of additional information about mutual positions of all nodes in a graph is doubtful and more tests should be performed.

Another types of experiments were performed in order to evaluate the shapes detection improvement by a usage of HSL color space. The results are presented in the Table III. There can be noted that for all objects the usage of HSL color space increased the number of detected primitives. The recognition of the third arc in a bicycle is not a mistake, because not only wheels were detected, but also a gearwheel. In the motorbike image also other parts were detected as circles correctly. It can be seen that the number of polylines is much higher when using HSL color space. This is caused by higher number of detected base line segments and more precise detection which allowed to create more complex primitives.

Due to the limited time, practical experiments for usage of the Edge Boxes algorithm will be performed as a future research.

VII. CONCLUSIONS AND FUTURE WORKS

In this paper a new Content Based Image Retrieval algorithm based on a sketch method was proposed. The main idea of the algorithm is based on decomposing an object into predefined set of shapes (primitives): line segments, polylines, polygons, arches, polyarches and arc-sided polygons. All primitives are stored as a graph in order to store the mutual relations between them. As an improvement to the algorithm, a conversion to the HSL color space was proposed in order to detect primitives more accurately. Moreover, computing all line slopes in relation to the object oriented bounding box was proposed which also increased the precision of the results. The experiments which were performed proved that such propositions increased both precision and recall values. Additionally, in order to better detect objects present in images, the usage of Edge Boxes algorithm was proposed which will be tested as a future research. The proposed results improvement by the information about mutual positions of all nodes is doubtful and more tests should be performed.

The future research includes testing the usage of Edge Boxes and deciding which proposed approach would be more suitable for most situations. Moreover, more tests should be performed for all proposed improvements in this paper. Additionally, the computation time should be also tested for different algorithm versions. Another tests may be performed in order to examine different database structure implementations (e.g. using SD2DS data structures and relational databases). Moreover, the primitives detection algorithm could be improved, e.g. using approaches proposed in [12]. Also other graph comparison algorithms may be evaluated, e.g. using the optimization methods with constraints [13].

***Abstract*— The article presents the influence of the used light sources (illuminators) on the result of the 3D reconstruction of the flaccid membrane surface shape. The research was carried out using a flaccid membrane developed by the authors for the pulsating, extracorporeal, pneumatic heart support pump model. Subsequently, the tested illuminators are an integral part of the sensor for measuring the stroke volume (SV) and the cardiac output (CO). Due to the operation principle of the computer video measurement method SV and CO developed by authors, the consistency of the obtained reconstruction of the flaccid membrane surface shape with the actual (reference) shape of the membrane is fundamentally important. For this reason, the influence of the developed lighting constructions was experimentally verified. For this purpose, a laboratory station and a rigid equivalent of the flaccid membrane were created, thus ensuring the reproducibility of the experiments. For LED-based illuminators, printed circuit boards were also designed, which eliminated the impact of changes in the position of light sources. Thanks to this, it was possible to determine the actual impact of the illuminator's construction on the obtained reconstruction result. The tests were performed for several selected light sources. The following were taken into account: LED diodes operating in the visible band, near infrared LED diodes, optical fibers and electroluminescent film.**

I. Introduction

The publication is the result of studying the effect of lighting on the result of the 3D reconstruction of the flaccid membrane surface shape. Reconstruction of the surface shape was carried out with a proprietary video sensor used to measure the instantaneous stroke volume (SV) and the cardiac output (CO) of the pulsating, extracorporeal, pneumatic myocardial support pump (ventricular assist devices - VAD), described in works [1 - 5]. One of the known VAD constructions is a heart pump made as part of the *"Polish Artificial Heart"* program, discussed in [6] and shown in Fig. 4. Based on its description, the first proprietary VAD model shown in Fig. 1 (currently no longer used) has been produced. The research discussed in this paper was carried out using the new pump models shown in Fig. 2 and Fig. 3. They represent modification made by the authors of the original VAD design. The model shown in Fig. 2 was made using a spatial printing technique. The pump shown in Fig. 3 was made using a casting technique. The presented models, except for the blood chamber, have a pneumatic chamber, which view is shown in Fig. 6. The chambers are separated by a non-elastic, flaccid membrane composite visible in Fig. 5 and Fig. 7. The up/down movement of membrane causes the blood to be pushed or sucked to/from the blood chamber. The membrane, along with the markers on it, is illuminated by the illuminator. At the same time, it is observed by the sensor camera. Reconstruction of the surface shape of the membrane, Fig. 2 and Fig. 3, necessary to determine the SV and CO is obtained by the visual technique discussed in [5, 7 - 9]. This technique uses the distance measurement method described in items [10 - 14].

In works [15 - 18], it was shown that by stabilizing the level of lighting the markers, it is possible to determine the distance from the markers to the image sensor of the camera and to determine the flaccid membrane surface shape.

II. Motivation

The motivation to undertake works aimed at determining the effect of lighting on the result of the reconstruction of the VAD flaccid membrane surface shape was to obtain, as a result of the 3D reconstruction, the shape of the membrane surface in accordance with the actual state. The consistency with the actual state of the determined shape of the flaccid membrane surface is extremely important due to the

precision of determining the VAD's instantaneous stroke volume and the cardiac output. Therefore, it was advisable to examine the influence of the lighting parameters on the accuracy of the determined reconstruction of the flaccid membrane surface shape.

III. Problem Definition

The fundamental problem that is being solved in this work is to compensate for the effect of the membrane lighting on the result of 3D reconstruction of the shape of its surface. This impact is the result of constant changes in the position of the surface of the flaccid membrane in relation to the elements that illuminate it.

The magnitude of the influence of lighting on the result of the reconstruction of the flaccid membrane surface shape depends on: a) the shape of the pneumatic chamber; b) the type of light source and its parameters; c) the mode of light distribution in the pneumatic chamber.

Despite many difficulties, this problem was effectively eliminated in the case of the pump shown in Fig. 1. The following was used: a) an illuminator built out of VSMY 1850X0 diodes arranged in a specially selected pattern; b) PCA 9622DRT controller; c) a visible light blocking filter mounted on the camera lens; d) PMMA material for making a pneumatic chamber. This ensured almost uniform lighting in the entire membrane operation range. Unfortunately, this method in the pumps currently used cannot be implemented, due to their construction, and the small distance of the membrane to the walls of the pneumatic chamber, Fig. 7. For this reason, work was undertaken to develop and study the new lighting constructions.

IV. Fitness Function

An important element of the conducted research was the creation of reference shapes of the flaccid membrane surface, consistent with the actual state. The compatibility study was carried out using the membrane surface shapes defined mathematically, Fig. 8a. These include: a) extremely convex – this is the condition of the membrane, in which the membrane is lifted upwards at its maximum; b) extremely concave – this is the state of the membrane in which the downward membrane is at its maximum; c) flat membrane –

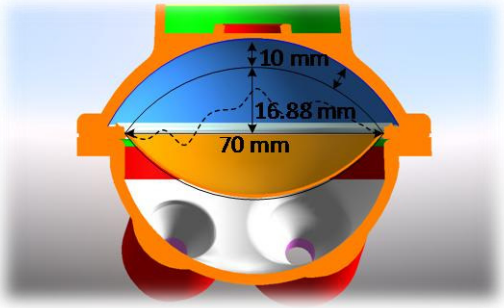

Fig. 7 Cross section of pump model presented in Fig. 6 along with selected dimensions

Fig. 8 Designed (a) and produced (b) model membrane shapes in 3D printing technology

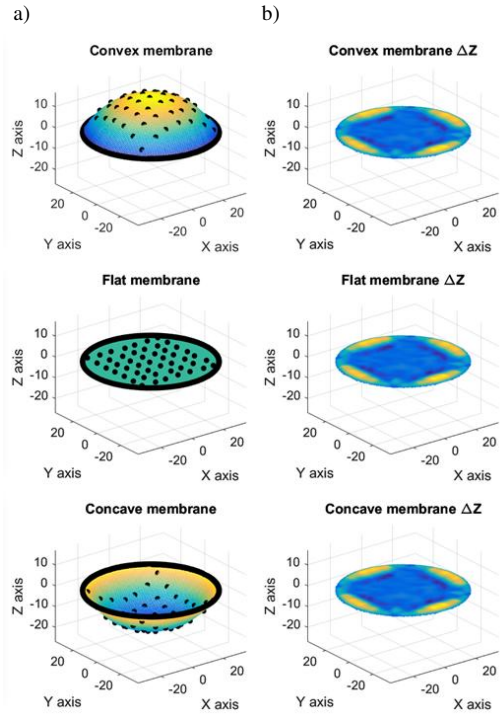

Fig. 9 Model grids determined for membranes from Fig. 8b (a), exemplary charts of membrane reconstruction errors (b)

this is the state in which the entire surface of the membrane is parallel to the plane of the camera image sensor. Due to "additional" material, this condition is not achievable by the membrane shown in Fig. 5. Nevertheless, this membrane is helpful when determining the error of the shape of the membrane surface when it is at the connection level of the blood chamber with the pneumatic chamber.

The reference membranes were modeled in CAD software. As a result, the three-dimensional models shown in Fig. 8a were obtained. These models were then saved in STL format and printed on a 3D printer. The membranes obtained in the manner presented are shown in Fig. 8b. The print was made with a layer height in the Z axis equal to 0.09 mm. The next step was to create reference grids describing the shape of the tested membranes. These grids were determined from known mathematical descriptions. The obtained reference grids are shown in Fig. 9a. Figure 9b shows sample error diagrams of reconstructing the shape of the membrane surface. They were obtained by determining the position difference in the Z axis for all the corresponding points on the reference grid and the measurement grid, representing the currently obtained reconstruction result of the membrane surface shape. The differences determined in this way were used to calculate the mean square error (MSE), which for the best solutions was only 0.0041 mm^2.

V. LIGHT SOURCE DESIGN

The tested illuminator constructions, (A) Fig. 10 and (B), (C) Fig. 11, were made based on the previously tested PCA 9622 DRT system, the application scheme of which is given in Fig. 16 in the paper [20]. 16 PWM channels were used in the illuminators. Each channel controls a LED, which is protected by a resistor limiting the current. The FYLS-0805UWC diode was used in the illuminator (A), working in the visible band at an angle of illumination $\varphi = 130$ deg and a current $I_F = 20$ mA. In systems (B) and (C), infrared diodes were soldered: VSMY 1850X01 ($\varphi = 120$ deg, $I_F = 100$ mA) and VSMG 10850 ($\varphi = 150$ deg, $I_F = 65$ mA). A high intensity LED OF-LED1G4W is used in the fiber optic illuminant (D) shown in Fig. 10, which introduces light into the fiber optic light shining on the side FOSS-3 [21]. The last tested illuminator (E) was made of EL

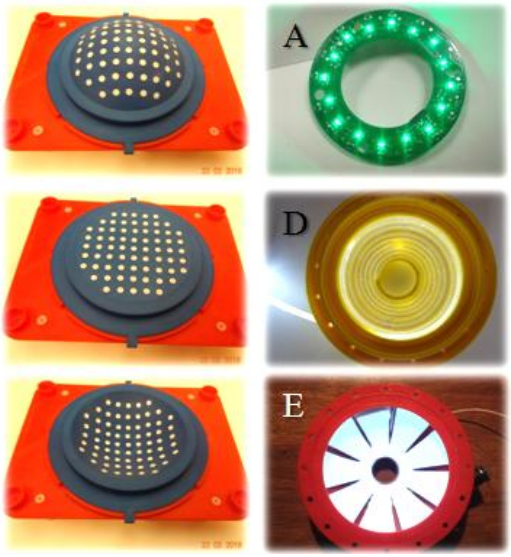

Fig. 10 View of stations and membranes for testing the illuminators (left), view of tested illuminators (right)

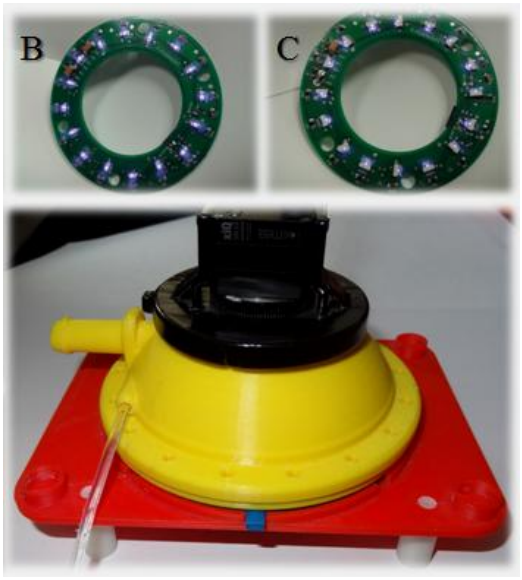

Fig. 11 View of tested illuminators (top), measuring station with a mounted fiber optic illuminator (bottom)

(electroluminescent) film. The EL film was cut into the shape shown in Fig. 10 (E). The film was powered by the converter, which converts 12V DC into AC with an amplitude of 330V and a frequency of 1.7 kHz. A white EL film was used in the study. Application schematics of specialized converters for powering electroluminescent film can be found in [22].

VI. Description of the Experiment

The experiments were carried out on a proprietary measuring station, made using 3D printing technology, Fig. 10 (left). Fig. 11 (bottom) presents the pneumatic chamber during testing with the optical fiber illuminator (D) shown in Fig. 10. The testing of illuminators (A) – (C) shown in Fig. 10 and Fig. 11 started by determining the diode current, which was unchanged for all tested membranes. The experiment involving system (A) gave a negative result – the flat and concave membrane (Fig. 12-2a and Fig. 12-3a) were underexposed. Similar effects were obtained for system (B). Although the flat membrane was properly illuminated, the convex membrane was clearly overexposed and the concave membrane underexposed Fig. 12-1b and Fig. 12-3b. Incorrect results were also obtained for system (C). This system uses infrared LEDs shining to the sides. The applied diodes reduced the spots observed on the surface of the convex membrane, but this adversely affected the illumination of the other two membranes, where most of the markers were below the limit of being distinguishable, Fig. 12-2c and Fig. 12-3c. System (D) turned out to be a promising solution. The fiber optic side lighting illuminated the flat and concave membranes well, Fig. 12-2d and Fig. 12-3d, however, the convex membrane remained underexposed, Fig. 12-1d. The reason for this was seen in the significant (approx. 16 mm) width of the camera lens, and consequently in the lack of the ability

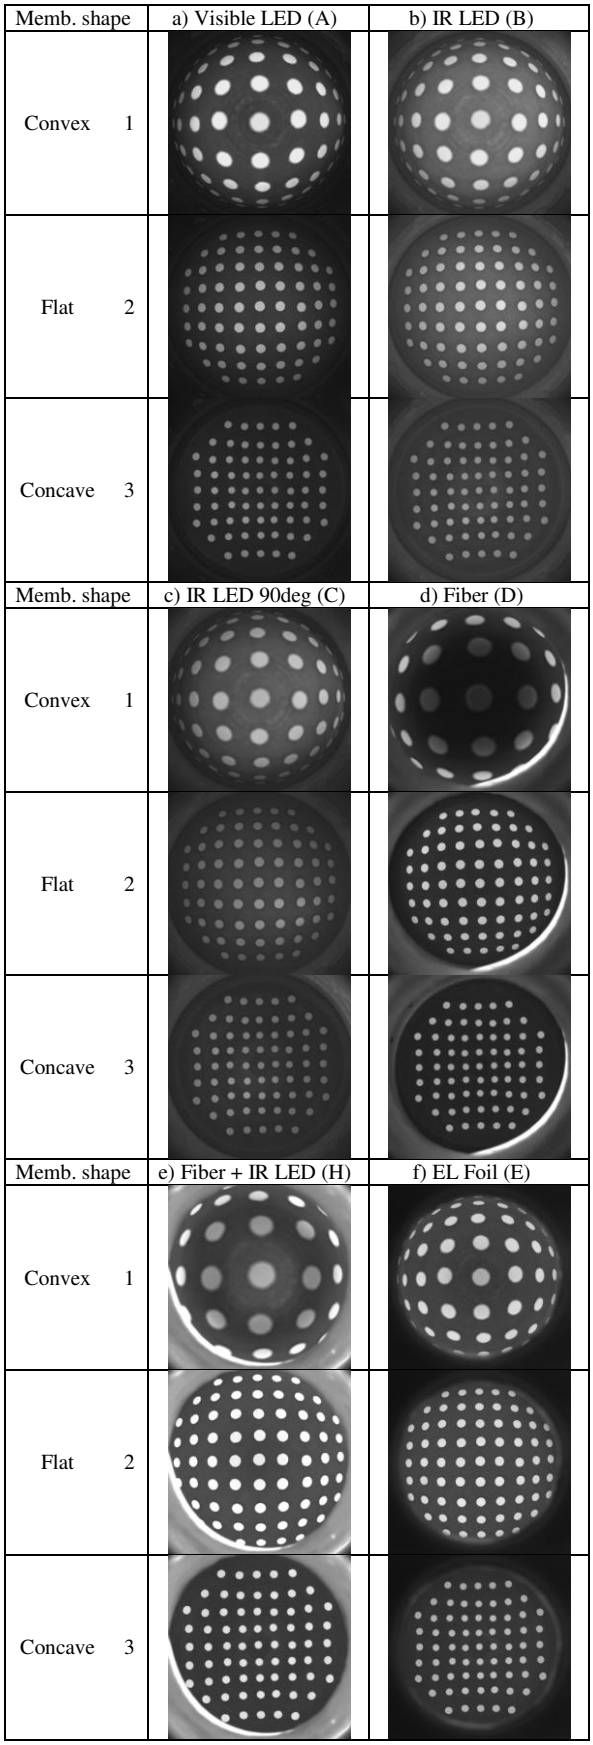

Fig. 12. Views of the studied model membranes, achieved at different lighting settings

to arrange the optical fiber on the entire surface of the dome of the pneumatic chamber. This inconvenience was solved by creating a hybrid (H) illuminator from systems (C) and (D). In the produced system, the optical fiber illuminated the concave membrane and flat membrane, Figs. 12-3e and Fig. 12-2e, and illuminator (C) illuminated the convex membrane, Fig. 12-1e. Moreover, the fiber optic liner arranged on the top of the pneumatic dome dispersed the infrared light, and thus eliminated the spots previously observed on the membrane surface in system (C). Better results were obtained only when testing the illuminator based on electroluminescent film (E). In this case, all the membranes tested were illuminated properly, Fig. 12f.

The evaluation of lighting was done using the technique presented in point IV, and discussed in detail in [5, 19]. Illuminators were examined on a group of three reference membranes shown in Fig. 10 (left). For all tested combinations of illuminator–membrane, measurement marker positions detection was conducted, the results of which are shown in Fig. 13. On this basis, the nodal points of polygons that reflect the surfaces of the tested membranes were determined using the technique presented in [5, 19]. In the following step, by using the two-dimensional data interpolation method, the obtained nets were supplemented with nodes (compacted) to the required measurement resolution. Next, the degree of marker identification, Fig. 13, and the correctness of the shape of the generated grids were analyzed, Fig. 14.

VII. IMAGE PRE & POST PROCESSING

The tests were carried out using a fixed camera equipped with a wide angle lens ($\varphi = 170$ deg) with a fixed focal length ($F = 1.2$). The acquired images were subjected to a distortion compensation procedure developed by the authors [8, 9, 23]. As a result, the membrane views shown in Fig. 12 were obtained. These views show measuring markers with a diameter of 3 mm distributed on the surface of the reference membranes. The observed variations in the size of the spots in the images result from the marker approaching or moving away to/from the plane of the camera image sensor. This effect is further enhanced by the marker zooming out or approaching to/from the focus point. As a result, the view of the marker is blurred. This fact was used in [10] to measure the distance, and in [5] and [23] to determine the shape of the membrane surface in virtual and real space. The condition for determining the shape of the membrane surface is to perform image defuzzification. It was carried out using a thresholding operation that is always carried out with a threshold preset. As a result, a binary image is obtained, ready for labeling. During labeling, (x, y) coordinates of the center of gravity for each spot, Fig. 13, as well as its area are determined. Knowledge of the determined area after the calibration of the measurement system is equivalent with knowing the distance from the marker to the camera image sensor [10]. During further analysis, only nodal points of the grid are processed

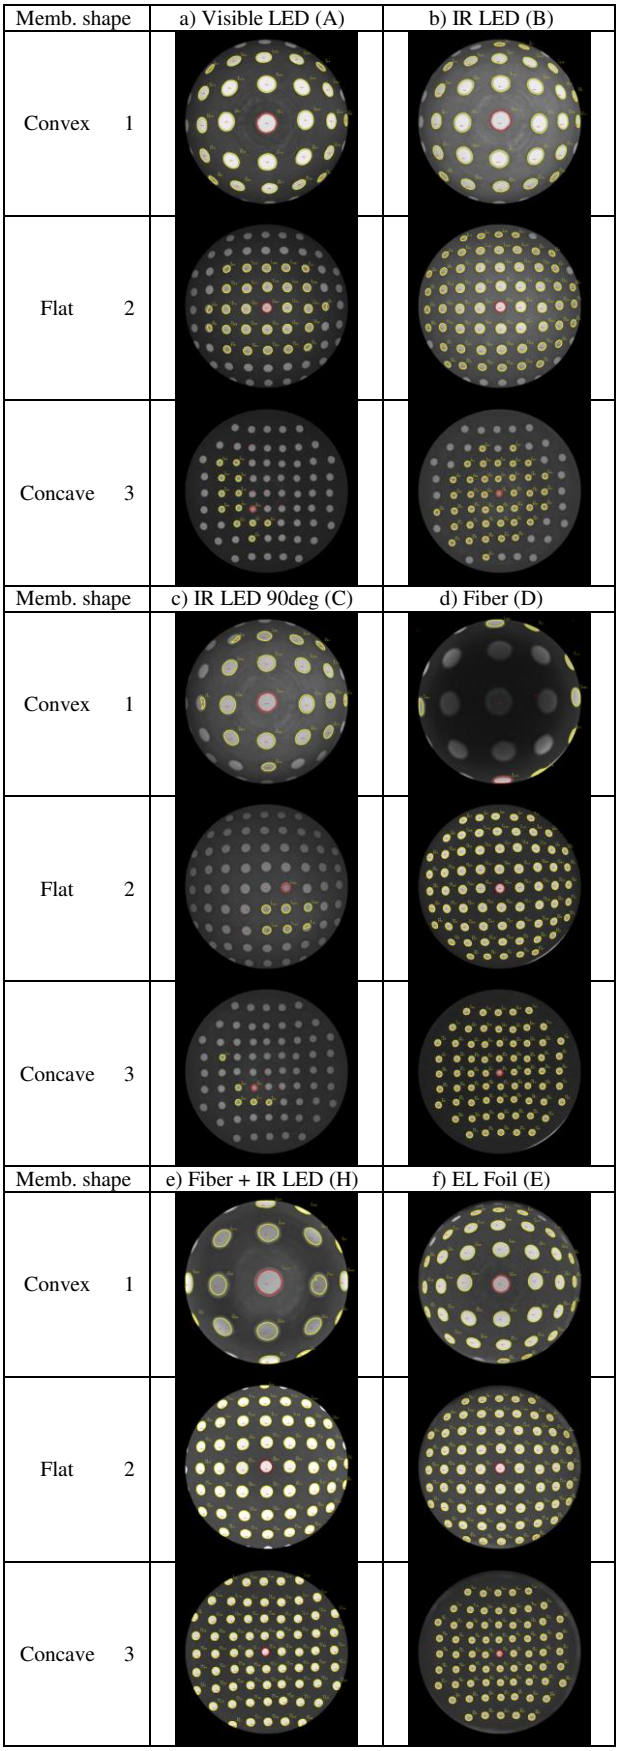

Fig. 13 Results of detecting the position of measurement markers achieved at different lighting settings

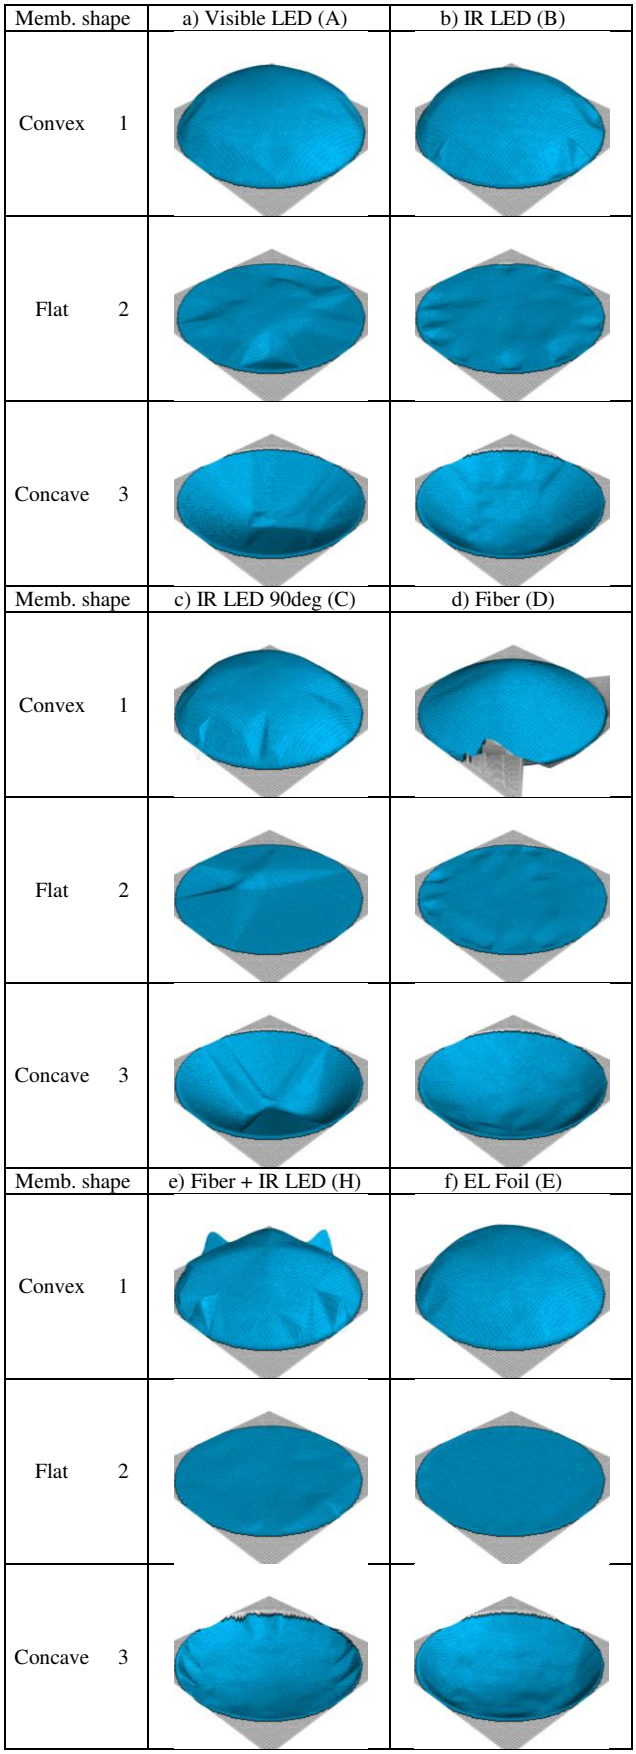

Fig. 14 Results of reconstructing the surface shape of the studied membranes achieved at different light settings

with coordinates (x_i, y_i, z_i) where i = 1,...,69. These points, using the interpolation method, determine a measuring grid of 300 x 300 points.

A graphical representation of the determined grids for all the studied membranes is presented in Fig. 14.

VIII. Results analysis

The analysis of the obtained reconstructions of convex membrane shapes shows that the best shape mapping was obtained for illuminator (E). Next were solutions (A), (B), (C), (H) and (D). In solution (A), some overexposure is visible, which led to local flattening of the determined membrane surface shape. The case of solution (B) is similar with the difference that the entire membrane was illuminated except for the four markers that remained underexposed. In effect the distortion correction function and their values have been "improved", which is visible in the form of characteristic inequalities. When using illuminator (C), it was noticed that the power of light was not fully sufficient. As a result, some of the markers did not work at all, and several markers were underexposed. A result similar to solution (B) is observed for illuminator (H). However, in this case the markers distant from the center of the membrane were overexposed and the markers located closer to the center were illuminated, but their brightness was noticeably lower. In addition, four markers under the given lighting conditions had too small a surface and were "improved" by the correction function. The worst illuminator in the study of the convex membranes was illuminator (D). Analyzing the picture shown in Fig. 13-1d it is easy to see that this state results from the underexposure of the middle portion of the membrane. No markers have been identified in this area. The obtained result is therefore the result of interpolation made on the basis of knowing the values of the characteristics determined for markers located only on the edge of the membrane.

The flat membrane, just like the convex membrane, was best visualized when illuminated with illuminator (E). A very good result was also obtained for illuminators (H), (D) and (B). When using the illuminators (H) and (D), all the markers on the membrane were working, Fig. 13-2e and Fig. 13-2d. In solution (B) only seven markers less worked, Fig. 13-2b. In this group, the smallest distortion of the shape of the membrane was observed for illuminator (H). Next came illuminator (D), and finally (B). When illuminating the membrane with system (D) the membrane was gently raised in the center. The use of the construction (B) allowed illuminating the central part of the membrane evenly, but the markers at the edge of the membrane were less illuminated. This is visible in the form of fluctuation observed near the edge of the membrane, Fig. 14-2b. The remaining solutions (A) and (C) did not work at all. When illuminator (A) was used only 22 markers placed in the center of the membrane were correctly marked. Along with them were still six markers operating, but they were not well-lit and, as a result, they were the cause of errors. In the case of illuminator (C),

only five markers worked correctly, which could not lead to a correct membrane shape reconstruction.

The last test was to determine the shape of the concave membrane. The best results were obtained for illuminators (E), (D), (H) and (B). Illuminators (A) and (C) due to bad lighting of the membrane in its lower position, did not allow obtaining correct reconstruction results.

According to the authors, the shape of the concave membrane was best determined using illuminator (E). Then the sides of the membrane are reproduced correctly, and only minor remarks can be made to the shape of the central part of the membrane. In the second position, it was decided to place illuminator (D), which properly illuminated the measurement markers, and yet in the central part of the membrane reconstruction errors were noticeable. An equally good result was obtained for illuminator (H). Just like in the previous case all markers on the obtained membrane shape "worked". As a result, the shape of the central part of the membrane is reproduced correctly (according to the authors even better than for illuminator (E)). However, disturbances were observed on the sides of the membrane, which forced illuminator (H) to be classified in third position. The last discussed illuminator is construction (B). This system achieved a surprisingly good reconstruction result, taking into account that only 41 out of 69 markers worked properly. Their lack, however, explains the reconstruction errors observed on the side surfaces of the concave membrane.

IX. Conclusions

The work discusses new illuminator constructions made for a vision sensor to measure the instantaneous stroke volume and the cardiac output of the heart pump. The experiments were carried out on a group of three reference membranes with a known mathematical description. Five variants of illuminators were subject to examination. Three tested constructions worked in the visible spectrum. The other two were implemented in the near-infrared band.

The experiments carried out have shown that it is possible to construct an illuminator that will effectively eliminate the problem of uneven surface illumination of a flaccid membrane. Among the illuminators, which design is partly based on LED diodes, the highest potential was demonstrated by the hybrid illuminator (H). It combines the advantages of a fiber optic illuminator operating in the visible band (D) and illuminator (C), made of IR LEDs illuminating the sides. Although this variant requires two supply circuits, it allowed obtaining the correct shape of a flat and a concave membrane. Initially, the incorrectly determined shape of the surface of the convex membrane was finally corrected, increasing the control current of VSMG 10850 diodes. This operation was carried out programmatically by changing the setting of the PWM circuits.

The best of the examined systems was an illuminator built with the use of an electroluminescent film. The membrane surface shapes obtained were the closest to model shapes. This solution, however, due to the significant voltage supply in a commercially produced a heart-assisting pump, requires a special approach for the production of a pneumatic chamber.

The final effect of reconstructing the shape of the membrane surface also depends on the number and position of the markers. The tests were carried out taking 49 markers, Figs. 8 and 69 markers, Fig. 10 - 13. A larger number of markers, when properly illuminated and unfolded, more precisely determines the shape of the membrane surface sought. It is worth noting that, in principle, the material from which the diaphragm is made may be any. The test membrane was made of a graphite-silicone composite. It was used in the VAD, for which the SV was determined. The obtained values of the volume were affected by an error smaller than 4.8 ml, which constituted about 4% of the volume of the blood chamber VAD [23].

***Abstract*—The method of secret key sharing between units that did not possess any secret keys in advance is considered. It is assumed that between these units there are duplex wireless MIMO fading channels. In a recent paper published by D. Qin and Z. Dingh a new key sharing protocol has been proposed between legitimate users based on eigenvalues which are invariant under permutation of two matrices in their product. We extend this statement to a characteristic polynomial and by the way to matrix trace. Methods of key bits extraction are optimized both theoretically and experimentally. On the contrary to a statement of D. Qin and Z. Ding we prove that their key sharing protocol occurs insecure if eavesdroppers have the same channels as legitimate users. In order to provide reliability and security of the shared keys both error correction codes and privacy amplification methods can be used.**

***Index Terms*—Physical layer security, key sharing protocol, MIMO transmission system, characteristic polynomial, privacy amplification, error correction codes**

I. Introduction

THE pioneered paper devoted to key sharing protocol for users that did not have any secret keys in advance belongs to Diffie and Hellman [1]. It is well known that security of this protocol rests on the intractability of the *Diffie-Hellman Problem* or simply the related *discrete logarithm computing problem* [2].

There is also a class of keyless cryptography (KC), where encryption of messages can be provided secure even without any prior secret key sharing. One of such KC can be implemented by some protocol if we have encryption algorithm satisfied to the following relation for any different keys K_A, K_B and any plaintext M:

$$f_{K_A}(f_{K_B}(M)) = f_{K_B}(f_{K_A}(M)) \quad (1)$$

where f_K is the encryption algorithm for plaintexts given a key K. Then the encryption/decryption protocol between users A and B can be performed as shown in Table I. But unfortunately the condition (1) is not valid for strong symmetric block ciphers.

Alpern and Schneier [3] proposed a cryptographic technique in which the security lies in hiding the identify of the message ordinator.

TABLE I
Encryption/decryption protocol.

M: $A(K_A)$		$B(K_B)$
1.	$C_A = f_{K_A}(M)$	
2.	$\rightarrow C_B = f_{K_B}(C_A)$	
3.	$\leftarrow C'_A = f_{K_A}^{-1}(C_B); f_{K_B}^{-1}(C'_A) = M$	

In [4] some extensions to the previous scheme was suggested that was called as *semi-anonymous channel*. Although the last scheme seems to be more realistic than the previous one but both scenarios require serious restrictions regarding communication network between users that want to share secret keys.

On the other hand it was developed in recent years a new domain known as *physical layer security* (PHY) *in multiuser wireless networks*. In this setting it is assumed that users are connected by some communication (mostly continuous) channels and the properties of these channels allow either implement directly secure information transmission between users or to share secret keys for their further usage with conventional encryption/decryption. It is worth to note that such keyless cryptosystem was based firstly on Wyner's *wire-tap channel concept* proposed in 1975 [5]. This approach has been developed later in fundamental papers [6]–[8].

But we should emphasize that in order to provide information theoretic security in wireless networks it is necessary to have in any case some advantages in legitimate communication channels against eavesdropper's channels. Such advantages are presented in Table II jointly with list of references where they were used in order to provide information security of messages or key string sharing in frames of given conditions.

Summarizing the content of Table II, we can conclude that no one of the keyless cryptosystems satisfy the natural requirements: to be secure independently on eavesdropper channel or equipment states. In fact, legal user cannot provide that SNR in eavesdropper channel is not larger than some

TABLE II
POSSIBLE ADVANTAGES OF THE LEGITIMATE CHANNELS AGAINST EAVESDROPPER CHANNELS.

Nr.	Advantages of the legitimate channels	Defect of such setting	References
1.	SNR in legitimate channels is superior to SNR in eavesdropper channel	SNR as a rule is unknown in eavesdropper channel	[5], [6], [8], [9]
2.	Not all symbols of legally transmitted blocks can be intercepted by eavesdropper	It is very specific and rare case	[10], [11]
3.	Legal users have authenticated channel for public discussion	Even so authenticated channel is provided by additional measures it is unknown SNR in the eavesdropper channel in order to optimize parameters of legal transmission	[7], [12], [13]
4.	Legal channels are sensitive to any adversary intervention. (Quantum cryptography)	Special legal channels and devices are required	[14], [15]
5.	Legal users are mobile and communication channels have multipath wave propagation. (MIMO technology can be used also for security enhancing)	Mobile units can stop sometimes. Eavesdropping is still possible on very short distance from legitimate units. Reciprocity theorem of radio wave propagation can be invalid in some cases.	[16], [17], [18]
6.	Smart antennais excited randomly by electronic means and a presence of multipath communication channels is requested. (It is not required that units can be nonstop; and eavesdropper channel can be even noiseless)	Eavesdropping is possible on very short distance from legitimate units. Reciprocity theorem of radio wave propagation can be invalid in some cases.	[19], [20]
7.	The number of antennas in legitimate MIMO system is not less than the number of eavesdropper antennas	Cryptosystem can be broken if the number of eavesdropper antennas is larger than the number of legitimate antennas	[21], [22], [23]

given value, that the number of antennas in eavesdropper MIMO system is not larger than the number of legitimate antennas and finally that reciprocity of channels is always valid.

But fortunately, it has been published recently the paper [24] in that some of mentioned above problems can be removed.

In Section II we describe one of key sharing schemes presented in [24] that is on our opinion very interesting from a practical point of view. Later we extend the protocol in [24] and examine theoretically how to optimize its parameters. In Section III we present experimental results obtained by simulation. Section IV devoted to error correction and privacy amplification of key string shared by legitimate units after performing of protocol. Section V concludes the paper and proposes some open problems for further investigations.

II. EXTENSION OF EVSKEY SCHEME

Let us remind the key sharing protocol proposed in [24] and called there *EVSkey scheme*. The scenario corresponding to this scheme is presented in Figure 1.

For simplicity reasons we restricted our consideration by the condition of equality for the numbers of antennas of the legitimate users Alice (A) and Bob (B), both at the transmitter and at the receiver are n.

Before transmission, Alice and Bob generate their own reference matrices $X_A, X_B \in \mathbb{C}^{n\times n}$, as well as randomly generated unitary matrices $G_A, G_B \in \mathbb{C}^{n\times n}$. In line with our previous assumption all matrices are square of order $n \times n$.

Let the noise matrices $N_{B1}, N_{A1}N_{B2}, N_{A2}$ have *additive white Gaussian numbers* (AWGN) as random values. After the postmultiplication of the channel matrices H_{AB} and H_{BA} by G_B and G_A, respectively and sending the resulting matrices back, users Alice and Bob get the following matrices:

$$\text{Alice:} \quad Y_A = PQX_A + PN_{B1} + N_{A2} \quad (2)$$

$$\text{Bob:} \quad Y_B = QPX_B + QN_{A1} + N_{B2} \quad (3)$$

$$\text{with } P = H_{BA}G_B \quad , \quad Q = H_{AB}G_A \quad (4)$$

For small enough noises $N_{B1}, N_{A2}, N_{A1}, N_{B2}$ we get a good estimation for the matrices PQ and QP respectively as

$$PQ \approx Y_A X_A^{-1} \quad , \quad QP \approx Y_B X_B^{-1}.$$

Since Alice knows Y_A, X_A and Bob knows Y_B, X_B, they are able to compute the matrices PQ and QP although with some errors due to the presence of noises.

In [24] it is suggested to extract a common key as the quantized complex eigenvalues of matrices PQ and QP since those eigenvalues coincide one to another although these matrices may be completely different. We extend their statement and prove the following:

Lemma 1: Given two non-singular complex matrices $P, Q \in \mathbb{C}^{n\times n}$, the matrices PQ and QP have the same *characteristic polynomials*.

Proof. By definition, the characteristic polynomial of PQ is $\pi(\lambda) = \det(PQ - \lambda I)$, where I is the identity matrix.

Then the roots λ of the characteristic polynomials satisfy the equation

$$\det(PQ - \lambda I) = 0. \quad (5)$$

It follows from (5), being Q a unitary matrix,

$$\begin{aligned} 0 &= \det(PQ - \lambda I) \\ &= \det Q \det(PQ - \lambda I) \\ &= \det(QPQ - \lambda Q) \\ &= \det(QPQ - \lambda Q) \det Q^{-1} \\ &= \det(QP - \lambda I) \end{aligned}$$

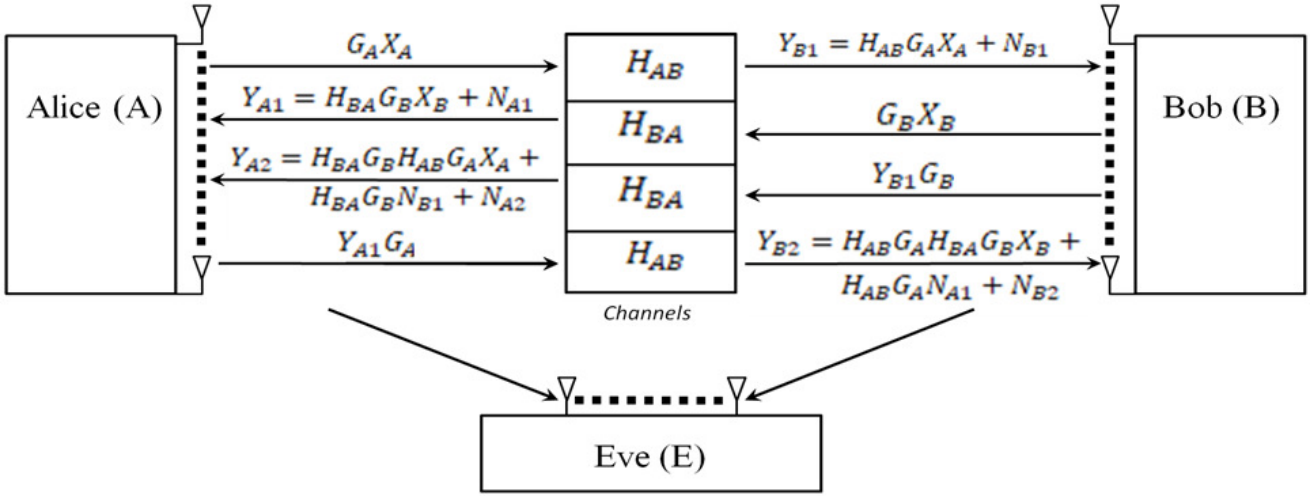

Fig. 1. The scenario corresponding to EVSKey scheme.

Then the roots of the characteristic polynomials of matrices PQ and QP coincide one to another and hence these matrices have the same characteristic polynomials. □

Thus we can calculate for the key bit generation not only the eigenvalues but also all coefficients of the characteristic polynomial and in particular case the traces of matrices PQ and QP or their determinants. Let us investigate, at first theoretically, which of the main invariants-eigenvalues or traces are less sensitive to channel noises, more closer to uniform distribution and give the most number of reliable key bits for legitimate users.

A. Using quantized matrix traces as shared key bits

Since the traces of matrices are complex values they can be quantized both on amplitude and on phase. It is proved in the Appendix that the quantization intervals on amplitude of the traces in order to provide equal probabilities of their occurrence should be chosen as follows:

$$r_{k-1} \le |Z| \le r_k \quad , \quad k = 1, 2, \ldots, N \tag{6}$$

where Z is the trace of the matrices, $r_k = \sigma\sqrt{-\ln\left(1 - \frac{k}{N}\right)}$ and N is the number of intervals.

Then the probabilities that quantized trace amplitudes coincide for users Alice and Bob will be determined by

$$p' = \sum_{k=1}^{N} \left((1 - (k-1)p)^{\frac{1}{\gamma^2}} - (1 - kp) \right) \tag{7}$$

where $\gamma = \frac{1}{1+\alpha}$, $\alpha = \sigma^2\left(1 + \frac{1}{N}\right)$, $p = \frac{1}{N}$.

In Table III there are presented the results of calculations by (7) for some parameters. We see from this table that the probability of errors are still acceptable for $N = 16$ if $\sigma^2 \le 0.001$ and for $N = 32$ if $\sigma^2 \le 0.0001$.

TABLE III
THE PROBABILITIES OF KEY COINCIDING BY (7) AFTER A PERFORMANCE OF KEY SHARING PROTOCOL BASED ON QUANTIZATION BY (6) THE MATRIX TRACES ON AMPLITUDE.

$N \setminus \sigma^2$	0.01	0.001	0.0001
4	0.98	0.998	0.9998
8	0.96	0.996	0.9996
16	0.92	0.992	0.9992
32	0.84	0.984	0.998
64	0.68	0.968	0.9968

σ^2: SNR N: Number of quantization intervals

B. Using quantized matrix eigenvalues as the shared key bits

Then every eigenvalue can be quantized on phase and amplitude intervals. Unfortunately there appears one problem: how to compare the numbering of eigenvalues adopted by the users?

Let us denote by N_P, N_A the numbers of quantization intervals on phase and amplitude, respectively. Then total number of quantization intervals is $N = N_A \cdot N_P$. We will fix the number of eigenvalues that hit in each of the N intervals (cells). After a completion of eigenvalues extraction, we get a string of integers $g_1, g_2, \ldots, g_i$, where g_i is the number of the i-th cell containing at least one eigenvalue. If several eigenvalues occur in the same cell, then the cell number is repeated as $g_i, \ldots g_i$. Next each number g_i is presented as a string of bits and such strings are connected in a consecutive binary manner. The final binary string forms a part of the shared key. It is easy to see that the total number of bits for each session of protocol can be, if $N \gg n$, approximately computed [25] as:

$$\log_2 \binom{N+n-1}{n} = \log_2 \left[\frac{1}{n!} \prod_{i=N}^{N+n-1} i \right] \tag{8}$$

C. Security of the proposed key sharing protocol

As it is shown in Figure 1, the eavesdropper Eve is able to receive only the matrices $G_A X_A, G_B X_B, Y_{A1}, Y_{B1}, Y_{A2}, Y_{B2}$ even for the ideal case when eavesdropping channels are noiseless. It is claimed in [24] that even in the very unrealistic case when Eve's receivers are located very close to the locations of Alice and Bob, and hence she is able to estimate correctly the channel matrices H_{AB}, H_{BA} of legitimate users, she is unable to compute the matrices P and Q (see eq (4)) because they are "randomized" by the unitary matrices G_B and G_A. The last matrices cannot in turn be estimated by Eve because they are "randomized" by the reference matrices X_A and X_B.

In [24] it is concluded that such key sharing system is *ideal secure* and its security is regardless of the state of the channels and the SNR in the eavesdropper channel, in contrast to all key distribution protocols described actually in Table II. *Unfortunately this statement is wrong.* In fact, following the steps below, Eve for sure is able to receive the key shared by the legitimate users:

1. $H_{BA}G_B = H_{BA}G_B H_{AB}G_A X_A \left(H_{AB}G_A X_A\right)^{-1}$
2. $X_B = \left(H_{BA}G_B\right)^{-1} H_{BA}G_B X_B$
3. $QP = Y_B X_B^{-1}$
4. $QP \rightarrow$ characteristic polynomial (equivalent to the shared key)

The key bit string should have good statistical properties as it is common for all secret cryptographic keys. (Such property is verified in the next Section using the NIST tests on pseudorandomness.)

On the other hand in order to provide a good key bit agreement between legitimate users it is very important a strong correlation between channel matrices in the first and in the second steps of the key sharing protocol.

In fact, if they would be different, say H_{AB}, H_{BA} at the first step and H'_{AB}, H'_{BA} at the second step, we would get (even in noiseless channels) instead of relations (2-4) the following ones:

$$\begin{array}{rcccl} Y'_A & = & Y'_{A2} & = & H'_{BA}G_B H_{AB}G_A X_A \\ Y'_B & = & Y'_{B2} & = & H'_{AB}G_A H_{BA}G_B X_B \end{array} \quad (9)$$

From the second equation in (9), there is no a matrix permutaition of the first one and hence the matrices Y'_A and Y'_B have not necessarily equal characteristic polynomials.

In order to provide a strong correlation between channel matrices in the first and in the second steps of the key sharing protocol (channel coherence property – in other words) it is necessary to agree physical channel properties with the rate of communication.

Typical data rates for Wi-Fi network or celular communication (LTE, 56) lies in a range of several hundreds ms. Coherence time for channels used in mobile unit communication is in range (1-10 ms) [26] and then during coherence time a number between 103 and 106 of bits can be transmitted which is sufficient to provide practical coincidence of Y_A, Y_B with matrices Y'_A, Y'_B.

TABLE IV
SIMULATION RESULTS OF THE BIT ERROR PROBABILITIES (IN PERCENT) FOR EXTRACTION THEM FROM EIGENVALUES. BOTH NUMBERS OF PHASE QUANTIZATION INTERVALS AND AMPLITUDE ONE ARE 8.

SNR $\frac{1}{\alpha}$ (dB) $\setminus$ n	4	8	16
20	21.6	22	24
30	7.7	10	12
40	2.7	3.5	4
Number of extracted bits	19	33	52

n is the number of antennas

TABLE V
LIST OF NIST TESTS ON PSEUDO RANDOMNESS.

10	The linear complexity test
11	The serial test
12	The approximate entropy test
13	The cumulative sums (cusums) test
14	The random excursion test
15	The random excursions variant test

Unfortunately the considered system (as well as all PHY-based systems) is vulnerable against active adversary. It is a scenario where an adversary, say Mallet, is presented by Alice or Bob as legitimate users and performs with any of them the above mentioned protocol. It is obvious that then he is able to share reliable key after completing the protocol. Such problem has to be solved by some additional activity of legitimate users, in order to reject falsely shared key before its implementation for encryption of secure messages [27].

III. SIMULATION RESULTS FOR THE PROPOSED KEY SHARING PROTOCOL

In order to verify our theoretical discussion it was undertaken a simulation of the EVSkey protocol. The results of simulation for extraction of key bits from matrix eigenvalues are presented in Table IV, where is presented also the number of key bits for different number of antennas n calculated by (8).

We see from Table IV that the acceptable SNR is at least 30 dB even for the case when we mean to use later error correcting codes (see Section IV). As far as the lengths of share key string they are too small for implementation even for block ciphers like 3DES or AES. Thus one can be recommended to repeat key sharing session several times. (Such approach is also presented in Section IV.)

The generated key bits were investigated by NIST tests on pseudo randomness [28]. The list of NIST tests is presented in Table V, while the results of testing on pseudo randomness in Table VI with their numbering taken from Table V.

TABLE VI
RESULTS OF THE NIST-BASED TESTING FOR THE KEY BITS SEQUENCE EXTRACTED FROM THE MATRIX EIGENVALUES UNDER THE CONDITION SNR = 30 DB AND ALSO AFTER A SHIFTING AND SUMMATION PROCEDURE.

		0.001	0.90
		0.0001	0.98
32	5	0.01	0.68
		0.001	0.83
		0.0001	0.97
64	6	0.01	0.67
		0.001	0.78
		0.0001	0.92

In the same Table VI there are presented also the results of NIST-based testing after a shifting right on the 20 bits and addition $\mathrm{mod}\ 2$ with the original sequence.

We see that after the transformation procedure the key sequence occurs slightly better. The results of simulation for extraction of key bits from matrix traces are presented in Tables VII, VIII. Comparing the results in Table IV and Tables VII, VIII we see that extraction of the key bits from the matrix eigenvalues results in larger errors than for the trace-based extraction but the number of extracted bits is significantly less for the case of extraction from the traces than for the extraction from eigenvalues.

The key bits extracted from traces were investigated by the NIST tests given in Table V. The results of testing are shown in Table IX jointly with "shift and addition" transformation. We can see from this Table that now an additional transform is not

necessary. This means that this case is superior to extraction from eigenvalues with point of key statistic view.

By comparing the results of Table III and Table VII we conclude that the quantization procedure based on (6) is acceptable. This is valid also for the case of 4 and 8 antennas.

IV. ERROR CORRECTION AND PRIVACY AMPLIFICATION

We assume that the length of the shared key should be at least 256 bits, taken into account for example that the length of key string for AES is 128 bits. This means that in order to provide the requested key length it is necessary to arrange

several sessions of key sharing protocol. Moreover in order to provide a good statistic of shared key bits it is necessary that states of channel matrices between sessions should be statistically independent. In order to short the number of such sessions the method of key bit extraction from matrix eigenvalues occurs preferential because it allows to extract more bits than matrix trace extraction during a single session (see Table IV and Tables VII, VIII). But anyway the values of bit error probabilities are too much for a good key agreement between legitimate users. This fact requires to correct errors by sending over public noiseless channel the check symbols of some good error correction code. But on the other hand a sending of check symbols over public (open) channel results in a leaking to Eve some information about key string. In order to guarantee that such leakage is limited by some value of Shannon information it is necessary to use so called *privacy amplification*. It can be provided by hashing of raw key string to more shorter final key string. It has been proved in [29] the enhanced *privacy amplification theorem.* This theorem says that using special two-stage hashing procedure the eavesdropper's expected Shannon information I_o about the final key shared by legitimate parties, satisfies the inequality:

$$I_o < \frac{1}{\gamma \ln 2} 2^{-(k-t_c-\ell-r)} \tag{10}$$

where k is the length of the raw key string shared by legitimate users after a completing of protocol, t_c is the Renyi (collision) information obtained by Eve, r is the number of check symbols sent from Alice to Bob in order to reconcile their key strings, ℓ is the length of the final key string after hashing, γ is a coefficient that approaches 0.42 for any fixed r, as k, ℓ and $k - \ell$ increase.

Since we assume that Eve is not nearby legal users, she has no eavesdropping at all, hence t_c can be removed ($t_c = 0$).

The probability P_d of error after decoding by some linear binary error correcting code with the number of information bits k, the number of check symbols r and for the probability of bit error after a completing at protocol *P'* has the following upper bound [29]

$$P_d \leq 2^{-k(1-R)} \left(1 + 2\sqrt{P'(1-P')}\right)^k \tag{11}$$

where $R = \frac{k}{k+r}$.

Using the formulas (10), (11) we can optimize the parameter r to provide the requested values I_o and P_d.

But of course for practical implementation it is necessary to use some constructive methods of encoding and decoding, say for the thing, the LDPC codes [30].

V. Conclusion

In the current paper we considered some extension of key sharing protocol proposed in [24]. It has been proved that key extraction can be performed not only from matrix eigenvalues but from matrix traces also. Moreover the extracted key bits occur for the last case even closer to pseudo random sequence in terms of NIST tests. But unfortunately the length of key strings is significantly less in the last case in comparison with extraction the key from matrix eigenvalues. Therefore this method is superior for practical implementation against matrix trace-based extraction.

We investigated how affect such parameters of key sharing protocol as the number of antennas, SNR in the legitimate channel and method of quantization. It was striked that key sharing protocol does not work if eavesdroppers has the same communication channels as legitimate users!

In fact it would be very strange to be the case because then legitimate users could share secret key without a presence of any fading channels and they could simply communicate through any channels with constant parameters.

We believe that key sharing between mobile unit is a promising approach because nothing restrictions on eavesdropping channels are suggested except of nearby locations of eavesdroppers against legal users.

The future work can be devoted to a modification of quantization procedures for the case of extraction from eigenvalues and investigation of constructive encoding and decoding for the most effective error correction in the shared key string.

APPENDIX

Proof of relation (7)

Let us consider an extraction of the key based on matrix traces. Assume that the elements of both channel matrices $P = [p_{ij}]_{1\le i,j\le n}$, $Q = [q_{ij}]_{1\le i,j\le n}$ are random, mutually independent and identically distributed: $p_{ij}, q_{ij} \sim \mathrm{CN}(0, \sigma_w^2)$. Similarly these conditions hold and for the noise matrices $N_1 = [n_{ij1}]_{1\le i,j\le n}$, $N_2 = [n_{ij2}]_{1\le i,j\le n}$: $n_{ij1}, n_{ij2} \sim \mathrm{CN}(0, \sigma_e^2)$. We admit also that channel matrices and noisy are mutual independent. The relation (3) entails

$$\begin{aligned} YX^{-1} &= PQ + PN_1X^{-1} + N_2X^{-1} \quad \text{and} \\ \mathrm{Tr}(YX^{-1}) &= \mathrm{Tr}(PQ) + \mathrm{Tr}(PN_1X^{-1}) + \mathrm{Tr}(N_2X^{-1}). \end{aligned}$$

It is easy to show that for large number of antennas ($n \gg 1$) due to Central Limit Theorem, the random variables

$$Z_A = \mathrm{Tr}(Y_{A2}X_A^{-1}) \quad , \quad Z_B = \mathrm{Tr}(Y_{B2}X_B^{-1})$$

have Gaussian distributions:

$$f_A(z) = f_B(z) = \frac{1}{\pi\sigma^2} e^{-\frac{|z|^2}{\sigma^2}} \tag{12}$$

where $\sigma^2 = DZ_A = DZ_B = n^2\sigma_w^2(\sigma_w^2 + \sigma_e^2)$.

Let us estimate the dependence of the random variables Z_A, Z_B using the notion of linear regression Z_A onto Z_B:

$$Z_B - E(Z_B) = \gamma \frac{\sigma_A}{\sigma_B} (Z_A - E(Z_A))$$

where

$$\gamma = \frac{1}{\sqrt{(DZ_A)(DZ_B)}} \mathrm{cov}\,(Z_A, Z_B)$$

is a correlation coefficient.

Since Z_A, Z_B are centered random variables with equal variances, the equation of linear regression Z_A onto Z_B has the form

$$Z_B = \gamma Z_A. \tag{13}$$

It is easy to show that $\mathrm{cov}\,(Z_A, Z_B) = n^2\sigma_w^2$. Thus we get

$$\begin{aligned} \gamma &= \frac{n^2\sigma_w^2}{n^2\sigma_w^2(\sigma_w^2 + \sigma_e^2) + n\sigma_e^2} \\ &= \left(1 + \frac{\sigma_e^2}{\sigma_w^2}\left(1 + \frac{1}{n\sigma_w^2}\right)\right)^{-1} \end{aligned} \tag{14}$$

Since the correlation coefficient γ is real-valued, it results that the random values Z_A, Z_B differ by modulus only.

If $n\sigma_w^2 \gg 1$ and the noise-to- signal ratio $\frac{\sigma_e^2}{\sigma_w^2}$ is small, then we get by (14)

$$\gamma = \frac{1}{1+\alpha} \approx 1 - \alpha \ , \ \alpha = \frac{\sigma_e^2}{\sigma_w^2}\left(1 + \frac{1}{n\sigma_w^2}\right) \approx \frac{\sigma_e^2}{\sigma_w^2} \ll 1.$$

Thus the dependence (13) between Z_A, Z_B is almost linear.

In order to get a uniformly distributed key, let us quantize the range of values Z_A (on the complex plane) in radial direction in such a way that the probability to hit Z_A into each of N rings $R_k = \{z \in \mathbb{C} |\ r_{k-1} \le |z| < r_k\}$, $r_0 = 0$, $r_N = +\infty$, occurs equally likely:

$$\Pr\,(r_{k-1} \le |z| < r_k) = \frac{1}{N} =: p \text{ for } k = 1, \ldots, N \tag{15}$$

Using (12) we are able to find the radial distribution function of Z_A:

$$F(r) = \Pr\,(|z| < r) = 1 - e^{-\frac{r^2}{\sigma^2}}$$

Thus (15) holds if and only if

$$\begin{aligned}\Pr\left(r_{k-1} \le |z| < r_k\right) &= F(r_k) - F(r_{k-1}) \\ &= e^{-\frac{r_{k-1}^2}{\sigma^2}} - e^{-\frac{r_k^2}{\sigma^2}} \\ &= p\end{aligned}$$

It results the relation

$$F(r_k) = kp = 1 - e^{-\frac{r_k^2}{\sigma^2}} \tag{16}$$

Eventually we get $r_k = \sigma\sqrt{-\ln(1-kp)}$.

Let us estimate now the probability of key coincidence for both legitimate users A and B. First we estimate the probability p_k to get Z_A and Z_B in the ring R_k. Taken into account that the dependence (13) is almost linear $Z_B \approx \gamma Z_A$, where $0 < \gamma \le 1$, we get $|Z_B| = \gamma|Z_A|$. Hence

$$\begin{aligned}p_k &= \Pr\left(Z_A \in R_k \ \&\ Z_B \in R_k\right) \\ &= \Pr\left(r_{k-1} \le |Z_A| < r_k \ \&\ r_{k-1} \le |Z_B| < r_k\right) \\ &= \Pr\left(r_{k-1} \le |Z_A| < r_k \ \&\ r_{k-1} \le \gamma|Z_A| < r_k\right) \\ &= \Pr\left(r_{k-1} \le |Z_A| < r_k \ \&\ \frac{r_{k-1}}{\gamma} \le |Z_A| < \frac{r_k}{\gamma}\right) \\ &= \Pr\left(\frac{r_{k-1}}{\gamma} \le |Z_A| < r_k\right).\end{aligned}$$

Using (16), we find that

$$\begin{aligned}p_k &= F(r_k) - F\left((\frac{r_{k-1}}{\gamma}\right) \\ &= e^{-\frac{r_{k-1}^2}{\gamma^2\sigma^2}} - e^{-\frac{r_k^2}{\sigma^2}} \\ &= (1-(k-1)p)^{\frac{1}{\gamma^2}} - (1-kp)\end{aligned}$$

Then the probability that even legal users get the same key (trace) under the condition $\gamma > \gamma_{cr} = \frac{r_{k-1}}{r_k}$ is equal to

$$\begin{aligned}p' &= \sum_{k=1}^{N} p_k \\ &= \sum_{k=1}^{N} \left((1-(k-1)p)^{\frac{1}{\gamma^2}} - (1-kp)\right).\end{aligned}$$

It is worth to note that a quantization problem of the matrix trace (in the case when legal users extract the key namely from it) can be solved trivially because the distribution (12) is independent of the "angle variable". This is valid also for all coefficients of characteristic polynomial including matrix eigenvalues. In fact, it is a consequence of circular symmetry of channel matrices and matrices of noises.

***Abstract*—In this paper one of the most accurate adaptive neuro-fuzzy modelling approach is investigated. It is suitable for modelling the nonlinear dynamics of any process or control systems. Basically, this new modelling approach is an improvement of a linear ARX polynomials models based on the least square errors estimation method that is preferred for its simplicity and faster implementation, since it uses typical functions from MATLAB system identification toolbox. For simulation purpose, to prove its effectiveness in terms of modeling accuracy, an appropriate case study of a centrifugal chiller is considered. The reason for this selection is given by the fact that the centrifugal chiller control system is one of the most seen in a large variety of applications in HVAC control systems. Since its dynamic model is of high complexity in terms of dimension and encountered nonlinearities, a tight control in closed-loop requires a suitable modelling approach**.

I. Introduction

THIS research paper investigates an alternative modelling design methodology for nonlinear systems dynamics, such as an adaptive neuro-fuzzy logic modeling approach, very useful for a large number of control systems applications from different fields, including also multimedia networks and communications. Basically, the new modeling approach is a combination of an artificial neural network (ANN) [1]-[3] and a fuzzy logic (FL) [4]-[6] modeling features. Nowadays considerable advances have been made in applying the ANN systems for problems found intractable or difficult for traditional computation [1]. Some representative preliminary results obtained and related to this field in our research work activity during the years can be found in [3]. The fuzzy logic modelling technique is a powerful tool for the formulation of expert knowledge and the combination of imprecise information from different sources [4]. The FL is in fact a control system modelling technique for a "*complicated system without knowledge of its mathematical description*", as is also stated in [4]. Fuzzy logic modelling technique was applied successfully in our research activity to design an improved hybrid fuzzy sliding mode observer estimator [5]. For simulation purpose and "proof-concept" considerations as a case study is chosen one relevant application from heating ventilation and air conditioning (HVAC) control systems, namely a centrifugal chiller system, that is one of the most widely used in this kind of applications. It is characterized by a great complexity and high nonlinear behavior, as is shown with many details in [7]. As is shown in [7], the centrifugal chillers have become the most widely used devices since they have high capacity, reliability, and require low maintenance. Furthermore, in this recent research paper work is completed a literature review in the field that reveals a significant amount of work done in a classic way on transient and steady state modelling for centrifugal chillers, such is revealed in [8]-[16]. Additionally, we try to complete in the following the literature review with the most recent sophisticated and intelligent approaches related directly to a combined neural networks and fuzzy logic or separately modelling methodologies applied to centrifugal chillers. An interesting integrated modelling methodology is used in [17] to improve the reconstruction of the performance map of axial compressor and fans, where the learning capability of ANN is integrated to the knowledge aspect of fuzzy inference system (FIS) to offer enhanced prediction capabilities rather than using a single methodology independently.

In [18] an application of combined neuro-fuzzy modelling techniques to develop a fault detection, diagnosis and isolation (FDDI) strategy for centrifugal chillers is presented.

A new modelling approach of steady state vapour-compression liquid chillers is presented in [19] that uses a generalized radial basis function (GRBF) ANN to predict chiller performance. As is mentioned also in [7] that centrifugal chillers are the most energy-consuming devices in HVAC applications, especially if they do not operate optimally, i.e. they cannot produce the required cooling load

This work was not supported by any organization

capacity, an improvement of their coefficient performance (COP) and to reduce the power consumption will be required. This objective is achieved in [20] by using for model prediction an ANFIS based Fuzzy Clustering Subtractive (FCS) and for classification and optimization an Accelerated Particle Swarm Optimization (APSO) algorithm.

The proposed technique "*reduces the total power consumption by 33.2% and meets the cooling demand requirements*", as is stated also in [20]. Also, "*it improves the cooling performance based on COP, thus resulting in a 15.95% increase in efficiency compared to the existing cooling system*". The studied ANFIS-based FCS outperforms the ANFIS-based fuzzy C-means clustering in terms of the regression. Then, the algorithm-based classifier APSO has better results compared to the conventional particle swarm optimization (PSO).

Thus, it is important to explore new modelling methodologies for HVAC centrifugal chillers dynamic systems. With this as motivation, the remainder of the paper is structured as follows. In Section 2 the ARX model of the centrifugal chiller based on the measured input-output measurements data set obtained by extensive simulations in open-loop is presented. In Section 3 the simulation results of both closed-loop control subsystems, evaporator and condenser based on ARX models built in Section 2 are shown. In Section 4 the neuro – fuzzy model of centrifugal chiller based on the same open-loop input-output measurements data set used in Section 2 is presented. In Section 5 performance analysis of both models are compared in terms of modeling accuracy. Finally, the Section 6 concludes the relevant contributions of this research paper.

II. THE ARX MODELS OF CENTRIFUGAL CHILLER

A. The Simulink Model of the Open Loop Centrifugal Chiller

Basically, a centralized centrifugal chiller control system can be considered as an interconnection of two main closed-loops control subsystems, the first one is a chilled water temperature control loop inside an evaporator, and the second one is a refrigerant liquid level control loop inside a condenser [7]. Since its dynamic model is of high complexity in terms of dimension and encountered nonlinearities, a tight control of the both closed-loops requires a suitable modelling approach. The centrifugal chiller efficiency can be improved by implementing advanced model-based controller design strategies. Consequently, the development of high-fidelity centrifugal chiller dynamic model has become a priority task of our research. For interested readers a complete dynamic model of centrifugal chiller under our consideration is given in Annex 1 of our research work [7], pp. 299-305.

In first step of the control design, based on the mentioned modelling development, a MATLAB SIMULINK model for a centrifugal chiller centralized system in open-loop is built, as is shown in Fig. 1 and Fig. 2, similar to those introduced in [7], p. 286.

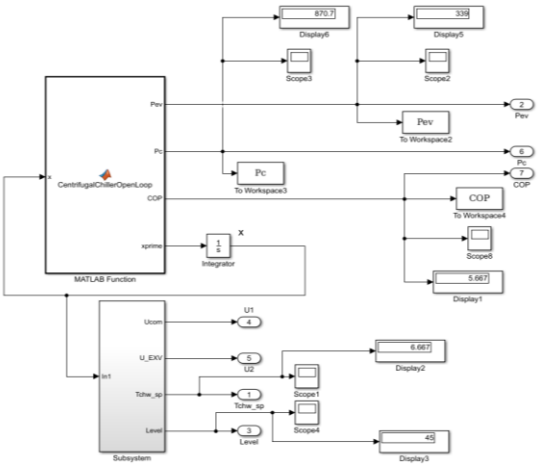

Fig.1 SIMULINK model of centralized centrifugal chiller in open-loop (see also (7), p. 286)

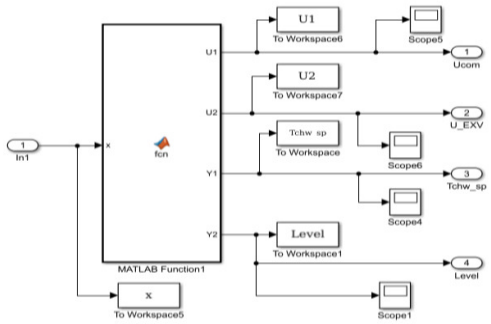

Fig.2 SIMULINK model of the bottom Subsystem block *(*see also (7), p. 286*)*

The SIMULINK centrifugal chiller open-loop model is an useful architecture structure support for ARX models, and also to build several closed-loop control strategies as the one based on two single input - single output (SISO) ARX models described in the next section for the overall system, in fact a distributed system, since in "real-life" there exist some interferences between the both loops [7]. Through extensive open-loop simulations is generated the most appropriate input-output data set required to build the linear SISO polynomial ARX models for both open-loops of the centrifugal chiller, as is shown in Fig. 3 for chilled water temperature and Fig.4 for refrigerant liquid level respectively. Consequently, a good open-loop model capable to capture entire dynamics of the overall chiller system under various operating conditions is essential to give more flexibility for closed-loop control design strategies.

B. The SISO ARX Model of Temperature and Liquid Refrigerant Level Open-Loops

Basically, the *arx* MATLAB *function* [7]–[8] estimates the parameters of two polynomials discrete-time models known as autoregressive with an exogenous input (ARX) and a more simple polynomial autoregressive without exogenous input (AR) that estimates the parameters of the scalar time

series, by means of the well-known least squares method the most used in control systems identification and parameters estimation, such as those well documented in [7]-[8]. Theoretically, the *arx* MATLAB function uses a prediction-error method and specified polynomial orders [7]-[8]. Also, a pure transport delay of the signal flow in the feedback path from the measurement sensors to the controllers is specified in each ARX structure. The ARX model is "*inherently linear and the most significant advantage is that we can perform model structure and parameter identification rapidly*", as is stated in [9]. To get the ARX model the data set is divided in two segments, first segment consisting of 1000 samples required for the prediction phase, and the second one consisting of the remaining 2600 samples required for validation phase respectively. The information obtained on the discrete-time chilled water temperature ARX model in MATLAB command window is:

$$A(z)y(t) = B(z)u(t) + e(t) \tag{1}$$

where the coefficients of the polynomials $A(z)$, $B(z)$ are estimated by the well-known least square errors (LSE) procedure, given in the next two equations:

$$A(z) = 1 - 1.096z^{-1} - 0.7723z^{-2} + 0.8689z^{-3} \tag{2}$$

$$\begin{aligned} B(z) &= 7.98z^{-2} - 8.074z^{-3} - 8.775z^{-4} + 8.31z^{-5} + \ldots \\ &2.009z^{-6} - 1.44z^{-7} + 0.002313z^{-8} - 0.009972z^{-9} + \ldots \\ &-0.002079z^{-10} + 0.001031z^{-11} \end{aligned} \tag{3}$$

Sample time: 1 second

Parameterization:

Polynomial orders:

$n_a = 3$ ($A(z)$ degree), $n_b = 10$ ($B(z)$ degree),

$n_k = 2$ (delay)

Number of free coefficients: 13

Status:

Estimated using ARX on time domain data.

Fit to estimation data: 100% (prediction focus)

FPE: 2.821e-11, MSE: 2.694e-11

The argument variable z^{-1} is the equivalent of the time-discrete delay operator q^{-1}, as is shown in [7]-[8], i.e. $z^{-1}y(t) = q^{-1}y(t) = y(t-1)$, and $e(t)$ is an additive white noise.

The simulation results obtained in both prediction phase (in the top graph side) and validation phase respectively (in the bottom graph side) are shown in Fig.5. These results reveal a good performance in the both phases for chilled water temperature. Similarly, for refrigerant liquid level SISO ARX open-loop the following information provided in MATLAB command window is very useful for controller design:

$$A(z)y(t) = B(z)u(t) + e(t) \tag{4}$$

$$\begin{aligned} A(z) &= 1 - 2.02z^{-1} + 0.5349z^{-2} + 0.8555z^{-3} + \ldots \\ &-0.2345z^{-4} + 0.08802z^{-5} - 0.4596z^{-6} + \ldots \\ &0.1761z^{-7} + 0.131z^{-8} - 0.07358z^{-9} + \ldots. \\ &0.001818z^{-10} \end{aligned} \tag{5}$$

$$\begin{aligned} B(z) &= -15.85z^{-1} + 19.63z^{-2} + 4.138z^{-3} - 3.039z^{-4} + \ldots \\ &-8.471z^{-5} - 0.677z^{-6} + 5.626z^{-7} - 0.2662z^{-8} + \ldots \\ &-1.1z^{-9} \end{aligned} \tag{6}$$

Sample time: 1 seconds

Parameterization:

Polynomial orders:

$n_a = 10$ ($A(z)$ degree), $n_b = 9$ ($B(z)$ degree),

$n_k = 1$(delay)

Number of free coefficients: 19

Status:

Estimated using ARX on time domain data.

Fit to estimation data: 99.98% (prediction focus)

FPE: 6.911e-08, MSE: 6.502e-08

The simulation results obtained in both prediction phase (in the top graph side) and validation phase respectively (in the bottom graph side) are shown in Fig.6. These results reveal a poor performance in the both phases for refrigerant liquid level, caused by the presence of the oscillations around the level set point of 45% of the liquid in Condenser.

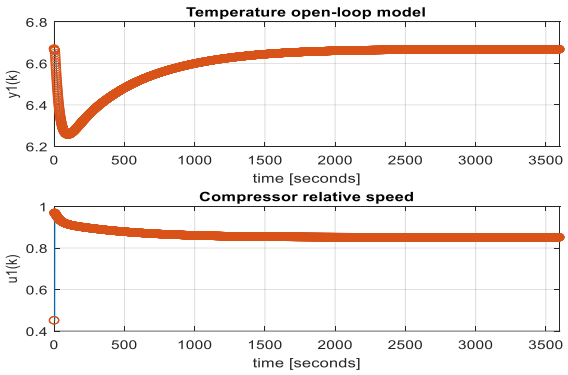

Fig.3 Temperature open-loop model

Concluding, the performance in Fig. 7 and Fig.8 appears to be very good for chilled water temperature, and worst for refrigerant liquid level. However, if a better performance level is desired, we might want to switch to a nonlinear model. In particular, we are going to use a neuro-fuzzy modeling approach ANFIS, to see if we can push the performance level of an off-line trained ANN with a fuzzy inference system (FIS), as can be seen in Section 4.

III. CENTRIFUGAL CHILLER SISO ARX MODELS CLOSED-LOOP SIMULATION RESULTS

In this section we show the great potential of both ARX models for control design in feedback closed-loop. Precisely, we show the results of the standard proportional integral derivative (PID) control used in each closed-loop to control the chilled water temperature and the refrigerant liquid level. The main idea is that even if the ARX models performance is not the best one, but it is satisfactory, two well-tuned PID controllers, i.e. their parameters $k_P, k_I,$ and k_D have optimal values, as is shown also in [7], compensate the modeling mismatches, by performing very well in closed-loop. The Simulink model of the both closed-loops is shown in Fig. 7, and the simulation results that reveal a very good performance in terms of robustness to the changes in set points and convergence with a very fast transient are shown in Fig. 8, for chilled water temperature, and Fig.9 for refrigerant liquid level.

IV. THE ANFIS MODEL OF CENTRIFUGAL CHILLER

Basically, the architecture of an adaptive neuro-fuzzy inference system (ANFIS) attached to the centrifugal chiller nonlinear model is a combination of an ANN that drives a fuzzy inference system (FIS). The ANN is trained online or offline based on an input-output measurements data set collected as a result of extensive open-loop simulations to find the most appropriate nonlinear relationship between the inputs and the outputs of the both open-loops of centrifugal chiller control system.

Essentially, the proposed ANN structure has the following three main features:

- Ability to find the solution of such problems for which algorithmic method is expensive or does not exist
- Ability to learn by experience, thus is not need to program them at much extent
- High accuracy and a considerable fast processing speed than traditional systems.

The proposed ANN computation is performed by "*of dense computing mesh nodes and connections*" [1], as is shown in Fig. 10 [2]. It is a driven data based, operating "*collectively and simultaneously*" [1], [3] to learn (e.g. in supervised or un-supervised learning mode) how to match the input and output training (offline or online) measured data set (prediction phase) of the centrifugal chiller control system under consideration, thus to establish an accurate relationship (i.e. model), validated on the supplemental segment data set (validation phase). The basic processing elements of the proposed ANN structure are called artificial neurons, or simply nodes, that typically operate in parallel and are configured in regular architectures, similar to those shown in Fig.10.

Within the ANN architecture the neurons perform similar to summing and nonlinear mapping junctions.

Basically, the ANN architecture structure contain input, hidden and output layers, as well as several feedback connections within the layer and toward adjacent layers.

Each connection strength is expressed by a numerical value called weight, which can be modified during the online or offline training in a prediction phase of computational process.

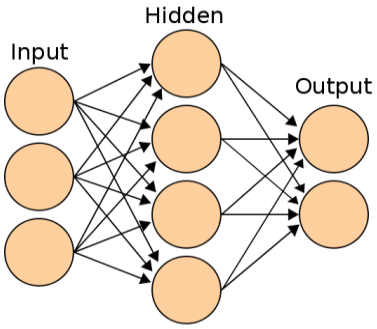

Fig.10 A simple ANN architecture (reproduced from [2])

Fuzzy logic modelling technique is a "*computational paradigm that is based on how humans think*", as is stated in [6]. According also to [6] in fuzzy logic, any statement assumes a probabilistic value between 0 and 1, representing the membership degree of an element that belongs to a given set.

The first step in ANFIS modeling system identification is the input selection to determine which variables should be the input arguments to the ANFIS model. For simplicity, as is suggested in [9] we assume that there are 10 input candidates for the ANN [3]:

$(y(k-1), y(k-2), y(k-3), y(k-4))$,

$(u(k-1), u(k-2), u(k-3), u(k-4), u(k-5), u(k-6))$

and the output to be predicted is $y(k)$. A heuristic approach to input selection is called sequential forward search, in which each input is selected sequentially to optimize the total squared error (RMSE). This can be done by using the MATLAB function *seqsrch*; the results are shown in Fig. 11 for chilled water temperature, and Fig.12 for refrigerant liquid level respectively.

$$[\,n_a \;\; n_b \;\; n_k\,] = 10 \;\; 9 \;\; 1$$

The inputs are selected with a training RMSE of 0.000320, and checking RMSE of 0.000120906, for chilled water temperature, and a training RMSE of 0.000274694, for refrigerant liquid level respectively.

The simulation results for the estimated nonlinear centrifugal chiller ANFIS models in open-loop are shown in Fig.13, for chilled water temperature, and Fig.14 for refrigerant liquid level.

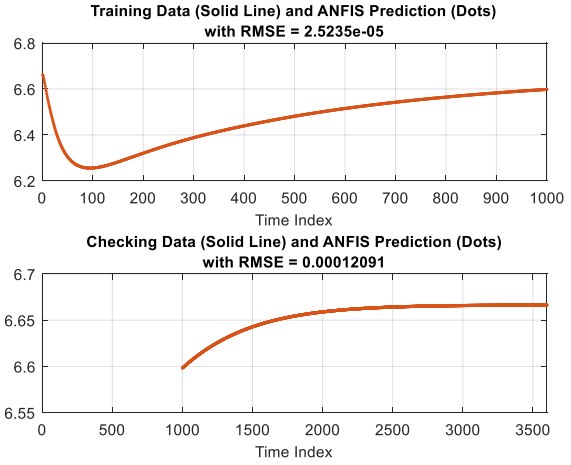

Fig.13 Temperature SISO ANFIS open-loop model

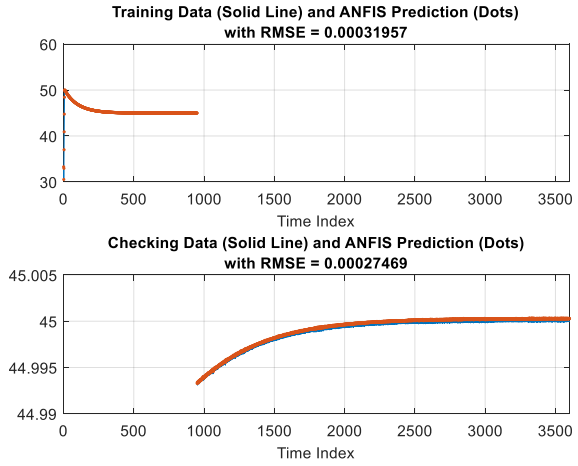

Fig.14 Refrigerant liquid level SISO ANFIS open-loop model

As mentioned in Section 2 for ARX models we follow the same procedure to split the original data set obtained by extensive open-loop simulations in two data subsets, the first one for training phase (the top side of the graphs), and the second one for prediction (estimation) phase (the bottom side of the graphs) respectively. These modeling aspects can be seen also in Fig.13 and Fig.14. The simulation results reveal a great accuracy modeling performance for the nonlinear ANFIS models compared to the performance of linear ARX models, and thus they have also a great potential for control design.

To simplify the ANFIS modeling design we suggest the use of the MATLAB function *anfis* provided by MATLAB Fuzzy Logic Toolbox, that is a hybrid learning algorithm to identify the membership function parameters of single output, Sugeno type FIS. A combination of LSE and backpropagation gradient descent methods [3] are used for training FIS membership function parameters [5] to model a given set of input-output data set, as is mentioned in MATLAB Fuzzy Logic Toolbox [8].

V. Conclusion

This research paper is an interesting MATLAB application of a modeling design approach that uses the most accurate nonlinear adaptive neuro-fuzzy ANFIS models, as an alternative to linear polynomial ARX models. If we want to choose between ARX and ANFIS models we need to think in terms of fast implementation or precision.

For fast implementation we can choose the ARX models since these are inherently linear and the most significant advantage is that we can perform model structure and parameter identification rapidly. If a high modeling accuracy performance is desired, we are going to use a neuro-fuzzy modeling approach ANFIS, to push the performance level with a fuzzy inference system. In the future work we will extend the investigations area to apply the nonlinear ANFIS models for many other similar applications in different fields, and to explore their great potential in closed-loop control systems, and also in sliding mode control [3], [10],[23].

***Abstract*—Binaural technology becomes increasingly popular in the multimedia systems. This paper identifies a set of features of binaural recordings suitable for the automatic classification of the four basic spatial audio scenes representing the most typical patterns of audio content distribution around a listener. Moreover, it compares the five artificial-intelligence-based methods applied to the classification of binaural recordings. The results show that both the spatial and the spectro-temporal features are essential to accurate classification of binaurally rendered acoustic scenes. The spectro-temporal features appear to have a stronger influence on the classification results than the spatial metrics. According to the obtained results, the method based on the support vector machine, exploiting the features identified in the study, yields the classification accuracy approaching 84%.**

I. Introduction

DUE to a growing popularity of binaural technology [1], large repositories of audio material with binaural sound will soon be created. This will inevitably give rise to challenges concerning the management of spatial audio content. The method proposed in this paper could potentially be used for automatic indexing, search and retrieval of binaural recordings according to their spatial properties, helping to manage future audio repositories.

Most of the studies in the area of acoustic scene classification (ASC) aim to identify an environment where a given scene was recorded [2]-[4]. Little work has been done towards the classification of the recordings according to their spatial characteristics. The key idea underlying this work is, therefore, to extract the features from binaural recordings and to develop a prototype classifier allowing for classification of the spatial properties of acoustic scenes.

Taking advantage from feeding binaural signals to the input of ASC algorithms does not constitute a new approach. Chu et al. developed an environment-aware robotic system equipped with binaural microphones [5]. Trowitzsch et al. demonstrated benefits from using a binaural signal processor for detection of environmental sounds [6]. More recently, such researchers as Han and Park, as well as Weiping at al., exploited binaural signals in their ASC algorithms submitted to the DCASE2017 Challenge [7], [8]. However, to the best of the authors' knowledge, no-one has yet attempted to classify spatial properties of auditory scenes evoked by binaural recordings.

This study extends and builds on the recent work by Zieliński [9]. In contrast to the aforementioned study, which was focused on the classification of five-channel surround sound recordings, the experiment described in this paper was devoted to the classification of binaural audio content.

II. Taxonomy of Basic Spatial Audio Scenes

Information provided at the output of the proposed classifier identifies one of the four basic spatial scenes, labeled as *FB*, *FF*, *BF*, and *BB*. These scenes constitute the typical distribution patterns of foreground and background audio content around the listener in the horizontal plane (see Table I). Foreground sound objects represent easily identifiable, important and clearly perceived audio sources, whereas background objects normally represent reverberant, unimportant, unclear, ambient, "foggy" and distant sound sources. A taxonomy of the acoustic scenes adopted in this study was inspired by Rumsey's simplified spatial audio scene-based paradigm [10].

Table I.
The Basic Spatial Audio Scenes

Acoustic Scene	Description
Foreground-Background (*FB*)	A listener perceives foreground audio content in the front and background content behind the head.
Foreground-Foreground (*FF*)	A listener is surrounded by foreground audio content.
Background-Foreground (*BF*)	A listener perceives background audio content in the front and foreground content behind the head.
Background-Background (*BB*)	A listener is surrounded by background audio content.

This work was supported by a grant S/WI/3/2018 from Bialystok University of Technology and funded from the resources for research by Ministry of Science and Higher Education.

III. Corpus of Binaural Recordings

In total 600 binaural recordings were gathered for the purpose of this experiment. Most of the selected excerpts were extracted from the recordings available in the Internet, while 28 recordings, which constitutes 4.7% of all the items, were obtained through a binaural processing of the commercially available 5.0 surround sound recordings. The gathered sound clips represented such recording genres as classical music, pop music, jazz, electronic music, nature, documentary, drama, ambient recordings, and film soundtracks. During the selection procedure, care was taken that each excerpt exemplified a single spatial scene (*FB*, *FF*, *BF* or *BB*). The recordings were annotated manually by the first author. The average duration of the acquired audio samples was equal to 20 seconds. The recordings were stored in uncompressed two-channel audio files with a sampling rate of 44.1kHz and a 16-bit resolution. The available recordings in the audio corpus were split into the two subsets intended for the training (75% of items) and validation purposes (25% of excerpts), respectively.

IV. Feature Extraction

In total 1012 features were extracted for the purpose of this study. They could be divided into two broad categories: spatial and spectro-temporal. An overview of the extracted features was given in Table II. The rms-based metrics and binaural cues were classified in this study as spatial features, whereas the spectral features, the Mel-frequency cepstral coefficients (MFCCs) and the discrete cosine transformed amplitude modulation spectrogram coefficients (DCT AMS) were categorized as the spectro-temporal metrics. The procedure used to extract the features was outlined below.

Let x and y denote the left and right ear signals of the binaural recordings, respectively. Some of the metrics were extracted directly from the above signals whereas the other features were calculated based on m and s signals, where $m = x + y$ and $s = x - y$. Prior to calculating the metrics, the signals were split into 20 ms time frames with a 10 ms overlap. In order to save the computation time the duration of the analyzed time-blocks of the recordings was reduced to 7 seconds.

For each time frame, a ratio between the rms values of the x and y signals was computed. This way the obtained descriptors constituted a crude approximation of the interaural level differences (*ILD*). Similarly, for every time frame, a ratio between m and s signals was also calculated. It was assumed by the authors that this ratio could also be considered to be a simple descriptor of spatial characteristics.

All the metrics, including those described in the remainder of the paper, were calculated for every time frame of the signals. Then, they were summarized using the absolute mean values and standard deviations. In order to account for temporal fluctuations of the rms ratio across the time frames, the standard *delta* metrics [11] were also computed in a similar way as explained above.

There are three fundamental cues responsible for the spatial perception of sound: interaural level difference (*ILD*), interaural time difference (*ITD*), and interaural coherence (*IC*) [1], [12]. These cues were computed separately for each output of a 40-channel gammatone filter bank using their corresponding rate-maps. The rate-maps constitute a representation of auditory nerve firing rates [13] and are used in ASC algorithms [6]. The standard *delta* metrics [11] were also computed based on the *ILD*, *ITD*, and *IC* cues. The binaural cues were estimated using the publically available software package developed as an auditory front-end of the TWO!EARS system [14].

The following spectral features were included in the study: *centroid*, *spread*, *brightness*, *high-frequency content*, *crest*, *decrease*, *entropy*, *flatness*, *irregularity*, *kurtosis*, *skewness*, *roll-off*, *flux*, and *variation*. They all constitute the standard metrics commonly used in music information retrieval algorithms [15]. The above spectral features were extracted separately from the x and y signals. Then, the differences between the obtained spectral descriptors (difference features) were computed for each time frame. In addition, the same procedure was also applied to the m and s signals.

Mel-frequency cepstral coefficients (MFCCs) are commonly used in the ASC algorithms as spectral descriptors [4]. In our study, the first 20 coefficients were extracted for the m and s signals, respectively, and summarized using means and standard deviations. The similar calculations were also performed for the *delta*-MFCC coefficients. Moreover, the same procedure was also applied to the difference values between the MFCC coefficients obtained for the m and s signals, respectively.

The last group of features included in this study was derived from the amplitude modulation spectrograms (AMSs) [16]. First, the AMSs were calculated for the m and s signals, respectively. Then, the modulation spectrograms were transformed using the discrete cosine transform (DCT). As a result, for each time frame 600 DCT coefficients were produced. In order to compress the data, only the first 40 coefficients were preserved (the value adjusted during the pilot experiments). Finally, the DCT coefficients were summarized across time frames using the mean values and standard deviations.

V. Experiments and Results

The following five algorithms were selected and compared in terms of their ability to classify the spatial scenes: (1) *k*-nearest neighbors algorithm (*k-nn*), (2) multinomial re-

TABLE II.
OVERVIEW OF THE EXTRACTED FEATURES (1012 METRICS IN TOTAL)

	Spatial Features		**Spectro-Temporal Features**		
Feature Acronym	RMS	Binaural Cues	Spectral Features	MFCC	DCT AMS
No. of Features	8	492	112	240	160

gression with a least absolute shrinkage and selection operator (*lasso*) [17], (3) random forest, (4) neural network, and (5) support vector machine (*svm*).

The training data consisted of 451 observations and 1012 variables (features). A standard 10-fold cross-validation was performed during the supervised training procedure.

Fig. 1. shows the average classification accuracy results obtained using a single classification algorithm, namely the random forest. The classifier employing a subset of only 8 features based on the rms estimators produced the worst results, with the mean accuracy below 60%. This outcome shows that such simplistic metrics are inadequate, on their own (that is used in isolation from the other features), to reliably discriminate between the audio scenes. Far better results could be obtained by using a set of 492 features based on the binaural cues, with an accuracy reaching approximately 70%. Spectral features (112 metrics), when used on their own, yielded a similar level of accuracy. Slightly better accuracy could be obtained employing solely the MFCC features (240 metrics). DCT-AMS features (160 metrics) used in isolation from the other descriptors produced slightly disappointing results with the accuracy level of approximately 65%. The best classification outcome was obtained by incorporating all the features simultaneously (1012 metrics), yielding a mean classification accuracy of approximately 78%.

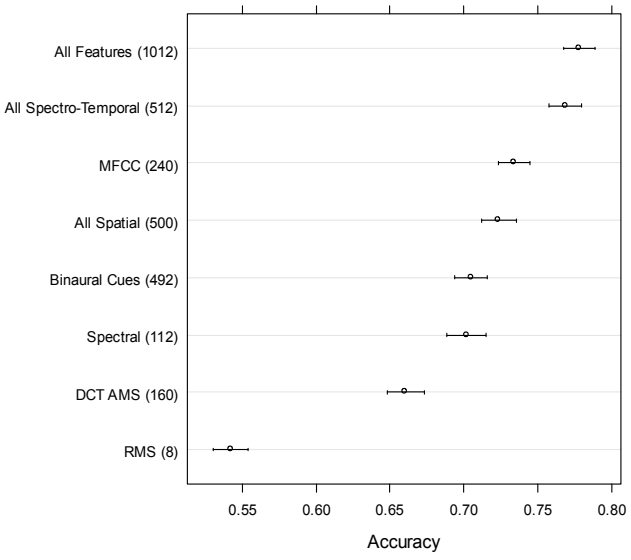

Fig. 1 Classification accuracy obtained using lasso regression for selected groups of features. The results show means and associated 95% confidence intervals. Numbers in brackets denote a quantity of features in each group.

Note that a conglomerate of all the 500 spatial features produced markedly worse results compared to those obtained using the combined group of all the 512 spectro-temporal features. This surprising outcome showed that the spectro-temporal features might be better at discriminating between the spatial scenes than the spatial metrics. This observation was confirmed during the validation test described below.

In order to reduce the risk of overfitting, a backward stepwise selection technique [17] was applied to the test data. An overview of the obtained results, including the accuracy levels, the number of retained features and the values of the model parameters, were presented in Table III. The obtained results show that the best models obtained for the lasso regression method, random forest, and support vector machines produced very similar results, with the accuracy level being equal to approximately 79.8%. The main difference between these models was the number of the selected features. For the lasso regression method, 116 features were selected, whereas for the random forest only 33 metrics were retained. The best model obtained for the support vector machine was based on 490 selected features. The worst outcomes were produced by the neural network and *k*-nn algorithms. The best models selected for each classifier during the feature selection procedure were subsequently used in a validation test.

During the validation test, based on the test dataset, the best classification accuracy results were obtained using the support vector machine (83.89%), followed by the random forest (77.18%), and the lasso regression method (76.51%). The neural network and the method based on the *k*-nearest neighbors produced the worse accuracy results, at the level of 75.17%. The confusion matrix obtained for the support vector machine (the winning method) was presented in Fig. 2. It can be seen that the algorithm could make a particularly good distinction between the *BB* scene and the remaining three scenes (sensitivity of 90.7%).

TABLE III.
OVERVIEW OF THE BEST MODELS OBTAINED THROUGH THE PROCEDURE OF FEATURE SELECTION

Classifier	**Accuracy (%)**	**No. of Features**	**Parameters**
k-nn	73.17	445	$k = 7$
lasso regression	79.84	116	*Alpha* = 0.55 *Lambda* = 6.460145×10^{-3}
random forest	79.81	33	*No. of trees* = 500 *mtry* = 17
neural network	77.64	394	*No. of hidden layers* = 1 *No. of hidden units* = 3 *Weight decay* = 0.1
svm	79.83	490	*Kernel – radial basis function (RBF)* *Sigma* = 1.822721×10^{-3} *Cost* = 1

VI. DISCUSSION AND CONCLUSIONS

The aim of this study was to identify the features useful for discrimination of the four basic spatial audio scenes of binaural recordings, labeled as *FB*, *BF*, *FF*, and *BB* (see Table I). The obtained results showed that spatial audio scenes could be classified using a mixture of spatial and spectro-

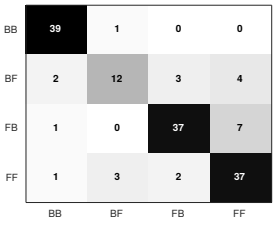

Fig. 2 Confusion matrix for the best classification algorithm (SVM, accuracy 83.89%, 490 features)

temporal metrics with an accuracy exceeding 80%. This outcome indicates that the standard spectro-temporal descriptors combined with the fundamental binaural cues (*ITD*, *ILD*, and *IC*) are adequate for the aforementioned task. Moreover, it provides evidence that the task of spatial audio scene classification may be successfully undertaken without employing a blind source separation algorithm or any other sophisticated techniques aiming to isolate and/or localize audio sources in complex binaural audio scenes. Such an approach could simplify the design of spatial audio scene classifiers.

It was surprising to observe that the spectro-temporal features appeared to have a stronger influence on the classification results than the spatial metrics. This effect, which requires further investigation, could have been caused by an unintended correlation between the spectral and spatial characteristics of the audio recordings used in this study.

Out of the five machine-learning algorithms compared in this study, the support vector machine exhibited the best classification performance, reaching an accuracy of 83.89% upon the validation test. While this result can be considered as satisfactory at this stage of research, there is still scope for improvements. In order to enhance the proposed method, a model accounting for a well-known binaural precedence effect [18] could be incorporated in future studies.

International Conference on Innovative Network Systems and Applications

MODERN network systems encompass a wide range of solutions and technologies, including wireless and wired networks, network systems, services and applications. This results in numerous active research areas oriented towards various technical, scientific and social aspects of network systems and applications. The primary objective of Innovative Network Systems and Applications (iNetSApp) conference is to group network-related events and promote synergy between different fields of network-related research. To stimulate the cooperation between commercial research community and academia, the conference is co-organised by Research and Development Centre Orange Labs Poland and leading universities from Poland, Slovak Republic and United Arab Emirates.

The conference continues the experience of Frontiers in Network Applications and Network Systems (FINANS), International Conference on Wireless Sensor Networks (WSN), and International Symposium on Web Services (WSS). As in the previous years, not only research papers, but also papers summarising the development of innovative network systems and applications are welcome.

- CAP-NGNCS'18—1st International Workshop on Communications Architectures and Protocols for the New Generation of Networks and Computing Systems
- INSERT'18 - 2nd International Conference on Security, Privacy, and Trust
- IoT-ECAW'18—2nd Workshop on Internet of Things—Enablers, Challenges and Applications
- WSN'18 - 7th International Conference on Wireless Sensor Networks

AREA SUPERVISORY COMMITTEE

- Furtak, Janusz, IoT-ECAW'18
- Hamrioui, Sofiane, CAP-NGNCS'18
- Ševčík, Peter, WSN'18

2nd International Conference on Security, Privacy, and Trust

ADMITTEDLY, information security works as a backbone for protecting both user data and electronic transactions. Protecting communications and data infrastructures of an increasingly inter-connected world have become vital nowadays. Security has emerged as an important scientific discipline whose many multifaceted complexities deserve the attention and synergy of the computer science, engineering, and information systems communities. Information security has some well-founded technical research directions which encompass access level (user authentication and authorization), protocol security, software security, and data cryptography. Moreover, some other emerging topics related to organizational security aspects have appeared beyond the long-standing research directions.

The 2nd International Conference on Security, Privacy, and Trust (INSERT'18) focuses on the diversity of the information security developments and deployments in order to highlight the most recent challenges and report the most recent researches. The conference is an umbrella for all information security technical aspects, user privacy techniques, and trust. In addition, it goes beyond the technicalities and covers some emerging topics like social and organizational security research directions. INSERT'18 is intended to attract researchers and practitioners from academia and industry, and provides an international discussion forum in order to share their experiences and their ideas concerning emerging aspects in information security met in different application domains. This opens doors for highlighting unknown research directions and tackling modern research challenges. The objectives of the INSERT'18 can be summarized as follows:

- To review and conclude researches in information security and other security domains, focused on the protection of different kinds of assets and processes, and to identify approaches that may be useful in the application domains of information security
- To find synergy between different approaches, allowing elaborating integrated security solutions, e.g. integrate different risk-based management system.
- To exchange security-related knowledge and experience between experts to improve existing methods and tools and adopt them to new application areas

TOPICS

Topics of interest include but are not limited to:

- Biometric technologies
- Human factor in security
- Cryptography and cryptanalysis
- Critical infrastructure protection
- Hardware-oriented information security
- Social theories in information security
- Organization- related information security
- Pedagogical approaches for information security
- Social engineering and human aspects in security
- Individuals identification and privacy protection methods
- Information security and business continuity management
- Decision support systems for information security
- Digital right management and data protection
- Cyber and physical security infrastructures
- Risk assessment and risk management
- Tools supporting security management and development
- Trust in emerging technologies and applications
- Ethical trends in user privacy and trust
- Digital forensics and crime science
- Security knowledge management
- Privacy Enhancing Technologies
- Misuse and intrusion detection
- Data hide and watermarking
- Cloud and big data security
- Computer network security
- Security and safety
- Assurance methods
- Security statistics

***Abstract*—In the field of Legal Metrology, a risk assessment is demanded by European directives for certain measuring instruments. In this paper, a previously published reference cloud architecture will be subjected to such an assessment to demonstrate its suitability for providing adequate software protection. A specially tailored and standardized method is used to identify essential threats and common attack vectors for the reference architecture. With the help of calculated probability score and risk factors, the fulfillment of the essential requirements of the applicable European directives are shown. Furthermore, Attack Probability Trees are applied to more complex scenarios to identify suitable countermeasures to increase the resilience level where necessary.**

I. Introduction

LEGAL METROLOGY'S raison d'être is to establish trust between all stakeholders such as customers, manufacturers and users of measuring instrument. Since none of the involved parties alone can guarantee the validity and integrity of measurements, a Notified Body, e.g. the Physikalisch-Technische Bundesanstalt (PTB) in Germany, is obligated to inspect measuring instruments. The essential requirements of the Measuring Instruments Directive (MID) [1], such as reproducibility, repeatability, durability and protection against corruption of measuring instruments and measurements, have to be fulfilled before entering the market. Enhancing public trust in measuring instruments is vital for Legal Metrology, especially in a world with new and increasingly complex technologies in use.

New technologies, like Cloud Computing enable manufacturers and users of measuring instruments to provide improved services to customers that are more flexible and comfortable to, for example, access meters via mobile devices or enable improved service via intelligent data services. However, Legal Metrology faces a radical change through the transformation of well-contained measuring instruments nowadays to future distributed measuring systems. In 2016, the stated transition and security implications for Legal Metrology were described, concluding with a proposition for a Secure Cloud Reference Architecture focusing on these challenges [2]. By fulfilling the essential requirements of the MID and the applicable WELMEC (Western European Legal Metrology Cooperation) guide 7.2 [3] a level of legally adequate security is met. The introduced architecture further tackles threats, such as a malicious insider and data manipulation in the cloud, via fully homomorphic encryption (FHE) [4]. Moreover, exposing FHE to real-world requirements, four application scenarios were developed and applied to Smart Meter Gateway (SMGW) tariffs. These tariff applications were derived from the SMGW's technical guide of the Federal Office for Information Security (BSI) in Germany.

In this paper, a risk analysis is applied to the Secure Cloud Reference Architecture to fulfill the legal requirements (see Section II). This risk analysis is based on software risk assessment for measuring instruments under legal control proposed by WELMEC Working Group 7 [5]. By objectifying the derived probability score for identified threats while following at the same time the guidelines of ISO/IEC 27005, ISO/IEC 15408 and ISO/IEC 18045, this risk assessment method enables comparability and standardizes the otherwise highly subjective assessment process. Furthermore, potential countermeasures are identified and quantified using Attack Probability Trees (AtPT) [6] for derived assets to be suitable protected.

The remainder of this paper is structured as follows. Section II sketches the Secure Cloud Reference Architectures and describes the considered parts for this risk assessment. Section II-A explains the derived assets and applies the risk assessment method and its shortcomings. In order to introduce the AtPT to tackle the further assets in Section III, Section IV gives an overview of the results, conclusions and further work.

II. Secure Cloud Reference Architecture

The distributed measuring instrument and its reference architecture are described in [2] and a summarized overview of its modules can be seen in Figure 1 and 2. The architecture uses virtualization techniques, in order to separate software modules subject to legal control from legally non-relevant ones. The purpose of a reference architecture is to provide a generic software framework which manufacturers can adopt in their products to provide adequate software protection in line with MID requirements.

This approach benefits not only from decreased idle times and an improved cost-efficiency ratio for employed servers, but also facilitates software update processes for manufacturers in the legally non-relevant software part. This improved update

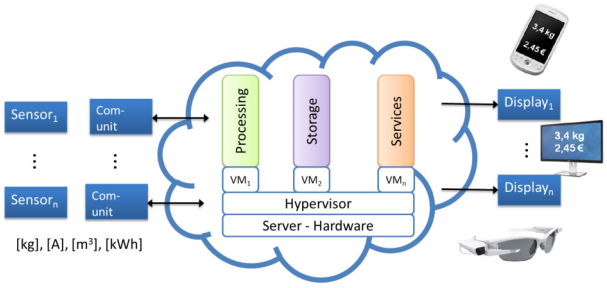

Fig. 1. Overview of the distributed measuring instrument. The measurement device is reduced to only a sensor and communication unit, while processing and storage will be moved to the cloud environment.

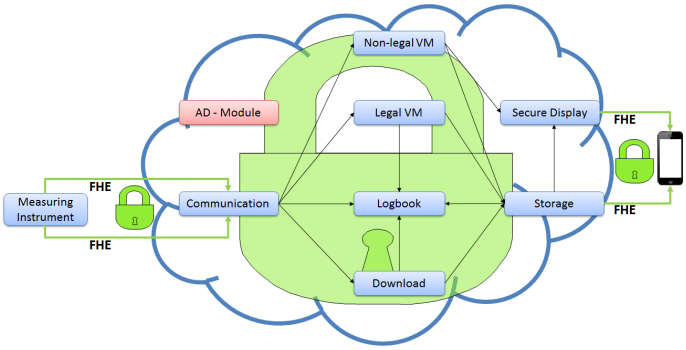

Fig. 2. Overview of the cloud reference architecture. The measurement data is completely secured throughout the whole process via FHE. The legally relevant processes are separated into different virtual machines with well defined communication paths.

process avoids a re-verification of the instrument by the market and user surveillance body and thus decreases downtimes and costs for the manufacturer.

The basis of the Infrastructure as a Service layer (IaaS) is built with the help of the Openstack framework. Core functionalities are mapped to physical devices, such as server, storage and network. Through separation into logical smaller entities via subnetworks, the network and thus the IaaS layer constitute the first low level separation between legally relevant and non-relevant processes.

The Platform as a Service layer (PaaS) consists of a microservice pattern build with Spring Boot and Spring Cloud as well as the Netflix software stack. By reducing services to their core functionality and at the same time minimizing the software lines of code (SLOC), the microservice pattern enables to maintain a clean code base. Furthermore, it offers flexible scaling and efficient resource pooling by cutting idle times of the underlying hardware. Deploying and developing services independently of each other fosters productivity within the software development team and encourages creativity. Nevertheless, stability and downtime will not be a threat to the architecture because of a rigorous separation. A stepwise transition of software versions is encouraged by running different releases side-by-side. The high level separation allows each microservice to be written in the best problem-fitting programming language.

The communication of messages is realized via RESTful API. An active message queue (ActiveMQ) guarantees reliability and pseudo resilience for messages. Messages can be stored in a queue and will be delivered later in time, in case of unavailability of services.

Fully homomorphic encryption (FHE) enables computation of encrypted messages without decrypting them first [7]. The smart meter gateway tariffs application are protected by FHE [4] and hosted at the Software as a Service layer (SaaS). Measurements are encrypted directly in the sensor unit to be processed securely in a centralized cloud structure.

In the next paragraphs, a brief description is given of the most significant legally relevant processes and virtual machines (VM). A summarized overview of the topology is illustrated in Figure 2. Increasing the portability, distributivity and scalability by separating the services via VM another security layer is introduced. The described services represent the common ground of all fields in Legal Metrology to fit a generic reference architecture.

a) Logbook: All relevant activities around the measuring system, i.e. arrival, processing, saving of measurement data, user activities, software updates etc are logged via the logbook service hosted in the Logbook VM.

b) Legal Processing: The Legal VM uses the most of all CPU cores available, because it is responsible for processing encrypted measurement data.

c) Download Manager: After an integrity and authenticity verification of the signed software update, the Download Manager will forward the software update, as intended from the manufacturer, to the dedicated machine.

d) Storage Manager: A database stores measurement data for a long period of time. The Storage Manager will make measurement data available via an REST-interface to other authorized services.

e) Monitoring Service: Detecting anomalies within the system, via continuously monitoring the behaviour of all VMs, is an important part of the security mechanisms of the cloud reference architecture. The Monitoring Service provides APIs for real time monitoring.

A. Derivation of Assets to be protected

Esche et al. [5] developed a risk assessment method based on ISO/IEC 27005 [8] and WELEMEC Risk Assessment Guide [9]. The approach consists of three stages and is shortly summarized in the following paragraphs. This algorithm is here applied to the secure cloud reference architecture (see Section III).

Every measuring instrument that undergoes conformity assessment has to fulfill the essential software requirements listed in Annex I of the MID before being put on the market. From these requirements three relevant assets are selected here that are noteworthy to be protected for all kind of measuring instruments, i.e. *measurement data*, *software that is critical for measurement characteristics* , and *metrologically relevant parameters* stored or transmitted. For each, the MID requires integrity and authenticity protection. Consequently, these assets

TABLE I
FORMAL DEFINITION OF THREATS

ID	Threat Intention	Description
B1	Integrity of transmitted measurement data	An attacker alters measurement data during transmission.
B2	Authenticity of transmitted measurement data	An attacker creates tampered measurement data, that will be assigned wrongly to a verified measuring instrument.
B3	Evidence of an intervention	An attacker prevents legally relevant events from being registered in the logbook.
B4	Integrity of Parameters	An attacker alters persistence saved parameters, e.g. connection parameters.
B5	Availability of the Logbook Service	An attacker prevents a legally relevant service from answering requests.

must be secured against intentional or unintentional changes. By fulfilling this demand, integrity and authenticity of these assets are guaranteed. In addition, the MID requires evidence of an intervention, i.e. events registered in a logbook, to be available during verification.

a) Threat definition: A threat is any invalidation of a security property of a given asset. To define a threat, aside from the asset definition, several attacker models should be taken into account, for example, inside attacker and external attacker. Usually the market participant with the highest skill level can be used as a reference model. Additionally, different access levels and their associated roles within a measuring instrument take an important part in the risk assessment. In Table I these five assets are linked to a threat intention and short description of what an attacker wants to achieve. The assets itself will be further described in separate tables, where the attack vectors (technical steps needed to implement a threat) are broken down into atomic attacks with a time, expertise, knowledge, window of opportunity and equipment column that are individually scored (see Section III), according to [10]. This procedure has the advantage of objectifying the risk assessment procedure based on scores for well-defined features of any attack. This enables manufacturers and Notified Bodies alike, to be able to compare the same threats for different measuring instruments.

b) Identification of Attack Vectors: The second risk assessment phase is the least formalized stage. It starts with the examination of the manufacturer's documentation of the measuring instrument. Followed by creating a collection of possible attack vectors, needed to realize the prior identified threats from stage one. The collection comprises attack vectors reaching from simple to very complex structured attacks.

c) Calculating Probability Score and Risk Score: In phase three, the interim results from stage one and two are combined, i.e. an adverse action with at least one associated attack vector. Thereafter, the likelihood of implementing such an attack has to be calculated. The evaluation is based on the following five features [11] that lay the foundation to score and identify the resources that all attacks have in common:

- Elapsed Time (0-19 points)
- Expertise (0-8 points)
- Knowledge of the TOE (0-11 points)
- Window of Opportunity (0-10 points)
- Equipment (0-9 points)

The amount of *elapsed time* represents the time needed to implement a specific attack by any chosen attacker. The score ranges from 0 (equals 1 day) to 19 (more than half a year). *Expertise* represents the skill set of an attacker, where 0 is a layman and 8 is given when an attacker has to have competence in more than one field. *Knowledge of the Target of Evaluation (TOE)* scores the needed information on an attacked measuring instrument. It starts with publicly available knowledge (0) and ends with critical insider knowledge (11), that usually resides with the manufacturer. The *window of opportunity* evaluates the possibility available to an attacker, where 0 represents unlimited access, which would be common for measuring instruments connected to the Internet. If the access is difficult, a value of 10 should be given. In case it is impossible to obtain access, no rating is done and the attack vector would be removed from the list. The last category scores the *equipment* needed to carry out the attack. Standard available hardware or software is described by 0, where 9 represents multiple bespoke devices or software.

After successfully calculating the sum yielded by the five categories for the chosen attack, a probability score is matched to the different ranges of the total sum. In Table II the Common Criteria evaluation is also included in the final probability score calculation, so that a basic resistance results in a total sum of 10-13 points while 24 or more points represent a high resilience against the rated attack. Finally, the resistance evaluation is associated with the probability score, where 1 represents an unlikely occurrence while 5 stands for high probability to occur.

The final risk will be calculated by multiplying the impact score for the threat with the probability score, that is issued in Table II, of the most likely realized attack vector:

$$\text{risk score} = \frac{\text{impact score}}{5} \cdot \text{probability score} \qquad (1)$$

TABLE II
CALCULATION OF A TOE AND ASSOCIATION OF A PROBABILITY SCORE ACCORDING TO [5]

Sum of Points	TOE Resistance	Probability Score
0-9	No rating	5
10-13	Basic	4
14-19	Enhanced Basic	3
20-24	Moderate	2
>24	High	1

TABLE III
ATTACK VECTORS FOR THREAT B1

Attack-ID	Attack Vector	Time	Expertise	Knowledge	Window of Opportunity	Equipment	Sum	Damage
A3	Manipulate data in transit	19	8	11	10	0	48	1
A4	Exchange processing unit	7	6	11	4	0	29	1

TABLE IV
PREREQUISITES FOR ATTACK VECTOR A3

Attack-ID	Attack Vector	Time	Expertise	Knowledge	Window of Opportunity	Equipment	Sum	Damage
A3.1	MITM-attack	1	6	11	10*	0	28	1
A3.2	decrypt-encrypt data	19	8	11	0	0	38	1

III. METHODOLOGY OF ASSETS

In this section, the risk assessment algorithm will be applied to the secure cloud reference architecture, that were both briefly introduced in the previous section. The threats listed in Table I will be treated sequentially and will pass the three stages of risk assessment. Afterwards, in Subsection III-C the Attack Probability Tree (AtPT) is introduced to describe more complex attack scenarios, by introducing a prescribed way to construct attack vectors in a standardized and compact way. At the end, suitable countermeasures for attack vectors will be discussed briefly.

A. Integrity of transmitted measurement data

The threat intention of the attacker is to undermine the integrity of transmitted measurement data by manipulating measurement data during transmission. The sensor unit will be considered, that collects the data and encrypts them with a protected public key via FHE before sending them to the cloud reference architecture. The transmission is secured by Transport Layer Security (TLS) and additionally by a x.509 certificate at the cloud service endpoint, so that the sensor unit usually knows the receiver. An insider attack is assumed with the attacker having the access rights of an administrator. For this threat, two attack vectors are taken into consideration, namely A3 and A4 (see Table III). A3 needs two prerequisites A3.1 and A3.2 (see Table IV), in order to be feasible.

To manipulate the data in transit, the attacker has to carry out an active Man-In-The-Middle attack (MITM) (see Table IV A3.1), that means the connection has to be rerouted via the attacker's interception device and the TLS-connection has to be captured during key exchange. Furthermore, the certificate has to be forged by, for example, getting the private key of the server and the client to establish active sessions at both ends with the impersonated certificates needed for authentication. The client's improper validation of the certificate would be a big advantage for the attacker.

The time needed to execute such an attack would be less than a day (1), if the attacker is an expert (6) and has critical knowledge of the system (11). While the window of opportunity is difficult (10), since the manipulation has to be carried out during transmission within the boundaries of transmission delay. There is no special equipment needed (1), that exceeds standard hardware. So the total sum of points for this attack (48) leads to high TOE resistance (see Table II).

Even if A3.1 (MITM) is successfully established, the data itself is still encrypted by FHE. Lattice based cryptography is provable secure and provides worst-case security that is still not broken by quantum algorithms. Therefore, the maximum time of more than half a year (19) assumed for A3.2. The attacker has to have expertise on several fields (8) to decrypt and/or break cryptography as well as having critical system knowledge (11) at disposal. Once, the cryptography is broken, the window of opportunity is unnecessary (0). From the authors' point of view standard hardware (0) is sufficient. This yields a total sum of 38 points and again implies high resilience against the attack vector.

The two attack vectors A3.1 and A3.2 both need to be executed to form A3. The result is shown in Table III and implies a high resilience (48) for this attack vector. According to Table II, the sum score translates to a probability score of 1. Since this threat has potential influence on all future measurement values, the impact score is 5 and the subsequent risk ($\frac{\text{impact score}}{5} \cdot \text{probability}$) also takes on a value of 1. PTB does not accept technical solutions with a risk greater than 3. This solution qualifies for PTB certification.

Another attack vector is to exchange the FHE-processing unit (A4) in the cloud, in order to manipulate the data during processing. First, the attacker needs to have access to the software repository, to manipulate the FHE-processing unit and then deploy the manipulated software into the cloud service. Furthermore, the hash of the manipulated software has to match the comparative hash, that the market surveillance monitor evaluates. Given the bonus of an insider attacker with the access level of an administrator, it should be feasible, yet the time frame for execution is less than two months (7). The attacker needs to be at least an expert (6) in IT and the window of opportunity is moderate (4), since a lot of security mechanisms have to be worked around. No special hardware (0) is needed. This yields a total sum of 29 and means a high TOE resistance and a probability score of 1. The threat influences all future measurements, the impact score is 5 and the resulting risk has a value of 1.

TABLE V
ATTACK VECTORS FOR THREAT B2

Attack-ID	Attack Vector	Time	Expertise	Knowledge	Window of Opportunity	Equipment	Sum	Damage
A1	Manipulate sensor unit	4	8	11	0	7	30	1
A2	Replace sensor unit	4	8	11	0	7	30	1
A3	Spoof identity	19	6	11	0	0	36	1

TABLE VI
PREREQUISITES FOR ATTACK VECTOR A3

Attack-ID	Attack Vector	Time	Expertise	Knowledge	Window of Opportunity	Equipment	Sum	Damage
A3.1	Steal key from vault	1	6	11	0	0	18	1
A3.2	Obtain certificate	19	6	0	0	0	25	1
A3.3	Generate false data	19	6	11	0	0	36	1

B. Authenticity of transmitted measurement data

The threat intention of B2 is to attack the authenticity of transmitted measurement data. In Table V three attack vectors A1-A3 are summed up, while the third is composed of three sub attack vectors displayed in Table VI.

The easiest way of attacking the authenticity is to manipulate the origin of the measurement data: the sensor unit itself (A1). The idea behind this attack vector is just to compromise the authenticity, thus it is enough to break the seal and replace the physical sensor with a tampered one, that calculates, for example, a smaller measurement value. Breaking the seal implicates forging a new seal, so that the instrument does not seem to be manipulated to market surveillance.

The time needed for this invalidation of authenticity (A1) is less than a month (4) and the attacker needs to be expert on several fields (8), since forging an official calibration seal needs knowledge and special equipment (7). Furthermore, replacing the physical sensor requires critical knowledge (8). The window of opportunity is unlimited (0) for this attack vector, because the instrument in the field is not subject to constant surveillance. In total, the attack vector reaches 30 points and represents a TOE with high resistance with an associated probability score of 1, which translate to a risk level of 1 because of its influence of all future measurement values (impact score of 5). However, it is noteworthy that in Legal Metrology there is no higher protection level achievable than a sealed hardware solution.

The second attack vector A2 deals with obtaining security features from the original sensor unit (physical sensor + communication unit) and replacing this unit with a tampered one that is identically constructed. Hereby, the attacker extracts, for example, the protected key (public key) needed for encryption from the original sealed instrument and then stores this security feature in an identical, but tampered unit. A2 differs from A1 since it does not involve tampering original hardware, but buying malfunctioning hardware on purpose and putting it into use. The scores are the same as for the previous attack vector. It is again considered very hard to forge an official verification seal, which is reflected in the total sum of 30 points and offers high resilience.

With the last attack vector A3 the identity of the sensor unit will be spoofed by masquerading the IP address of the attacker's sensor unit, for example, by faking the source address field in the TCP header. In order to be successful at the cloud service endpoint, the attacker has to first obtain the protected key from the software vault in the cloud service, in order to be able to encrypt its fake measurement data (A3.1). Given the fact that an insider attacker with the privileges of an administrator is considered, the access to the cloud architecture is self-evident. The attacker will retrieve the information in less than a week (1). The postulated skill set of an expert (6) is needed in an IT related area and critical knowledge (11) of the system is demanded. A3.1 yields in total 18 points, which is considered as an enhanced basic resistance level.

As a next step (A3.2), the attacker has to get his hands on the private key of the x.509 certificate. It is assumed that this is very time consuming (>6 month) (19) but feasible for an expert (6), in order to forge the x.509 certificate and overcome the authentication barrier. The attack vector A3.2 has a total sum of 25 points and achieves high resilience against this threat.

As a last action, the attacker has to generate false measurement data with the stolen key from A3.1 and authenticates himself against the cloud service endpoint with a forged certificate, in order to achieve the objective to compromise the authenticity of the measurement data. Because of the logical AND operation of A3.1 and A3.2 the highest value will run into A3. That leads to the time frame of more than 6 months (19), an expert level (6) and the requirement of critical system knowledge (11), which totals into 36 points and reaches a high resistance level. The probability score evaluates to 1 with an associated risk level of 1 because of the influence of all future measurements (impact score 5).

For threat intention B3 the same risk assessment procedure is carried out and noted in tables. Yet, this methodology is limited and it quickly becomes extremely difficult to map all requirements and dependencies for all possible attack vectors. As a solution, Esche et al. introduced the attack probability tree that visualizes in a very compact manner the attack vectors and make it easy to deduce a probable attack path. Furthermore, it enables to derive the attacker motivation. In the next section a short theoretical introduction of the AtPT will be given and

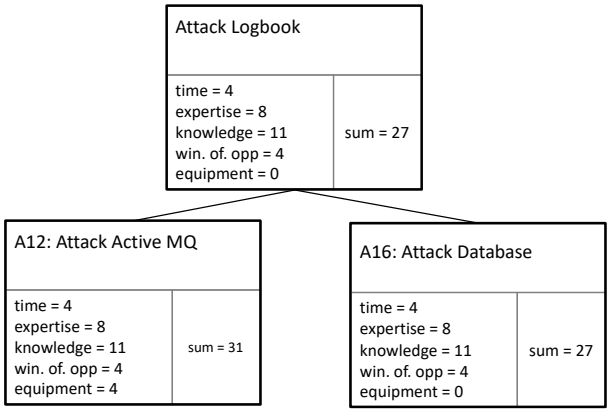

Fig. 3. AtPT for threat intention B3. View: root node and two attack vectors.

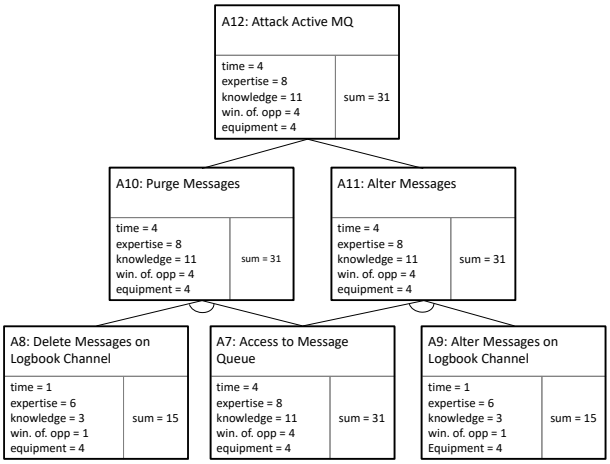

Fig. 4. AtPT for threat intention B3. View: Subtree of attack vector Active Message Queue.

subsequently applied to B3 until B5.

C. Attack Probability Tree

Esche et al. introduced attack probability trees (AtPT) as an extension of attack trees by Mauw and Oostdijk [12] to tackle two main objectives: developing a method to standardize the deduction of attack vectors and to efficiently visualize the interdependencies of attack vectors in order to easily derive attacker motivation and as a result the most likely attacker path. [6]. Additionally, each node embodies features with its own score, such as time, expertise, knowledge, window of opportunity and equipment, that have been previously collected in tables. Furthermore, the logical relationship between parent and child attacks are visualized and attack nodes are linked either by an AND- or OR-statement.

Information enter the tree via the leaves, so that parent nodes' and finally the root's attributes can be calculated from the bottom to the top. The rules for both statements and each attribute/point score are extensively described in [6]. Briefly summarized: for AND-statements, the *maximum* for each attribute chosen; for OR-statements, the *smaller* sum score indicates the threat to select. A great side-effect of AtPTs is the reduction of required time for revaluation of individual attacks, because of the possibility of reusing attack nodes, that are common among different attacks without recalculating attributes.

The following subsections use the AtPT approach for risk assessment of the cloud reference architecture. Nevertheless, the corresponding tables were generated, as introduced in the previous sections. However, due to space constrains, they are not published here.

D. Evidence of an Intervention

In this scenario an attacker prevents legally relevant events from being registered in the logbook. The threat intention is to attack the availability of the evidence of an intervention. In case of a successful manipulation, the user cannot present all relevant logbook entries that market surveillance demands.

In this paper, only the AtPT for a logbook attack is presented. Another attack scenario with the same attack attributes is evaluated for the storage service of the instrument, with a similar-looking AtPT. Because of the complexity of the attack, the AtPT is divided into four subtrees (see Figures 3-6), that will be described in the next paragraphs.

An AtPT is read from the root to the leaves. For attacking the logbook, two possibilities are available. Either the attacker aims for the active message queue (Active MQ) or for the database of the logbook service (see Figure 3). Since these two attack vectors are alternatives, they are linked by an OR-connection. If the two vectors would be needed to be executed together, they would be linked by an AND-connection graphically expressed by an arc.

When attacking the Active MQ (A12), an attacker could either purge messages (A10) or alter message (A11) on the logbook channel. For both actions, access to the message queue is required (A7) with the combination of deleting a message (A8) or changing a message (A9) on the logbook channel represented by an arc below the linked nodes (see Figure 4).

The actual scores in Figure 4 are calculated from the bottom to the top, for example, attack vector A10 consists of nodes A8 and A7. Since the latter two nodes are linked by an AND-statement the greater value is put across to A10. The time to purge a message takes less than a month (4) and stems from A7 accessing the message queue. Furthermore, it is required to be an expert in several areas (8), to have critical knowledge of the system (8) and the window opportunity is moderate (4). These attributes stem also from A7. However, the equipment to purge messages on the active MQ is specialized (4), since the software is an expert tool written in python without a graphical user interface. Yet it is indeed publicly available.

Now one could argue, that using a specialized software and obtaining access to the message queue needs less time than proposed here. However, the whole AtPT does not end with obtaining access to the message queue (A7), but rather continuous and becomes more detailed in how the access could be obtained in a malicious way.

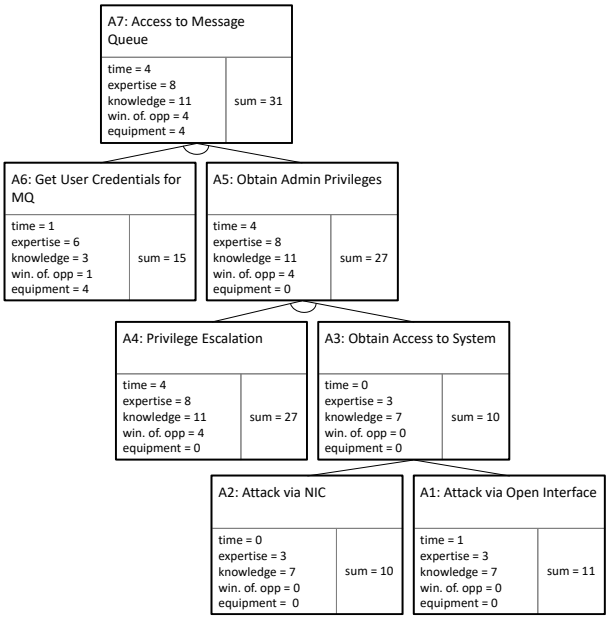

Fig. 5. AtPT for threat intention B3. View: Subtree of attack vector Access to Message Queue.

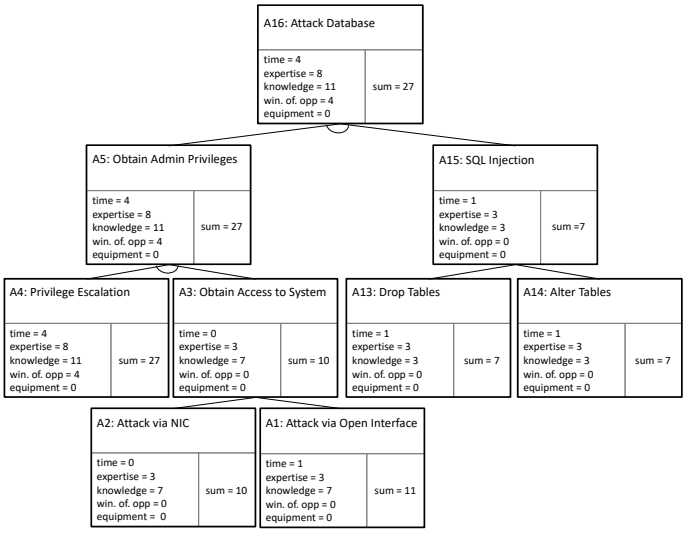

Fig. 6. AtPT for threat intention B3. View: Subtree of attack vector Attack Database.

In Figure 5 an exemplary attacking path is detailed. Node A7 consists of obtaining administrator privileges in the virtual machine (A5), that runs the active MQ or is at least in the same subnet. With these new privileges the specialized software can be executed, which triggers node A6 to get the credentials for the message queue.

To get hold of the user credentials, less than a week (1) is estimated. An expert level (6) and restricted knowledge of the measuring system is required. The window of opportunity for an inside attacker is easy (1) even so specialized software (4) is needed. Node A6 holds a total sum of 15 points which would be considered as an enhanced basic resistance level. However, A6 is to be evaluated in conjunction with A5 through the AND-connection.

The attack vector A5 depends again on a privilege escalation through exploiting Common Vulnerabilities and Exposures (CVE) of the underlying system (A4) and obtaining access to the virtual machine (A3). To accomplish a privilege escalation, the attack is assessed with less than a month (4), expertise on more than one field (8), critical system knowledge and moderate window of opportunity (4). Further, no special equipment (0) is expected. A privilege escalation is considered as a difficult endeavor with 27 points in total that translate to a high resilience. This corresponds again to a probability score of 1 with an impact score of 5 and results into a risk of 1.

Obtaining access to a virtual machine and therewith to the distributed measuring system (A3) is possible in two ways that are alternatives (OR-connection). Either the system is penetrated through a network interface card (NIC) (A2) or via an open physical interface (A1), such as a USB port. Considering the fact that an inside attacker with administrator privileges is assumed, that logs remotely into the measuring system for maintenance reasons, this attack is achievable in less than a day (0). To clarify, it is assumed that the inside attacker does not automatically have administrator privileges on the remote machine, but as an employee of the manufacturer. Furthermore, to login remotely requires only a proficient expertise and sensitive system knowledge (7). The window of opportunity is negligible (0), since this can belong to the attacker's daily routine. No special equipment is needed (0). The TOE resistance is basic (10 points in total).

The attack via an open interface (A1) differs from A2 only in the time attribute. It is assumed that the attacker has to physically approach the hardware to carry out the attack. That takes additional time (less than a week (1)) and is more inconvenient than opening a SSH-shell from the desktop pc in the office.

To sum up, the attack path just described consists of A2, A3, A4, A5, A6, A7 then a decision has to be made if the messages should be altered or deleted. However, in terms of likelihood the nodes do not differ, but practically spoken deletion is often easier. The path would continue via A8, A10.

To completely describe the AtPT for compromising the evidence of an intervention via a logbook attack, the alternative path via the database attack vector (A16) has to be described, as shown in Figure 6. For attacking the database, administrator privileges (A5) are needed combined with an attack against the database such as SQL injection (A15) or via command line interface (CLI). The path down to the leaves for A5 is already described in the previous paragraphs. Its TOE resistance depends on leaf A4, that describes the privilege escalation via a CVE. Attack Vector A15 is divided into dropping tables (A13) or modifying tables (A14).

The scores for A13, A14 are equal and subsequently A15 is identical as well. For both attacks, less than a day is assumed, only a proficient expertise level (3) is needed, no special equipment (0) is required and the window of opportunity

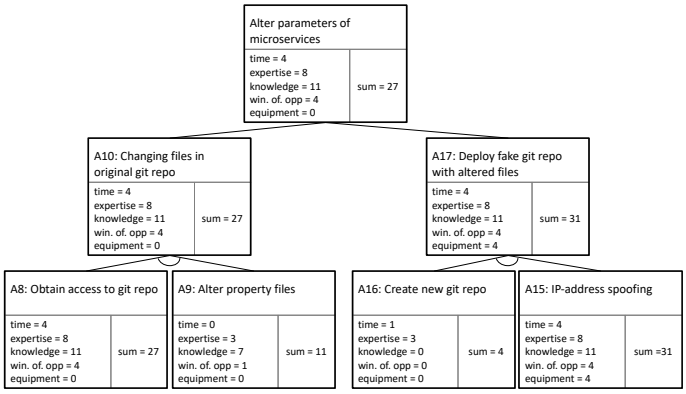

Fig. 7. AtPT for threat intention B4. View: Root, Alter parameters of microservices.

is unlimited (0). In total, the database attacks combine to 7 points, which translate to no resistance at all (no rating). However, since A5 and A15 are connected via an AND-statement the parent node A16 receives the TOE resistance high, since the attacks depend on the privilege escalation to be carried out.

The most likely attack path would be via the database, since no special software is needed, thus less time is required for learning and incorporating the software. To compromise a database, no new software has to be deployed so that the effort on the attacker side is less than attacking the message queue, especially if the intention is to just compromise the integrity of the measuring instrument.

E. Integrity of Parameters

Threat intention B4 aims for harming legally relevant software parameters to violate the security properties integrity and authenticity. In the following paragraphs the presented scenario offers an attacker to alter persistent saved parameters of the logbook service by attacking the configuration service. Two possible attack scenarios are presented via an AtPT. The tree is compartmentalized into several subtrees, because of its size (see Figures 7-9). As already pointed out, the subtree consisting of the node A1-A5 could be reused for several attack scenarios without revaluation. Due to space constraints it was renounced to map the whole subtree of A5 downwards in Figure 8. A complete subtree can be seen in Figure 5.

It is proposed that the attacker changes microservice property files in the original git repository to attack the microservice architecture (A10) and provides, for example, false message queue groups. That could lead to loss of messages in the legal relevant logbook. Aiming for the configuration basis can cause fundamental harm and chaos to the whole system.

To be able to carry out attack vector A10, it is assumed that the attacker has to obtain access to the original git repository (A8) and is able to alter the property files (A9). Nodes A8 and A9 are linked via an AND-connection to A10 (see Figure 7).

In order to obtain access to the git repository (A8), a SSH-key has to be created (A7) and placed into the specific folder for the git repository to be evaluated (A6). A7 and A6 are

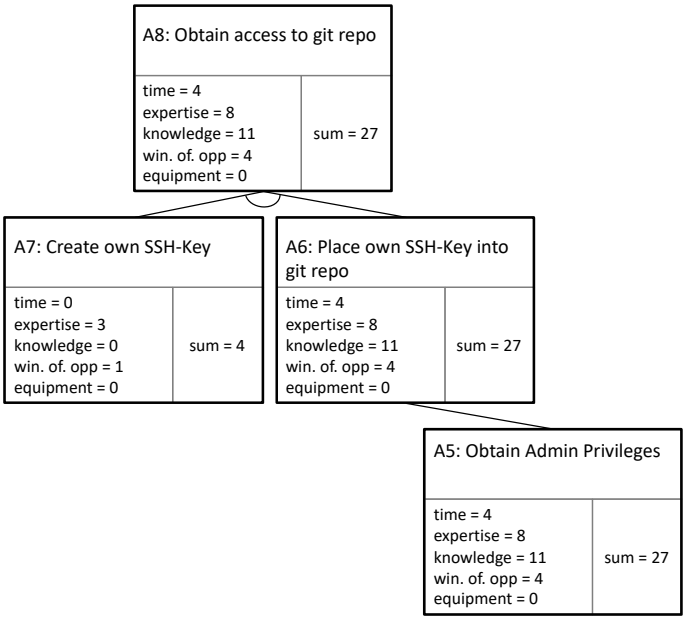

Fig. 8. AtPT for threat intention B4. View: Subtree of attack vector A8.

linked via an AND-statement to A8 (see Figure 8). Attack vector A6 is linked to subtree A5, that describes accomplishment of obtaining administrator privileges (a complete subtree is shown in Figure 5).

The score for subtree A5 has been described in the previous section, so that the evaluation starts with A6. All of the attributes stem from A5 and the difficulties to obtain administrator privileges, which are prerequisites for A6. To create an SSH-key (A7) takes less than a day (0) with proficient expertise (3). How to do this is public knowledge (0) and tutorials are easily to find on the Internet. Furthermore, assuming that an inside attacker is already in the system, the window of opportunity is easy to accomplish (1) and also no special equipment (0) is necessary. This yields a total sum of 4 points and a TOE resistance with no rating.

Attack vector A8 receives the point score from A6, since because of the AND-connection only the maximum of both attributes will be passed upwards. That leads to a total sum of 27 points for obtaining access to the original git repository and implies high resilience.

Altering property files can be done in less than a day (0), with only proficient expertise (3), an easy window of opportunity (1) and with any text editor (equipment = 0). That totals in 11 points and matches basic resilience for this attack.

A10 receives the attributes in total from A8 and thus defines the total score of 27 points and a high resilience for this attack path (see Figure 7).

The alternative attack vector for B4 is to deploy a fake git repository with already altered property files (A17). This attack vector splits into first creating and deploying a new git repository (A7) and then tricking the system into trusting and pulling the files from the fake git repository via IP spoofing (A15). The spoofing attack itself is subdivided into carrying

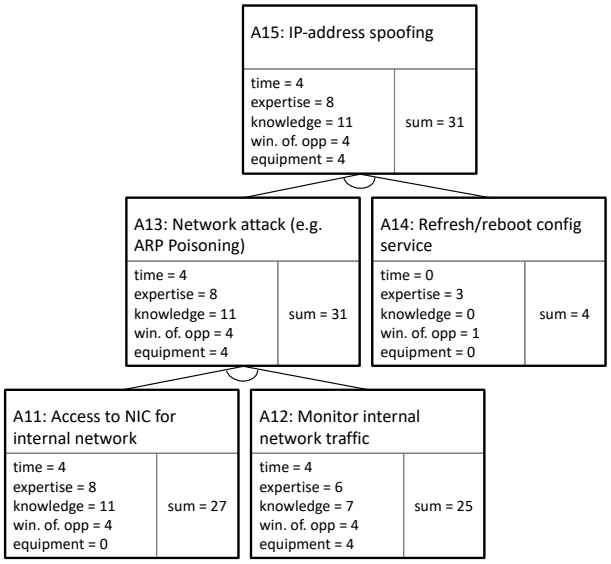

Fig. 9. AtPT for threat intention B4. View: Subtree of attack vector IP-address spoofing.

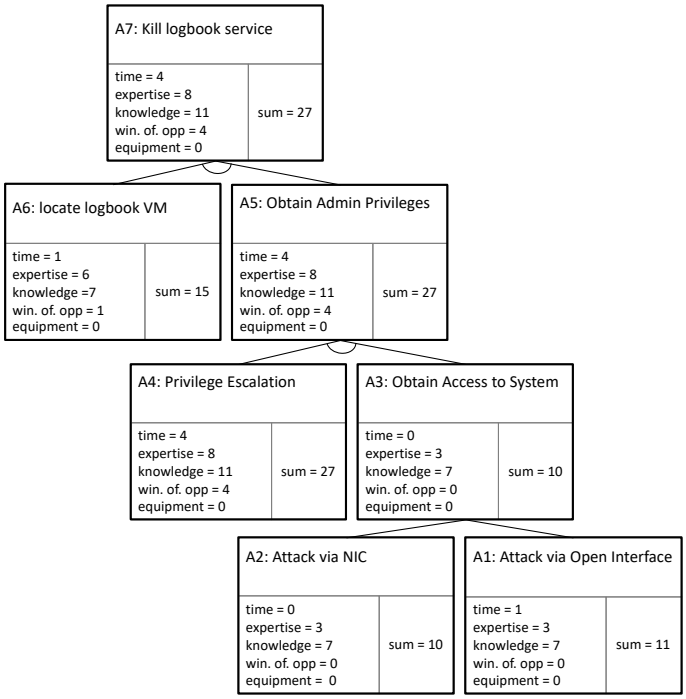

Fig. 10. AtPT for threat intention B5 to violate the availability security property.

out a network attack such as Address-Resolution-Protocol-Poisoning (ARP-poisoning) (A13), in order to replace the IP address and then rebooting the configuration service (A14). To be able to carry out a network attack, the attacker is assumed to have full access to the internal network of the distributed measuring system (A11). To monitor the internal network traffic (A12), the attack vector A11 is necessary (see Figure 9). Once again subtree A5 is required to successfully implement A11.

The score of gaining full access to the internal network interface card (NIC) and thus to the internal network (A11) is inherited from A5 and the struggle of obtaining administrator privileges. To gain a full picture of the structure of the internal network with its services (A12) takes less than a month (4) with an assumed expertise in networking (6) and a sensitive knowledge of the measuring system (7). A moderate window of opportunity (4) is predicted, because it is difficult to explore a supervised internal network undetected. Furthermore, specialized software is needed to monitor network traffic (4). This yields in total 25 points and maps to a high resistance to attacks with probability score of 1 and a risk of 1.

Carrying out network attacks, such as ARP-poisoning (A13), requires less than a month (4) for experts on several fields (8) with sensitive knowledge of the system (11), a moderate window of opportunity (4) and specialized software (4). For most network attacks, it is not necessary any more to write specialized software. There exists publicly available grey software, that can be used to detect vulnerabilities or can be misused to attack computer systems. This attack vector combines to 31 points and a high resistance factor. From here on, no significant changes to the resilience are contributed until the final attack vector A17. Minor actions are required to finally deploy a fake git repository but both acquire only 4 points in total with a negligible threat resistance (see Figure 7).

The most probable attack path will be via A10, changing the properties files in the original repository, since it is the least complex one and without the hassle of deploying software and monitoring traffic etc. This is also reflected in the total score of 27 against 31 points.

F. Availability of Service

Threat intention B5 targets the availability of a legally relevant logbook service. In Figure 10 the complete AtPT is illustrated with the already introduced subtree A5, that enables access to the measuring system and comes along with an escalation of privileges. This subtree in conjunction with the localization of the logbook service's virtual machine (A6) enables the final attack vector that kills the logbook service (A7).

The final score stems from the difficulty to gain access to the system and to elevate the privilege level (subtree A5), which totals 27 points. With an associated risk level of 1 and a probability score of 1. Locating the logbook's virtual machine is with 15 points in total an enhanced basic TOE resistance level, but has no significant influence on the final score of killing the logbook service (A7).

G. Effect of Attacker Motivation

Esche et al. described in [10] possibilities to represent attacker motivation during risk assessment. The presented AtPTs are created for a highly motivated attacker. In order to reconsider these trees with a low or medium motivated attacker, the expertise and equipment score have to be replaced

TABLE VII
MAPPING OF EXPERTISE AND MOTIVATION LEVEL ACCORDING TO [10]

Expertise	Score	Motivation	Score
Layman	0	no motivation	9
Proficient	3	low	6
Expert	6	moderate	3
Multiple Expert	8	high	0

with a higher motivation score according to Table VII if they are originally smaller. This will result in a decreased probability score for a lower motivation and vice versa for a highly motivated attacker. It is noteworthy, that the likeliest attacker path can shift, when the motivation is adjusted.

H. Suitable Countermeasures

To find the best suitable place for countermeasures in an AtPT, it is recommended to locate an inverted subtree for mitigating attack vectors and increasing the impact of applied countermeasures. An inverted tree is usually any leaf that is connected to more than one node of the previous level. Subsequently, the size of an inverted tree matters, since the greater it is, more parent nodes are impacted. In the trees for B3 and B4, A7 and A16 depend on A5 as well as A6 and A11 depend on A5. Subtree A5 is of general importance, because it describes the unauthorized access to the measuring system and privilege escalation. A countermeasure specifically tailored for A5 will exacerbate to obtain administrator rights. This node will have the biggest impact on all three threat scenarios from B3-B5.

A suitable countermeasure is to strengthen the access rights and to enforce a least privilege policy. For example, one could implement Security Enhance Linux (SELinux) for virtual machines (VM), that provides a mandatory access control system and security policies. Instead of using a standard Linux, the kernel extension SELinux provides by default a least privilege policy that denies everything except if it is specifically allowed by access policies (enforcing mode). All violations against these rules are logged and an alarm can be triggered. To obtain administrator privileges by an escalation of access rights would need significantly more time (less than 2 months (7)) with SELinux in place. Furthermore, if the attacker is able to bypass SELinux via switching form enforcing to permissive mode it needs to be done on every VM with a bespoke software (7). However, rolling out SELinux to the measuring system would mean a lot of configuration overhead, but it would elevate the security score by 10 points to 37. This security enhancement would propagate via the inverted tree to the top of each AtPT.

IV. SUMMARY

In this paper, a secure cloud reference architecture for distributed measuring instruments under legal control was presented and subjected to a especially tailored risk assessment method for software in Legal Metrology. After formally introducing the risk analysis, five threats for the reference architecture were described and evaluated extensively. The first two threats were assessed using the traditional method via tables. However, this approach seemed infeasible for more complex threats. Therefore, the Attack Probability Tree (AtPT), that eases the handling of more complex attacks, was introduced and applied. It was shown that adequate protection of the essential requirements formulated by the MID is provided by the secure cloud reference architecture. Therefore, the architecture is qualified to be implemented in measuring systems under legal control.

The detailed analysis of the threat intentions using AtPTs revealed for all formulated threats and attacked security properties a high resilience factor. Nevertheless, through the inverted subtree method for AtPTs the optimal entry point for countermeasures was identified. The implementation of countermeasures reduced the risk to the level provided by physical sealing and increases the resilience to attacks.

Future work will focus on different attacker motivation and therewith diverse attack paths. Furthermore, the formalization of creating AtPTs has to be optimized and standardized.

ACKNOWLEDGMENT

This Paper would not exist without the help and fruitful discussions with our colleague Federico Grasso Toro.

***Abstract*—This paper is devoted to the description of a new block cipher that will be applicable in the post-quantum era and will not need a lot of resources. The main advantages: probabilistic encryption, the cipher block chaining mode, the ability to transfer to distributed systems. All this combined with the use of PRNG, working on the Cremona transformations, has significantly increased the cryptographic strength and increased the scope of this encryption.**

I. Introduction

NIST recommendations for block encryption consist in increasing the size of the key. We believe that instead of increasing the key, it is necessary to build completely probabilistic encryption in such a way that the output file size would be unpredictable, that is, to make the output file size unpredictable, even if the key is the same. In addition, it is necessary to build a pseudo-random number generator that receives parameters depending on the time, or other parameters of the computer. To achieve this, the finite rings - adapted Cremona transformation is used. The case is that this kind of transformation in real numbers is in use for fractals constructing.

II. Algorithm description

A. Formulation of the problem

It is necessary to encrypt a block of text B, which has n symbols of b-bit size each with secret key.

B. Key

The key is used to generate matrices and to fill in the tables of frequencies in Huffman coding. The assumed key size is:

$$l = 2 * b * n \tag{1}$$

To extract all the necessary data from the key we would use a PRNG (hereinafter the Generator), which is described in more detail below.

C. Preparation phase

1) Module Choice

Let us choose a set of prime integers $M_1 < M_2 < \ldots < M_m$ such as:

$$M = M_1 \cdot M_2 \cdot \ldots \cdot M_m \in [2^b, 2^{b+1}] \tag{2}$$

It is necessary for having unique decomposition any symbol of b-bit size in remainders by these numbers [2].

2) Generation of Permutations

To provide nonlinear encryption it is necessary to obtain permutations for arithmetic operations for each module from the secret key.

To the module M_i a permutation is a set of prime integers of the type: $\langle a_0, a_1, a_2, \ldots, a_{M_i-1} \rangle$, where $a_i \in [1, M_i - 1]$ and $a_i \neq a_j$, $i \neq j$. This set is obtained by Generator by the induction algorithm [1].

The permutation changes the addition and multiplication tables for each module [1].

3) Generation of Matrices

For each module invertible matrices $A_1, A_2, \ldots, A_m$ of $n \times n$ size are generated [1].

4) Generation of Huffman Table

In order to increase the cryptographic strength of the algorithm at one of the stages of encryption, we use the Huffman algorithm [1], [3], in which the occurrence frequency for each symbol are obtained by Generator. This choice may be justified by the fact that the combination of Huffman coding and insertion of fake symbols which are described below leads to the changes in the size and content of the encrypted message at every other ciphering though the key is not changed. This helps to resist entropic methods of cracking and known-plaintext attacks [4].

D. Move-To-Front

In order to add the block chaining mode - the phenomenon in which changing the block of source text leads changing not only the corresponding encrypted block, but all following blocks, the technology Move-To-Front [3] is used.

Let us present the Huffman table in the form of two arrays: one contains symbols, which are need to be encrypted, a dictionary, and the other is bit representations. Initially, the dictionary will be represented as a sequence from 0 to M_m. The encoding consists of sequentially traversing all the characters of the encrypted vectors. The symbol is searched for in the dictionary, and its bit representation is written to the output stream. After that, the symbol is removed from its position and inserted into the beginning of the dictionary. The second array remains unchanged.

This work was supported by JetBrains Research

For decoding it is necessary to do similar actions with encoded text, in this case the initial state of the dictionary must be identical to the initial state of the encoding dictionary.

E. Fake Symbols

As mentioned above, the algorithm has a stronger cryptography if encrypted data look different at every other ciphering with the same key. We use fake symbols, which change the look of the encrypted message for this purpose.

Obviously, with a symbol size of b, the encrypted characters can not have a value greater than 2^b. Also, according to the Chinese remainder theory, from the remainders of the division of an integer we can collect a number which is smaller than the multiplication of all modules M [2]. Then, if a number λ is added into a block would satisfy following condition $2^b < \lambda < M$ it will be clear that the number is not a symbol of the source file when the block is deciphered and collected.

Each time a new block is read, a decision, whether to insert a fake symbol, made by Generator. The symbol λ itself is also obtained by means of the Generator [1].

F. Ciphering

We will choose modules: $M_1, \dots, M_m$. Secret key is used to generate permutations, matrices $A_1, A_2, \dots, A_m$ for each module and a Huffman table. Read the block B of size $n * b$ and ciphered as follows:

1. The block $B = q_1, q_2, \dots, q_n$ is represented in the form of a vector $\vec{B} = \begin{pmatrix} q_1 \\ q_2 \\ \vdots \\ q_n \end{pmatrix}$. The coordinates of the vector is remainders of $M_1, \dots, M_m$. We would have vectors $v_1 = \begin{pmatrix} v_{1_1} \\ v_{1_2} \\ \vdots \\ v_{1_n} \end{pmatrix}, v_2 = \begin{pmatrix} v_{2_1} \\ v_{2_2} \\ \vdots \\ v_{2_n} \end{pmatrix}, \dots, v_m = \begin{pmatrix} v_{m_1} \\ v_{m_2} \\ \vdots \\ v_{m_n} \end{pmatrix}$, where $v_{i_j} = q_j \ mod \ M_i$.
2. Matrices are multiplied by the relevant vectors (in every module), all operation we do by tables of multiplication and addition generated previously, vectors of such form are obtained
$$v_i' = A_i \cdot v_i, \quad \text{where } i = 1..m. \tag{3}$$
3. The resulting vectors are recorded a special order in accordance with the Huffman table. The order is defined by the sequence of numbers $P = \{p_1, p_2, \dots, p_m\}$, where $p_i \in [1, m]$ – position of this module, $p_i \neq p_j$ if $i \neq j$. So, the vectors are recorded as a sequence: $v_{p_1}, v_{p_2}, \dots, v_{p_m}$.

When moving from block to block, matrices, Huffman tables and the order of record of the encrypted vectors are changed. Matrices are changed through string/column exchange operations or transpositions to save their invertibility.

The order of record of the encrypted vectors is changed through the right circular shift of P to the right to number obtained from the Generator.

The Huffman table is modified according to the Move-To-Front algorithm described above, based on the result of vectors multiplication.

G. Deciphering

We will choose modules: $M_1, \dots, M_m$. Secret key is used to generate permutations, matrices $A_1, A_2, \dots, A_m$ for each module and a Huffman table. Inverse matrices $A_1^{-1}, \dots, A_m^{-1}$, all operation we do by tables of multiplication and addition generated previously.

1. We read m encrypted vectors $v_1', \dots, v_m'$, decoding each symbol in accordance with the Huffman table and change the Huffman table according to the MTF dictionary in the opposite direction.
2. An invertible matrix is multiplied by the relevant vector, all operation we do by tables of multiplication and addition generated previously: $A_i^{-1} \times v_i', \ i = 1, \dots, m$. Result of this operation is deciphered vectors $v_1, \dots, v_m$.
3. According to the Chinese remainder theory the obtained vectors are collected into the block B. This is a deciphered block. If it has a symbol the numerical value of which is more than 2^b, the symbol is assumed as fake and is thrown out of the block.

When moving from block to block, the changes in the reading order and in Huffman tables are done similarly to the ciphering procedure. In case of invertible matrices, string permutations are replaced by column permutations. Transposition remains unchanged.

III. PRNG AND CREMONA TRANSFORMATION

A fairly large part of the encryption job is tied to a pseudo-random number generator. In order to exclude the possibility of such an important detail to become a weak point, we decided to take the Cremona transforms [5], [6] as the basis of the principle of the generator's operation. The Cremona transformation is an invertible polynomial mapping from the vector space R^n onto itself, which is given by polynomial functions:

$$\begin{gathered} h_1(x_1, x_2, \dots, x_n), \\ h_2(x_1, x_2, \dots, x_n), \\ \dots \\ h_{n-1}(x_1, x_2, \dots, x_n), \\ h_n(x_1, x_2, \dots, x_n); \end{gathered}$$

invertibility means that equations system:

$$\begin{gathered} h_1(x_1, x_2, \dots, x_n) = a_1, \\ h_2(x_1, x_2, \dots, x_n) = a_2, \\ \dots \\ h_{n-1}(x_1, x_2, \dots, x_n) = a_{n-1}, \\ h_n(x_1, x_2, \dots, x_n) = a_n; \end{gathered} \tag{4}$$

is solvable for any right-hand side.

We fix some module m such that raising to the power $k_1, \dots, k_n$ is a one-to-one mapping modulo m. These degrees can be the same.

We will introduce the mapping:

$$\begin{gathered} p_1 = (u_1)^{k_1} + f_1(u_2, u_3, \dots, u_n), \\ p_2 = (u_2)^{k_2} + f_2(u_3, \dots, u_n), \\ \dots \\ p_{n-1} = (u_{n-1})^{k_{n-1}} + f_{n-1}(u_n), \\ p_n = (u_n)^{k_n}; \end{gathered} \tag{5}$$

Here $f_1(u_2, u_3, \dots, u_n)$, $f_2(u_3, \dots, u_n)$, …, $f_{n-1}(u_n)$ are arbitrary polynomials in the indicated variables. We call this mapping an upper-triangular Cremona mapping and denote this mapping **F**.

The lower-triangular Cremona map is defined similarly. Let the raising to the power $s_1, s_2, \dots, s_n$ to be a one-to-one mapping modulo m. Lower-triangular mapping Cremona:

$$\begin{gathered} q_1 = (v_1)^{s_1}, \\ q_2 = (v_2)^{s_2} + g_1(v_1), \\ \dots \\ q_{n-1} = (v_{n-1})^{s_{n-1}} + g_{n-2}(v_1, v_2, \dots, v_{n-2}), \\ q_n = (v_n)^{s_n} + g_{n-1}(v_1, v_2, \dots, v_{n-2}, v_{n-1}); \end{gathered} \tag{6}$$

we will denote this map **G**.

It is obvious, that both maps are invertible.

We can take a superposition with linear invertible mappings that are represented by $n \times n$ matrices, and these matrices are invertible modulo m. In addition, we can use invertible affine mappings that are determined by an invertible matrix and the vector **w**. Let us give a simple example. Consider the case:

$$\begin{gathered} n = 2, \\ m = 11; \end{gathered}$$

Upper-triangular transformation:

$$\begin{gathered} p_1 = (u_1)^3 + 2 * (u_2)^2, \\ p_2 = (u_2)^5; \end{gathered}$$

Lower-triangular transformation:

$$\begin{gathered} q_1 = p_1, \\ q_2 = p_2 + (p_1)^2; \end{gathered}$$

Superposition:

$$\begin{gathered} q_1 = (u_1)^3 + 2 * (u_2)^2, \\ q_2 = (u_2)^5 + [(u_1)^3 + 2 * (u_2)^2]^2 = \\ = (u_2)^5 + (u_1)^6 + 4 * (u_1)^3 * (u_2)^2 + 4 * (u_2)^4; \end{gathered}$$

Suppose given a matrix

$$\mathbf{A} = \begin{pmatrix} 3 & 5 \\ 10 & 2 \end{pmatrix}$$

Consider the superposition of **GAF**.

AF:

$$\begin{gathered} \begin{pmatrix} 3 & 5 \\ 10 & 2 \end{pmatrix} \begin{pmatrix} (u_1)^3 + 2(u_2)^2 \\ (u_2)^5 \end{pmatrix} = \\ = \begin{pmatrix} 3(u_1)^3 + 6(u_2)^2 + 5(u_2)^5 \\ 10(u_1)^3 + 9(u_2)^2 + 2(u_2)^5 \end{pmatrix} \end{gathered}$$

GAF:

$$\begin{gathered} 3(u_1)^3 + 6(u_2)^2 + 5(u_2)^5 \\ 10(u_1)^3 + 9(u_2)^2 + 2(u_2)^5 + \\ + [3(u_1)^3 + 6(u_2)^2 + 5(u_2)^5]^2 \end{gathered}$$

This composition can be used any number of times, thus increasing the degree of polynomials. In this case, if the degrees of the transformations p_i and q_i are less than or equal to 2, then the possibility to restore the initial data will be preserved. That as a result will make it possible to infinitely complicate the relationship between the initial data. The best application of this fact can be found in the generation of public keys and the exchange of keys.

By increasing the dimensionality of the matrix, we can also control the length of the resulting vector, which makes the algorithm easily scalable.

Cremona transformations can be used not only to generate a sequence of polynomials of any degree, but also to generate pseudo-random vectors. Consider the following example:

$$\begin{gathered} m = 11, \\ x = u^7 + v^4 + 5, \\ y = v^5, \\ p = x, \\ q = x^2 + 2y, \\ x_1 = 10, \\ y_1 = 8, \\ x_{i+1} = {x_i}^7 + y_i^4 + 5, \\ y_{i+1} = ({x_i}^7 + y_i^4 + 5)^2 + 2 * y_i^5; \end{gathered}$$

$\binom{10}{8}; \binom{4}{9}; \binom{0}{5}; \binom{10}{5}; \binom{9}{5}; \binom{3}{6}; \binom{8}{9}; \binom{8}{6}; \binom{1}{10}; \binom{3}{1}; \binom{0}{6}; \binom{10}{1}; \binom{1}{0}; \binom{2}{5}; \binom{6}{0}; \binom{9}{1}; \binom{6}{7}; \binom{1}{3}; \binom{6}{6}; \binom{7}{2}; \binom{1}{2}; \binom{7}{7}; \binom{10}{10}; \binom{1}{7}; \binom{5}{2}; \binom{9}{9}; \binom{10}{3}; \binom{4}{2}; \binom{0}{1}; \binom{2}{7}; \dots$

This sequence has a period of about 30 operations, but if you change the input data and the transformation degree, we can achieve a lager period. This fact has yet to be explored in more detail. Since for the generator we do not need the invertibility of operations, the degrees of the transformations p and q can be arbitrary. However, the largest period is observed in powers that can be uniquely inverted for most field elements.

Generators of this kind will be useful if there will be necessity for generating a set of numbers for further work, for example, determining the insertion of fake symbols into a sequence of blocks at once, and not on each block separately.

IV. Cryptanalysis

A. Probabilistic encryption

The basis of probabilistic encryption in our algorithm is fake symbols. These symbols can easily be added to the source text, using any PRNG to determine the character and its position, and it is also easy to detect them while decrypting. The algorithm also does not impose any restrictions on the number of fake characters in one block, which allows you to change their number depending on our needs. Therefore, on small texts you can use not only fake symbols, but also the fake blocks, distributing useful information among random places of ciphertext.

The number of multipliers, the source text block divided by, also affects the size of the ciphertext. In combination with the Huffman table, this fact allows you to fully control the size of the encrypted text, that means you can both increase the size of the output text, and reduce.

Thus, the size of the resulting text becomes unpredictable, which forces the attacker to pick up the initial parameters before the attack begins, that is completely restore the algorithm. So, the problem of hacking is a full search of options. Even on the same source text and the same key, the

ciphertext will be different. This is ensured by the use of a PRNG, based on some non-persistent parameter, for example, the time, the processor clock rate. As a source of entropy, any time-dependent variable will do.

B. Avalanche effect and block chaining mode

If any bit in any block is changed, the entire block changes on average by 45% after encryption [4]. This property increases encryption strength, due to the fact that attacks, based on small changes in the source text, stop working.

Block chaining is provided by changing the Huffman table for all following blocks, depending on the results of the encrypted block. So, changing any bit in the block, changes the result of encryption not only of this block, but of all the following. Depending on the Huffman table, changes in subsequent blocks are in range from 40% to 60% and on average provide good block chaining.

C. Cremona transformations

In the existing version, the Cremona transformation is used to increase the entropy of the Generator seeds, which allows use the Generator based on the current time not so often. The key is sufficient to create a whole set of generators, based on these transformations, which can be switched during operation, ensuring the Generator operation unpredictability.

Another option is to generate fake characters at once for a set of blocks. This way will allow to access to the generator less often, which will significantly increase the speed of encryption. Moreover, the fact of working in the fields allows not to worry about a great increase in the transformations degrees, which will provide an acceptable generation rate.

V. PERFORMANCE

The sizes of the read character and block are 16 bits and 8 characters respectively. The key is 256 bits. Modules are: 5, 7, 11, 17, 19. Processor: Intel Core i7-4720HQ 2.6 GHz. The test results for files of different sizes are presented below:

TABLE I.
TEST RESULTS

Algorithm	**File Size (Bytes)**	**Encrypt time (s)**	**Decrypt time (s)**	**Encrypt file size (Bytes)**
Our algorithm	1 048 576 (1 MB)	0.24 – 0.27	0.23 – 0.25	1 726 399 – 1 727 072
AES-256	1 048 576 (1 MB)	0.035	0.068	1 048 576
Our algorithm	104 857 600 (100 MB)	25.12 – 25.96	23.87 – 24.42	172 611 865 – 172 622 351
AES-256	104 857 600 (100 MB)	2.63	5.96	104 857 600

It can be seen that our algorithm loses in speed. This is due to the fact, that the algorithm is probabilistic and, in fact, a greater amount of data is encrypted, than is fed to the input. Also, the current version of the algorithm is just an early prototype, and we are still working on optimization. Nevertheless, even now, because of the great flexibility of the settings, you can achieve a significant speed increase.

VI. CONCLUSION

In this article, a modification of a fully probabilistic cipher based on the theory of information compression and Cremona transformation was presented. This modification can be useful in various areas, since it has a modular structure. Probabilistic encryption guarantees high cryptographic strength for any application. In future research, we hope to optimize this algorithm to make it lightweight, and explore the application of Cremona transformations more. We hope that in the near future there will be an increased interest in probabilistic encryption, so that there is an opportunity to actively develop this direction and compare this algorithm with analogues.

ACKNOWLEDGMENT

We greatly thank our scientific director Sergey Krendelev for support and comments that improved the paper. We would also like to show our gratitude to the team of key exchange, under the direction of Sergey Krendelev, for sharing their ideas with us during the course of this research.

***Abstract*—Cloak-and-Dagger attacks targeting Android devices can completely hijack the UI feedback loop, with one possible consequence being that of hijacking SMS functionality for cybercrime purposes. What is of particular concern is that attackers can decouple stealth activities from SMS hijacking. Consequently the latter could be pulled off using completely legitimate apps that normally would allow users to manage text messages from their personal computers (SMSonPC), but this time all hidden away under attacker control. This work proposes a digital investigation process aiming to uncover SMS-hijacked devices. It uses bytecode instrumentation in order to force the dumping of volatile memory areas where evidence for the hijack can be located. Eventually both the malware that conceals the SMS-hijacking and the compromised or smuggled SMSonPC app can be identified. Preliminary results are presented using a case study based on the popular SMSonPC app: Pushbullet.**

I. Introduction

THE Cloak-and-Dagger set of attacks demonstrates how through the abuse of two permissions, Android malware can take control of the entire User Interface (UI) feedback loop [1]. Essentially what this means is that through malicious crafting an attacker can snoop on or even take full control over a user's intentions when interacting with a smart-phone using touch screen taps and swipes, and conversely of all the device's reactions to them. The consequence is a Man-in-the-Middle (MiTM) posture for an attacker sitting in between users and their devices. This is a critical game changer in the sense that up till this point it was generally thought that UI attacks were more about forcing users to send clicks to marketing referral web-sites, rather than completely hijacking a device. This role up till this point was reserved to rooting/jail-braking malware that takes advantage of memory corruption errors inside firmware. The two abused permissions relate to accessibility (a11y) and overlay drawing (draw-on-top) functionality. The former permits an app to access the UI widgets of a second app, whilst the latter permits an app to draw overlays on top of on another app's UI. Their combined abuse can be disastrous due to the long-term stealth an attacker can attain.

The threat that we are concerned with in this work leverages these two permissions to silently install or compromise one of those apps that let users send/read SMS text messages from their personal computers (PCs). These apps are gaining popularity since in the larger context they let users manage all of their smart devices (phones, tablets, wearables and what not) from a single machine[1]. In the specific case of text messages, typing them on a PC keyboard is of particular convenience whenever possible, and for the rest of this paper we will refer to apps that offer this functionality as *SMSonPC*.

Once Cloak-and-Dagger malware tricks victims into giving up or stealing their login SMSonPC credentials, it moves on to activate a11y and conceal SMS-related activity by abusing draw-on-top permissions. At this point the SMSonPC app provides an attack vector to hijack the device's SMS functionality in a highly stealthy manner. What is of major concern is that the SMSonPC app in question is totally legitimate, possibly installed by the user in the first place. Furthermore, the use of draw-on-top and a11y features have been picked up by popular apps and at this point it can be very difficult to make amends from Android's end.

While Google Play's screening has been tightened accordingly, it is a well known fact that persistent attackers tend to succeed in eventually having their malware included in this trusted app store. Android Oreo also includes tightened security, yet its fragmented adoption is still expected to stand in the way[2][3]. Moreover, mitigations only address overlay drawing and which could potentially be replaced by social engineering tricks nonetheless. Further details with respect to the hijacking procedure and existing digital investigation options are provided in section II.

The idea behind the proposed digital investigation process (section III) is that in the event of a suspected SMS-hijacking, or else on a routine basis, users will be able to investigate their devices for possible infection. This approach aims directly at the core of the issue: long-term stealth. During a first stage those apps that look suspicious, either because of the aforementioned requested permissions or else due to SMS functionality, are extracted from the device in order to have their bytecode instrumented. The injected bytecode forces the dumping of those volatile memory areas where evidence uncovering the hijack could be located, without necessarily requiring device rooting. During a second stage

[2]https://www.wired.com/story/cloak-and-Dagger-android-malware/
[3]https://developer.android.com/about/versions/oreo/android-8.0-changes.html#all-aw

of the investigation forensic analysis is conducted upon the collected memory dumps. They are combined with the context provided by text messages from flash/SIM memory along with any suspicious destination numbers as obtained from operator billing logs. In the interim, the device is used normally except for the additional recording of potential artifacts that can uncover both the malware that sets up and conceals the SMS-hijack, as well as the compromised/smuggled SMSonPC app. Basically any text message flows inferred to originate/end from/at SMSonPC apps without the device's owner consent, and in the presence of a draw-on-top/a11y app, indicate an ongoing SMS-hijack.

A case study using Pushbullet, a popular SMSonPC app, is used for initial exploration of this technique in terms of its effectiveness and practicality (section IV). The proposed SMS-hijack investigation process along with the preliminary results from this case study are the primary contributions of this work.

II. SMSonPC hijacking

The essential ingredients for the stealthy SMS-hijack being considered in our threat model consist of an SMSonPC app combined with a number of Cloak-and-Dagger attack techniques. In this work we focus on the abuse of Pushbullet to serve this purpose.

A. The Pushbullet SMS-hijack scenario

In order to make use of Pushbullet users need to install a controlling application on their PC in the form of a stand-alone native application or a browser extension. Otherwise they may simply log into a web interface[4]. Whichever client option, a device is instructed to send a text message by means of what is called an ephemeral message, which is possibly encrypted, and an example of which is shown in Listing 1. This is a JSON-formatted object which is sent to the Pushbullet server by the controlling application. In this case the instruction is to send a `Hello!` text message to `+1 303 555 1212` on behalf of user-id `ujpah72o0` through her Pushbullet-registered device with identification `ujpah72o0sjAoRtnM0jc`. This is an example of a Pushbullet `push` event, intended for dispatch to the identified Android device, and which accesses its SMS services as specified by the `messaging_extension_reply` type using the `com.pushbullet.android` package.

Listing 1
A Pushbullet ephemeral message instructing a phone to send an SMS text message.

```

  ``push": {
    ``conversation_iden": ``+1 303 555 1212",
    ``message": ``Hello!",
    ``package_name": ``com.pushbullet.android",
    ``source_user_iden": ``ujpah72o0",
    ``target_device_iden": ``ujpah72o0sjAoRtnM0jc",
    ``type": ``messaging_extension_reply"
  },
  ``type": ``push"
}
```

[4]https://www.pushbullet.com

Cloak-and-Dagger is really a collection of attacks [1] that abuse Android draw(ing)-on-top of opaque or transparent overlays and a11y system services. They require the `SYSTEM_ALERT_WINDOW` and `BIND_ACCESSIBILITY_SERVICE` permissions respectively. Since attacks #3 and #4 (as identified in [1]) are able to hijack the device's virtual keyboard, they could be used to steal Pushbullet credentials during installation/configuration. The prior attack succeeds by placing multiple transparent "pass-through-clicks" overlays per keyboard button and then snoops on keystrokes by having all the overlays capture clicks outside their region. Subsequently it identifies the tapped button using a clever Z-order trick. The latter attack abuses accessibility services by listening to keyboard button click notifications. Attack #5 provides an alternate hijacking strategy and combines the two permissions. It exploits accessibility services to detect that the user has navigated to the Pushbullet app, and then proceeds to exploit draw-on-top by displaying a fake but authentic-looking Pushbullet log-in screen. At that instance it lures users to send their credentials directly to the attacker.

Through Cloak-and-Dagger an attacker can even move on from compromising a user-installed Pushbullet installation to the silent installation of a covert one. Specifically through attack #8, using the standard Android API an attacker can initiate an installation of Pushbullet as well as programmatically confirming the same action when prompted, all the while covering this activity through a draw-on-top overlay. Subsequently, through a11y services, the malware can proceed to cover its tracks by accessing the "recent windows" view and dismissing all of its content. The final step is to launch attack #9, i.e. navigating to app settings and outright enabling all the permissions required by Pushbullet. Consequently the user won't get prompted to grant permissions when subsequently Pushbullet is launched remotely by an attacker to disclose or send SMSes on the device's owner behalf, and thereby maintaining stealth. It is noteworthy that both draw-on-top and a11y features come along with mechanisms to protect from abuse, yet the Cloak-and-Dagger attacks don't simply bypass these protections but also go as far as abusing them. For example the aforementioned Z-order trick exploits the same security flag that informs a clicked widget about whether the click passed through an overlay drawn on top of it.

Having obtained access to draw-on-top and a11y permissions through deceit, along with a compromised or smuggled SMSonPC app through Cloak-and-Dagger, an attacker can now proceed with mischief. For example, the device can be turned into a crime text messaging proxy or even into a spying device by leaking message content. Maintaining stealth in the former case can be achieved by deleting all sent messages, once again possibly through Cloak-and-Dagger means. In the latter case it is a question of whether the SMSonPC has been smuggled or compromised. In the first case, it is simply a question of keeping the SMSonPC app installation concealed from the device owner, while the second case also requires that attackers hide their tracks within the SMSonPC controlling

app. Whatever the scenario the end result is that of a stealthy SMS-hijack.

B. Android SMSonPC apps

Any SMSonPC app requires the `SEND_SMS` and `READ_SMS` permissions in order to be able to interact with the device's SMS features. The `INTERNET` permission is also required to provide a communication link with the SMSonPC server. This also applies to Pushbullet. In particular, the `SEND_SMS` permission provides access to the SMS manager service and through which app components can send text messages by calling `SmsManger.getDefault().sendTextMessage()`. An alternate method forgoes permissions by instead delegating message sending to a privileged app by means of a `startActivity(intent)` call, where the `intent` argument would have been associated with an SMS-related action. Reading of inbox/draft/outbox/sent messages on the other hand requires access to the SMS provider (`android.provider.Telephony.Sms`), which is populated from an SQLite database file that persists text messages, and which can be accessed through `getContentResolver.query()` calls.

As of Android Kitkat[5] only a designated default messaging app is actually permitted to write to this provider. This app also has exclusive privileges to handle incoming text messages. However it is then obliged to inform all interested apps of a newly delivered message, as well as to be delegated with message sending duties by unprivileged apps. It is perfectly possible that an SMSonPC app is also the designated default messaging app. That would facilitate even further the deletion of sent messages as part of the crime-proxy's functionality.

C. Limitations with existing digital investigation options

In the event of an SMS-hijack incident, existing options for digitally investigating it encompass examining the phone's SIM and flash memory for all stored text messages. This process comprises forensic imaging followed by the decoding steps concerning the manner with which text messages are encoded. SIM memory uses GSM-7 or the now obsolete GSM-8 or UCS2 encodings [2]. Android phones store text messages inside SQLite database files where UTF-8 or UTF-16 string encoding can be employed [3]. In this case there is the added difficulty that Android does not allow flash memory imaging without prior device rooting. In many cases this could be problematic due to warranty voiding, as well as it leaves the device's protection again future re-infection weakened. A more practical solution would be to simply install an SMS backup/recovery app that extracts all tables/columns individually from the SMS provider's SQLite database file. Such apps only require the `READ_SMS` permission to function, in addition to permission to copy messages to the some target destination.

[5]https://android-developers.googleblog.com/2013/10/getting-your-sms-apps-ready-for-kitkat.html

In any case the SMS crime-proxy text messages would have been cleared up using Cloak-and-Dagger steps that interact with the default messaging app. In the spying device's case the context associated with text messages inside the SMS provider only identifies the creator rather than the reading apps and is therefore useless. In fact both scenarios could only be fully reconstructed by tracing and preserving the entire sequence of events that lead to sending/deletion/reading of specific messages. Artifacts found inside volatile memory could potentially serve this purpose, however the ones concerning text messages are expected to be short-lived and all existing volatile memory dumping techniques require device rooting [4], further complicating matters.

III. Volatile memory-centric investigation

The proposed SMS-hijack investigation process is based directly on those components involved in the sequence of events when sending and reading SMS text messages, as controlled by a Cloak-and-Dagger malware. The volatile memory of these components is a candidate source for investigation-relevant artifacts, specifically the text messages themselves. The interfacing between these components is also of interest since the relevant code execution presents candidate triggers, indicating the presence of text messages within the memory areas of interest at that point in time.

A. Abused SMS components

Event sequence mapping for message sending/reading flows as abused during an SMS-hijack incident was carried out directly upon Android's source code[6], with guidance from literature sources that describe its core inter-process communication [5] and telephony stacks [6]. Figure 1 depicts the components and interfacing involved when covertly sending text messages. Firstly, the Cloak-and-Dagger malware itself needs to conceal from the user any activity related to SMS being conducted by the SMSonPC app. Draw-on-top overlays require a `TYPE_SYSTEM_OVERLAY` layout and which has now been deprecated by the more restrictive `TYPE_APPLICATION_OVERLAY`. However the new permission is only relevant for user-installed apps that do not need to be compatible with Android versions older than Oreo. Attackers interact remotely with the SMSonPC app to send instructions for sending/retrieving text messages, e.g. Listing 1, typically through HTTP(S).

The direct route for sending text messages is through the `SMSManager` service and which is hosted by the phone process `com.android.phone`. Most inter-process communication in Android happens through `Binder`, a Remote Procedure Call (RPC) mechanism, in order to trigger `SmsManager.sendTextMessage()`'s code execution. Message dispatching includes two important steps. First, the outgoing message is written to the `mmssms.db` SQLite database file by calling into the Linux Virtual File System (VFS) and eventually writing to the phone's

[6]https://source.android.com/

flash memory. This step is mandatory unless the originator of the message is the default messaging app. Secondly, the message is dispatched to the baseband processor. The `RIL.sendMessage()` triggers a chain of events that cause the outgoing message to formatted in a communication protocol-independent manner (PDU format). It is sent through a UNIX domain socket to the `rild` native daemon that in turn interfaces with a vendor-specific library. When its `ProcessCommandBuffer` event loop receives the RIL request number 25 (`RIL_REQUEST_SEND_SMS`), this library initiates message sending by calling into the baseband driver code via an `ioctl`. Eventually the baseband processor physically sends the text message onwards to the operator's core network via the closest base transceiver station. The operator logs the event for billing purposes even though this excludes message content [2].

An alternate indirect path is possible whenever an unprivileged SMSonPC app interacts with the default messaging app using intents. Intents are resolved by the `ActivityManagerService`, which is hosted by the `System Server` daemon and reachable through Binder RPC. The continuation path is similar to that of the direct path, except that at this point the persistence of outgoing messages is at the discretion of the default messaging app.

The primary components involved with the reading of text messages are shown in Figure 2. The SMS provider inside the phone process, as populated from `mmssms.db` through a call to `SQLiteQueryBuilder.query()`, is central to this operation. This provider can also get populated from the SIM memory through a `SmsManager.getDefault().getAllMessagesfromICC()` call, and which in turn sends a RIL request number 28 (`RIL_REQUEST_SIM_IO`). The task of obtaining a reference to a `ContentResolver` instance for calling `query()` is mediated by `ActivityManagerService`. Ultimately, the retrieved message is covertly leaked to the attacker via HTTP(S).

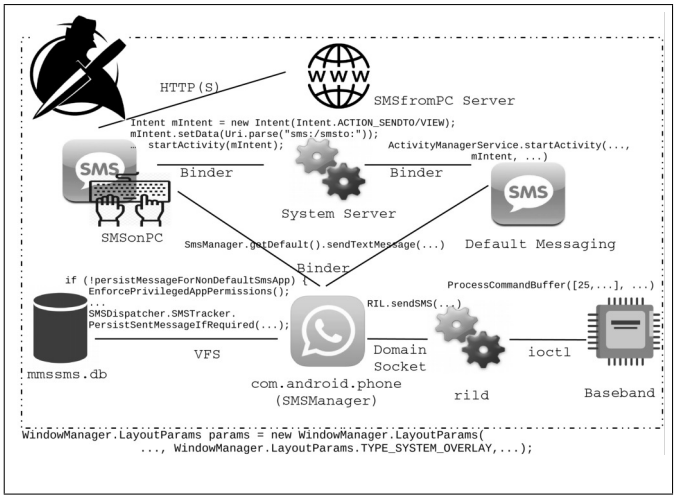

Fig. 1: Android components abused to send SMS text messages and concealed by Cloak-and-Dagger.

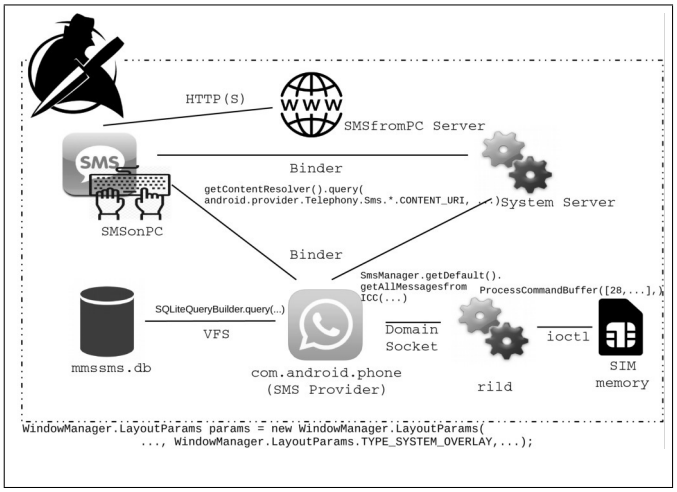

Fig. 2: Android components abused to read SMS text messages and concealed by Cloak-and-Dagger.

B. Observations

Potentially, any text message flow originating from an SMSonPC app and which after passing through system components terminates in flash/SIM memory, coupled with suspicious draw-on-top and a11y activities, should raise an alert of a possible SMS-hijack. The same argument applies for the inverse route. The device owner can confirm whether the observed flows had their consent or otherwise, at which point the suspicious app is identified as the Cloak-and-Dagger malware while the SMSonPC app is confirmed to have been compromised. Given that fully tracing these flows for prompt SMS-hijack detection is expected to be particularly expensive in terms of runtime overheads, an alternate practical approach is to defer detection during memory forensics analysis [7]. The idea is to keep track just of the key in-memory artifacts related to these flows, as occurring inside the memory space of apps and intermediate system components, and from which to infer their occurrence.

The main challenge however is presented by the brief permanence in memory of the said artifacts, calling for an event-driven collection approach. Bytecode instrumentation is a key enabler, whereby injected bytecode is responsible for initiating memory dumps at the appropriate SMS-hijack triggers. The most obvious solution is to focus on SMSonPC apps, since they can be statically instrumented through app repackaging and without the need of device rooting. Furthermore, instrumenting system components is still deemed a less desirable option due to the instability that it might incur. Yet, on a non-rooted device the injected bytecode would only have the faculty to dump the Dalvik (Java) heap, and would therefore miss those artifacts that would rather reside on the native heap whenever native components are employed. In cases where device rooting is viable, rather than having to analyze all native heaps of a myriad of SMSonPC apps it could suffice to inspect just that of the Android phone process. This heap is expected to be relatively constant across devices.

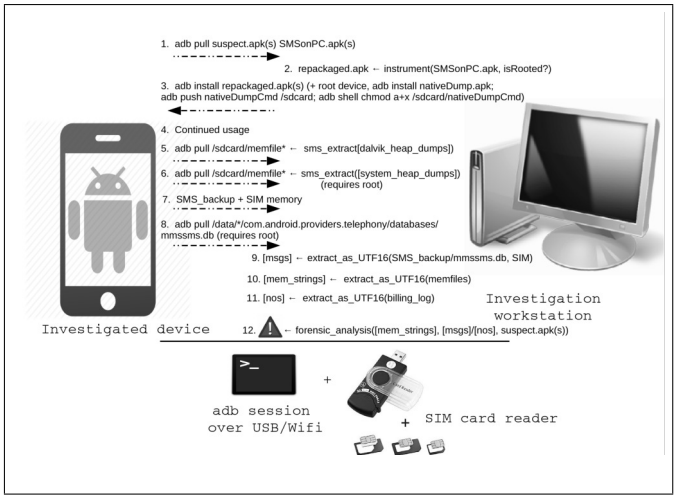

Fig. 3: The volatile memory-centric process for digitally investigating SMS-hijacking.

As can be observed from Figures 1 and 2 the phone process is central to both the SMS sending and reading flows. Also, due to the native Binder RPC mechanism it must process text message flows on its native heap.

C. The SMS-hijack investigation process

The proposed digital investigation steps carried upon devices with a suspected SMS-hijack, as shown in Figure 3, are based on the observations just made. They require the inspected device to be connected to an investigation workstation over an Android Debug Bridge (adb) session. The first 3 steps are concerned with identifying suspicious apps and instrumenting the trigger points for dumping volatile memory. The focus is on those packages (in apk format) that request relevant permissions. They must either request access to draw-on-top/a11y services that render them Cloak-and-Dagger suspects, or else they request SMS permissions and therefore are potentially abused SMSonPC apps. These apps are discernible from the device's `/data/system/packages.xml`.

Once pulled from the device (step 1), the potential SMSonPC apps are repackaged (step 2) with memory-dumping instrumentation and re-installed on the device in place of the original ones (step 3). Algorithm 1 describes the `instrument()` function applied on each `SMSonPC.apk`, and which takes into account whether the device will be rooted in step 3 as indicated by the `isRoot` flag. Lines 1-4 populate the filters for SMS or native method call-related trigger points as per component interfacing described in section III-A. These are defined using smali syntax[7] which is an assembly language for Dalvik bytecode[8]. The additional wild cards $\star$ are meant to match any smali statements in a non-greedy manner.

Trigger points are instrumented with Dalvik heap-dumping bytecode (`dalvik_dump_instr` on lines 5-12) and possibly also that of the native heap of the phone process (`systemmem_dump_instr` on lines 13-20). The

[8]https://source.android.com/devices/tech/dalvik/dalvik-bytecode

latter relies on device rooting as well as the the installation of `nativeDump.apk` and `DumpCmd`, as per step 3 of Figure 3. `nativeDump.apk` exposes the `nativeDumpSrvc` service component reachable through `startService()` calls from the instrumented apps. In turn, `nativeDumpSrvc`'s implementation calls the `su; /sdcard/DumpCmd` shell command sequence. `DumpCmd` is a native process responsible for dumping the phone process's native heap via `/proc/<pid_suspect/phone>/maps` and `/proc/<pid_suspect/phone>/mem`. All memory dumps are placed on external (common app) storage area on the file-system (`/sdcard`). Within the same location the `sms_extract()` component is responsible to extract just the SMS-related memory areas, saving on space requirements. This file-system location facilitates later retrieval from the investigation workstation without requiring device rooting.

For both instrumentation code, the Dalvik VM register numbers `vA-vD` have to be adjusted so that no clashes occur, possibly also requiring an adjustment to the `.locals` smali directive. This directive declares the number of Dalvik VM registers needed to store the local variables of a class method (excluding method parameters). Furthermore, not shown in the instrumentation bytecode of Algorithm 1 is exception handling code, as well as an additional snippet that combined with `AndroidManifest.xml` permission entries for `READ_EXTERNAL_STORAGE` and `WRITE_EXTERNAL_STORAGE` requests access to the external storage. This operation would be required only by those apps not already including this functionality, with the instrumentation bytecode placed inside the `onCreate()` method of the app's main activity.

The trigger filters are applied for each smali representation of the compiled app classes (`smali_class_file`), as obtained through apk unpacking (`unpack_apk()`) (lines 21-31) by calling `getNextTriggerPoint()`. The identified trigger points are then instrumented by calling `InstrMethodStart()`. This is a routine that attempts to inject the instrumentation bytecode at the very start of the method containing the trigger point. This approach avoids having to renumber Dalvik registers to address clobbering, and therefore not running the risk of exceeding the highest register usable by most Dalvik opcodes (`v15`). Instrumentation for native heap dumping is only carried out in case of device rooting. Each, possibly instrumented, smali class file is eventually added to the repackaged app `repackaged.apk`. Finally, the app is signed (line 32) and is ready to be deployed back to the investigated device.

The pending explanation concerns lines 23-24. These are two pre-processing operations that would have to be applied in case the SMSonPC apk is hardened with anti-tampering (`crack_anti_tamper()`) and packed (`unpack()`) code. Their implementation is orthogonal to our work, rather the investigator must seek the assistance of third-party tools in order to successfully pre-process the said class files, with good disassembly skills coming in very handy.

Once step 3 (Figure 3) is complete, the device is returned to its owner for continued usage during step 4. Its duration is bounded by the space available for memory dumps (the `memfiles`). On investigation resumption, steps 5 and 6 take care of retrieving them from the device. Step 7 retrieves the available SMS text messages from flash memory using any SMS backup app, as well as those in SIM memory using an appropriate card reader. Additionally, on rooted devices text messages can rather be extracted directly from the `mmssms.db` SQLite database files in step 8. Steps 9-10 proceed with extracting and normalizing to UTF-16 the text message details as well all strings from the memory dumps. Step 11 on the other hand performs the same operation for those suspicious destination numbers obtained from the billing log.

The normalized content is now ready to be used for forensic analysis. In the case of a text message leakage investigation, the text messages from step 9 are central to the investigation starting point. In the case of a crime-proxy attack, where sent messages are deleted for stealth, the suspicious destination numbers from step 11 become essential. At this point, the aim of the investigator is to trace the messages/numbers inside the dumped strings, and from which to attempt to maximize the identification of SMS-hijack related artifacts. The non-comprehensive list includes: sent/leaked message times, crime-proxy message content, SMSonPC account details in case it has been smuggled, identification of the implicated SMSonPC app in case of multiple candidates, and ultimately the Cloak-and-Dagger malware itself.

IV. Case study: Pushbullet

In order to assess the potential of the proposed SMS-hijack investigation process we present a case study involving the widely used Pushbullet SMSonPC app. The chosen scenario is a simulated crime-proxy attack. Its objectives are to: *i)* Report on the instrumentation step (Algorithm 1) as applied to Pushbullet; *ii)* Measure the storage requirements needed for memory dumps, and *iii)* the overheads imposed by bytecode instrumentation; and finally *iv)* Report on the artifacts identified during the forensic analysis step.

The case study assumes a Cloak-and-Dagger malware to have stealthily installed Pushbullet and set up the device to act as an SMS crime-proxy. Eventually a sequence of suspicious outgoing text message destination numbers show up on a detailed break-down of the device owner's phone bill. Step 1 of the investigation identifies a suspicious app that requests draw-on-top and a11y permissions, as well as the Pushbullet app as the possibly abused SMSonPC app. At this stage the investigator is required to conduct the follow-up investigation steps. The full setup consists of an Android Virtual Device (Goldfish), Android Nougat (for Intel Atom), Pushbullet version 17.7.19-288 and Android Debug Bridge 1.0.39. Apktool 2.3.1 was used to assist bytecode instrumentation. Bash scripting was used for prototyping the instrumentation tool as well as native heap dumping.

A. Pushbullet instrumentation

The first two trigger filters from Algorithm 1, i.e. those relevant to SMS crime-proxy, identified two trigger points both inside `com.pushbullet.android.sms.h`'s `void a(String, String, String)` static method. The result of `InstrMethodStart()`'s execution is shown in Listing 2. Line 1 identifies the instrumented method and line 2 shows that the requested number of Dalvik VM registers has been increased from 8 to 12. The registers utilized by the instrumentation bytecode are in the `v2-v9` range, since attempts to make use of `v0` and `v1` resulted in compiler (`dex2oat`) errors. As compared to the abstracted version presented earlier in Algorithm 1, the injected instrumentation does not hard-code the location of the external common storage (line 10), makes use of the convenient `StringBuilder` class (line 15), had to resort to using `const-string/jumbo` (line 21) due to the large number of strings used by Pushbullet, and makes use of a try/catch block (line 31). On successful execution, control flow skips the exception handler and goes straight into the original entry point of the non-instrumented method (line 43), as indicated by the original `.prologue` directive (line 42).

In terms of obscured trigger points Pushbullet shows no signs of packed code or SMS-related native code. This situation simplifies matters with respect to trigger point coverage and avoids the need to dump native heaps. The use of ProGuard (a code obfuscator that is enabled by default in Android Studio) is not an obstacle either since since trigger points are defined over Android API calls. No anti-tamper protection was encountered either, although the repackaging of Pushbullet did affect Google sign-in's functionality. The case study was eventually conducted using the Facebook sign-in option since this functionality was not broken. Yet, this was an eye-opener on the perils of instrumentation. Finally since Pushbullet already requests access to external storage, no further bytecode instrumentation was necessary in this respect.

B. Storage requirements

The storage requirements were calculated on the basis of an estimated average of 33 daily sent text messages[9]. In turn this translates to 33 Dalvik heap dumps and a possible additional 33 native heap dumps per day. Table I shows the storage requirements for Pushbullet (Dalvik heap) and Android's default phone process (native heap) dumps. While this case study does not strictly require the latter they are included to present a more complete picture.

In both cases the figures for both full and SMS-related area dumps are provided. In the case of Pushbullet, the SMS areas are those containing ephemeral messages as per Listing 1. In the case of the phone process a more generic approach was followed by taking into consideration all areas containing UTF-8/16 strings. This is the main reason why native heap dump sizes are significantly larger ($> \times 100$). However, dump size reduction is staggering in both cases. The 0 standard deviation for full native dumps derives from the fact that their size did not change throughout the entire time-frame of sending the text messages. On the other hand the garbage-collected Dalvik heap was more dynamic.

[9]https://www.textrequest.com/blog/many-texts-people-send-per-day

TABLE I
EST. DAILY STORAGE REQUIREMENTS FOR MEMORY DUMPS.

Dump mode	mean (kB)	std. dev. (kB)	sum (kB)
Dalvik heap - Full	11,608	244.752	380,000
Dalvik heap - SMS only	5	1.929	163
Native heap - Full	31,457	0	1,000,000
Native heap - SMS only	505	89.298	16,656

TABLE II
RUNTIME OVERHEADS.

Configuration	mean (s)	std. dev. (s)	Mann-Whitney (p-value=0.93)
`pushbullet.apk`	0.22	0.02	Sum of ranks - 1099
`repackaged.apk`	0.72	0.4	Sum of ranks - 1112
Overheads	227%	-	U - 538

Overall, the 163kB/day required by Dalvik heap dumps compares well to the approximate 3-5MB typically consumed by a selfie with default resolution. However this figure rises sharply to nearly 17MB had the phone to be rooted and native heap dumping enabled.

C. Runtime overheads

From an end-user's point-of-view the runtime overheads incurred by Pushbullet due to bytecode instrumentation are not noticeable. However, even minimal runtime overheads could be a factor from an attacker's point-of-view had they be exploited to detect an ongoing SMS-hijack investigation. Therefore, overheads were measured when sending SMS text messages from Pushbullet's browser interface. In doing so we gained access to the SMS event profiling logs created by `pushbullet.js` inside the javascript console. The relevant log entries are those of `sms_changed` type and examples of which are shown in Listing 3.

Table II shows statistics for the turn-around times, measured between when a text message is sent and the point at which a notification of completion is received asynchronously in a typical Ajax fashion. When computing overheads incurred by the combined Dalvik/native heap dumping instrumentation over an unmodified Pushbullet configuration, the mean overhead for a daily amount of text messages is a considerable 227%. However, when comparing ranks of the two configurations using a Mann-Whitney test the U value is roughly half that of the sum of ranks for both configurations. This indicates that the difference in mean turn-around times between the two is not statistically significant. This outcome indicates that while the turn-around times for the repackaged configuration were higher, other external factors also had an impact. Therefore their difference is not a reliable measure for attackers to detect an ongoing investigation.

Listing 4. Extract from `mmssms.db`.

D. Forensic analysis

Listing 4 shows an extract from an `mmssms.db` export produced after all text messages were sent. Each entry clearly identifies the destination number (`123456`), message content (`CrimeProxy sms text message n`) and the creator app (`com.pushbullet.android`). If this content was present on the device, any SMS backup app with `READ_SMS` permission would have been able to extract this information to solve the SMS-hijack case. However, with a Cloak-and-Dagger malware that deletes the SMS crime-proxy messages, an investigator would have to resort to the volatile memory dumps for evidence. Starting off from the suspicious `123456` destination number extracted from a detailed bill breakdown (step 11 of the investigation process), the subsequent forensic analysis (step 12) retrieved the entries shown in Listing 5. Each entry provides the missing context from the deleted `mmssms.db` entries, namely the message content. Furthermore given that we are dealing with a Pushbullet dump automatically implicates the app in this SMS activity. Moreover the prefix `ujBeKPNHgJMs` is observed to remain constant throughout all the `iden` entries, identifying the utilized Pushbullet account, and therefore also provides the necessary evidence for reporting abuse. Finally, the `created` and `modified` fields store the timestamps related to the text message sending events.

Listing 6 shows the corresponding native heap dump artifacts as retrieved from the phone process. In this case the user account identification is missing, however the message content and creator app are clearly identifiable. Concluding, in both the Dalvik and native heap dump cases, all information that could have gone missing from `mmssms.db` could be reconstructed. At this point with the device owner's assistance the investigator would be able to confirm whether those outgoing messages were related to an SMS-hijack by confirming the user's consent or otherwise. In the latter case, the suspicious app's bytecode from step 1 should be analyzed in order to identify the Cloak-and-Dagger code.

E. Limitations

An alternative to using message turn-around times in order to detect an ongoing investigation, the Cloak-and-Dagger malware could be equipped with checks for the presence of memory dumps inside external storage, suspending its activities if found. While in a way this can be seen as beneficial, this could be problem if the SMS-hijack operation is resumed as soon as the device returns to normal operation. Furthermore, while in the case of Pushbullet no anti-tamper or obfuscation came in the way, the Google sign-in failure is an eye-opener with respect to the difficulties expected during SMSonPC app instrumentation.

V. Related work

Ideally SMS-hijack attacks are thwarted during the app store upload stage using automated malware analysis. Given that a significant part of the attack is actually carried out by a legitimate SMSonPC app, it is rather the identification of the Cloak-and-Dagger malware that should be targeted. Yet, a number of challenges abound. Firstly app obfuscation, e.g. using encryption and runtime class loading, could hide the malware's real intention from static analysis. This issue could be addressed with dynamic analysis [8] where suspicious apps are executed inside a malware sandbox. However this alternative is not without its own limitations, with trigger-based behavior [9], [10] and device emulation detection-based evasion [11] posing major hurdles. The same limitations are encountered whenever malware analysis is carried out for forensics purposes [12], where malware samples are hunted and extracted from within a mobile device for event reconstruction purposes.

In contrast, our proposed digital investigation process differs in scope. It targets those situations where Cloak-and-Dagger malware succeeds in evading app store scanning. Furthermore, the malware's behavior is tracked within its intended runtime environment, with the exception for SMSonPC app repackaging and the resulting dumps. Our work is more akin to related work concerning the digital investigation of mobile devices, for example for SMS text message forensic purposes [13], [14]. Yet, our proposed technique involves a prolonged investigation period, where the device is returned to its owner for continued usage as enhanced with memory dumping instrumentation. Finally, our proposition can also pave the way to thwart the 'Trojan Horse defense' [15], where text messages considered as evidence for a crime investigation are refuted by claims that the device could have actually been compromised to serve as a communication proxy by the actual criminals.

VI. Conclusions

In this paper we considered the problem of Cloak-and-Dagger malware pulling off stealthy SMS-hijacks by abusing legitimate SMSonPC apps. We proposed a solution whereby injected bytecode instrumentation dumps the SMS-relevant areas of volatile memory from the device under investigation at the right triggers. A case study was carried out using Pushbullet as the SMSonPC app abused for setting up an SMS crime-proxy. Results show that the technique can be both effective in collecting the evidence required to solve the SMS-hijack, as well as practical in terms of SMSonPC app instrumentation and storage costs. The runtime overheads incurred were shown to be difficult to exploit by attackers to uncover an ongoing investigation, while at the same time not impacting the device owner.

This case study provided the right setting for initial exploration of the proposed SMS-hijack investigation process, with results showing promise. A similar case study for information leakage is planned. Further experimentation also aims to evaluate the technique at a larger scale using an array of physical smart-phone devices and possibly even involving malware samples captured in the wild. A primary pre-requisite for such an undertaking is the engineering of the investigation tool that also incorporates existing techniques that deal with obfuscated

code and anti-tamper checks. Even more importantly, collaboration with SMSonPC app developers is required to deal with app instrumentation in a cleaner way whenever this breaks functionality in some way. Collaboration is specifically sought on the anti-tampering front.

2nd Workshop on Internet of Things—Enablers, Challenges and Applications

THE Internet of Things is a technology which is rapidly emerging the world. IoT applications include: smart city initiatives, wearable devices aimed to real-time health monitoring, smart homes and buildings, smart vehicles, environment monitoring, intelligent border protection, logistics support. The Internet of Things is a paradigm that assumes a pervasive presence in the environment of many smart things, including sensors, actuators, embedded systems and other similar devices. Widespread connectivity, getting cheaper smart devices and a great demand for data, testify to that the IoT will continue to grow by leaps and bounds. The business models of various industries are being redesigned on basis of the IoT paradigm. But the successful deployment of the IoT is conditioned by the progress in solving many problems. These issues are as the following:

- The integration of heterogeneous sensors and systems with different technologies taking account environmental constraints, and data confidentiality levels;
- Big challenges on information management for the applications of IoT in different fields (trustworthiness, provenance, privacy);
- Security challenges related to co-existence and interconnection of many IoT networks;
- Challenges related to reliability and dependability, especially when the IoT becomes the mission critical component;
- Zero-configuration or other convenient approaches to simplify the deployment and configuration of IoT and self-healing of IoT networks;
- Knowledge discovery, especially semantic and syntactical discovering of the information from data provided by IoT;

The IoT conference is seeking original, high quality research papers related to such topics. The conference will also solicit papers about current implementation efforts, research results, as well as position statements from industry and academia regarding applications of IoT. The focus areas will be, but not limited to, the challenges on networking and information management, security and ensuring privacy, logistics, situation awareness, and medical care.

TOPICS

The IoT conference is seeking original, high quality research papers related to following topics:

- Future communication technologies (Future Internet; Wireless Sensor Networks; Web-services, 5G, 4G, LTE, LTE-Advanced; WLAN, WPAN; Small cell Networks. . .) for IoT,
- Intelligent Internet Communication,
- IoT Standards,
- Networking Technologies for IoT,
- Protocols and Algorithms for IoT,
- Self-Organization and Self-Healing of IoT Networks,
- Trust, Identity Management and Object Recognition,
- Object Naming, Security and Privacy in the IoT Environment,
- Security Issues of IoT,
- Integration of Heterogeneous Networks, Sensors and Systems,
- Context Modeling, Reasoning and Context-aware Computing,
- Fault-Tolerant Networking for Content Dissemination,
- Architecture Design, Interoperability and Technologies,
- Data or Power Management for IoT,
- Fog—Cloud Interactions and Enabling Protocols,
- Reliability and Dependability of mission critical IoT,
- Unmanned-Aerial-Vehicles (UAV) Platforms, Swarms and Networking,
- Data Analytics for IoT,
- Artificial Intelligence and IoT,
- Applications of IoT (Healthcare, Military, Logistics, Supply Chains, Agriculture, ...),
- E-commerce and IoT.

The conference will also solicit papers about current implementation efforts, research results, as well as position statements from industry and academia regarding applications of IoT. Focus areas will be, but not limited to above mentioned topics.

EVENT CHAIRS

***Abstract*—The paper presents novel solutions for systems used to create air pollutions maps in smart cities. Ability to record pollution levels with a function of a short-term prediction of their fluctuations may be useful for cyclists and pedestrians moving through the city. Based on such data they can choose their route through the city in such a way, as to avoid the most polluted areas. Systems of this type are in the range of solutions characteristic for smart cities. Their effectiveness requires a relatively dense wireless sensor network (WSN) composed of miniaturized and cheap intelligent pollution sensors, capable not only of data recording and transmitting, but also of some data processing with the prediction abilities. Sensors of this type require a development of various circuit components that feature small sizes and ultra-low energy consumption. One of the main blocks, in this case, should be an artificial neural network (ANN) implemented at the transistor level. In this work, we present prototype circuits designed by us for the described purposes. The realized blocks include a finite impulse response (FIR) filter, programmable analog-to-digital converters (ADCs) with internal controlling clock generators and main building blocks of a parallel ANN. The specialized chips (ASIC – application specific integrated circuit) with the described components were implemented in the CMOS technology in the full custom style.**

I. Introduction

CITIES are not homogeneous systems. Depending on the area, different may be the terrain as well as urban occupation. The type of buildings includes such parameters as its density and height, width, and location of streets in relation to wind directions, distribution of green areas, etc.

Particular areas of the cities play a different function, which often translates into the intensity of traffic, which is one of the main factors causing pollutions. The described factors affect the natural possibilities of ventilation and the absorption of pollutants, and thus the susceptibility of particular areas of the city to changes in pollution levels. An important factor here is the time of persistence of specific levels of pollutions, even after the expiry of stimuli affecting them.

Air pollution is also affected by the seasons. This is due not only to the fact of a larger emission due to heating but also to natural changes in green areas. The biologically active surface (lawns, parks, green walls, green roofs, trees) has a significant impact on the absorption of pollutants.

In such cities as Kraków in Poland, the terrain does not support the natural ventilation, so the pollution levels are frequently at high levels. On the other hand, when designing new cities, this factor may be taken into account. An example here is the Zenata Eco-city developed in Morocco near the city of Casablanca. One of the examples of the smart approach at the city's design stage is taking into account natural conditions. For example, the wind directions in the area were examined in order to build the city in such a way, to allow for natural ventilation and lowering the temperature by several degrees in the summer [18]. It is also planned to collect rainwater in retention reservoirs and use it to maintain green areas – in plans, 30 % of the area of the city will be covered by greenery (compared to 3 % in Casablanca).

With such a diversity of conditions, relying only on a few or a dozen stations measuring levels of pollutions in a given area is not sufficient. At present, in main cities in Poland, on average, there are only a few to a dozen or so automatic stations measuring the pollution levels [1], [2].

The price of currently offered devices and their sizes do not support dense maps. To solve this problem, it is necessary to significantly reduce the price of a single device. The solution here may be miniaturized integrated sensors realized in the CMOS technology, implemented either as a System-on-Chip or as a System-in-Package. As shown in the next section, examples of the implementation of integrated pollution sensors can be already found in the literature. This is an important step towards advanced small and cheap measuring devices.

Another need is to increase the prediction abilities offered by the monitoring systems, especially for the short time horizon. Such information may be of fundamental importance, for example for cyclists and pedestrians moving around the city. Based on such data, they may consciously choose particular sections of their route through the city. The next step in the development of the monitoring systems may be the implementation of more complex measurement devices that offer an onboard ability to make predictions, fully independently from the main station.

The paper has the following structure. In the next Section, a state-of-the-art study is presented. Pollution monitoring systems cover many different elements that need to be presented separately. This part first discusses the monitoring systems considered as a whole. Subsequently, details relevant to the implementation of the integrated measuring devices are described. Then examples of the use of ANNs in the pollution

prediction problem are being presented. In the following Section, the authors' contribution to the development of integrated intelligent sensors is described, with such circuit components of such devices, as Analog-to-Digital Converters (ADCs), filters and components of the ANN. In the last Section, the conclusions are drawn.

II. State-of-the art study

A. Air pollution monitoring systems

In Poland, Voivodship Environmental Protection Inspectorates provide data from environmental monitoring for particular voivodships [3]. The offered system is based mainly on networks of measurement stations located in sensitive points of voivodships – mainly in large cities. Such stations measure concentrations of, among others, such gases and substances as sulfur dioxide, nitrogen oxides, benzene, carbon monoxide, ozone, suspended dust PM_{10} and $PM_{2.5}$. In 2017, in Poland, air quality measurements were carried out by 1,924 measuring stations, including 1,098 automated stations (57 %).

Airly company develops its own system, which is supposed to be much denser. Currently, the highest density of measuring devices is offered in Kraków. The measurement results offered to the public throughout the company's webpage show, this is justified, as concentrations can change significantly in short periods of time, while large differences may be visible even between areas located close to each other. Selected results from the Airly website, are shown in Figure 1. Diagrams (a) and (b), show results for two following hours (one Saturday in May) for the overall city.

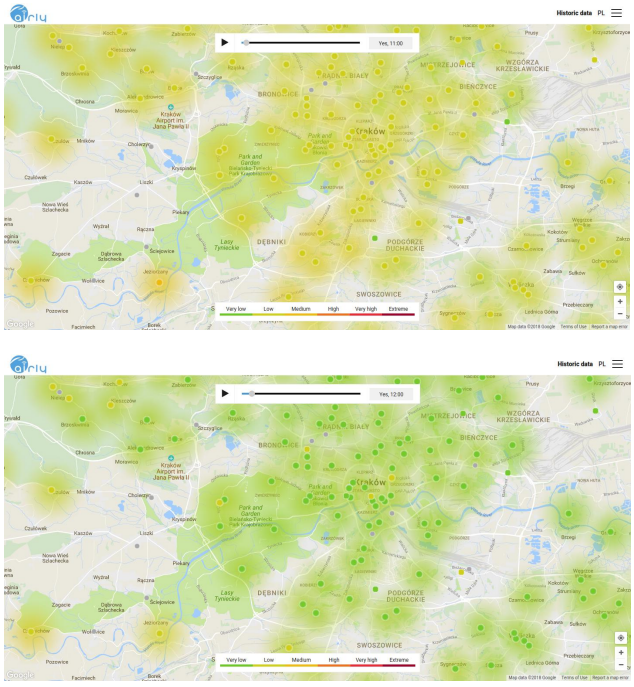

Fig. 1. Selected maps obtained from the Airly company's webpage (source: Airly sp. z o.o., Aleja Pokoju 1a, 31-548, Kraków, Poland, https://map.airly.eu/pl/) for the overall city for two following hours.

At this point, it is worth mentioning wearable pollution sensors already offered on the market. Their usage is limited, as they require a person equipped with such a sensor to be present in a given area of the city. It does not protect this person from the effects of the pollutions. A better solution would be stationary sensors providing data to a central computation station, which would be able to perform a short-term prediction based on the collected data. In this way, city users could plan their route or the mean of transport more consciously in advance. One of the useful options related to the described wearable sensors would be sharing collected data with a central system so that other people could use. Such an approach could support the stationary system, increasing the prediction abilities and the map resolution.

B. Microelectronic sensors of pollution particles

In the literature, one can find several examples of the implementation of particle sensors of various air contaminations. Texas Instruments company proposed an optoelectronic system for the detection and measurement of the $\mathrm{PM}_{2.5}$ and the PM_{10} particles. The system is based on the detection of scattered light by particles suspended in the air [14]. In [15] presented are methods of implementing the $\mathrm{PM}_{2.5}$ and PM_{10} particle micrometer using the zinc oxide based on the Solidly Mounted Resonator (SMD). The authors of [15] present a complete system mounted on a printed board (PCB). On the board, apart from the particle sensor PM_{10} and $\mathrm{PM}_{2.5}$, there is also a specialized ASIC, used by the sensor. The system works correctly, however, it consists of two separate blocks – the sensor and the system managing it. This is a disadvantage, for it increases the dimensions of the device, and what is also important, in such a solution there is a lack of encapsulation of the electronic circuits, which is important taking into account sometimes hard environmental conditions.

Another example is an integrated capacitive sensor designed in the CMOS 0.35 μm technology [16], [17]. The advantage of this system is the fact that it is implemented inside the integrated circuit, which enables, apart from the detection of molecules, also other parallel operations. The system is capable of detecting microscopic particle sizes of pollutants. This work is an important novelty in this area in the world, as the sensor solutions inside the integrated circuit are presented for the first time here.

The availability of the described works is very important. The combination of such solutions with the ANN offered by the authors of this article is important from the point of view of the development of fully intelligent and autonomous sensors.

C. Using ANN to monitor and predict air pollutants

Development of smart cities would not be possible without the use of artificial intelligence (AI) algorithms, including artificial neural networks (ANN), genetic algorithms (AG), fuzzy systems (FS), or expert systems (SE). AI will play a significant role in the development and functioning of such cities. On one hand, this is due to the very large complexity of the system which the city is, and on the other hand, the

lack of the possibility of an accurate mathematical description of the interdependencies between various parameters of this system. Complexity means also a huge amount of data, which is often difficult to express unequivocally with the help of unified indicators.

ANNs are universal tools frequently used in different areas of daily life. They are frequently employed for data classification, prediction, recognition, detection, etc. Neural networks operate more effectively if they receive properly prepared data (e.g. normalized) and when they have the sufficiently large computing power to process them within an acceptable time interval. It is also necessary to match a given type of the ANN to a specific problem. One of the areas in which these tools are more and more frequently used is the problem of air pollution, described in this paper. In this case, they are capable of contamination forecasting [11], [12], [6], [5], [13], [10], [7], [4].

One of the examples here, is the application of the Multi-Layer Perceptron (MLP) and the Radial Basis Function (RBF) neural networks for a long-term prediction of pollutants dust (PM_{10}, $PM_{2.5}$) (especially in cities) [11], [12]. In another work [6] a multilayer perceptron (MLP) has been used to forecast the impact of pollution caused by road traffic (exhaust fumes) on the health of residents. In [13] three different machine learning algorithms are presented, including, among others, a neural network for the monitoring and forecasting of pollutants, such as ground-level ozone O_3, nitrogen dioxide NO_2 and dioxide sulfur SO_2. Another work in this area [10] presents the concept of self-organizing networks [7] used for the classification of data on sulfur dioxide hazards SO_2 is presented.

III. Proposed Contribution to the Development of Intelligent Pollution Sensors

In this Section, we present a model of an integrated system for the detection and prediction of air pollution particles in the form of a specialized chip implemented in the CMOS technology. State-of-the art works in this area, described above, focus on the implementation of either the pollution particles sensors in the form of an integrated circuit or the use of software implementation of neural networks to detect impurities. In this work, we present the solutions that will allow joining those two areas into a single integrated device, capable of working at WSN.

The proposed intelligent sensor consists of several main components, such as: (i) air pollution sensor (a standard solution) used to collect data from the city, (ii) a filter used to remove noises from the signal, (iii) an ADC used to convert measured analog data into a digital signal further processed in, (iv) data processing unit with a hardware realized ANN. The processed data are transferred to the base station using (v) an RF communication block (standard block to be used).

The neural network, that can be used in the sensor, may be either analog or digital. In the second case, a preliminary analog-to-digital conversion with the appropriate resolution is required. Even though, the preferred solution is the use of a digital neural network, due to its robustness to various types of external conditions and the impact of the imperfections of the technological process. Both filters and ADCs were previously designed by us [19]. A prototype ASIC containing these components is shown in Figure 3.

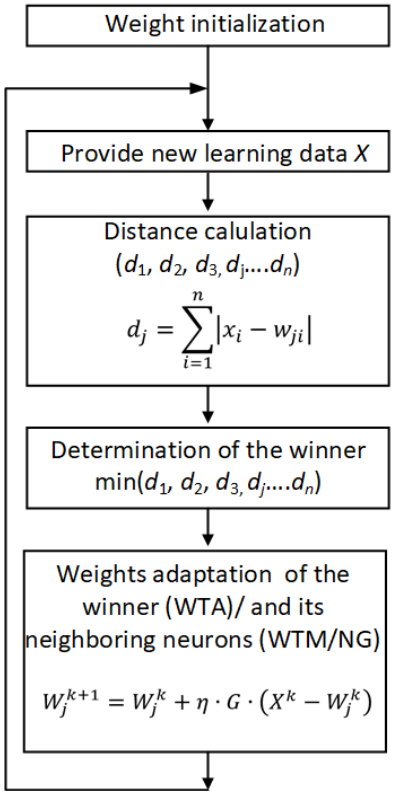

Fig. 2. Self-organizing neural network algorithm.

In this work, we focus on ANN, that will be integrated directly with other components of the sensor. In the proposed approach we use self-organizing networks since such networks are already used with success for the analysis and prediction of the air pollutions. Moreover, such networks offer a relatively simple structure, which is crucial from the point of view of the implementation in the ASIC. Low mathematical complexity allows for a large miniaturization. The structure of such a network is schematically shown in Figure 2. The basic operations performed for each learning pattern X are as follows:

- initialization of the neuron weights,
- providing new learning pattern X from the ADC and indirectly from the pollution sensor,
- calculation of distances (d_1, d_2, d_3, d_j, ..., d_n) between the learning pattern X and weight vectors W of particular neurons. One of the typical distance measures may be used, namely Manhattan or Euclidean one [8],
- determination of the winning neuron. Mathematically it is the min(d_1, d_2, d_3, d_j, ... ,d_n) operation,
- determination of the neighborhood of the winning neuron

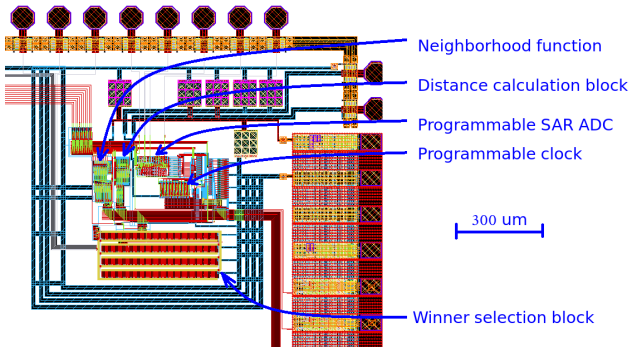

Fig. 3. A prototype ASIC designed by us for the application in the intelligent sensors, containing components of the ANN and a programmable SAR ADC, controlled by internal programmable clock generator.

and the calculation of the learning rate η for particular neighbors,

- adaptation of the winning neuron (in WTA only this neuron is adapted) and its neighbors (in WTM and NG). The adaptation is realized according to a formula:

$$W_j(k+1) = W_k(l) + \eta(k) \cdot G() \cdot [X(k) - W_j(k)] \quad (1)$$

In this formula W_k is the weights vector of a j^{th} neuron. The neurons that belong to the winner's neighborhood, are trained with the intensities determined by the applied neighborhood function $G()$ [8], [9].

The prototype chip, shown in Fig. 3, contains most of the components of the proposed intelligent sensor, including particular building blocks of the self-organizing neural network described earlier. Particular subcircuits of this chip are responsible for the computations performed at particular stages of the learning algorithm of the NN, as described above. The chip also contains an ultra-low power, programmable, 10-bits ADC. All these components were tested by means of laboratory measurements.

IV. Conclusion

The paper presents the concept of a system for the monitoring of air pollution in smart cities. The proposed concept is based on the usage of a dense network of miniature intelligent pollution sensors. The assumption is to build cheap sensors, self-sufficient in energy so that they can be easily deployed on city streets without having access to the power line.

The implementation of such sensors requires the development of particular building components. A special attention should be paid to the sizes of these blocks and their computing power while maintaining their functionality in the comparison with similar typical software solutions.

For this reason, we presented selected hardware solutions designed by us, with particular emphasis on miniature artificial neural networks capable of working in parallel.

In this work, we present intermediate results. The next step will be to assemble the designed blocks into a larger system. It is worth to add, that the proposed solutions can cooperate not only with the pollution sensors. Their usage is universal. A modular structure of the resulting device may be considered, in which the sensor would be an element selected depending on the needs, while the signal processing scheme would be similar.

***Abstract*—Using mobile phones for accessing the Internet has become a standard use case of such devices, nowadays even more important than the good old phone call. WiFi at home or public ones allow for a low-cost or even unpaid access to the virtual world of the Internet. But, as we will show, this is only true to some degree in terms of monetary cost. One thing we're paying a lot with is the loss of our privacy. In this paper, we will show how easily and cheap potential attackers can track your mobile phone and, thus, you via data it sends all the time, so-called probe requests. Additionally we show by experimental data how this tracking can be used for traffic jam analysis on roads.**

***Index Terms*—Raspberry Pi Real-Time Traffic Security Privacy**

I. Introduction

DURING the last years, the use of mobile devices like mobile phones and tablets for accessing the Internet has celebrated a breakthrough due to technological advances and social changes. Mobile access has overtaken stationary one from desktop computers and statically used laptop computers.

As a result of this development, end users can access the huge library of the Internet from many places all over the world including situations when traveling by car, by train or even by airplane. From one point of view, this is great news since data can be retrieved easily, and this new level of information can be used for the good. On the other hand, data transmitted via the Internet often turns out to be spam, noise or just jokes. But at least we get the potential to do more useful things with the almost ubiquitous mobile Internet.

A matter of particular interest for huge market penetration is the pricing of the goods and services. A cost-efficient semi-mobile Internet access is typically provided by the use of a WiFi connection according to IEEE 802.11 standard. Its typical range is some $100\,\mathrm{m}$ in the field and $20\,\mathrm{m}$ or $30\,\mathrm{m}$ in buildings depending upon the material of the walls. Several mobile devices can be associated to one and the same access point in parallel, and all of them can be freely moved. Hence, in order to guarantee a stable connection, there needs to be a key for identifying every device. The established key having been used for enabling a target-oriented delivery of packets is the *Media Access Control* or *MAC* address.

A serious problem with the technically well-motivated MAC address approach is the significant decrease of privacy for the end user carrying a mobile device. A static 1-to-1-link between a device and an identifier perfectly allows at least for tracking, and, by some reverse or social engineering finally to uncover the identity of the person who carries a particular device. Combining both mechanisms by data merging ultimately allows for tracking everyone all over the world, a scenario completely violating all privacy requirements. Note that such a kind of tracking is by far not only an academic issue, but can happen and happens on a grand scale [1].

A heavily promoted counter-action of mobile device sellers fighting this privacy issue was *MAC address randomization* as implemented by major companies, cf. [2], starting from 2014. Unfortunately, recent publications [3] [4] show clearly that attacking privacy has only become a little bit more difficult, but by far not impossible as initially claimed by mobile devices companies.

In this article, we will show by some experiments how such a tracking can be performed with a little bit of knowledge and some inexpensive equipment. Finally, we will present and discuss the results of our most advanced setup for performing a traffic jam analysis via a so-called *section control*[1].

Here, individual cars' average velocities are calculated via the measurement of their time passing a fixed-length (some kilometers) section of a road. Of course, exceeding the speed limit in terms of the average speed implies also an illegal speeding in terms of peak speed whatever the actual velocity profile looks like. On the other hand, on the majority part [5] of the German autobahn, there is no speed limit at all. While the first *section control* was installed in Austria more than 10 years ago, there are only plans to apply it in Germany as well. In 2011 in Poland, an experimental section control on a $16\,\mathrm{km}$ section close to the city of Gdańsk revealed 28 drivers driving at average velocities of more than $200\,\mathrm{km\,h^{-1}}$ while $140\,\mathrm{km\,h^{-1}}$ was the allowed top speed [6]. Conventional *section control* is based on automatic number plate recognition. We discuss here an alternative mobile-device-based approach.

The remainder of this paper is structured as follows: In section II we discuss projects and publications related to our findings. Next, we give a short overview of our experimental hard- and software in section III. In section IV we describe a series of experiments of increasing complexity we conducted. We discuss the setup and summarize the main results. The

[1]This is actually a pseudo-anglicism like *handy* for a mobile phone or *beamer* for a video/digital projector. The term used in UK is SPECS for *Speed Check Services*, see also http://www.jenoptik.co.uk/product/specs.

paper ends with a summary of our main findings and an outlook to open questions.

II. Related Work

Vehicular traffic monitoring is a very popular field of research [7][8]. Conventional sensor technologies use inductive loop, piezoelectric, magnetometer, pressure switch, video camera, microwave radar, ultrasonic, optical, and laser radar data [8]. None of them will be used in our experiments. Instead, our data will be MAC addresses extracted from probe requests.

The general topic of tracking mobile devices and finally end users via their MAC addresses passively via probe requests is a common topic in the literature.

Many authors are aware of the privacy issue of the approach. Demir [9] proposed a multiple hashing of MAC addresses. Fuxjäger *et al.* [10] show that brute-force attacks on just hashed MAC addresses are quite simple, and, thus suggest a truncated and hashed MAC address approach with a higher level of privacy. Finally, Martin *et al.* [4] recently showed that even the more advanced technique of MAC address randomization can be attacked with a $100\,\%$ success ratio.

Chilipirea *et al.* [3] performed experiments on WiFi tracking of pedestrians. They could improve the quality of the data sets by various data filters.

Fuxjäger *et al.* [10] report on traffic jam analysis experiments on Austrian roads, but they used a more expensive equipment with external antennae.

A comprehensive study of WiFi probe requests for tracking and monitoring was given by Freudiger [11]. He managed to recognize several phone and OS types via profiling. But—compared to us—he used as well a more expensive monitoring equipment.

III. Experimental Platform

As cheap and ubiquitous hardware platform we used the Raspberry Pi Version 3 which offers an integrated WiFi chipset (Broadcom bcm43438). As mass storage medium we utilized cheap microSD cards of 32 GiB size. To ensure a maximum of autonomous operability, the systems were powered by external power-banks with a capacity of 20.000 mAh, which appeared to be somewhat over-sized. Hardware cost for one system amount to 50$. We utilized off-the-shelf Raspbian[2] Linux Version 8 as operating system base which provides a tailored Linux kernel version 4.4.50-v7+. Both systems were configured and used in headless mode.

The Raspbian standard firmware for the WiFi chip is not able to switch to monitor mode, therefore we installed the alternative firmware `nexmon`[3], version 7_45_41_26. The received data frames were captured using `dumpcap`, version 1.12.1, which is part of the well-known `wireshark` tool suite. By means of a capture filter, only probe requests were logged to persistent memory.

[2]http://www.raspbian.org

[3]https://github.com/seemoo-lab/nexmon

The resulting dumps were transferred to an external computer and converted to text records using `tcpdump`. Afterwards, we eliminated all irrelevant information except sender MAC addresses and accompanying timestamps within the measurement interval with the help of standard UNIX tools.

IV. Experiments

A. Receiving Probe Requests while Driving on the Autobahn

As a first attempt, we wanted to find out whether the Raspberry Pi is able to capture probe requests when moving fast. We placed the board under the windshield just like a dashcam and captured while driving.

On 04/11/2017, we entered the German autobahn A17 at access no. 3 "Dresden-Südvorstadt" at 15:45, headed for Dresden, changed to the A4 heading to Erfurt and left it at 16:33 at A4 exit no. 66 "Wüstenbrand". The distance was $83\,\mathrm{km}$ the average speed amounted to $104\,\mathrm{km\,h^{-1}}$.

During these 48 minutes, we captured 3379 MAC addresses, 609 of them were unique. It seemed that we were able to receive probe requests not only from cars driving in the same but also in the opposite direction, especially when both were using the leftmost lane.

This and the result of the next experiment were encouraging and proved that the board is very well capable of capturing a large number of probe requests while moving.

B. Receiving Probe Requests on a Train

In this experiment, we took the regional train *RE 26984* departing from *Dresden Hbf* to *Plauen(Vogtl) ob Bf* on 3rd May 2017. Only the section *Dresden Hbf* to *Chemnitz Hbf* corresponding to a scheduled travel from 15:52 to 16:54 was part of this experiment. Due to the recording of approximately one hour, we hoped for many probe requests with a lot of various MAC addresses.

We recorded as many as 6752 probe requests, i.e., on the average almost 2 per second. Among them, there could be 219 different sender MAC addresses of broadcast probe requests extracted. This number gives us a raw estimation of the order of magnitude of the number of travelers in this part of the train.

C. Receiving Probe Requests at the Road

Description: To receive probe requests from passing vehicles on a multi-lane highway, two principal positions could be used: a) on a bridge above the middle lane of one travel direction or b) by the right side of the road. Position a) seems favorable due to its elevation (and probably better receiving conditions) but requires constructions which cross the highway such as bridges. Position b) seems better suited in terms of cost and convenience (the system could easily be attached to some post or crash barriers).

In contrast to the scenario described in section IV-A we statically positioned the receiver a) on a bridge three meters above the middle lane (it is the same as measurement point B in section IV-D) and b) ten meters to the right of the rightmost

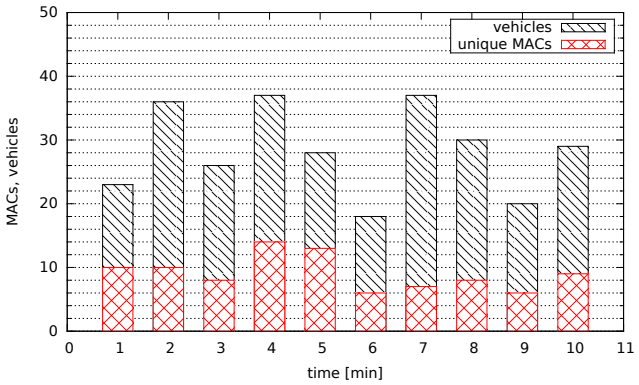

Fig. 1. Capturing on a bridge

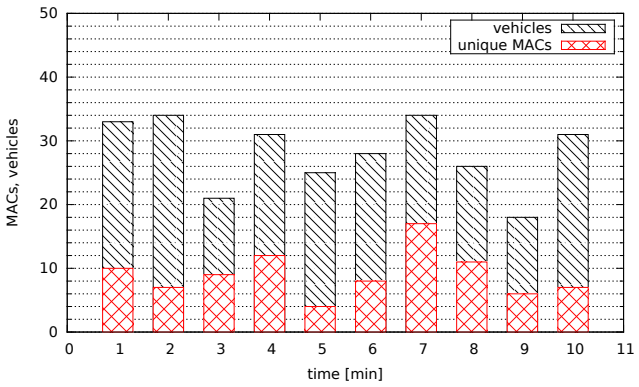

Fig. 2. Capturing at the side of the road

lane of the German autobahn A4[4] at a height of $1.50\,\mathrm{m}$ above ground (the GPS position was N 50.821650°, E 012.761600°). Due to restriction fences we were not able to get any closer to the lane.

Results: During the 10 minute capture interval, a total of 284 vehicles passed the position on the bridge and 281 vehicles were observed at the side of the road. During that interval, we were able to capture 91 unique MAC addresses resulting from probe requests at both positions which is almost a third. Figures 1 and 2 compare the number of cars and received unique MAC addresses on a minute-per-minute basis for both positions.

The ratio between passing cars and unique MAC addresses varies from $16\,\%$ to $50\,\%$ (both extrema were observed at the side of the road) with an average of $32\,\%$. Variance seems also a bit higher when capturing for the position at the side of the road but the short measurement interval prohibits deeper analysis.

Of course, there is no 1:1 relation between vehicles and MAC addresses for several reasons. First, some drivers may have switched off the WiFi functionality or could even have no smartphone at all. Second, other vehicles could carry more than one smart device, especially all kind of buses. Receiving more than one MAC from the same vehicle is redundant when trying to estimate vehicle speed (cf. section IV-D), but increases the chance of receiving two probe requests at different locations. Third, received MAC addresses from outside the context (passing bicyclists, vehicles from the opposite lane) could deteriorate our perceived numbers.

Nevertheless we can conclude, that a reasonable fraction of the passing vehicles sends probe requests such that our receiver hardware is able to capture them. Further, both logging positions seemed equally suitable.

D. Estimating Vehicle Speed

Description: In the final experiment, we tried to measure (or at least estimate) the average velocity of vehicles cruising in one direction for a certain section of the German autobahn. To this aim, we positioned two Raspberry Pis at a height of 3 to 4 meters above the middle lane of the A4 in direction of traffic Erfurt on two crossing bridges (The GPS coordinates are N 50.833591°, E 012.792370° for Point A, and N 50.819305°, E 012.745936° for Point B, respectively). Between A and B, the track runs almost straight. Figure 3 depicts the relevant topographical aspects. The distance between both points amounts to $5.03\,\mathrm{km}$ according to *openrouteservice.org*.

One motorway access is located between A and B therefore the numbers of passing vehicles may not be identical for both positions. During the time of our experiments, no explicit speed limit was mandated, visibility was very good.

Beforehand, the system clocks were synchronized manually with a Δ of ca. one second. Both systems logged all received probe requests for a fixed time interval of 15 minutes starting at 17:12 on 09/05/2017, a normal workday. Additionally, we manually recorded the number of passing vehicles per minute.

Because most MAC addresses were broadcast in short bursts we eliminated all but the first occurrence of a new unique MAC address. Then we searched for MAC addresses occurring in both log files (at different times) representing one and the same vehicle passing sequentially both measurement positions. We then determined the temporal difference t of the respective time stamps rounded to full seconds. Using the equation $v = s/t$ and the driving distance $s = 5.03\,\mathrm{km}$ between both points A and B, we finally computed the average speed of the vehicles.

Results: During the measurement interval of 15 minutes, a total of 453 vehicles passed point A. During that time, we observed a total of 115 unique MAC addresses. That 25 percent fraction seems to be somewhat optimistic, because a certain number of probe requests might also result from the opposite driving direction (see below). Figure 4 illustrates the number of passing cars and the number of received unique MAC addresses on a minute-per-minute basis. Nevertheless, we consider the number of unique MAC addresses surprisingly high given the cheap hardware platform and the high velocity of the passing vehicles which results in a visibility interval of a few seconds at the most.

[4]It is part of the longest European route, E40 from France to Kazakhstan. The majority of the A4 in Germany is a 3-lane-per-direction highway, including the part considered here.

Fig. 3. Measurement points for the estimation of vehicle speed

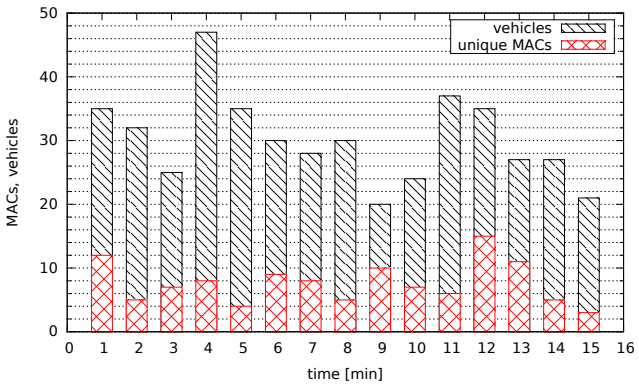

Fig. 4. Numbers of vehicles and unique MAC addresses per minute

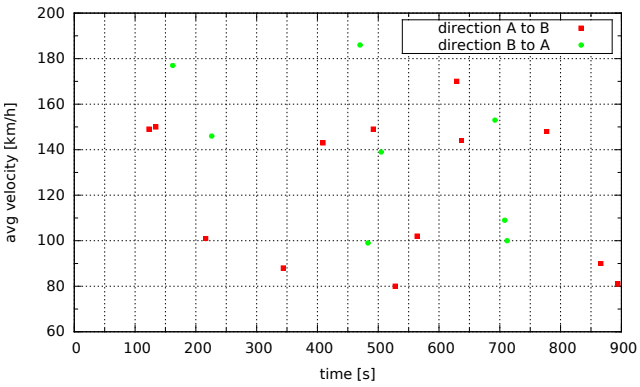

Fig. 5. Vehicle velocities measured over an interval of 15 minutes

Out of 115 unique MAC addresses recorded at point A and 128 unique MAC addresses recorded at B, we obtained 21 MAC addresses occurring at *both* positions. The slightly higher number of addresses at point B could result from a $1\,\mathrm{m}$ to $1.5\,\mathrm{m}$ lower position relative to the road surface. Figure 5 illustrates the individual velocities during our 15 minutes measurement interval.

Two of the address pairs had exactly the same time difference (121 seconds). Obviously, we monitored two different smart devices residing in the same car and sending their probe requests at the same instant. Further, it is interesting to note that we monitored 8 out of the 21 address pairs stemming from vehicles driving in the opposite direction. Third, a clear distinction between slow-driving trucks ($v < 120\,\mathrm{km\,h^{-1}}$) and faster passenger cars ($v > 140\,\mathrm{km\,h^{-1}}$) can be made. This reflects our empirical perception of the traffic situation and very good driving conditions. All obtained velocity values are plausible.

We can conclude that our setup allows to reliably estimate average velocity of vehicles for a given section on the autobahn and one driving direction. Further, it seems effortlessly possible to cover both driving directions by placing the Raspberries above the middle of the highway.

V. Conclusion and Outlook

Our considerations and experiments have shown that a tracking of mobile devices based on MAC addresses is feasible even with low-end equipment like a *Raspberry Pi Version 3* without any external antennae. Recently added features of modern smartphones like MAC address randomization render a tracking of such devices more difficult. But there is still a high market share of older mobile phones and such ones where the feature is not (yet?) implemented due to compatibility issues, cf. [4].

Use cases of such a tracking could be traffic jam analysis on a road. Here, we don't need to track many cars, some representative data is perfectly sufficient. Such real-time data can be used immediately for congestion alerts in navigation systems or in the good old FM radio.

Second, a preliminary assessment of road sections in terms of the percentage of speeding cases and their respective severity can be done. Our setting is very inexpensive and works anonymously. The recorded MAC addresses serve only as a matcher between two measurement points and can even be deleted directly after raw data processing. Our configuration is much cheaper than a conventional section control system and, thus, can be used more extensively for finding out where to place speed control points or sections.

Our results raise some interesting questions. First of all, we want to provide bounds for the accuracy of our velocity values. To that aim, two influence factors must be studied: one has to know the receiving range of the built-in antenna of the Raspberry Pi which depends on the position of the system itself and the period and sending pattern of probe requests has to be known which depends, among other, from the particular device type, its operating system version and operating mode.

We think that our approach is robust against heterogeneous and lane-less vehicular traffic being typical for countries like India due to lacking lane discipline or lacking lane infrastructure [8]. But this hypothesis needs to be verified by some additional experiments.

Further, because for our use case the Raspberry Pi has quite some unnecessary peripheral components, it seems promising to try even cheaper platforms, such as the Raspberry Pi Zero or the Espressif ESP8266 and ESP32. To drastically increase the duration of our measurements or even let the platform work autonomously, some means for solar powering the Pi should be investigated.

Finally, cost of an individual system approaching five dollars or even less would permit to equip a longer section of the highway with systems who are able to connect to each other via WiFi and propagate traffic data accordingly. Such a *smart highway* will probably lead to new interesting use cases.

Rapid Embedded Systems Prototyping – an effective approach to embedded systems development

Robert Brzoza-Woch, Łukasz Gurdek, Tomasz Szydło
AGH University of Science and Technology
Al. Mickiewicza 30, 30-059 Krakow, Poland
Email: robert.brzoza@agh.edu.pl

***Abstract*—In this paper we introduce the Rapid Embedded Systems Prototyping (RESP) approach aimed at accelerating the development of novel, experimental, and proof-of-concept implementations of embedded devices based on microcontrollers and Field Programmable Gate Array (FPGA) chips. It is intended to be used in the fast-paced business environment in which an early working prototype is required. The RESP approach can be useful for remote developing and temporary monitoring of various embedded devices: primarily for resource-constrained IoT platforms, microcontroller-based sensor nodes, and customized ad hoc systems. The RESP-compliant system uses a central server and one or multiple Remote Reconfiguration and Monitoring (RRM) modules. Each RRM allows the software developers to manage reprogramming and monitoring of multiple target embedded devices. It can be applied to a device that needs to be remotely reconfigured, tested, or reprogrammed in its target environment without implementing a reliable bootloader. The RRM described in this paper has been successfully implemented and its functionality and performance have been tested.**

I. Introduction

IN COURSE of research projects and at an early stage of embedded systems development cycle there is often a need to quickly develop a working prototype of an embedded device which will operate in its target environment as an IoT node or as an innovative solution for control, acquisition or monitoring purposes. In the start-up business environment, a client or an investor may wish to see a demonstration of a working proof-of-concept prototype of an application-specific embedded system. In a traditional approach, an embedded device is handed to a customer after the device's software is developed to a point in which it has full functionality and, usually, its bootloader program is working to update the device's program memory or its configuration. Developing a fully functional embedded device with a reliable operating bootloader may be a tedious and time-consuming task.

When utilizing an adaptive and evolutionary approach to software development, the functionality of the final product may not be precisely specified at an early development stage. It can be beneficial to start developing the application-specific embedded hardware and software for demonstration purposes and then to continue the product development when initial results are evaluated in practice and client's expectations are more specific. In this article we discuss various aspects of this strategy which we call the Rapid Embedded Systems Prototyping (RESP). The approach is based on fast prototyping iterations with an ability to remotely reconfigure or reprogram a hardware platform using the Remote Reconfiguration and Monitoring (RRM) module intended to support the RESP development. The idea of RESP is to deliver a working prototype of an embedded device as fast as possible to a client and demonstrate its functionality. Then, the product is evaluated in its target environment by the client or the investor. The product's operation can be monitored and its software functionality may be easily tested or changed using the remote reconfiguration and monitoring capabilities. Thus, following the RESP approach can lead to more competitive time of proof-of-concept prototype development which, in turn, may result in gaining swifter funding for a project and better time-to-market.

In the domain of extremely resource-constrained, cost-sensitive, and tentative ad hoc devices with short-term support, the RESP combined with RRM can also be useful during the development in a target environment instead of a bootloader. We hypothesize that in those classes of embedded devices the bootloader itself could even be omitted and the development can be done using the RESP approach with RRM.

The described RRM subsystem is primarily intended to be utilized for embedded software development purposes when the device under development is placed in its target environment, but a reliable remote program memory upload or reconfiguration with a bootloader is not available or is not yet developed. After the successful software development with RESP approach, the RRM module can be extracted from the target platform and the device may work as a stand-alone unit. Alternatively, depending on a specific use case, the RRM can be utilized for the embedded system long-term testing by monitoring its operation with a set of sensors and digital interfaces. Then the RRM will operate as a remote sensing node.

The concepts described in this paper can be applied to multiple classes of embedded systems including microcontroller-based IoT platforms. The RESP approach is applicable for embedded platforms (a) based on microcontroller units (MCUs) in which program memory can be reprogrammed using common in-system programmers or debugging interfaces or (b) platforms based on Field Programmable Gate Arrays (FPGAs). When using FPGA hardware platforms, the presented RRM

The research presented in this paper was partially supported by the National Centre for Research and Development (NCBiR) under Grant No. LIDER/15/0144/L-7/15/NCBR/2016.

device can be used for convenient remote development of both programmable hardware and embedded software. Also, if the RESP augmented with RRM is utilized for programming or reconfiguration of a remote device under development, the Internet connection will be required. Alternatively, the system can be utilized in a local network and in that case the Internet connection is not necessary.

The physical hardware development is not in the scope of this paper as present-today ad hoc prototypes can be based on ready-to-use computing platforms such as well-known Arduino boards family or inexpensive evaluation boards offered by many semiconductor manufacturers, for example STM32 Discovery or Nucleo series from ST Microelectronics or Freedom FRDM from NXP. Those boards can be enhanced with a wide selection of sensor or actuator modules equipped with common integrated extension circuits available at low cost. In the case of the FPGA-based platforms, we assume the use of an already developed physical hardware. The RRM can then be utilized not only to modify the embedded software but also the programmable part of the hardware project.

The rest of this paper is organized as follows. In Section II we summarize recent related research in the area of effective approaches to embedded systems development and remote reconfiguration. In Section III we present the RESP method of developing embedded device prototypes in time-critical manner and in fast-paced business competition environment. Section IV provides a general idea on how to implement a RESP-compliant system. Section V describes the construction methodology and a sample implementation of the RESP with RRM device. Finally, in Section VI we summarize our work.

II. Related research

The embedded hardware platforms are characterized by their diversity when compared to the general-purpose computing platforms. Some of the differences between embedded software and computer application development are the results of the fact that the embedded software must tightly cooperate with usually non-standard, specialized hardware platform and a set of peripheral devices. An embedded software developer needs an access to either a good simulation environment or to the real hardware platform. At the very early development stages, the product requirements are not yet fully specified and they may change multiple times. Engineers can then utilize a general-purpose solution from a wide portfolio of ready-to-use sensing, data acquisition, and actuation devices controlled with e.g. National Instruments hardware and software solutions. However, a prototype can be more enticing for the investor if it could be backed up with a demonstration of a custom working hardware and software even at an initial development stage.

In commercial and industrial MCU firmware development practice, the bootloader is one of the most specialized software parts. There are multiple MCU platforms that provide a dedicated bootloader without any additional installation, but that solution usually relies on a predefined interface and protocol. Changing the default settings requires either to re-implement the bootloader or to modify it. The Nordic Semiconductor's nRF52832 is a good example of integrated circuits (ICs) which provide a very well developed Bluetooth Low Energy (BLE) bootloader. However, not all ICs can utilize BLE to update firmware and not all manufacturers provide such a convenient firmware update functionality. Usually, a bootloader is a very application-specific part of embedded software and it needs to be either developed solely for a given platform and interface or ported from another project. Embedded systems based on an application microprocessor (with Memory Management Unit and running e.g. Linux) often use U-Boot as a first stages' bootloader. For the MCU-based embedded devices it is difficult to point out a most common bootloader solution – different platforms offer different solutions, such as the STM32 Bootloader [1]. An example of a custom bootloader is described in [2]. The bootloader program must be well designed and tested to avoid firmware corruption eventually resulting in an inability to reprogram the device with the provided bootloader. Another common problem in writing a bootloader is to make it insensitive to transmission errors and complete transmission interruption. Preventing those situations require much time, engineering effort, and some design redundancy (additional memory, correcting errors in software, etc.). All the problems mentioned here can be solved, but it usually costs additional development time.

The ability to remotely reprogram, reconfigure, and supervise an embedded system is especially useful in the domain of programmable logic, mainly FPGA. We should also be aware that the software and hardware development flows may proceed in parallel, depending on a design (e.g. in [3]). The reconfiguration allows developers and maintenance staff not only to remotely update firmware, but also to change the functionality of the system [4]. For example the FPGA-accelerated smart camera described in [5] is able to run multiple configurations which can be substituted depending on a higher level adaptation policy. Enhancing an FPGA-based device with the remote reconfiguration feature costs design issues due to losing the programmable logic functionality during the reconfiguration process [6]. In that case the partial reconfiguration feature [7], [8] could be helpful, but it tends to complicate the hardware-software design flow hence it may be ineffective for time-critical project. Less sophisticated, but much more convenient methods include using remote programmers, such as the Intel FPGA Ethernet Cable (formerly the Altera EthernetBlaster II) as described for example in [9]. Those devices offer only limited computing capabilities at the target side. In our solution we greatly increased the computing power of the remote programmer by utilizing a single-board computer (SBC). It allowed us not only to easily implement modern communication protocols, but also to gain much more flexibility compared to other solutions.

The idea of remote programming can be extended to the remote firmware management. It is also a well-known topic, and some aspects of networked systems performing such tasks are patented e.g. in [10], [11]. Currently the remote reconfiguration and management are, however, typically per-

formed by using similar architecture and by utilizing e.g. OMA Lightweight M2M (LWM2M) protocol. The LWM2M is an increasingly popular remote management protocol for intelligent connected and IoT devices [12], [13]. It has low transmission overhead and its implementation can be relatively easily ported to many connected platforms. LWM2M also supports a framework for a remote firmware update which was especially desirable in the solution described in this paper.

Despite the fact that the embedded and general computing hardware platforms are different, embedded software development can be based on similar principles as the computer software development. For example, agile development model has been adapted to embedded systems [14], [15]. Other approaches to embedded systems development, such as the *V-Model* descibed in e.g. [16], can also be applied to fast development of embedded software.

As presented in this section, there are multiple systems, methods and approaches to fast development of embedded software. There are also multiple solutions for remote reconfiguration, programming, and management of embedded systems. Those methods can be applied to ad-hoc embedded systems firmware and software development process. Based on the presented state of the art we propose the following solutions. First, we suggest, that the remote programmers and firmware management systems can be improved. To prove that statement we propose the practical implementation of the RRM described further in this paper. Moreover, the RRM can be utilized to implement the RESP approach. We state and prove that utilizing the proposed RESP approach can reduce time-to-market and allow developers to deliver a working prototype of the resource-constrained embedded system faster compared to traditional approaches.

III. Proposed development method

To explain and justify the proposed RESP development method, we introduce a simplified model of the experimental embedded system software development. The model reflects practical experiences while cooperating on an innovative IoT solution with actual business representatives. We assume that the model is applicable when the MCU-based embedded hardware platform is developed and it is ready for initial firmware implementation.

The simplified development flow is following. We assume that the development time can be represented by a number of *iterations*. In this case the *iteration* can be perceived e.g. as a *time interval* or as a *programming task*. In our considerations each iteration represents an amount of work required for one developer or for a team to complete a given task. Many developers can work on the project concurrently, but in the simplified model we just count the total number of iterations as if the project was developed in a fully sequential manner. A goal is specified for each iteration. Reaching Alpha development stage requires at least two iterations: the initial development stage and the actual Alpha development-testing stage.

In this model the device is ready to be shipped to the potential customer or an investor for further review if the following two conditions are met: 1) the application has at least minimum experimental functionality with basic Alpha stage tests done, and 2) the device firmware can be reliably and remotely updated or changed to allow developers and the client to collaborate on the final firmware version and further features. The consequence of the latter prerequisite is that the bootloader should be developed up to the final release version unless the RESP approach is used. In this model the embedded device is passed to the potential customer or investor after its development reaches the Alpha stage. Then the customer initially evaluates the product. If the customer accepts the initial results, the developers shall continue to work on the product's software (*success*). Otherwise the development of the product in the current form shall be ceased (*failure*). That situation can happen e.g. when the product is unable to meet the requirements or it needs a major redesign. In the *failure* case, most of the recent developing effort is wasted because the project or the idea has been rejected by the investor or the client.

Figure 1 shows a graphical representation of a sample embedded system development time line using the presented model. The goals of each iteration are denoted inside a box representing that iteration. Two cases are analyzed.

The first case, which is shown in Figure 1 (a), represents a scenario with a classic approach applied. In order to reach the product development stage at which the prototype can be passed to the client, the developers require six iterations: four iterations for the bootloader development and two for the initial application development. In case of success, only the application needs to be further developed, but in case of

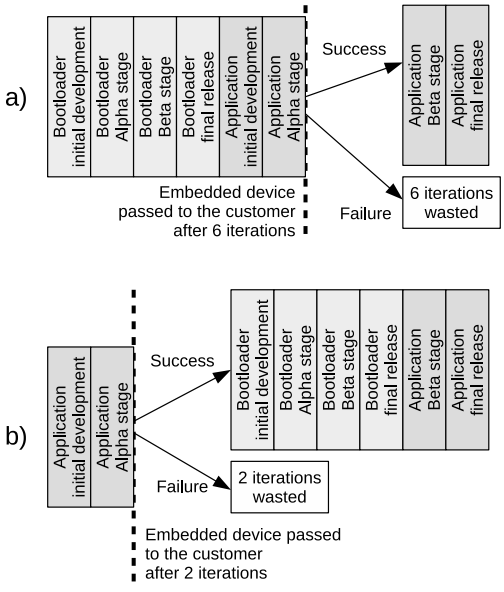

Fig. 1. Sample development time lines for the described model and: typical approach (a), utilizing RESP approach with RRM module (b).

failure, the six iterations are wasted.

In the second scenario shown in Figure 1 (b), the developers utilize the RESP approach with the dedicated RRM module. The device can be shipped to the client even at an early development stage, after just two iterations and the bootloader development can be postponed for later stages. In case of the project failure, only two iterations are wasted.

IV. Implementation concept and overview

In this section we present a general ideas which concern realization of RESP approach with the RRM module.

To implement the RESP development approach the developers should utilize the *RESP-compliant system*. The RESP-compliant system consists of a management unit and the RRM hardware with a dedicated software. One RRM can be connected to one or multiple instances of the device under development. The number of devices under development connected to one RRM depends on hardware interface capabilities of the utilized RRM embedded computer. Moreover, it is possible to manage multiple RRMs using a single server with a remote application. Those features allow software developers to manage hundreds of devices with a single server. The sample set-up of a multi-node reconfiguration-debugging system using RRMs is presented in Figure 2.

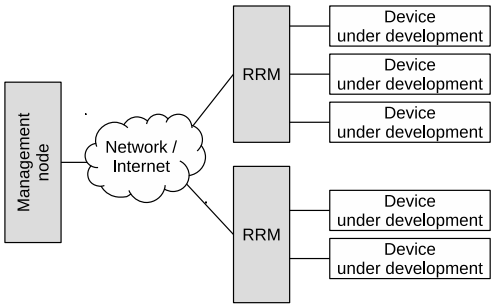

Fig. 2. Sample RESP-compliant hardware architecture with multiple RRMs capable of managing several devices under development.

After the embedded software development is complete, the RRM can either be disconnected from the device under development, or it can be left connected to monitor the operation of the embedded system by utilizing e.g. external sensors, such as temperature, voltage or current.

To provide flexibility and advanced functionality, the implementation of RRM is based on an SBC. The use of SBC allows developers to implement much more advanced features compared to typical programmers with network interface.

The choice of generic hardware platforms combined with free and open source software solutions is one of the key concepts in the implementation of RESP-compliant system. The configuration needs to be performed with the use of scripting languages. Combining those features allows the RESP-compliant system to be very flexible and easily adapted to new target hardware platforms and specialized use cases. The SBC-based RRM can potentially log, filter, and transmit the debug messages printed on e.g. a serial port of the device under development. The messages then can be transmitted over Internet to developers and testers in a remote location. The functionality of RRM can be extended even further. As an example, the RRM after extending its software may allow developers to obtain even a live view of the system under development. That feature obviously cannot be utilized to reliably monitor the operation of a safety-critical equipment, however it can be utilized to determine overall environment conditions for which sensors were not included in the initial design or to detect some obvious reasons of malfunction. For example the camera can facilitate determining if the light intensity in general is low or high, if the device has been covered, or if it has been moved.

V. Practical implementation of the RESP-compliant system

This section contains technical description of the sample RESP-compliant reconfiguration and monitoring architecture developed according to the information in previous sections of this paper.

A. RRM hardware design

Currently there are many different SBCs available at very low cost. In our sample implementation we have chosen Raspberry Pi Zero to implement the RRM. The Raspberry Pi Zero has multiple advantages as a choice for RRM. That computer is characterized by its very low cost and compact size. Another advantage of it is a General-Purpose Input-Output (GPIO) interface presence and its 3.3 V logic levels compatibility, which makes it well suited to implement versatile digital interfaces, including programming interfaces.

The network interface is provided with a generic Wi-Fi dongle with Universal Serial Bus (USB) interface. Depending on the SBC used, the network interface could also be implemented using a built-in peripheral as in e.g. full-sized Raspberry Pi computers.

Devices under development are connected to RRMs directly using Joint Test Action Group (JTAG) or Serial Wire Debug (SWD) interface for programming and reconfiguration purposes. Those interfaces are implemented using GPIO hardware of the SBC. Devices equipped with a built-in programmer with USB interface, can connect to the SBC with that interface. In the proof-of-concept implementation no additional protection circuits were added, but they should be considered in the RRM hardware.

Another important aspect of the RRM implementation is the possibility to measure various physical quantities: the operation parameters of the device under development (e.g. input-output voltages, temperature, logic states, power supply current) and the general parameters of the environment (e.g. temperature, humidity). We have chosen Inter-Integrated Circuit (I^2C) as a typical interface for RRM external sensors because it is supported in hardware and software of many SBC platforms or it can be relatively easily implemented using GPIO. There is also a wide selection of compatible sensors

with I^{2}C interface and, what is very convenient, multiple sensors can be connected to a single bus.

As a sensor for the first implementation of the RRM we have chosen a current sensor intended to monitor a power supply current of the target device under development. The reason was to provide a sensor which is commonly needed during the process of developing embedded software. In our practice, the power management of an embedded system is one of the vital parameters that needs to be monitored and we often need embedded systems to be optimized for energy efficiency. The choice of INA219 current sensor appeared to be reasonable because it is equipped with digital I^{2}C interface and it is able to measure current at the power supply rail (high-side).

B. RESP-compliant system logic and software architecture

The internal structure of RRM and its sample connections to multiple devices under development are shown in Figure 3.

We intended to chose a free, open source, and highly configurable solution for interfacing management software with hardware reconfiguration-programming interfaces of target devices under development. An actively developed project that seems a very good choice for that purpose is OpenOCD. It is a powerful and flexible debugging and memory programming tool which can be configured with TCL scripts and which provides multiple convenient control interfaces.

As the management interface needs to easily cooperate with standard software solutions, we decided to utilize the more and more popular OMA LWM2M protocol. The management node is implemented as a server for the OMA LWM2M protocol. Eclipse Leshan LWM2M server demo was chosen for the project implementation purposes. It provides basic unified network interface and Representational State Transfer (REST) application programming interface (API). Custom LWM2M object definitions have been added to the server in order to properly recognize custom resources which are specific to the project. The LWM2M API utilizes Firmware Update object from the specification and three custom LWM2M objects: OpenOCD LWM2M RPC, Firmware Target Selector and INA219 current sensors interface.

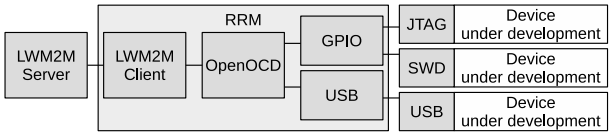

Fig. 3. General block diagram of the RRM and an example of connecting devices under development.

The internal software architecture of the RRM is shown in Figure 4. The software operates as multiple separate LWM2M client instances, one for each device connected to the RRM hardware. The LWM2M allows software developers to reprogram the target device and fetch sensors readings. It holds an OpenOCD instance for each device.

The software is written in Java with Eclipse Leshan libraries. For every device instance it creates a separate LWM2M client instance and runs OpenOCD. In our implementation the OpenOCD uses remote procedure call (RPC) interface for clients to issue TCL commands and obtain results from TCL engine. The commands are generated according to information derived from configuration files passed as arguments. The configuration files are described in detail further in this paper (please refer to Section V-C).

When using Eclipse Leshan the binary image for the reconfiguration purposes of the device under development can be transferred from the management server. Alternatively, the reconfiguration can be initiated from the server along with providing an Unified Resource Identifier (URI) to a location in which the binary image is available. We have implemented the latter option, because in practice it proved to be more flexible and convenient for the developer who manages the process of reconfiguration or reprogramming. In current implementation, two protocols are supported for transferring firmware images: Hypertext Transfer Protocol (HTTP) and HTTP Secure (HTTPS).

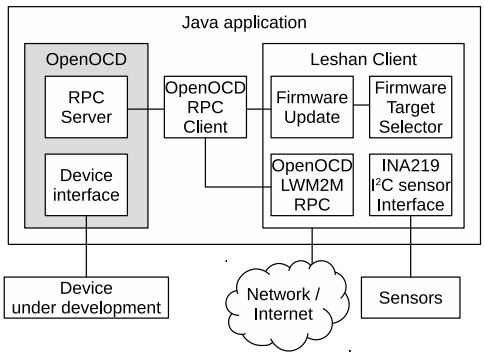

Fig. 4. Software architecture (gray block means external process managed by parent process).

C. Configuration

The configuration method was devised especially for RRMs. YAML was chosen as a file format for its simplicity and readability. SnakeYAML library was chosen to load YAML files into configuration objects. It also provides runtime validation of configuration syntax.

There are two types of configuration: the first for each device class and the second for device instances connected to RRM. Device class configuration is stored in files separate for each device class (such as STMF4DISCOVERY, ZYBO). It contains OpenOCD initialization and flash commands. Instance configuration specifies communication interface and sensors for each of the actual devices connected to RRM (such as stm-prod, zybo1).

Listing 1. Sample instances configuration file for two identical devices connected to the RRM hardware.

```
instances:
- name: stm-by-gpio
  deviceConfigPath: stmf4discovery/config.yml
  interface:
    bcm2835gpio:
```

```
      swdNum1: 25
      swdNum2: 24
      trstNum: 7
      srstNum: 18
      transport: swd
- name: stm-with-current-sensors
  deviceConfigPath: stmf4discovery/config.yml
  interface:
    custom:
      initCommands:
       - source [find interface/stlink-v2.cfg]
       - transport select hla_swd
  sensors:
    - ina219:
        i2cAddr: 0x40
        i2cBus: 1
        shuntResistance: 0.1
```

A sample configuration is shown in Listing 1. It is a configuration file for two identical device instances connected to the RRM hardware. The first instance is connected by JTAG directly to the GPIO ports of the SBC, whilst the second instance is using board built-in USB debugger and also has current sensor attached. It was prepared for BCM2835 chip present in Raspberry Pi boards. It eliminates the necessity of writing OpenOCD commands, yet allowing to specify custom GPIO port numbers and transport.

An example of the device configuration file is shown in Listing 2. It allows system developers to define device class specific OpenOCD initialization commands as well as commands that are executed as a result of executing Update resource on Firmware Update object.

Listing 2. Device configuration file

```
initCommands:
 - source [find target/stm32f4x.cfg]
 - reset_config srst_only
firmwareTargets:
 - name: mcu
   flashCommands:
    - reset init
    - flash write_image {{ image }}
    - reset
```

D. Implemented sensor support

In the sample implementation, the RRM software supports multiple sensors connected using I^2C bus supported by the physical interface of the utilized SBC. In the presented software implementation, each RRM instance supports zero, one or many INA219 current sensors as a sample implementation of that functionality. The RRM software fetches data from sensors using Pi4J library and provides on-demand access with multi-instance INA219 sensors LWM2M object (*urn:oma:lwm2m:ext:3403*). For convenience, current, voltage, and power values are provided.

E. Reconfiguration flow

Reconfiguration flow is presented as a sequence diagram in Figure 5. The reconfiguration process consists of two dependent stages. In the first stage, the developer provides a URI for a new binary image to be uploaded to the target embedded system using Eclipse Leshan and LWM2M protocol. In the second stage, the execution of the reconfiguration itself takes place – the RRM performs the reconfiguration with an instance of OpenOCD.

F. Basic security considerations

The RRM is primarily intended to be applied only temporarily during the embedded system's development stage, but the security is still an important issue. The basic transport-level security using Datagram Transport Layer Security (DTLS) is supported by default for LWM2M. RRM software supports HTTPS to enable secure path of fetching images. User might want to add another layer of security such as an encrypted virtual private network (VPN) or Secure Shell (SSH) tunnel.

G. Achieved prototype functionality and practical verification

We have successfully developed a working prototype of RRM device according to the ideas described in previous sections. The presented example of the RESP-compliant system provides LWM2M-based remote firmware upgrade API for a wide variety of embedded systems. Thanks to the fact that we have chosen OpenOCD as the software for reconfiguration control, the RRM supports virtually any target platform that can be reconfigured or reprogrammed with OpenOCD – the main requirement is that the system administrator provides adequate configuration scripts. We have designed and implemented a specialized configuration scheme using YAML scripts. The utilization of free and open source software and common versatile off-the-shelf hardware allows developers to easily modify, extend, and tailor the functionality of the RRM for a particular use case. The implemented and presented sensor extension for measuring a target's power consumption may be extremely useful in remote debugging and development of energy constrained embedded systems.

We have measured reconfiguration times achieved with RRM and the module's average power consumption. The reconfiguration time results are summarized in Table I and visualized in Figure 6. Each reconfiguration time is an average computed from 10 sample transmissions. The results were obtained during reprogramming or reconfiguring MCU and FPGA on development boards. The reprogrammed MCU was STM32F407VGT6 and the programming interface was SWD implemented with GPIO of Raspberry Pi Zero. The reconfigured FPGA was Xilinx Zynq-7000 on Digilent Zybo ARM/FPGA SoC Trainer Board with the JTAG programming interface connected to SBC using USB interface. The SBC was connected to a local network using a generic Wi-Fi card with USB interface. We have measured power consumption of the RRM hardware. It averages to 1.3 W when idle (Wi-Fi connectivity enabled, LWM2M server is during registration) and to 1.4 W when performing firmware update. To set-up a Wide-Area Network (WAN) we used a virtual machine (VM) located in New York which was hosting LWM2M server and binary images. The LWM2M client was located in Krakow, Poland. The measured WAN Round Trip delay Time (RTT) was 120 ms at maximum transfer rate of 12 Mb/s. The

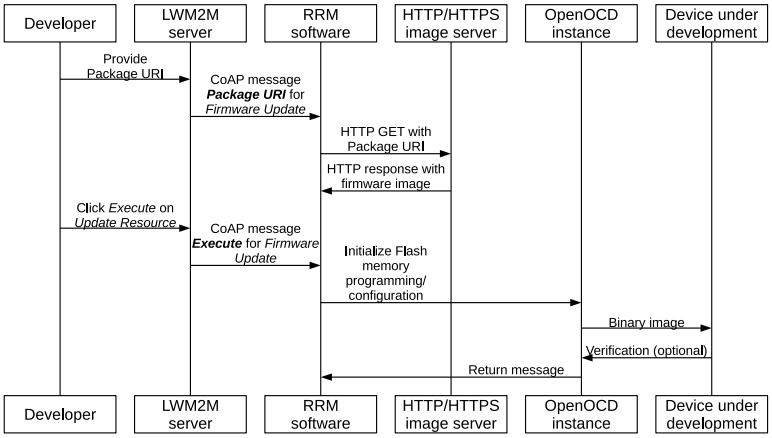

Fig. 5. Reconfiguration flow

TABLE I
RESULTS OF PRACTICAL EXPERIMENTS

Target type	Firmware/ configuration file size (KiB)	Network for LWM2M	Image server protocol	DTLS for LWM2M	Total reconfiguration time (s)	Binary upload time (s)
MCU	21.8	LAN	HTTP	disabled	1.9	1.3
MCU	21.8	WAN	HTTPS	enabled	3.3	1.3
MCU	295.3	LAN	HTTP	disabled	10.5	9.1
MCU	295.3	WAN	HTTPS	enabled	12.1	9.1
MCU	978.9	LAN	HTTP	disabled	26.0	23.9
MCU	978.9	WAN	HTTPS	enabled	28.3	23.9
FPGA	4185	LAN	HTTP	disabled	12.2	9.1
FPGA	4185	WAN	HTTPS	enabled	14.7	9.1

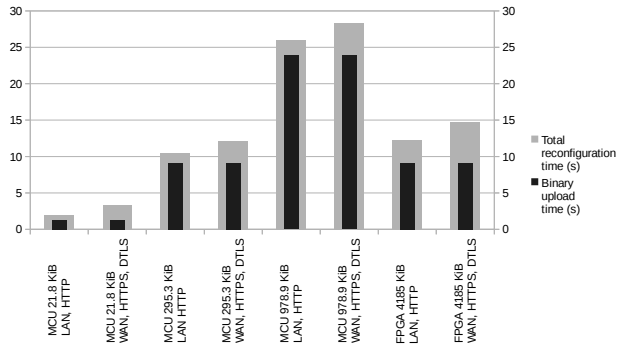

Fig. 6. Remote reconfiguration and programming times comparison.

reconfiguration time consisted of two components: an actual binary image upload time (target memory programming) and a communication overhead. According to the results the actual binary image upload was always taking an overwhelming amount of time.

VI. CONCLUSION AND FUTURE WORK

In this article we present the RESP approach for fast embedded systems prototyping. The presented RESP approach may be one of the future directions in embedded software development, especially for experimental and ad hoc systems, because it is aimed at effectiveness, low development cost, short time-to-market, and minimizing implications of a project failure. We propose a theoretical justification for the proposed solution and a sample practical implementation of the compliant system that supports the described approach. The RESP approach does not limit the use of common software development techniques and approaches, such as agile, but it may extend their possibilities and simplify their application in practice.

We also propose a new approach to remote programming and reconfiguration of microcontrollers and FPGAs by implementing much more advanced functionality in the RRM than in common off-the-shelf programmers. The use of the RRM can speed-up the embedded software development before the final version of an application-specific bootloader is developed. We present a sample working implementation of the RRM. It supports modern and promising network protocols, mainly OMA LWM2M, and flexible monitoring features. Thanks to the application of OpenOCD software along with the described implementation of scripting configuration, the RRM can be adapted for a wide variety of embedded hardware platforms, MCU-based IoT nodes, and their respective memory programming interfaces. It can be a versatile remote reconfiguration and development hardware-software tool. Thanks to the use of compact but full-fledged computer platform, the developed RRM system has far superior versatility compared to commercially available remote programmers-debuggers. The comparison between the RESP-RRM approach and solutions reviewed in Section II is summarized in Table II.

The RRM can be used not only for RESP development, but also as a multi-purpose remote reconfiguration and management extension as well as long-term operation monitor or

COMPARISON BETWEEN THE REVIEWED AND THE PROPOSED SOLUTIONS.

Reviewed solution	Aspects which can be improved	Aspects improved by utilizing the RESP approach and/or the RRM
Bootloaders for embedded MCU-based devices [1], [2]	Bootloaders require much development time and effort.	Bootloader is not required during initial development, and can be added at later development stages.
Remote FPGA reconfiguration, programmable logic partial reconfiguration with traditional design flow approach [5], [6], [7], [8]	Complex design which includes a reconfiguration subsystem and more elaborate design flow when considering partial reconfiguration.	RESP can improve time-to-market by allowing for remote development of both programmable hardware and software. The RRM substitutes additional fixed hardware and logic resources for remote reconfiguration. Later, the RRM can be disconnected when not needed.
Remote programmers for FPGA designs as utilized for example in [9]	Single-purpose hardware, no advanced management features, not customizable.	High flexibility of the hardware and software. Possibility to implement advanced firmware and configuration management.
General approach to remote firmware management [10], [11], [12], [13]	More versatile and general-purpose approach with standardized protocols can be considered.	The proposed solution can be easily customized to various applications.
Common approaches to embedded software development [14], [15], [16]	Usually considered for software development with hardware available locally.	RESP does not interfere with a selected embedded software development approach, but it allows developers to achieve a working prototype faster and without a direct access to a hardware platform.

logger for various embedded and connected devices, including IoT nodes. We plan to implement some of that features during further development. An example of a very useful extension is an integration of a camera module for basic visual inspection of the device under development. The RRM could also be considered as a tool which allows remote access to specialized embedded systems for educational and training purposes.

***Abstract*—Finding the right resource at the right time and space is a key enabler for a wide adoption and spread of the Internet of Things (IoT). The Constrained Application Protocol (CoAP) and related standards are among the most prominent efforts working towards such a goal. Indeed, CoAP-related standards provide interesting mechanisms for resource discovery in both centralized and distributed architectures based on the CoAP's GET method. In this paper, we, first, highlight the limitations of GET-based discovery mechanisms. The paper, then proposes a new solution using the recently standardized FETCH method and develops its specifications, rules and semantics. The proposed solution is implemented in the recently released, secure and reliable OpenThread platform and compared with GET-based approaches in different home automation scenarios. Obtained results demonstrate the performance of FETCH-based discovery in achieving fine-grained, time-efficient and reliable discovery while preserving network resources.**

I. Introduction

WITH the growing number of sensors, actuators, devices, smartphones and embedded chips, along with the (r)evolution of computer and network technologies, the world is talking more and more about the Internet of Things (IoT); a term designating the extension of the Internet to everyday objects. When interconnected, these objects can form a network for measuring, storing, transferring, processing, and exchanging data between physical and virtual worlds. Today, such smart objects are able to discover, detect and exchange messages across the Internet thanks to the newly introduced protocols such as 6LoWPAN [1], RPL [2] and CoAP [3]. In fact, with the provided features, smart object networks can be built spontaneously and can be doted with capabilities of self-configuring, self-regulating and self-healing.

In IoT, the vision is that a significant number of new devices including refrigerators, clothes, cars, and traffic-lights will be dynamically connected to the Web for communication, command and control of the surrounding environment. This trend creates the so-called Web of Things (WoT) with the introduction of new constrained servers that have different features from traditional web servers and users. This pushes the WoT to face many challenges related mainly to the heterogeneous nature of networks constituted by these objects and their very limited capacity in terms of computing resources, communication capabilities, memory and energy. To overcome such challenges, the offered functionalities in the WoT are encapsulated as autonomous constrained REST (Representational State Transfer) resources [4] that are accessible from other objects or traditional Web services. This simplifies transparent integration of the physical world with the virtual one. However, to do so, there must be mechanisms to discover available resources and their capabilities with the minimum of human intervention. Thus, resource discovery becomes a fundamental requirement for the success of any IoT solution.

One of the main protocols implementing the REST-based mechanism for resource description and discovery in the web of things is CoAP [3]. Indeed, besides being the de-facto standard for data exchange in the WoT, CoAP provides distributed and centralized solutions for achieving resource discovery. It does so by employing the GET method for the sake of finding available resources in an IoT environment. For instance, a device searching for available temperature sensors in its environment issues a GET request to a *well-known* URI (Uniform Resource Identifier) asking for all sensors offering resources of type temperature. The queerer will get responses with the description of such resource and chooses the ones that best meets its needs.

This GET based mechanism is limited in many aspects that will be discussed and detailed in this paper. To overcome such issues, we introduce a new usage of the FETCH method [5] for the sake of efficient resource discovery in the IoT. The specification of such a usage along with the definition of rules allowing to achieve rich, expressive and compact resource discovery in the web of things are the main contributions of this paper.

Finally, it should be noted that to the best of our knowledge, this is the first paper introducing the use of the newly standardized FETCH method for resource discovery in the IoT. The paper also adds a resource discovery layer to the secure and reliable openThread networking protocol making the proposed approach ready for commercial deployments.

The remainder of this paper is organized as follows: Section II reviews related resource discovery work over CoAP. This will be followed by identifying the main issues of such approaches before proposing our approach and detailing its mechanisms in section III. section IV is devoted to implementing and evaluating the performance of the proposed approach in multiple IoT scenarios over the commercially-proven, secure Thread platform. The paper ends in Section V with a conclusion and directions for future work.

II. Related Work

Resource discovery is a well-investigated topic in traditional Networks with a plethora of solutions proposed in the literature. IoT objects have radically different features than traditional Web servers. As a result, traditional discovery approaches can not be applied directly and will not produce accurate and efficient results in many IoT scenarios. Consequently, new solutions are emerging for the IoT. Such solutions follow two main architectures, centralized and distributed, with standards being proposed for both architectures. The most promising ones are based on CoAP and/or DNS-SD [6]. While DNS-SD is starting to get intention, currently, CoAP-based discovery is the main standard solution in today's IoT applications.

CoAP-based resource discovery can be achieved via three main mechanisms, namely: CoAP Resource Directory (RD) [7], CoAP Distributed Resource Directory (DRD) [8], and CoAP Resource Discovery [9]. The main purpose of these mechanisms is to provide URIs, also called links, for the resources available within a server, as well as the attributes that describe them [9].

With the RD, all the resources offered by the servers are saved in a single directory so that clients can discover any required resource by looking up the RD. For instance, once the RD has been successfully discovered, a server can register its resources in the RD by performing a POST request to the path indicated by the RD. When a client wants to search the RD, they must issue a GET request to the RD. For this, the client uses a specific request to obtain the results that correspond to its interest. The use of GET imposes many constraints on the expressiveness of the request since the parameters must be "bundled up in some unspecified way into the URI" [5]. It should be noted that Following the success of RD, many solutions including [10] have been proposed. All, however, suffer from the same problems related to the use of GET for resource discovery.

In DRD-based discovery [8], before an object can register its resources, it must find an Entry Point (EP) at the DRD. The initial EP can be any object connected to the DRD. In order to find an EP, one method is to use a multicast address */.well-known*, where the object sends a POST request to that */.well-known* address to obtain the DRD information. Other means include searching for the nearest EP or DRD using dynamic discovery [8]. To improve this approach, work based on hierarchical repertoires has been proposed. Indeed, authors of [11], have introduced a usage of the REsource LOcation And Discovery (RELOAD) protocol [12] to discover CoAP resources. RELOAD forms an overlay network to provide storage and messaging services in a peer-to-peer (P2P) environment and allows applications to define specific use cases. For instance, [11] authors describe how to use CoAP with RELOAD to discover interconnected CoAP resources across a large geographic area. However, as with the RD, the discovery is based on GET, which in addition to the above limitations, only supports discovery in the CoRE Link Format (CLF) [9].

Direct approaches rely on IP multicast to achieve discovery [9]. Similarly to the above approaches, it uses the GET method to diffuse a request to all nodes in an IP domain targeting the well-known URI (*/.well-known/core?search**) of all nodes members of the group's multicast address. Unlike RD and DRD, here, not being able to filter the request may generate a huge number of irrelevant responses that consume network resources and slow its operations. Thus, direct resource discovery must include the *search** filter in its requests, which is still insufficient for fine-grained efficient discovery. Finally, a hybrid approach that tries to take advantages of both direct discovery and RD is proposed in [13]. However, similarly to the above, it also relies on the GET method to formulate the requests.

To the best of our knowledge, all CoAP-based discovery approaches deploy the GET method that limits their capabilities into achieving rich and concise discovery in IoT. Such limitations will be discussed in the following section before introducing our FETCH-based resource discovery for the IoT approach.

III. FETCH-based resource discovery for the IoT

Before introducing the FETCH-based resource discovery for the IoT, the following subsection identifies and discusses the main issues with the GET-based approach.

A. Issues with the GET-based resource discovery

As in HTTP, the GET method is used to obtain the complete representation of a resource, which can be refined according to the additional parameters conveyed in the request. However, using GET, a user/device can only allow the specification of a URI and the query parameters in CoAP options [3] as can be seen in Figure 1. Indeed, the GET method does not support the transmission of a payload detailing the request, which generates verbose replies (Figure 1) that consume energy and throughput. These restrictions have caused some applications to use the POST method for the sake of formulating queries with semantic alteration and standard compatibility violation [5].

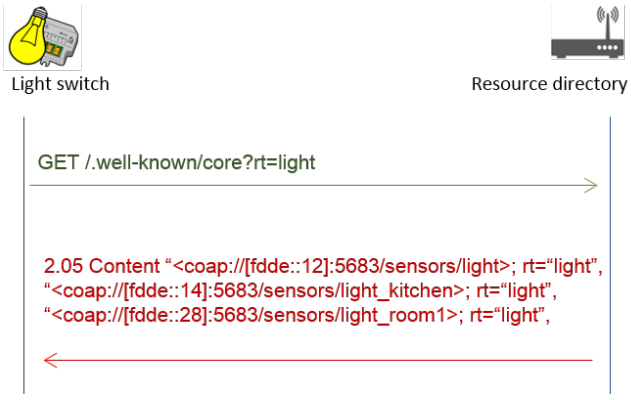

Fig. 1. An example of GET-based resource discovery

The following points summarize and discuss some of the major limitations and gaps related to using GET for the sake of resource discovery:

- Query parameters of GET-based requests are limited by the form and the size of the URI, which restricts their capacities to convey user/device requirements. This constraint imposes strict limitations on the expressiveness of requests, which may result in generating verbose replies that will, at the end, be discarded by the client.
- Despite some research efforts aiming to increase the number of filters included in a GET request, until now, CLF [9] limits this number to one by query. Indeed, a GET discovery request follows the scheme: (*/.well-known/core ?search**), where *search* represents a single parameter. For example: *GET /.well-known/core?rt=light*.
- The GET method does not support filtering based on logical operations (AND, OR, <,>,> = ...) between query parameters. These types of filtering are necessary to refine queries to receive only the most relevant answers.
- With GET, we can not include and/or exclude nodes/resources based on cached descriptions or any information known by a user or device. The use of these features is important for resource discovery in the IoT. Indeed, with such features, the user/device will have the possibility to specify the known resource descriptions in order not to include them in the answer. More importantly, having such an option will provide the possibility of specifying particular nodes to avoid or include, as well as the specification of the particular requirements in terms of security, reliability and the required quality of service.
- With GET, we can not specify/limit the search domain, the location of the searched resources, the maximum number of hops a query can reach, and so on. Such information is of paramount importance for a more fine-grained, effective and efficient discovery. For example, a client looking for temperature sensors in his immediate environment is not interested in having answers from all the temperature sensors available in the network.
- Finally, GET-based resource discovery only supports discovery operations in the CoRE link format [9], which limits its applicability when resources are described in other formats such as JSON, CBOR, EXI, etc.

From the above, and knowing that in IoT most objects are very constrained in terms of resources, a substitute mechanism that offers an explicit, compact and comprehensive expression of user requirements is required. Indeed, it is very important for an alternative approach to minimize congestion, excessive use of resources, energy consumption and latency, while offering more relevant results to better satisfy user requests. Such an approach will be the subject of the following sections.

B. The CoAP FETCH method

The FETCH method has been proposed in draft-ietf-core-etch-04 [5], which has just become RFC 8132 [14]. FETCH tries to provide a solution that covers the gap between the use of GET and POST. In the same way as POST, the parameters of FETCH are transmitted in the payload of the request rather than in the context of its URI. However, unlike POST, the semantics of FETCH is more specifically defined to ensure tasks similar to those of GET.

As defined in RFC 8132 [14], the FETCH method of CoAP is used to get a representation of a resource, providing a number of query parameters. Unlike GET, which requires a server to return a representation of the resource identified by the request URI (as defined by RFC 7252 [3]), the FETCH method is used by a client to request the server to produce a representation as described by the query parameters (including query options and payload) based on the resource specified by the effective URI. As a result, the payload returned in response to a FETCH request can not be assumed to be a complete representation of the resource identified by the effective request URI.

Using the FETCH method for the sake of resource discovery in IoT can remedy GET-related problems identified in the previous section. It is also extremely useful when efficient result filtering that preserves network resources is desired. For instance, if a client is only interested in the types of resources available at a server, it formulates a FETCH request asking of that part of the representation as can be seen in Figure 2. The server, then, replies only with the required information, which saves throughput and energy.

Furthermore, if several resources of similar types are provided by different objects and the client knows beforehand the existence of certain resources not meeting its requirements, it can indicate them in the request payload to avoid undesired replies. Thus, a client can exclude non-needed resources, nodes, and parameters by specifying them in the body of its request. In the same way, a client can specify the desired parameters, nodes, content-formats, etc. to be included. Moreover, a client/device can combine all their requirements and knowledge in a single request to further filter returned responses.

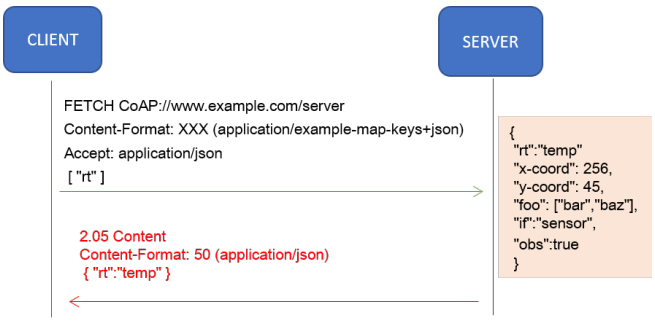

Fig. 2. A FETCH request in JSON

From the above, it is clear that the new FETCH method opens up promising prospects for successfully filtering the returned results, which can significantly reduce network traffic, congestion, collision problems and power consumption when performing resource discovery in constrained networks. In view of these advantages, the question, which will be ad-

dressed in the following section, is how to design an effective use of FETCH for resource discovery in the IoT.

C. FETCH-based Resource discovery for the IoT

Having discussed the limits of GET-based resource discovery and presented the opportunities provided by FETCH, this section introduces the proposed design of an effective scheme of FETCH-based resource discovery.

To do so, we took inspiration from the IGMPv3 protocol for the use of resource filtering based on the INCLUDE and EXCLUDE modes; EXINC for short. These modes are considered very adaptable to the context of resource discovery in the IoT. Indeed, it is useful to have a mechanism that allows to EXCLUDE the resources we do not need. At the same time, providing a technique allowing to INCLUDE the desired features is crucial for an fine-grained resource discovery. Indeed, with these two modes, several combinations of user/device discovery requirements can be formulated in the same request in a very compact format. Building on this, we have developed a scheme allowing to provide rich combinations of desired parameters to be included along with resources, nodes, and parameters to be excluded when replying. Such a scheme is presented in Figure 3, where a EBNF representation is given for the case of CoRE link format. It should be noted, however, that our scheme is not tight to CLF and can be adopted to any other description format including JSON, EXI, CBOR to allow resource discovery in formats other than CLF.

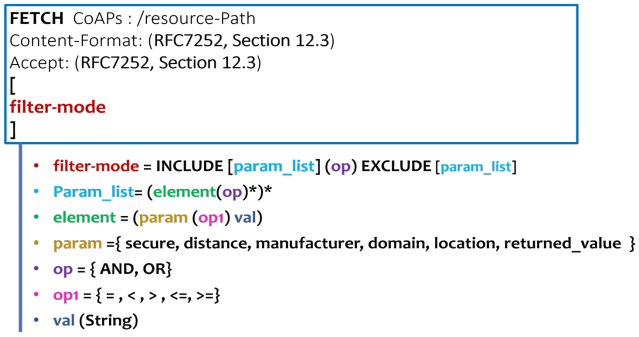

Fig. 3. Semantics of the FETCH-based resource discovery

In addition to the EXINC filtering technique, we propose to format the payload of the FETCH request in such a way as to take logical operators into account when specifying parameter lists to INCLUDE or EXCLUDE. For instance, a client may specify the parameters to be included AND/OR those to be excluded. It can also formulate the request to only get a specific part of the description in a specific media type. In this context, implementations can formulate a request payload of any media type that is compatible with the semantics of FETCH-based resource discovery, detailed in Figure 3. Finally, Figure 4 presents an example of a FETCH discovery request formulated in accordance of the proposed scheme.

To further highlight the importance of the proposed FETCH-based resource discovery, we employ it in a home automation scenario illustrated in Figure 5. In this scenario, the smart air-conditioner must get the average temperature of the house from the thermostats located in different rooms. However, this air conditioner only trusts in Nest thermostats that are secured with Thread and are located less than five hops away. The realization of such a scenario is not possible with GET-based discovery as defined in [9]. On the other hand, with FETCH, we can filter the results by using the proposed EXINC scheme. The FETCH request for this scenario along with the resolution process and returned results are shown in Figure 6.

Finally, the proposed FETCH-based discovery opens up promising prospects for significantly reducing network traffic, congestion, collisions, and power consumption during resource discovery. Note that the proposed technique is expandable to take into account more parameters and more combinations between these parameters in the same query. It is also designed to be adaptable for future uses. In addition, it is as valid with direct (distributed) discovery as with the centralized approaches and any other CoAP-based discovery approach. Indeed, it only requires changing the formulation of the queries by using FETCH with the semantics given above.

IV. Performance Evaluation

This section details the performance evaluation of the proposed method when compared with the GET-based approach adopted by CoAP. It starts by detailing the methodology and used tools, before presenting the evaluation scenarios and measured metrics along with discussing the obtained results.

A. Evaluation tools and Implementations

All our evaluations were carried out in the recently released Thread platform targeting IoT applications in home automation and similar environments. The choice of Thread is motivated by the fact that is a proven secure and reliable solution. It is, also, already implemented in many commercial products on sale for several years now. Moreover, this secure and open network protocol is built on a collection of existing standards similarly to environments such as Contiki [15]. Finally, a user can employ a smartphone, an application, and/or any device to communicate, directly or via the Cloud, with the Thread network.

Based on the open-source implementation of Thread, dubbed OpenThread [16], and inspired by Contiki, we have added a resource discovery layer over CoAP as specified in Figure 7. This layer contains three main components; namely: the request engine implementing the semantics of both GET and FETCH look-ups; the publication engine that is responsible on resource registration; and the resource description component. Subsequently, we developed prototypes of nodes that implement client and/or CoAP server along with the RD.

B. Evaluation protocol and scenarios

To evaluate our solution, we created different home automation and similar network configurations. Each configuration

```
FETCH CoAPS: ./well-known/
Content-Format: application/link-format
Accept: application/link-format
[
 [INCLUDE]: {secure=[Sval_1],Distance[=;<;>;<=;>=]Dval_1,location=[Nodes_List;],Domain=[domain],Manufacturer=[name]}
 [EXCLUDE]:
{secure=[Sval_2],Distance[=;<;>;<=;>=]Dval_2,location=[Nodes_List;],Domain=[domain],Manufacturer=[name]}
]
```

Fig. 4. Example of the proposed scheme for FETCH

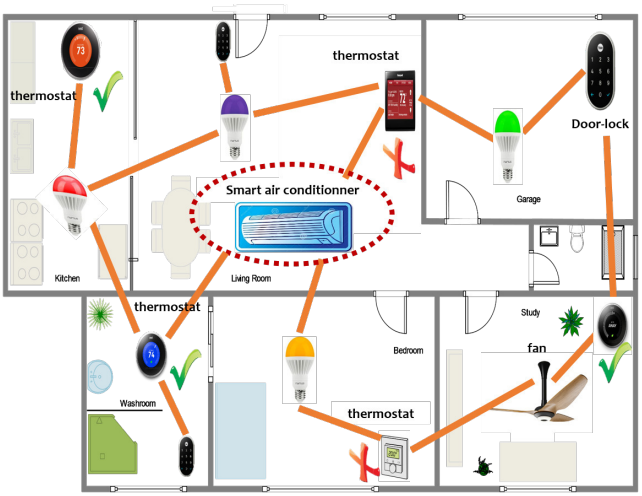

Fig. 5. A use-case of FETCH-based resource discovery

contains 13 nodes over which we run several single-hope and multi-hop scenarios for both centralized and distributed cases. Below are the details of multi-hop scenarios.

- Centralized discovery (CoAP-RD) in multi-hop networks: in this test, we designed a scenario where three servers will register their resources in the RD, then two concurrent clients consult the RD to obtain the descriptions of registered resources. To do so, clients send their requests in unicast, using the Thread unicast routing protocol, to the RD. This latter will respond with unicast messages containing the requested parts.
- Distributed discovery in multi-hop networks: in this test, one client sends a multicast request to discover required resources. This request will be propagated in the network by the multicast routing protocol MPL [17]. Once this request arrives to a node having the desired resources, it will respond directly to the client with a unicast response.

The above test cases were performed by simulations using virtual instances of Thread objects. Hence, environment-related parameters such as signal propagation, influence of obstacles and interference with other wireless signals are not taken into account. Also, the estimation of parameters, such as the consumed energy will not be possible. For each test case, we set the simulation time to 600 seconds and varied the request frequency. To put the results in context, we compared our FETCH-based discovery approach with the standard GET-based approach under the following performance metrics.

- Average discovery time: this parameter is defined as the average waiting time between the transmission of a request and the reception of the first response averaged over several requests. This metric is used to evaluate the efficiency of our solution in terms of latency.
- Discovery success rate: measures the number of received responses to all sent queries. This metric is used to evaluate the reliability of the proposed technique.
- Size of request/reply messages: accumulate the size of request/reply messages. It is defined as the ratio between the sum of request/reply sizes for each node over the total number of nodes.

By comparing our approach with that of GET under different networks and discovery scenarios, we aim to encompass most of the performance indicators of the proposed approach. Simulation parameters are summarized in Table I and obtained results are discussed in the following subsection.

TABLE I
SIMULATION PARAMETERS

Parameter	Value
Duration of one simulation	600 seconds
Number of iterations	5
Number of nodes	13
type of nodes	Thread CLi Instances
Message payload	Variable size
Network layer	IPv6 over 6LoWPAN
MAC layer	802.15.4 with enabled MAC security

C. Results and discussions

This section discusses the obtained results in both centralized and distributed scenarios.

1) Centralized approach: In this section, we will discuss the results obtained for the centralized approach of our FETCH-based solution (CoAP-RD-FETCH) and that of GET (CoAP-RD-GET). Obtained results are depicted in Figure 8.

Figure 8.(a) presents the average time of discovery of both approaches when varying the request frequency. As can be seen from this figure, discovery with FETCH achieved a lower discovery time compared to that of the GET method. This can be explained by the fact that GET generates more traffic since the response message contains descriptions of all available resources in the RD. It takes a longer time to reach the client because of its size and the congestion created in the network. However, the FETCH method performs efficient filtering so

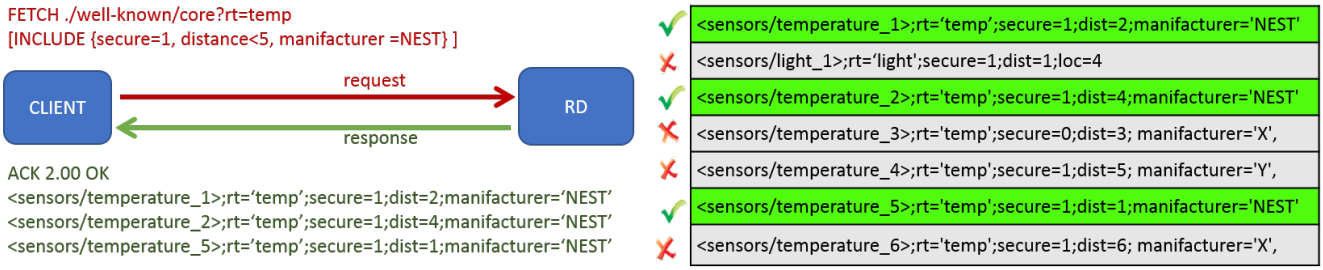

Fig. 6. Details of a FETCH-based resource discovery process

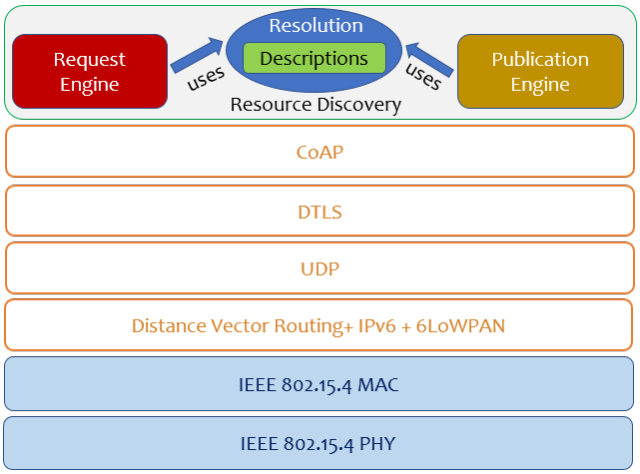

Fig. 7. Resource discovery implementation in OpenThread

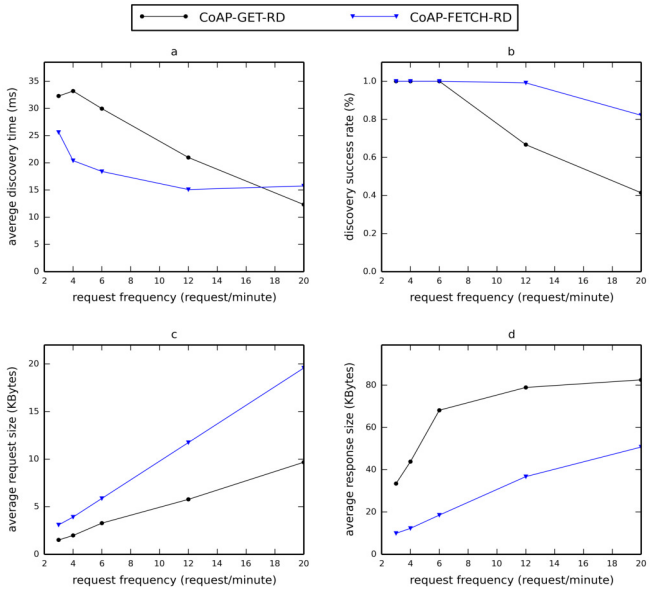

Fig. 8. Evaluation of proposed mechanisms in a unicast discovery scenario

that the RD only returns the desired resource descriptions, which significantly reduces the size of the response messages and also allows for faster routing (less congestion).

Concerning the average discovery success rate, Figure 8.(b) shows that both GET and FETCH registered a high success rate approaching 100 % in low request frequencies. This is due to the reliable routing protocol deployed in Thread along with the fact that the simulation environment is considered perfect. With a high query frequency, however, the discovery success rate becomes very low, approaching 40% for the GET method. This could be explained by the very high congestion of the network caused by the high frequency of query generation and the size of GET responses that may even lead to the elimination of responses at the transmission buffer. However, with the FETCH method, we notice that the rate does not decrease too much and approaches 80% at the highest frequency thanks to the minimized size of returned responses.

With regards to the size of requests, it is clear from Figure 8.(c) that the queries generated by FETCH are slightly larger compared to those generated by GET. This is due to the extra data that FETCH needs in its payload to specify the filter that will be used during the discovery process. This has the advantage of minimizing response size by only returning the desired resources. Knowing that a single query can match several large responses, this surplus provides an acceptable compromise. Indeed, it improves the relevance of responses along with the discovery time and network utilization as can be seen from Figure 8.(d). For instance, this figure shows that the difference in size, between the responses generated by GET and those generated by FETCH, is very important. This is due to the fact that, with FETCH, the RD only returned description parts that exactly matched user's specifications. This ensures both user satisfaction concerning discovery relevance and time as well as network fluidity with regards to congestion and resource utilization.

2) Distributed approach: This subsection discusses the results obtained on the distributed resource discovery scenario with the two discovery approaches: GET (CoAP-GET-multicast) and FETCH (CoAP-FETCH-multicast). Obtained results are depicted in Figure 9.

As can be seen from Figure 9.(a) FETCH-based resource discovery achieved noticeably lower discovery time compared to that achieved by GET-based discovery. This difference reaching up to 130 ms, shows the power of FETCH especially for multicast traffic, which is slow and expensive in terms of time and energy. With regards to the average discovery success

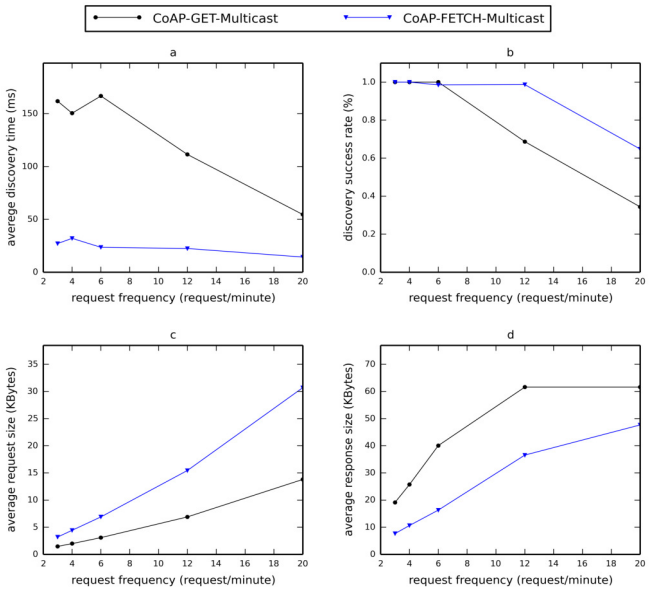

Fig. 9. Evaluation of the proposed mechanisms in a multicast discovery scenario

rate, Figure 9.(b) shows that both methods are equally reliable in both centralized and distributed approaches through the use of the MPL, which ensures the efficient routing of messages.

Finally, and concerning the size of generated messages, it is clear from Figure 9.(c) that the size of the multicast requests sent by FETCH is slightly larger than those of the GET. These results are similar to those of the centralized approach because it is the same client that sends the same requests. On the other hand, the size of returned responses is noticeably smaller in FETCH-based discovery in comparison with GET as can be seen from Figure 9.(d). Similarly to the centralized case, this is due to the fact that with FETCH the servers only returned the descriptions of the adequate resources.

By analyzing these results, we can confirm that the use of FETCH method for the sake of resource discovery is very important and outperforms GET in many aspects regarding the granularity, efficiency, and relevance of discovery along with resource utilization. Such performance is equally efficient and effective for both approaches (centralized and distributed). Therefore, an in-depth elaboration of the FETCH-based specification will open up more advanced and more efficient prospects for resource discovery in the IoT.

V. Conclusion

In this paper, a new CoAP-based discovery mechanism was proposed building on the newly standardized FETCH method. Obtained results demonstrated the capacities of FETCH to achieve fine-grained, expressive and efficient discovery when compared with the GET-based discovery adopted by CoAP. These achievements open up new horizons to formulate a compact and expressive resource discovery framework for the IoT. Our future work ports on the generalization of FETCH-based resource discovery to encompass a wide-range of IoT look-ups in view of proposing a specification of IoT resource discovery based on FETCH.

Using Publish/Subscribe for Short-lived IoT Data

Frank T. Johnsen
Norwegian Defence Research Establishment (FFI)
P.O. Box 25
2027 Kjeller, Norway

***Abstract*—Efficient distribution of IoT sensor data requires one-to-many communication, for which publish/subscribe is a better communication approach than request/response. In this paper, the goal is to identify the/those publish/subscribe protocol(s) that are best suited for IoT data. The premise is that data should be as fresh as possible. Hence, the metric is end-to-end delay and the recommended approach is the solution that yields the lowest delay under the test conditions. Raspberry Pi 3 was used as the testbed, since it is representative as an IoT platform. The protocols evaluated are: AMQP, MQTT, MQTT-SN, STOMP, WSN, and XMPP, as well as using a mediation service to translate between them.**

I. Introduction

The term Internet of Tings (IoT) can be traced back as early as 1999 when Kevin Ashton used it to describe a network that linked physical "stuff" to the Internet. Nevertheless, it would be a few years before "IoT" became an active research area and the buzzword it is today. There are many different interpretations of what IoT is, but the core idea stems from Ashton. A more recent and elaborate definition of IoT is as follows:

> The Internet of Things (IoT) describes the revolution already under way that is seeing a growing number of internet enabled devices that can network and communicate with each other and with other web-enabled gadgets. IoT refers to a state where Things (e.g. objects, environments, vehicles and clothing) will have more and more information associated with them and may have the ability to sense, communicate, network and produce new information, becoming an integral part of the Internet. A widespread Internet of Things has the potential to transform how we live in our cities, how we move, how we develop sustainably, how we age, and more. – From [1]

The reason why IoT has become commonplace over the last five years is that a number of factors that can be considered mandatory precursors to this phenomenon have come into place:

- Cheap sensors (easily accessible from eBay, deal extreme, etc).
- Cloud computing (serves as a backend for IoT systems and can handle big data)
- Powerful smartphones (often used as a consumer's control panel in the IoT context)

Given these precursors, there have been many business ideas in the healthcare sector, logistics and other areas that give rise to a number of applications that fuel the current IoT trend. IoT as a concept is definitely relevant in a defense context. An example of this is the pioneer work described in [2], which deals with the use of sensor networks and lightweight processing platforms that require low power. IoT includes several disciplines, as one needs networking, embedded hardware, software architectures, sensors, information management, data analysis and visualization to fully leverage the concept. A key component within IoT is the use of distributed online devices that communicate using Internet protocols. A "thing" in IoT may be any device that is able to communicate, gather data or offer some kind of control. With this wide interpretation of "things", IoT may include, but is not limited to: Vehicles, appliances, medical equipment, power grids, transport infrastructure and production equipment.

Military organizations can exploit IoT deployed in battlefields and operational theaters to improve situational awareness, mission performance and achieve information superiority [3]. Within NATO, the Research Task Group (RTG) IST-147 "Military Application of Internet of Things" is investigating how to best employ IoT in a coalition force, particularly in the context of augmenting situational awareness in military operations in smart cities [4].

Today there is a great focus on using Commercial off-the-shelf (COTS) products where possible because it is considered a cost-effective way of acquiring a capability. This idea is well rooted in NATO, and has been considered foundational for an effective Network Enabled Capability (NEC) as identified in the NATO NEC Feasibility Study [5]. In this study it was also pointed out that the principles of service orientation must be taken into account when building distributed systems. These observations can be continued within the IoT venture, as there will also be a need to build large, efficient and interoperable systems.

NATO has identified a set of *Core Services*, which provide common communication functionality that other services (e.g., C2 services) depend upon. An example of a Core Service is messaging, which includes both request/response and publish/subscribe services. In this paper, the focus is publish/subscribe services as applied to support IoT. Here, the focus is on short-lived IoT data, in other words data that comes fresh from a sensor and needs to be delivered as soon as possible. Publish/subscribe is considered the most efficient communication paradigm for this type of data, in contrast to long-lived data, where the new approach of Information-Centric Networking offers some desirable properties [6].

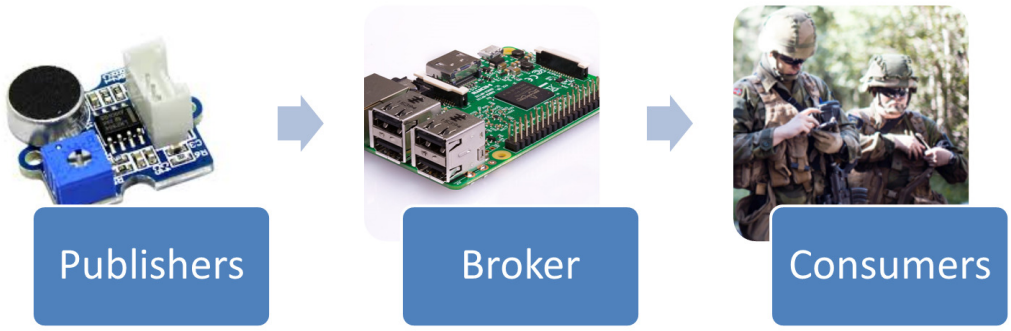

Fig. 1. Publish/subscribe information flow. It is assumed that subscriptions have been set up prior to this occurring.

II. Publish subscribe protocols

The publish/subscribe pattern implies that a consumer explicitly signals its interest in a given type of data by registering a subscription. The most common approach to signal such an interest is through a *topic*, i.e., a string that is used to identify the data a consumer is after. When new data is available on a certain topic, all consumers that have expressed interest in that topic receive it. This pattern is particularly well suited for IoT, as many sensors produce information more or less periodically, and thus, a push-pattern can reduce network activity considerably when compared to using a request/response or pull-pattern. A *broker* is used between the producer and consumer. Its tasks include subscription management and message dissemination according to topics, so that the producer only has to send new data to the broker, which then handles all further dissemination. For an illustration of the publish/subscribe pattern, see Fig. 1.

A number of publish/subscribe standards exist. This paper considers several of the most commonly available standards today. A short overview of the protocols follows.

A. Message Queue Telemetry Transport (MQTT)

MQTT is a popular publish/subscribe protocol for IoT, standardized as ISO/IEC PRF 20922 [7]. It provides publish/-subscribe messaging for resource-constrained devices: Low processing power, low memory, as well as network constraints. MQTT is designed to function well over unreliable networks by providing three levels of Quality of Service (QoS): Level 0, “at most once”-semantics – messages are delivered on a “best effort” basis. As MQTT is based on TCP, this is usually enough to ensure delivery. However, if the TCP connection is broken there will be no retransmission later on reconnection with this QoS level. So, though not likely, message loss can occur. Level 1 provides “at least once”-semantics, where messages are assured to arrive but duplicates can occur, hence systems must be able to handle duplicate packets. Level 2 gives “exactly once”-semantics, so messages are assured to arrive exactly once. This latter method requires an exchange of four packets, and decreases performance of the broker.

B. MQTT for Sensor Networks (MQTT-SN)

MQTT-SN is, in short, a version of MQTT that is optimized specifically for sensor networks [8]. The major difference is that it uses UDP as the underlying transport protocol rather than TCP.

C. Advanced Message Queuing Protocol (AMQP)

AMQP [9] is a binary wire protocol, which was designed as a reliable and interoperable open replacement for existing proprietary messaging middleware. As the name implies, it provides a wide range of features related to messaging, including reliable queuing, topic-based publish-and-subscribe messaging, flexible routing, transactions, and security. AMQP has been shown to be scalable and reliable, and is much used for civilian applications, notably for supporting financial transactions and also as a backbone in cloud computing clusters.

D. Web Services Notification (WSN)

NATO has chosen WSN [10] for publish/subscribe in its SOA baseline [11]. WSN is a part of the family of SOAP Web services standards. SOAP services promote interoperability, but being based on XML the cost is increased overhead compared to other protocols.

E. Simple/Streaming Text Oriented Messaging Protocol (STOMP)

STOMP [12] is text-based, making it somewhat similar to how HTTP operates. The main design principle was to create something simple to use and understand. However, the STOMP flavor of topics (called a *destination* in STOMP) is not mandated in the protocol specification, meaning that different brokers may support it differently. This, in turn, lowers interoperability across brokers, since publishers and consumers that function well with one broker implementation may not work with another. If you don’t encounter portability issues, then STOMP is simple, lightweight, and offers a wide range of language bindings.

Fig. 2. The Raspberry Pi 3B single board computer.

F. Extensible Messaging and Presence Protocol (XMPP)

Just like WSN, XMPP [13] is an XML-based protocol. Unlike WSN, XMPP does not use SOAP, so it does away with the extra abstraction layer (and thus extra overhead). XMPP is most known as a chat (instant messaging) and presence protocol, however it does offer additional features as well, like SIP-compatible multimedia signaling for voice, video, file transfer, and other applications as well as publish/subscribe functionality. XMPP aims to be the main competitor to MQTT for civilian IoT applications, and is, as such, interesting to compare with MQTT to see which protocol is "best".

III. Testbed setup

The testbed was put together of two Raspberry Pi 3B single board computers. The main motivation for using this as the testbed was that the Raspberry Pi 3B is a somewhat capable yet cheap computer that is representative for IoT development. The board is shown in Fig. 2. The technical specifications of the board are as follows [14]:

- Broadcom BCM2837 64bit ARMv7 Quad Core Processor powered Single Board Computer running at 1.2GHz
- 1GB RAM
- BCM43143 WiFi
- Bluetooth Low Energy
- 40pin extended GPIO
- 4x USB 2 ports
- 4 pole Stereo output and Composite video port
- Full size HDMI
- CSI camera port for connecting the Raspberry Pi camera
- DSI display port for connecting the Raspberry Pi touch screen display
- Micro SD port for loading your operating system and storing data

One Raspberry Pi 3B functioned as the client: That is, it set up subscriptions to pre-determined topics up front, published messages to said topics, and ran the consumers that received the messages. This was done so that time measurements across publishers and consumers (via the broker) would be accurate, since timestamps would originate from one and the same node rather than several, where clock skew could become an issue. The second Raspberry Pi 3B offered the protocol brokers and the mediation service to translate between protocols. All publishers and consumers were implemented using Java, and the respective protocols' native Java libraries. The brokers and mediation service (let us call this component a *multi-protocol broker*) was also Java software. In fact, the multi-protocol broker was an extended version of the federation mechanism described here [18], enhanced for the purpose of this paper to support all the protocols discussed above. For networking, 100 Mbps Ethernet was used, and both Raspberry Pi 3B's were connected to a switch. This was done to ensure the best possible networking conditions during the tests, so that local disturbances and interference should not affect the results, which could have been an issue if using e.g., WiFi.

Tests were executed as follows:

1) The multi-protocol broker was started.
2) A subscription to a topic was set up for a particular protocol α.
3) A publisher was initiated to fire off a burst of 100 messages over protocol β.
4) Having received 100 messages, the consumer terminated its subscription to protocol α.
5) The duration of steps 3-4 above was measured.
6) Steps 1-5 above were repeated for all α, β of protocol permutations.

IV. Results

Tab I shows the results when transmitting 100 messages. This table shows when the publisher sends 100 consecutive messages via the multi-protocol broker. The consumer receives the messages, and terminates the subscription after message number 100. The time (in seconds) of this entire burst of messages was measured here.

We see that WSN is the overall loser when considering our protocol delay metric. Consistently WSN shows the highest delays here. We see that having WSN as either the publisher or subscriber results in a high delay, with an even higher delay exhibited (just over 20s – the highest in the test) when both publisher and subscriber used WSN. This can be attributed to the SOAP layer used in the protocol; having this extra abstraction layer on top of HTTP does have an impact performance wise.

Of the other protocols, the performance difference is not so large when considering publisher/subscriber pairs of the same protocol (no translation is involved – indicated in **bold** in the table). Here, we see that AMQP is the "worst" (just above 4.5s) and STOMP is the "best" (just above 2.5s). This is understandable when thinking about the fact that AMQP provides a reliable message queue. Messages are ensured delivery and acknowledged in the queue. STOMP does not perform this added value service. MQTT achieves slightly better results than MQTT-SN, which again is slightly more efficient than XMPP (just over 3s). At first glance this may seem strange, since MQTT-SN is based on UDP which inherently has lower overhead than TCP, which is the underlying transport in

TABLE I
PROTOCOL DELAY PUBLISHING AND RECEIVING 100 MESSAGES.

	AMQP Sub.	**MQTT Sub.**	**MQTT-SN Sub.**	**STOMP Sub.**	**WSN Sub.**	**XMPP Sub.**
AMQP Publisher	**4.577313**	5.054525	5.065977	3.529224	16.309429	4.443499
MQTT Publisher	3.022697	**2.655891**	2.303168	2.448346	14.992253	4.470155
MQTT-SN Publisher	3.438891	2.716955	**2.895711**	2.466580	14.462532	4.340074
STOMP Publisher	3.017157	3.215914	4.876303	**2.256608**	15.458013	4.347493
WSN Publisher	12.518343	11.745184	12.116381	11.534597	**20.769935**	13.644167
XMPP Publisher	7.165085	6.414229	6.492992	6.086224	16.023309	**3.001673**

MQTT. The reason why MQTT-SN has slightly higher delays here, is that it is actually implemented as a gateway that uses plain MQTT in the backend. Hence, MQTT-SN gets a slight performance impact going through this gateway which moves it from UDP to TCP and vice versa locally on the broker node (UDP is used between client and broker across the network).

The remaining rows in the table show the different protocols' delay where the impact of translating between them is also included. We see that XMPP and WSN here show the cost of translating to/from XML based protocols. WSN has the impact of using both XML and SOAP, whereas XMPP only uses XML. An interesting observation is the above mentioned performance of the XMPP publisher/subscriber pair, which shows that the XML-based XMPP does not perform too badly when no translation is involved.

V. RELATED WORK

The NATO IST-090 RTG has demonstrated the use of WSN at the tactical level. WSN has the benefit of being a NATO recommended standard for information exchange in a coalition environment. However, it is a resource heavy protocol and its application at the tactical level requires applying proprietary optimizations [15].

More recently, the IST-118 RTG conducted initial experiments comparing different publish/subscribe approaches on tactical broadband radios. Namely, WSN, MQTT and AMQP were investigated in a preliminary small-scale study [16]. Here, MQTT was found to be a very lightweight alternative to the other two protocols when applied in the tactical network. Currently, the IST-150 RTG is continuing work where IST-118 left off, and is considering MQTT specifically for use in soldier systems on the tactical level [17].

In [18], the authors provided a solution for federating between different publish/subscribe protocols, i.e., WSN, MQTT, and AMQP. The work in this paper uses an extended version of that open source implementation with support for additional protocols as the broker and mediation service (aka multi-protocol broker) in the testbed.

VI. CONCLUSION

If you need to use UDP from your sensor to the mediation service, then your choice is MQTT-SN, which is the only one based on UDP of the protocols tested.

If you need interoperability with NATO (i.e., you need WSN subscribers), then the most efficient protocols to use when going through the mediation service are MQTT-SN (UDP) and MQTT (TCP). You definitely don't want your sensors to deliver data using WSN directly, as that is the protocol with the overall highest delay.

If you are free to choose any protocol you want for the entire network, then using STOMP as both publisher and receiver was marginally quicker than using any of the other protocols. However, if you need advanced capabilities like multi broker meshing, then MQTT or AMQP can offer that, though they had slightly larger delays than STOMP. Though never best, XMPP shows overall favorable results given that it is based on XML. It goes to show that it is possible to implement a somewhat efficient XML based protocol, in comparison with WSN, which has very high delays. The reason for this is that WSN, being based on SOAP, adds an extra abstraction layer in the protocol that none of the other protocols have.

The overall recommendations are summarized in Tab. II.

TABLE II
RECOMMENDATIONS FOR PUBLISH/SUBSCRIBE COMBINATIONS.

GOAL	**Publisher**	**Subscriber**
Lowest overall delay	STOMP	STOMP
UDP necessary	MQTT-SN	MQTT-SN
NATO Interoperable	MQTT or MQTT-SN	WSN
Meshable brokers	MQTT or AMQP	MQTT or AMQP

The table gives an overview of which protocol combinations to use to achieve a specific goal. Note that where the lowest delay is not the primary goal, it is considered the secondary goal when giving the recommendations.

VII. FUTURE WORK

The testbed consisted of a publisher and subscriber running on one Raspberry Pi and the broker on another. Hence, it is only a small scale test of how the protocols perform. One of the challenges of IoT is the scale, so for future work it would be interesting to make similar tests of a larger scale setup.

Also, it would be beneficial to test the protocol performance over a typical IoT networking technology, such as LoRa. Other relevant networking options would be 4G and WiFi, to name a couple.

***Abstract*—The road network of big cities is a complex and hardly analyzable system in which the accurate quantification of interactions between nonadjacent road segments is a serious challenge. In this paper we would like to present a novel method able to determine the effects (the time delay and the level of the correlation) of distinct road segments on each other of a smart city's road network. To reveal these relationships, we are investigating unexpected events such as traffic jams or accidents. This novel analysis can give a significant insight to improve the operation of currently widespread traffic prediction algorithms.**

I. Introduction

NOWADAYS smart city services are becoming more widespread than ever as cities are growing and becoming more and more crowded as a result of urbanization and growth of the world population. The rapid progress of urbanization improved life of many people, but also brought remarkable challenges, like traffic congestions that can lead to increased energy/fuel consumption and enormous emission of pollutants [1]. These phenomena heavily and directly impact the health, the life quality and expectancy of city dwellers. According to [2], laboratory studies indicated that transport-related air pollution may increase the risk of developing allergies and can exacerbate symptoms, particularly in susceptible subgroups, while [3] showed that traffic jams increase the risk of heart attacks.

Intelligent management systems, such as Advanced Traffic Management System (ATMS) and Intelligent Transportation System (ITS) can help overcome or significantly reduce the impact of such negative effects on city dwellers. Forecasts of these systems can support traffic control centers in managing the road network and allocating resources systematically, for example opening/closing lanes, pricing dynamically parking places or adapting the traffic lights to the current traffic trends.

In vehicle navigation the knowledge of traffic forecasts for different routes during the route planning is advantageous, as the devices will be able to calculate more efficient routes and reduce travel time. Insight into vehicular flows of smart cities could make searching for parking spaces much easier and faster. It could also provide added value for emerging V2X based traffic control systems, which can play an important role in route planning of self-driving cars.

In the literature, there are numerous prediction models utilized for traffic flow prediction, however the road network of big cities is a complex and hardly analyzable system in which unexpected events could significantly decrease the correctness of the result of the prediction models.

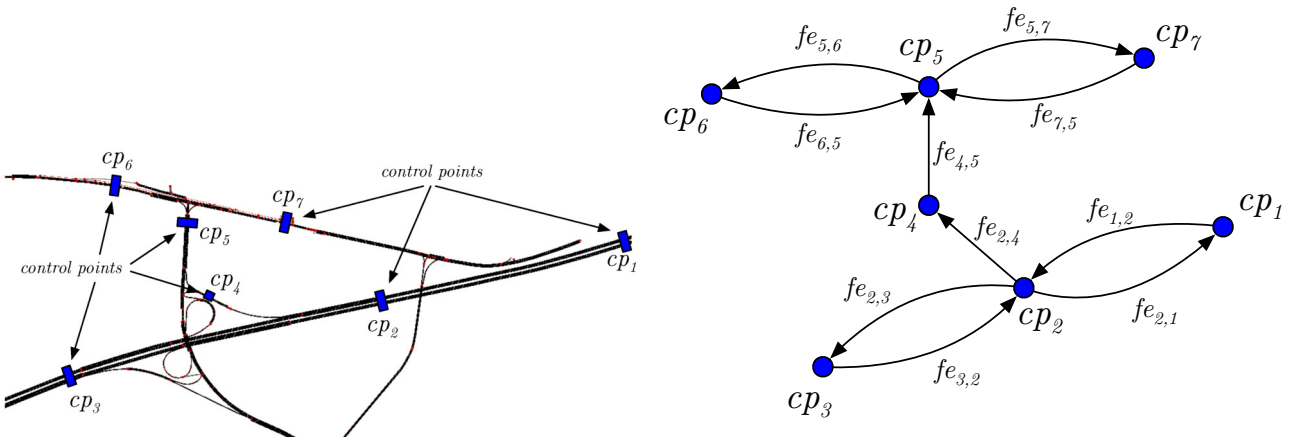
Every predicted value is composed of a predictable component and an error [4], which includes both prediction error and unpredictability of uncertainty. Thus the predictable value is derived from the deterministic part and the predictable part of uncertainty. Therefore it follows, that the predictability of the traffic flow depends on whether the model is able to predict the uncertainty part or not. Fortunately, lots of prediction models can be prepared for handling the uncertainty part by integrating different external data sources. The uncertainty is influenced by many factors, like weather condition, mass events, road constructions, road closures, accidents etc. By considering these external environmental factors, the error of prediction models can be decreased.

In this paper, a new method will be presented, which aims to reduce the previously mentioned uncertainties. The algorithm focuses on unexpected events, such as traffic accidents, which can have a negative impact on the traffic prediction. By investigating the effect of these phenomena, the algorithm is able to:

- identify neighboring road segments that could be affected by the event
- to determine the level of correlation between the road segment affected by the accident and its neigboring road segments,
- to quantify the time delay: the time needed for the effects of the accident to propagate to neighboring road segments.

By fusing this information with real-time traffic information, the prediction models will be able to provide more accurate predictions even in the case of an unexpected event happening nearby.

The paper is organized as follows. In Section II., various prediction techniques are introduced aimed at reducing the error of prediction models. This section also contains a short summary of usable data sources. In Section III, the algorithm is presented in detail, which is followed by a case study simulation in Section IV. Section V concludes the paper and points out the current weaknesses and future improvements of the algorithm.



(a) A road network with control points

(b) The flow graph model of the road network

Fig. 1: An example of the traffic graph model interpretation. On Figure 1a, the original road network is depicted with control points, while Figure 1b shows the road network's graph representation.

II. Traffic Prediction Methods in Smart Cities

A. Prediction Techniques

There are several proposed prediction models [5], which perform well for regular conditions, however an unexpected event could significantly decrease the quality of their traffic forecasts. The reason is that the predictability of the traffic flow depends on whether the model is able to predict the uncertainty part of the traffic flow with the required precision. The uncertainty is influenced by many factors, like weather, events, road constructions, lighting conditions etc. Incorporating external environmental factors and fused data [6] to the model is crucial to decrease the error of the prediction and increase the predictable part of uncertainty.

Traffic is predictable in the sense that it does not vary significantly during weekdays and during most months of the year [7]. In [8] similar results were obtained as well as they have found a relatively high daily predictability of traffic conditions despite the absence of any apriori knowledge of drivers' origins and destinations and the quite different travel patterns between weekdays and weekends.

A neurowavelet prediction algorithm was proposed [9] to forecast the hourly traffic flow considering the effect of rainfall. In the article, the authors use a stationary wavelet transform to reveal correlation between different weather conditions and changes in the traffic flow. An examination was carried out [10] whether or not road usage on a particular location determines the impacts of various weather conditions. The study showed that the precipitation, cloudiness and wind speed reduce traffic intensity, while high temperatures and hail significantly increase traffic intensity.

Other papers contentrated on the spatio-temporal property of the traffic flow, by using different Autoregressive Integrated Moving Average (ARIMA) model variants [11]–[13], applying K-Nearest Neighbors (KNN) models [14], [15] while others employed Convolutional Neural Network (CNN) for this purpose [16]–[18]. Deep learning based prediction model was also presented for spatio-temporal data [17]. The prediction model uses spatial and temporal relations and integrates global information (such as day of week, meteorological conditions, etc.) to decrease the uncertainty.

Relation between traffic predictability and prediction time horizon was investigated [4] by examining spatio-temporal traffic relationship using Cross-correlation function (CFF). The time lag calculated by CFF can be used to determine prediction time horizon, and the cross-correlation coefficient can be utilized to identify the spatial relations that can be used in prediction.

Solutions enumerated in this section aim to handle the previously listed uncertainties of traffic flows. However, we have not found significant work aimed at increasing the predictability of traffic flow through the investigation of unexpected events like accidents or traffic congestions of uncontrolled traffic flow. In this paper, we will present a novel method, which can exploit these events to measure the time delay and calculate the level of influence between distinct road segments.

B. Data sources

In the first generation of ATMSs and ITSs [19] the utilized data sources were various presence sensors in fixed positions, able to detect the presence of nearby vehicles. Initially inductive loop detectors were the most popular, but nowadays a wide variety of sensors became available [20].

Recently, the advent of GPS equipped smartphones and vehicles has given rise to a relatively new type of data source that could supplement presence type sensors to gather more detailed information or get data about roads, which have not been covered with presence sensors yet.

Our method can leverage both types of data sources, but in the case of GPS traces, a preprocess step is needed to be inserted before the data model building.

III. Methodology

The road network of big cities is a complex and hard to analyze system in which the accurate quantification of interactions between nonadjacent road segments is almost an insolvable objective, because of the unique decisions of thousands of drivers which makes the interactions invisible. However an unexpected event could be used to reveal hidden connections between road segments, because they always appear as an outlier in the timeseries of the investigated data type (traffic speed, traffic flow count, travel time, etc.). It follows, that if the emergence of an unexpected event is known, the ripple of that event can be observed through the network, thus the hidden correlations will become observable. As an analogy, we suppose that one can think of a road network as a huge black box system, which has one input and numerous outputs. If the system is fed with an unusual input, the inner behavior of the system can be inferred through the outputs.

In this section, the Algorithm for Identifying Hidden Influences (AIHI) will be introduced in detail, which targets to exploit unexpected traffic events to reveal the previously mentioned connections. In Subsection III-A, the graph based data model will be presented which is suitable for the analysis of unexpected events, then the distinct steps of the algorithm will be explained in Subsection III-B.

A. Data model

In our solution, the road network is modeled with a $FG = (CP, FE)$ directed flow graph. Each $cp \in CP$ node represents a control point, which is a special point of the road network, where the traffic measurement is feasible by different type of traffic sensors (such as inductive loop detectors, radar sensors, audio sensors, etc.). A cp control point itself does not store any traffic data, they just measure the traffic flow at their position.

The $fe \in FE$ directed flow edges represent a link between two adjacent control points (cp_{src}, cp_{dst}), where there is at least one lane between the two control points in the spreading direction of the traffic. To every fe directed flow edge, a ts time series is assigned, which stores historical traffic flow data. The ts time series of fe flow edge will contain those measurements, which are provided by the cp_{dst} destination control point of fe. For instance, if there is a directed flow edge between cp_1 (source) and cp_2 (destination) control points denoted by $fe_{1,2}$, then the $fe_{1,2}$ edge will contain the measurements of cp_2 control point.

Besides the data from fixed position sensors, the data model is also able to utilize GPS traces, if virtual control points are defined and trace data is aggregated in these points.

On Figure 1, an example of the traffic graph interpretation is depicted, it shows how the data model have to be interpreted on a simple road structure. Figure 1a illustrates a simple road network with control points, which are marked by cp_i identifiers. On Figure 1b, the directed flow graph of the previous road network is visualized. The cp_i identifiers on this figure are identical with the identifiers of the ones on Figure 1a, and there are $fe_{x,y}$ directed flow edges in the graph, if cp_x and cp_y control points are connected in the road network in the spreading direction of the traffic.

We also have to deal with the timeliness of our model. The different fixed position or GPS sensors sample the measured data type with different frequences based on their settings. Consequently the traffic analysis requires a homogeneous sampling frequency. Different aggregating time intervals are used in the literature for this purpose, which mainly depend on the task at hand.

Generally, narrow intervals, for example 10 seconds, are meaningless and really noisy. We have found that the most common time intervals are in minutes (5-10 minutes) [21], [22], but there are also many papers claiming that longer time intervals would be more effective, like quarter or half an hour [16], [23]. For our model, we chose a 30 seconds time interval because too long time intervals could hide important features of an unexpected event and the noisiness of the 30 seconds scale does not affect the correctness of the AIHI.

B. The steps of the algorithm

1) Initialization: Let us denote a time series of $fe_{src,dst}$ flow edge by $ts_{src,dst}$ in which data can be described as an ordered sequence of discrete measurements:

$$ts_{src,dst} = \{m_t\} \qquad t = 1, 2, \dots T \tag{1}$$

where m_t is the measured traffic count value at time t at the cp_{dst} control point.

The entry point of the algorithm will be an fe directed flow edge, for which the associated ts time series shows unexpected event between an arbitrary (t_{start}, t_{end}) time interval. The (t_{start}, t_{end}) time interval contains an unexpected event, if a statistically significant change can be detected in the behavior/shape of the ts time series between t_{start} and t_{end} compared to the ts_{hist} historical average, or in other words, ts time series contains an anomalous part compared to the ts_{hist} historical average.

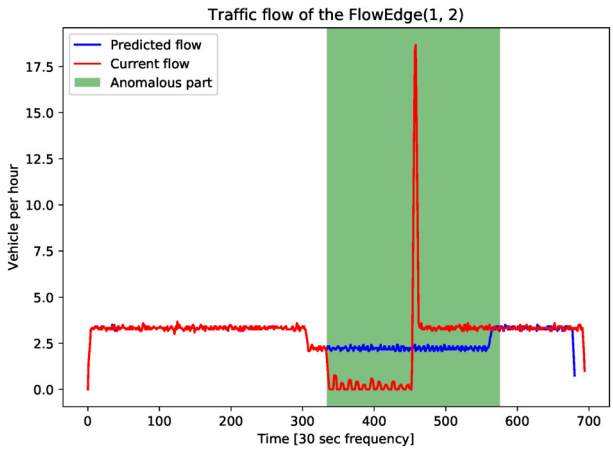


Fig. 2: Visualization of anomaly behavior compared to Predicted flow

Input :
- FG: Directed flow graph of the road network
- fe: The investigated directed edge
- t_{start}: The start time of the unexpected event

Output: The effects of the event organized in a tree structure

```
1  job_pool ← [];
2  visited_edges ← [];
3  ts_an = findAnomaly(fe.ts, t_start);
4  addJob({fe, ts_an, t_start, forward});
5  while job_pool is not empty do
6      j = getNext(job_pool);
7      addVisitedEdge(j.fe);
8      (b, i) = bestFitLag(j.ts_an, j.fe.ts, j.t_start,
         j.dir);
9      is_anomaly, next_ts_an =
         findAnomaly(j.ts, nj.t_start + b);
10     if is_anomaly then
11         s_neighs = getEdges(j.fe.cp_src);
12         foreach edge in s_neighs do
13             if j.fe.cp_src is edge.cp_dst and edge not
                 in visited_edges then
14                 addJob({edge, next_ts_an,
                     t_start + b, backward});
15             end
16         end
17         d_neighs = getEdges(j.fe.cp_dst);
18         foreach edge in d_neighs do
19             if j.fe.cp_dst is edge.cp_src and edge not
                 in visited_edges then
20                 addJob({edge, next_ts_an,
                     t_start + b, forward});
21             end
22         end
23     end
24 end
```

Algorithm 1: AIHI algorithm

There are two methods to discover such time intervals. The easiest way when we have apriori knowledge about the occured unexpected events like accidents or road closures as these can be used directly as the input of the AIHI algorithm. The other possible approach is to execute an extensive search in the raw historical dataset for unexpected events. This approach requires a classification model that is able to decide whether a $ts_{src,dst}$ time series contains an unexpected event or not.

The AIHI algorithm needs the following three inputs:

- The FG flow graph of the road network
- The fe flow edge, which was the source of the unexpected event
- The t_{start} time of the emergence of the unexpected event on fe

Utilizing these three inputs, the algorithm will follow the effect of the unexpected event through the traffic flow graph and determining those flow edges that could be affected by the input event.

2) Processing of a job: AIHI algorithm 1 uses a job pool based approach in which the whole investigation task is separated to smaller independent subtasks. In this case, a subtask is responsible for the investigation of whether the currently examined fe flow edge's ts time series is affected by the source unexpected event or not. To run a job, the following elements are necessary:

- An fe flow edge
- The ts_{an} time series, which contains the whole anomaly part identified by the source job
- The t_{start} emergence time of the anomaly in the source job
- The dir direction of the spread of the event (forward or backward), because the unexpected events of the road network can have an effect in both directions.

To start the algorithm, the first job will be created from the entry point. The entry point contains all necessary job input parameters, except the ts_{an} time series, thus by using the findAnomaly function (in Section III-B4), the anomalous part of the ts time series of fe flow edge have to be calculated. After that, the execution of the algorithm can be started and the processing of jobs will be continued until the pool has been emptied.

A job will execute these steps:

1) Find the best fitting $best\_lag$ time lag between the ts time series of fe flow edge and ts_{an} anomalous time series from t_start in the chosen dir direction (see Algorithm 2)
2) Check that an anomalous event can be identified from $best\_lag$ or not (see Algorithm 3)
3) If an anomalous event is detected during the second step, then the adjacent flow edges of the investigated fe flow edge are put into the job pool as new jobs in which the source job will be the current job

3) Find best lag: The BestFitLag function is responsible for determining the start of an anomalous event in the ts time series of the current $job.fe$ flow edge.

We can assume that the shape of the anomalous time series ts_{an} is quite similar to the anomaly observed in the actual ts time series of $job.fe$. To measure this similarity we defined a new distance function, called shape_dist (Equation 2). Contrary to other distance function like Manhattan, Euclidean or DynamicTimeWarping [24], it measures the similarity the time series' shape by differentiating changes in the different time series:

$$shape\_dist(x, y) = \sqrt{\sum_{i=1}^{n}((x_i - x_{i-1}) - (y_i - y_{i-1}))^2} \quad (2)$$

The shape_dist function is calculated with increasing $lag = 0, 1, 2, ...$ between ts time series and ts_{an} time series. It can

Input :
- ts_{an}: The time series containing the whole anomaly part
- ts: The time series of the fe flow edge
- t_{start}: The emergence time of the anomaly in the time series
- dir: The direction of the spread of the event (forward or backward)

Output:
- $bestlag$: The best fitting time lag
- $influence$: The level of influence

$last \leftarrow$ `dist` $(ts_{an},$ `shift` $(ts, t_{start}))$;
if dir *is* $forward$ **then**
  $i \leftarrow 1$;
end
if dir *is* $backward$ **then**
  $i \leftarrow -1$;
end
$lastlag \leftarrow 0$;
while `dist` $(ts_{anom},$ `shift` $(ts, t_{start} + i)) \leq last$ **do**
  $lastlag \leftarrow lastlag + i$;
end
$bestlag = i$;
$length = len(ts_{an})$;
$influence = \frac{1}{1+exp(\frac{1}{length} * last)}$;

Algorithm 2: BestFitLag

be assumed, that while the delay is increasing, the distance between the two time series will decrease until the best fit is reached. Thus if the calculated distance values start to increase, the possible best delay has been reached, because the adjacent road segments show high correlation in general. However sometimes the calculated delay can be just a local minimum, thus a simulate annealing is applied to find the global optimum.

Furthermore, the best distance value can be used to express the influence between the two flow edges, however a transformation is required, converting the shape_dist function's $[0, \inf)$ domain to $[1, 0]$ domain. Higher values mean a stronger influence, while lower values mean a weaker influence. Equation 4 is designed for this purpose:

$$distance = shape\_dist(ts_{an}, shift(ts, lastlag)) \quad (3)$$

$$influence = \frac{1}{1 + exp(\frac{1}{length} * distance)} \quad (4)$$

, where the $length$ parameter equals with the length of ts_{an}.

4) Find anomaly: The findAnomaly function (Algorithm 3) is responsible for determining whether an anomalous part starting from t_{start} can be identified. If an anomalous part is found, the function also returns its length.

The findAnomaly function exploits the observation, that the error of a prediction model significantly increases when

Input :
- ts: The time series of the fe flow edge
- ts_{hist}: The historical average time series of the fe flow edge
- t_{start}: The emergence time of the anomaly in the time series

Output:
- $is\_anomaly$: The input ts time series contains anomaly from t_{start} or not
- $next\_ts_{an}$: The anomaly part in the input ts time series if it exists

$model \leftarrow$ `exp_smooth` (ts_{hist});
$error \leftarrow$ `measure_error` $(model, ts_{hist})$;
$error\_dist \leftarrow$ `norm_dist` $(error)$
$length \leftarrow 0$;
while $ts[t_{start} + length]$ *from* $error\_dist$ **do**
  $length \leftarrow length + 1$;
end
if $length$ *is* 0 **then**
  $is\_anomaly \leftarrow false$;
else
  $is\_anomaly \leftarrow true$;
$next\_ts_{an} \leftarrow ts[t_{start}, t_{start} + length]$

Algorithm 3: findAnomaly

anomalous behavior can be observed. The error of prediction was analyzed and we could conclude, that the prediction error has a normal distribution in case of normal behavior (depicted on Figure 3), while the distribution of the error significantly differs in case of anomalous behavior. Thus the operating principle of findAnomaly is:

1) Fitting a prediction model on ts_{hist}
2) Running until the prediction error of the model returns to a normal distribution

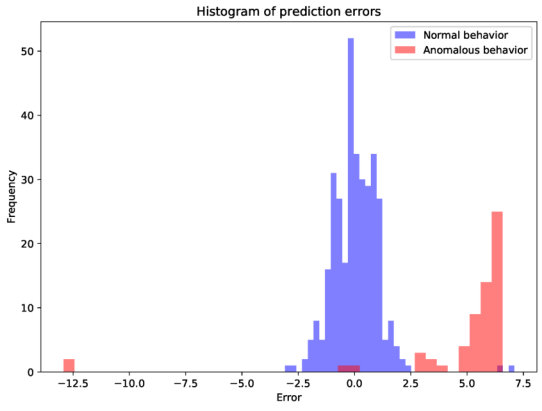

Fig. 3: Histogram of different prediction errors

Therefore for findAnomaly, a prediction model is constructed by applying a simple moving average on ts_{hist}, then

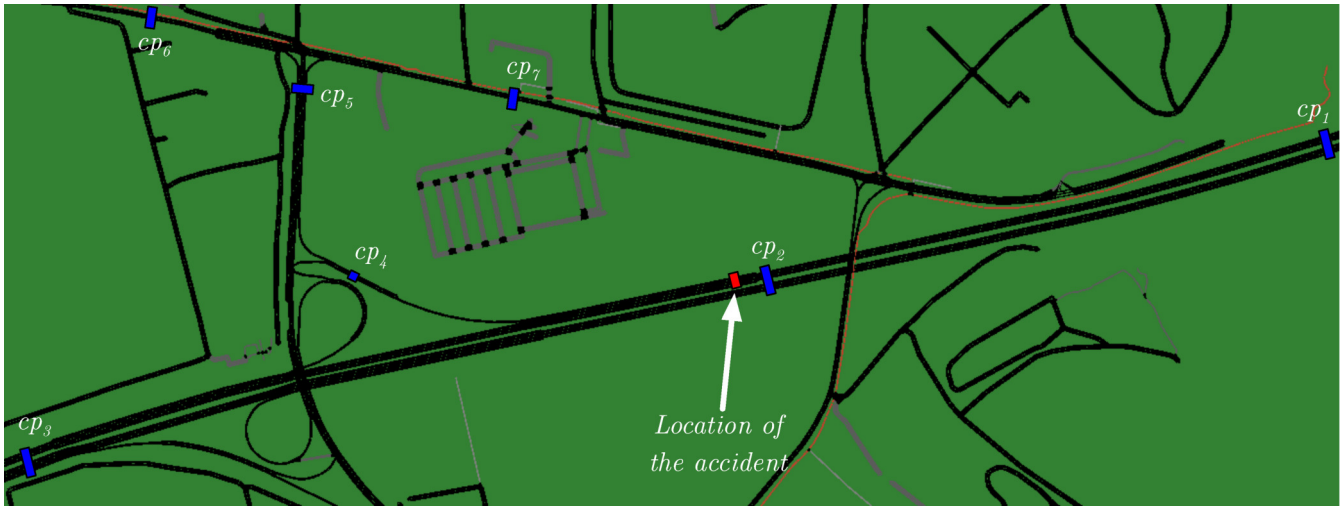

Fig. 4: The simulation map with location of traffic accident and control points

based on that model the distribution of the prediction error is determined. The algorithm starts from t_{start} and runs until the prediction error of the model returns to a normal distribution. This point in the time series is $length$ apart from t_{start}, therefore the length of the anomaly can be calculated. If the $length$ equals with zero, it means that ts does not contain an anomaly.

IV. Case study

After the implementation of the AIHI, in this section we will demonstrate its ability to follow the spread of the effect of a traffic accident through a traffic flow graph.

At first, we searched for datasets containing traffic flow data and traffic accidents as well, but unfortunately there was no such publicly available traffic flow dataset at the time of writing. Because of this, a simulation framework was used for the evaluation.

As the simulation framework, we chose Simulation of Urban Mobility (SUMO), a free and open traffic simulation suite, which is available since 2001. SUMO allows modeling of intermodal traffic systems, including roads, vehicles, public transport and pedestrians. Included with SUMO is a wealth of supporting tools, which handle tasks such as route finding, visualization, road network import from open street maps and emission calculation.

In our scenario, besides the real traffic flow data, a traffic accident had to be generated. The authors of [25] used traffic lights for this purpose, thus this approach had been applied in our simulation as well. The accident is simulated by opening only one of the four available lanes on a road.

In the simulation, high rank roads of Budapest's suburb are examined. Seven control points (using inductive loop detectors) were placed on the map as depicted on Figure 4. We simulated five hours of traffic flow, which was similar to afternoon rush hours. The vehicles are simulated with $speedFactor = normc(1, 0.1, 0.2, 2)$, which means that 95% of the vehicles drove between 80% and 120% of the legal speed limit. In the beginning we simulated normal traffic flow, then an one hour long traffic accident had been inserted after two and a half hours near to cp_2, so the effect of the accident could be identified first on $fe_{1,2}$ flow edge (Figure 2).

As mentioned in Subsection III-B1, the entry point of AIHI was $fe_{1,2}$ flow edge with t_{start} start time of the simulated traffic accident. The result of AIHI, is displayed on Figure 5. The spreading tree of the accident shows that the farther control points were, the bigger the detected time lags became, while the influences were decreasing as expected. The change of the pattern of the anomalous part was also visualised between cp_4 and cp_5 on Figure 6.

V. Conclusion

The road network of big cities is a complex and hard to analyze system in which the accurate quantification of interactions between nonadjacent road segments is almost an insolvable objective, because of the unique decisions of thousands of drivers which makes the interactions invisible. In this paper a novel algorithm (AIHI) has been presented, that is able to exploit unexpected traffic events to reveal the hidden connections between nonadjacent road segments and provides the following information:

- identify nearby road segments that could be affected by the event
- if a road segment is affected, the exact level of influence between the affected and accident road segments,
- the time delay: the time between the event and its detection on the affected road segments

Combining these new information sources with real-time traffic information, the accuracy of prediction models able to integrate external environmental variables can be increased.

We have demonstrated the capabilities of AIHI with simulations on a real road network which results can be depicted as spreading tree of the accident.

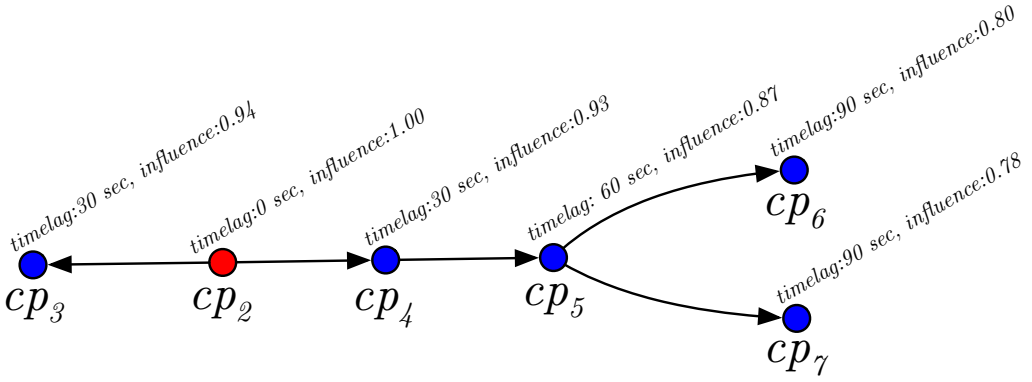

Fig. 5: Visualization of the AIHI's result. The examined control point was cp_2 (red dot), where the time lag is zero and the influence is 1.0. Other influenced control points in the road network identified by AIHI are marked with blue dots.

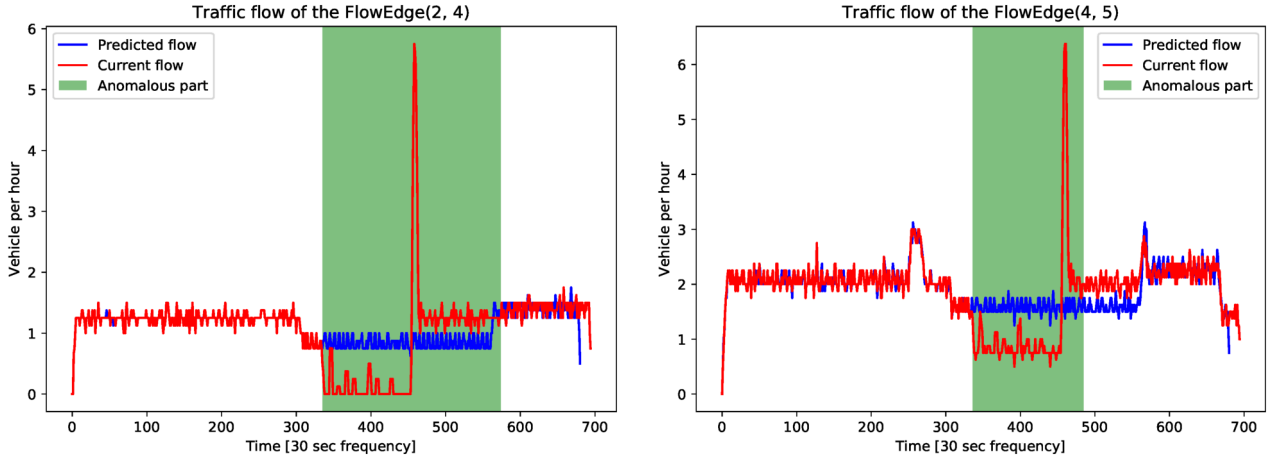

(a) Traffic flow of FlowEdge(2, 4)

(b) Traffic flow of FlowEdge(4, 5)

Fig. 6: On Figure 6a and Figure 6b the measured traffic flows are depicted at cp_4 and cp_5, respectively. On Figure 6b the effect of other connected roads can be seen, where the anomalous part starts to differ compared to the anomalous part of Figure 6a

.

In the future, we are planning to extend prediction models like Neural Networks (NN) and KNN to utilize the result of AIHI. We also want to develop a classification model able to decide whether a time series contains an unexpected event or not, because the input of parameters of AIHI are currently determined manually. Applying the classification model, the determination of AIHI's input parameters will be automated.

***Abstract*—We analyze performance of slotted ALOHA systems with energy harvesting nodes and retry limit. We assume that the capacities of data and energy buffer at a node are one packet and E packets, respectively, and that one data packet transmission consumes one energy packet. The data and the energy packet arrival processes are modeled by independent Bernoulli processes. Under these assumptions, we develop a node-centric two-dimensional discrete time Markov chain model. Based on the equilibrium point analysis, we derive the fixed point equation with respect to the ratio of nodes transmitting a data packet. The accuracy of numerical results derived from the fixed point equation is verified by computer simulation. The numerical results indicate that throughput, the offered traffic and the discard probability roughly depend on the minimum of the data packet generation probability and the energy packet generation probability.**

I. Introduction

ENERGY harvesting techniques have been attracting researchers' interest in minimization of nodes by removing batteries. For example, in Wireless Sensor Networks (WSNs), a huge number of such battery-less tiny nodes may be dispersed in a wide area. Each node may harvest their energy from environment. When a huge number of nodes with bursty traffic contend with one another for a common communication channel such as WSNs, a Medium Access Control (MAC) protocol plays an important role which can greatly influence performance of networks with or without the use of energy harvesting techniques [1].

Performance of MAC protocols with energy harvesting nodes has been extensively investigated in the literature. Moradian and Ashtiani [2] analyzed the maximum stable throughput of slotted ALOHA systems consisting of finite number of energy harvesting nodes. They constructed a node-centric two-dimensional Discrete-Time Markov Chain (DTMC) model with (j, x), where j is the number of energy packets in the energy buffer and x is the elapsed time for the next retransmission. Foss et al. [3] discussed stability conditions of slotted ALOHA systems with infinite population of energy harvesting nodes from the system-centric viewpoint of a queueing network. The system is described by a two-tuple (q, v), where q and v are the total number of data and energy packets in the system, respectively. Bae [4] analyzed the delivery ratio of slotted ALOHA systems with energy harvesting nodes under delay constraints. A node-centric two-dimensional DTMC model (W, E) was constructed, where W is the elapsed sojourn time of the leading data packet in the data buffer and E is the number of energy packets in the energy buffer. Notice here that no retry limit of unsuccessful data packet is considered in the above literature [2], [3].

In this paper, we analyze performance of slotted ALOHA systems consisting of energy harvesting nodes with retry limit [5] using a node-centric two-dimensional DTMC model. Then, the performance is analyzed in terms of throughput, average transmission delay and discard probability of data packet due to excessive retransmission trials.

II. System Model

Consider a slotted ALOHA system consisting of N energy harvesting nodes contending for a common channel. Each node is equipped with not only a single data packet buffer but also an energy packet buffer of E-packet capacity. From the single-buffered assumption each node can store only one data packet. The length of data packet to be transmitted is assumed to be fixed to the unit length. The time axis is divided into slots which suffices for a single data packet transmission. The propagation delay between nodes and the common receiver is negligible. A data packet arrives independently at each node with probability λ in a slot. A node harvests an energy packet with probability ε in a slot. A node can transmit a data packet with probability p, if its energy buffer is not empty. One energy packet is consumed when a node transmits a data packet. We consider neither capture effects nor channel noise, so that a data packet transmission succeeds, only if no other data packets are transmitted simultaneously. All data packets involved in collision are to be retransmitted, until the number of retransmission trials including the first transmission reaches to the retry limit L. As an example, a system model with two energy harvesting nodes is depicted in Fig. 1.

This work was partly supported by Japan Society for the Promotion of Science under Grant-in-Aid for Scientific Research (C) (KAKENHI No. 25420379).

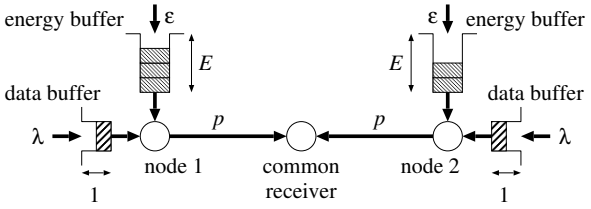

Fig. 1. System model of two energy harvesting nodes with single data buffer and with energy buffer of E-packet capacity.

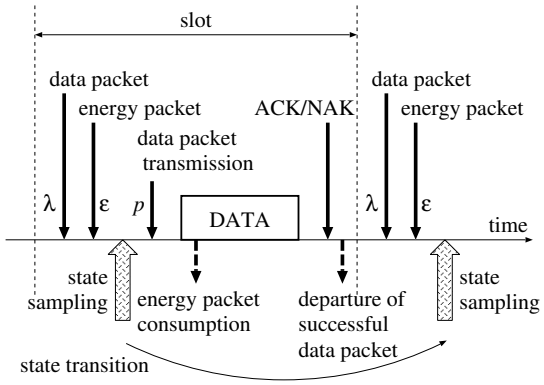

Fig. 2. Timing chart for state sampling.

III. Discrete Time Markov Chain Model

In order to accurately analyze the steady-state performance of the system, it is required to construct and solve a system-centric DTMC model. However, it demands a considerably high dimensional DTMC model, which is complex to solve. Here, we take advantage of an equilibrium point analysis (EPA) [6], [7], which approximately evaluate the steady-state performance by using a node-centric DTMC model with an assumption that each node operates in an independent manner.

A. State Sampling

Consider a certain node. Let i be the next number of transmission trials for a data packet in the node; $i = 0, 1, 2, \ldots, L$. Note that a node with $i = 0$ implies that it has no data packet. Let j denote the number of energy packets in the node; $j = 0, 1, 2 \ldots, E$. Then, from the single-capacity assumption for data packets, the state of each node in a slot can be described by a two-tuple (i, j).

In order to facilitate construction of a DTMC model with respect to the state of a node, we first define the order of the stochastic events in a time-slot. As addressed in the previous section, there may be four stochastic events in a slot; data packet generation with probability λ, harvest of an energy packet with probability ε, data packet transmission with probability p and outcome of data packet transmission; success or failure. At the end of a slot, a node which just transmitted a data packet receives a positive acknowledgment (ACK) or a negative acknowledgment (NAK).

B. Two-Dimensional DTMC Model

According to the sampling timing of the state, we can construct a node-centric two-dimensional DTMC model with respect to (i, j) for $i = 0, 1, \ldots, L$ and $j = 0, 1, \ldots, E$. States (i, j) for $i > 0$ imply that a node is backlogged; that is, a data buffer at a node is occupied. States (i, j) for $i > 0$ and $j > 0$ are those in which a node can transmit a data packet with probability p, since it has sufficient energy packets for data packet transmission.

C. State Transition Probabilities

State transition probability $p_{(i,j),(k,\ell)}$ from State (i, j) to State (k, ℓ) can be obtained by taking into consideration the four stochastic events between two consecutive sampling points in Fig. 2;

1) data packet transmission at a backlogged node with non-empty energy buffer,
2) outcome of data packet transmission; success or failure,
3) data packet generation at a node with empty data buffer,
4) arrival of an energy packet.

First, suppose that a node has no data packet; that is, a node is in State $(0, j)$ for $j = 0, 1, \ldots, E$. If no data packet arrives and if an energy packet arrives, then a node moves to State $(0, j + 1)$. We have state transition probabilities for thsese events;

$$p_{(0,j),(0,j+1)} = (1 - \lambda)\varepsilon \tag{1}$$

for $j = 0, 1, \ldots, E - 1$. If a data packet arrives without an energy packet, then state transition probabilities are

$$p_{(0,j),(1,j)} = \begin{cases} \lambda(1 - \varepsilon) & \text{for } j = 0, 1, \ldots, E - 1 \\ \lambda & \text{for } j = E \end{cases} \tag{2}$$

If both data and energy packets arrive, then we have

$$p_{(0,j),(1,j+1)} = \lambda\varepsilon \tag{3}$$

for $j = 0, 1, \ldots, E - 1$.

Next, suppose that a node is backlogged. A state transition from (i, j) to $(i, j + 1)$ occurs, if a data packet is not transmitted and if an energy packet arrives. Then, we have

$$p_{(i,j),(i,j+1)} = \begin{cases} \varepsilon & \text{for } j = 0 \\ (1 - p)\varepsilon & \text{for } j = 1, 2, \ldots, E - 1 \end{cases} \tag{4}$$

for $i = 1, 2, \ldots, L$. Note that no data packet can be transmitted if a node is in State $(i, 0)$, since it has no energy. A node moves from State (i, j) to State $(i+1, j-1)$, if a data packet transmission results in failure and if no energy packet arrives:

$$p_{(i,j),(i+1,j-1)} = pP_{\text{fail}}(1 - \varepsilon) \tag{5}$$

for $i = 1, 2, \ldots, L - 1$ and $j = 1, 2, \ldots, E$, where P_{fail} is the probability of transmission failure of a data packet, which is formulated later. If a node fails in data packet transmission and if an energy packet arrives, then state transition probabilities are

$$p_{(i,j),(i+1,j)} = pP_{\text{fail}}\varepsilon \tag{6}$$

for $i = 1, 2, \ldots, L-1$ and $j = 1, 2, \ldots, E$. If a data packet transmission succeeds and if no data packet and no energy packet arrive, then a node transits from State (i, j) to State $(0, j-1)$:

$$p_{(i,j),(0,j-1)} = \begin{cases} p(1-P_{\text{fail}})(1-\lambda)(1-\varepsilon) \\ \qquad \text{for } i = 1, 2, \ldots, L-1 \\ p(1-\lambda)(1-\varepsilon) \quad \text{for } i = L \end{cases} \tag{7}$$

for $j = 1, 2, \ldots, E$. Note that for $i = L$, a node moves from State (L, j) to State $(0, j-1)$ when it transmits a data packet irrespective of success or failure. If only an energy packet arrives without a new data packet after successful data packet transmission, then we have

$$p_{(i,j),(0,j)} = \begin{cases} p(1-P_{\text{fail}})(1-\lambda)\varepsilon & \text{for } i = 1, 2, \ldots, L-1 \\ p(1-\lambda)\varepsilon & \text{for } i = L \end{cases} \tag{8}$$

for $j = 1, 2, \ldots, E$. If a new data packet is generated without an energy packet generation after successful data packet transmission or after data packet discard, state transition probabilities are

$$p_{(i,j),(1,j-1)} = \begin{cases} p(1-P_{\text{fail}})\lambda(1-\varepsilon) \\ \qquad \text{for } i = 1, 2, \ldots, L-1 \\ p\lambda(1-\varepsilon) \quad \text{for } i = L \end{cases} \tag{9}$$

for $j = 1, 2, \ldots, E$. If an energy packet is generated for the above case, then we have

$$p_{(i,j),(1,j)} = \begin{cases} \lambda p(1-P_{\text{fail}})\varepsilon & \text{for } i = 1, 2, \ldots, L-1 \\ \lambda p\varepsilon & \text{for } i = L \end{cases} \tag{10}$$

for $j = 1, 2, \ldots, E$.

Finally, the state transition probabilities for trivial state transitions are obtained as

$$p_{(i,j),(i,j)} = 1 - \sum_{(k,\ell)\neq(i,j)} p_{(i,j,),(k,\ell)} \tag{11}$$

for $i = 0, 1, \ldots, L$ and $j = 0, 1, \ldots, E$.

D. Steady-State Probabilities

Let us denote the steady-state probability of State (i, j) by $\pi_{(i,j)}$ for $i = 0, 1, \ldots, L$ and $j = 0, 1, \ldots, E$. Then, according to the theory of Markov chains, the steady-state distribution $\{\pi_{(i,j)}\}$ can be obtained by solving a system of linear equations;

$$\begin{bmatrix} \vdots \\ \pi_{(m,n)} \\ \vdots \end{bmatrix} = \begin{bmatrix} & \vdots & \\ \cdots & p_{(i,j),(m,n)} & \cdots \\ & \vdots & \end{bmatrix} \begin{bmatrix} \vdots \\ \pi_{(i,j)} \\ \vdots \end{bmatrix} \tag{12}$$

and

$$\sum_{i=0}^{L} \sum_{j=0}^{E} \pi_{(i,j)} = 1. \tag{13}$$

IV. Performance Analysis

A. Fixed Point Equation

Let τ denote a ratio of transmitting nodes tentatively. Since a backlogged node with one or more energy packets transmits its data packet with probability p, we have

$$\tau = p \sum_{i=1}^{L} \sum_{j=1}^{E} \pi_{(i,j)} \tag{14}$$

As shown in the previous subsection, the steady-state distribution $\{\pi_{(i,j)}\}$ is a function of the probability of transmission failure P_{fail}, which can be formulated as

$$P_{\text{fail}} = 1 - (1-\tau)^{N-1} \tag{15}$$

from the assumption of the independent operation of nodes underlaid in EPA. Here, a combination of (14) and (15) together with (1)–(13) provides a fixed point equation with respect to τ for given N, L, E, λ, ε, and p, which can be numerically solved.

Once we obtain the value of τ, we can evaluate various performance measures as follows.

B. Throughput

The offered traffic is the average number of nodes which are transmitting their data packet in a slot. It follows from the independent operation assumption of nodes that

$$G = N\tau. \tag{16}$$

Then, we can evaluate the throughput as the average number of successful nodes per slot;

$$S = (1-P_{\text{fail}})G = N\tau(1-\tau)^{N-1}. \tag{17}$$

C. Average Transmission Delay

According to Little's result [7], the average transmission delay can be obtained as the ratio of the average number of backlogged nodes to the average number of nodes departing from the backlogged states. In the steady-state, the average number of backlogged nodes is given as

$$B = N \sum_{i=1}^{L} \sum_{j=0}^{E} \pi_{(i,j)}. \tag{18}$$

Nodes can depart from the backlogged states due to successful data packet transmission or discard of their data packet experiencing an excessive transmission failures. The average number of successful nodes per slot is given by (17). On the other hand, a data packet is discarded, if data transmission from a node in State (L, j) results in failure for $j = 1, 2, \ldots, E$. The average number of discarded packets per slot is evaluated as

$$N_d = NpP_{\text{fail}} \sum_{j=1}^{E} \pi_{(L,j)}. \tag{19}$$

Therefore, we can obtain the average transmission delay as

$$D = \frac{B}{S + N_d}. \tag{20}$$

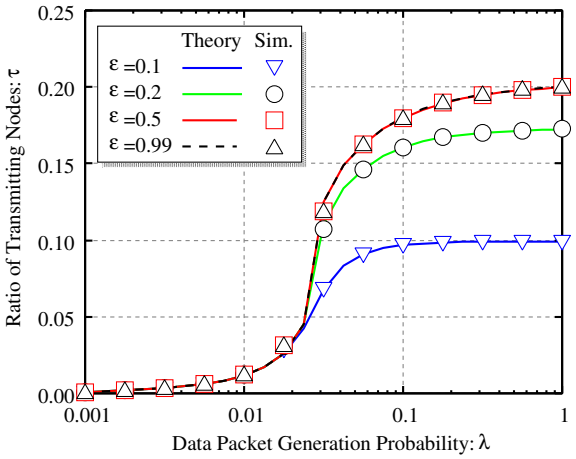

Fig. 3. Comparison of the ratio of transmitting nodes between the fixed point analysis and computer simulation for $N = 20$, $L = 20$, $E = 5$ and $p = 0.2$.

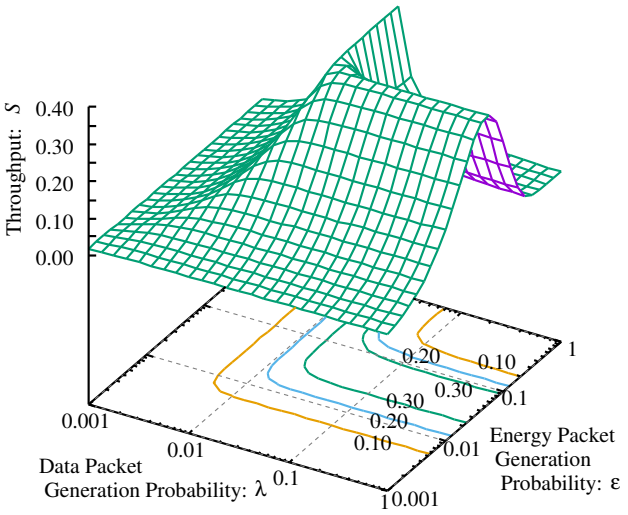

Fig. 4. Throughput for $N = 20$, $L = 20$, $E = 5$ and $p = 0.2$.

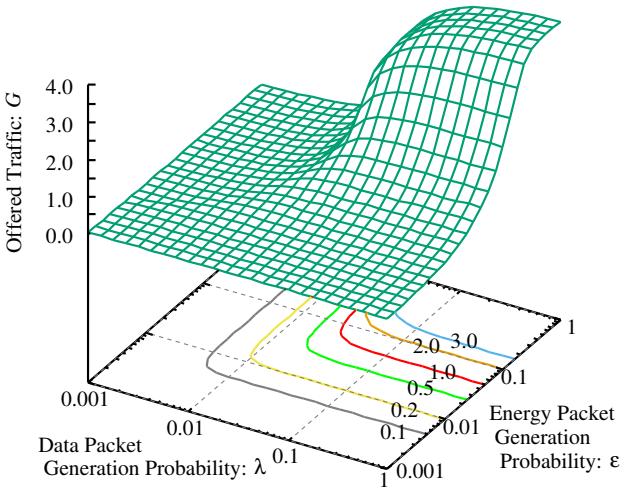

Fig. 5. Offered traffic for $N = 20$, $L = 20$, $E = 5$ and $p = 0.2$.

D. Discard Probability of Data Packet

When we impose the retry limit on a data packet, the probability that a generated data packet is discarded is important performance measure. A data packet is released from data buffer at a node because of successful transmission or compulsory discard. Thus, the ratio

$$P_d = \frac{N_d}{S + N_d} \tag{21}$$

provides the discard probability of a data packet.

V. Numerical Results

A. Accuracy Verification

Since EPA assumes the independent operation of nodes, it is required to verify the accuracy of the derived results. As shown in the previous section, various performance measure can be evaluated from the numerical result of τ obtained by solving the fixed point equation (14). Here, we examine the accuracy of our analysis via the ratio of transmitting nodes τ.

The analytical and computer simulation results are shown in Fig. 3 for $N = 20$, $L = 20$, $E = 5$ and $p = 0.2$. From Fig. 3 it is clear that the analysis using EPA offers sufficiently accurate numerical results. Also, it can be found that the ratio of transmitting nodes is independent of $\varepsilon \geq 0.5$

B. Performance Measure

Based on the fixed point equation (14), the numerical results for $N = 20$, $L = 20$, $E = 5$ and $p = 0.2$ in terms of throughput (17), the offered traffic (16), the average transmission delay (20) and the discard probability of data packet (21) are shown in Fig. 4, Fig. 5 Fig. 6 and Fig. 7, respectively, as a function of the data packet generation probability λ and the energy packet generation probability ε.

From Fig. 4, we can observe that the shape of throughput surface exhibits a weak symmetric relationship between data packet generation probability λ and energy packet generation probability ε. That is, we can recognize that throughput roughly depends on $\min[\lambda, \varepsilon]$. A backlogged node can transmit no data packet, unless it has one or more energy packets. Conversely, a node with empty data buffer can transmit no data packet, even if it has one or more energy packets. This relationship results in weak symmetry of throughput between λ and ε. It is widely confirmed that throughput of slotted ALOHA systems is maximized when the offered traffic is one data packet per slot. In fact, it follows from Fig. 5 that the offered traffic which achieves the maximum throughput in Fig. 4 is around one data packet per slot; $G \approx 1.0$. Comparing Fig. 5 to Fig. 4, we can find that the shape of the contours projected on the λ-ε plain is closely related. Also, we can perceive that the well-known relationship $S = Ge^{-G}$ approximately holds between Fig. 4 and Fig. 5.

Next, from Fig. 6, both the shapes of the surface of the average transmission delay and the contours on the λ-ε plain differ from those of those in Fig. 4 and Fig. 5. We can observe no symmetry between λ and ε. Transmission delay

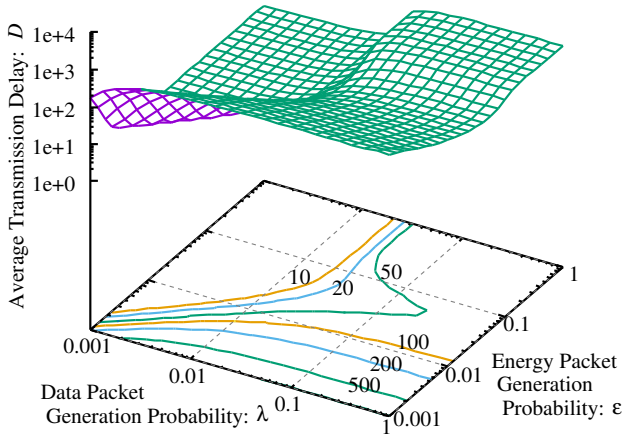

Fig. 6. Average transmission delay of data packet for $N = 20$, $L = 20$, $E = 5$ and $p = 0.2$.

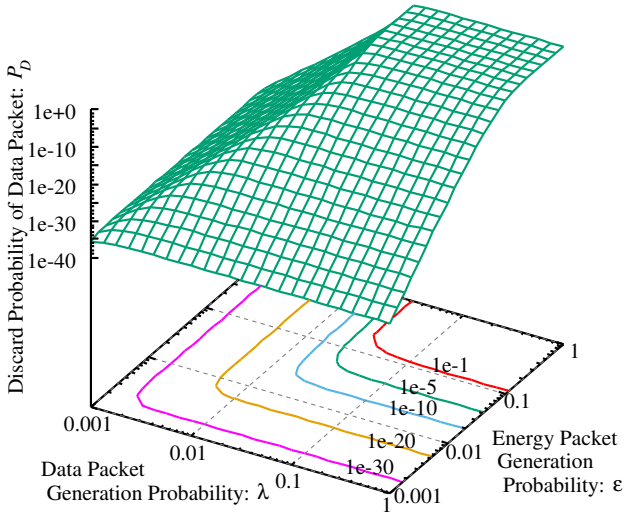

Fig. 7. Discard probabiltiy of data packet for $N = 20$, $L = 20$, $E = 5$ and $p = 0.2$.

is defined as the elapsed time-slots between the data packet generation and its departure from the system due to successful transmission or discard. Hence, transmission delay increases for small ε, since the generated data packet has little chances to be transmitted due to the lack of the energy despite the data packet generation probability λ. For small λ the average transmission delay tends to decrease according to an increase of ε. This is because the data packet has more chances to be transmitted for large ε and it has less possibility to collide with other simultaneously transmitted data packets because of small λ. For given $\lambda > 0.05 = 1/N$, the average transmission delay has its minimum at around $\varepsilon = 0.05 = 1/N$. For small $\varepsilon < 0.05$, the average transmission delay increases due to less chances for transmission. On the other hand, for $\varepsilon > 0.05$, increment of the offered traffic, as shown in Fig. 5, results in more packet collisions, so that the average transmission delay is enlarged.

Finally, the contour of the discard probability of data packet P_D in Fig. 7 exhibits the same tendency as throughput in Fig. 4 and the offered traffic in Fig. 5. However, in contrast to Fig. 4 and Fig. 5, the discard probability is rapidly degraded several orders of magnitude against small fluctuation of λ and ε even if λ and ε are sufficiently small.

VI. Conclusion

In this paper, we analyzed the performance of slotted ALOHA systems consisting of energy harvesting nodes with retry limit. We assumed that the capacities of data and energy buffer at a node are one packet and E packets, respectively, and that one data packet transmission consumes one energy packet. The data and the energy packet arrival processes are modeled as independent and identically distributed Bernoulli processes. Under these assumptions, we developed a node-centric two-dimensional discrete-time Markov chain model, whose states represent a node state described by a two-tuple of the number of data packets in the data buffer and the number of energy packets in the energy buffer. According to the concept of the equilibrium point analysis, the fixed point equation with respect to the ratio of nodes transmitting a data packet was derived.

Based on the numerical results obtained from the fixed point equation, we derived expressions of throughput, the offered traffic, the average transmission delay and the discard probability of data packet. We verified the theoretical results by means of computer simulation. The numerical results indicated that throughput, the offered traffic and the discard probability roughly depend on the minimum of the data packet generation probability and the energy packet generation probability.

Generalization and relaxation of the assumption such as an independent property of the energy packet arrival process are left for further investigation.

***Abstract*—Universal serial bus can be considered a cost-effective and high-throughput communication medium for sensor networks and multinode control or data acquisition systems, especially for prototyping purposes. In a prototype system, a PC or Mac computer with a general-purpose operating system is often selected as a host or root node for the USB bus and it acts as a central data collector, supervisory user interface, and network traffic scheduler. However, achieved communication performance is often unsatisfactory since USB stack drivers incorporated in Windows, Linux, or macOS operating systems are not optimised for such specific purposes. The paper shows how an appropriately selected and implemented user application communication schedule, making use of operating system drivers pipelining and multitasking capabilities, can substantially improve USB network throughput and reduce communication latency.**

Keywords*—*universal serial bus; sensor network; distributed and networked control and data acquisition systems; rapid prototyping; communication scheduling; USB stack pipelining and multitasking.

I. Introduction

A COMMUNICATION channel constitutes a crucial part of every sensor network, distributed data acquisition system, or a networked control system. Its performance affects the overall system quality of service. For measurement data acquisition solutions, which often process large streams of data, the most important network characteristic is its throughput. For closed loop control applications the most critical parameter is the round trip time as it directly influences the net loop time delay. There are various networks and protocols available with different properties and characteristics. They differ in popularity, openness, initial costs and implementation efforts.

For small-scale distributed control and data acquisition systems, a full-speed variant of the Universla Serial Bus (USB) 2.0 can be considered an attractive and convenient choice, especially well suited for prototyping purposes. It provides low-cost, high-throughput communication channel with favourable performance-to-price ratio. The network infrastructure can be built using inexpensive and easily available hardware components. Software USB stacks and drivers are readily available for most common general-purpose operating systems (OS), like Windows, Linux, or macOS, which can host popular rapid control prototyping (RCP) software engineering tools like MATLAB/Simulink or LabVIEW. Modern microcontrollers (MCU) and system on chips (SoC), on which network nodes are likely to be built, are routinely equipped with a USB device port peripheral with an integrated PHY module. High-performance USB device stacks are usually available free of charge from MCU manufacturers.

Unfortunately, a USB stack incorporated in a general-purpose OS is usually not well suited for measurement data acquisition or real-time closed-loop control systems, since it has been designed and optimised for different applications. Hence, the performance of such prototype configurations can be poor unless special measures are undertaken. The paper shows how an appropriately selected communication schedule can substantially improve throughput and timing characteristics of a multinode USB 2.0 network comprising PC computer running Windows 7 OS and MATLAB RCP tool as a host node and several MCU-based full-speed device nodes. The schedule is realized by a user application coded as a MATLAB M-file script and does not require any modifications to the standard OS USB stack. Hence, it could be easily implemented under any RCP tool and executed by any unprivileged OS user. The solution takes advantage of a pipelined and multitasked processing implemented by the OS USB driver stack.

The topic of USB bus applications for data acquisition or control purposes is relatively popular in the literature where numerous examples of various such systems can be found. However, less work is reported concerning communication performance optimization and characteristics adaptation. Some researchers restrict their investigations to one-to-one communication systems, comprising a single host and a single device node [1], [2], [3], [4], [5]. Their solutions employ either a USB-to-UART adapter [1], an integrated circuit standalone USB device controller connected to an MCU [2], [3], or

† Deceased.

an MCU or SoC device with an integrated USB peripheral module [4], [5]. Performances of such systems, expressed in terms of data throughput or timing properties, are considered in [6], [7], [8], [9]. Other authors present applications of multinode USB networks for various data collecting or control purposes, including industrial systems, home automation, or virtual instrumentation for power monitoring [10], [11], [12], [13], but do not investigate system performances extensively. Such a study can be found in [14], while the problem of nodes synchronisation is addressed in [15], [16]. Some authors propose hybrid solutions with the USB bus connecting a host computer and a single controller of another multidrop bus, like RS485, CAN, or I2C [17], [18].

The abundance of USB control and data acquisition solutions, on one hand, and rarity of extensive performance analysis and communication optimisation recommendations, on the other hand, encouraged the authors of this article to devote their research to the latter topic.

The paper is organised as follows. An introduction with motivations and a literature review has been given in section I. Section II presents hardware and software architecture of the test bench system that has been used to verify effectiveness of proposed communication schedules for network performance improvement. Four different schedules considered in the paper are elaborated in Section III. Results of experiments are given and discussed in section IV. Section V provides final remarks and further considerations and is followed by acknowledgements and a reference list.

II. Hardware and software architecture of a test system

A. Host and device nodes

Main hardware and software components of a test system, built in order to measure communication performances for various polling schedules, are shown in Fig. 1. Their technical characteristics are given in Tab. I. A portable PC computer running MS Windows OS and hosting MATLAB application is used as a host node of the USB network. A user application responsible for polling all device nodes is coded as an M-file script running in MATLAB environment. The standard USB driver stack of the OS is employed and standard OS Application Programming Interface (API) is used. Device nodes are implemented on an MCU with integrated USB device port using C++ language and bare metal programming approach. A software USB device stack provided by the MCU manufacturer is employed, however some modifications of the stack code for latency reduction are implemented. In a real application, the device node is expected to interface with a physical system being controlled or monitored. However, for communication performance evaluation, this system functionality is irrelevant and has been omitted.

B. USB transfer mode and speed selection

Out of three possible transmission speeds offered by the USB 2.0 specification: low (LS), full (FS), and high (HS), the full speed is a reasonable choice for moderately demanding applications. The data rate is relatively high compared to CAN, RS-485, or similar standards, and the hardware implementation on the USB device side is simplified, as most modern MCU-s and SOC-s incorporate complete full-speed USB peripheral modules. Hence, the FS variant has been selected for USB devices in the study presented in the paper.

There are four transfer modes available with the USB 2.0 protocol: control, interrupt, isochronous, and bulk [19], [20]. Of these, the bulk mode is a natural choice for a distributed system transferring potentially a large amount of data. Unlike the isochronous one, it provides error detection and correction features. Number of transactions allowed in a single USB frame is not limited as with interrupt mode. Although there is no bandwidth reservation for a bulk transfer, it can consume up to 100% of the available bandwidth, provided that there are no other modes transfers scheduled. Large allowable data packet size helps to reduce transmission overhead and thus allows high data throughput.

A standard and popular Communication Device Class (CDC) has been selected for the test application. Software drivers for CDC class are routinely incorporated in most OS-es, making it attractive for rapid prototyping purposes, as no extra programming is required from the user. Virtual Com Port (VCP) driver is used on the host site. It allows standard OS API as well as standard MATLAB functions set for serial port handling to be employed.

C. Data and control flow in the system

Fig. 2 shows relations between MATLAB API function calls, OS API function calls, USB bus transactions, and device node actions. A user M-file script implements polling policy with each individual device node contacted once in a single cycle. The cycle is repeated endlessly. MATLAB *serial* object as well as *fwrite* and *fread* functions are used. Their calls are translated into *write* and *read* OS API calls and interact with the OS USB stack via VCP and CDC drivers. Hardware host and device controllers on the PC and MCU side, respectively, as well as USB 2.0 hubs are engaged in data transfer over

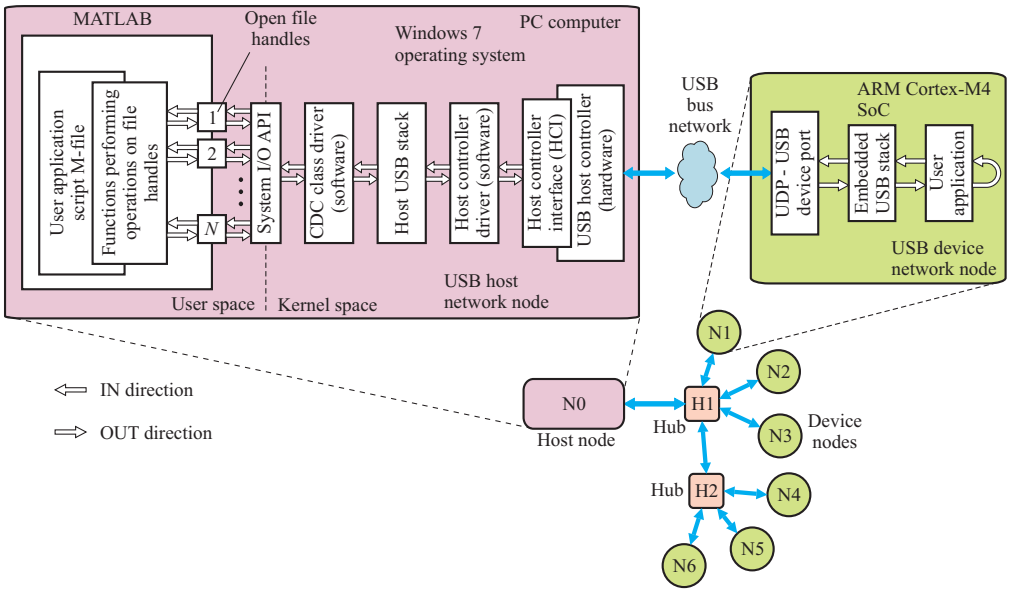

Fig. 1. Hardware and software architecture of the test bench system.

the network. The embedded MCU application on the device side responds to each host query with a predefined amount of data. Greyed and dash-dotted components to the right in the figure, usually present in a real systems, are omitted in the test configuration. The USB device stack provided by the MCU manufacturer has been streamlined by the authors to reduce latency it introduces. It helps to focus the performance study on the network rather than device properties.

In a real control or measurement acquisition system the host is supposed to send to the device control values to be fed to a control plant or parameters controlling the measurement process. The device, on the ohter hand, sends to the host measurement results. One can expect data size asymmetry between *write* and *read* operations with small units of data being sent to the device and large amounts of data being received due to a multichannel or high speed measurements. This expected asymmetry has been taken into account during tests presented further in the paper.

III. User Application Polling Schedules

Four different schedules of device nodes polling by the host side user application are investigated in the article. They are defined, explained and named in the following subsections.

A. Direct interleaved schedule.

Arguably the simplest and the most natural polling scheme is presented in Fig. 3. The user application running on the host node uses *write* call to send a query to a device node and then calls *read* function to wait for a reply. As soon as the data arrives, the host proceeds to the next device. Having finished a full cycle, the host begins a subsequent one. Let us call the duration of a single cycle the *network repetition time* (NRT). It will be used for communication performance evaluation. We will refer to the presented scheme as *direct interleaved schedule*, as *write* and *read* calls alternate and the scheme does not involve any distinct preparatory stage.

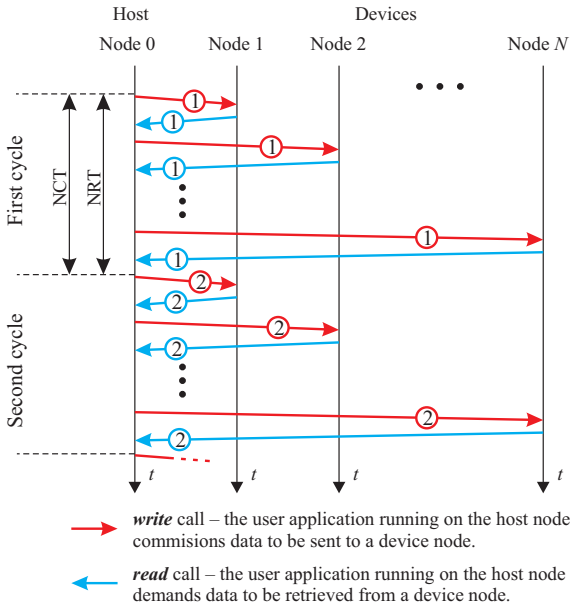

Fig. 3. Direct interleaved schedule – pattern of *write* and *read* I/O functions calls by the user application running on the host node. Encircled numbers on arrows help to match related writing and reading operations (the query and the response corresponding to it).

B. Advanced interleaved schedule

The *advanced interleaved schedule* shown in Fig. 4 differs from the one presented in the previous subsection in having a special initial stage. During this state the host *in advance* writes data to all devices in turn without waiting for any reply. Then it proceeds as with the *direct interleaved schedule*, applying *read* and *write* operations pair to each device in turn

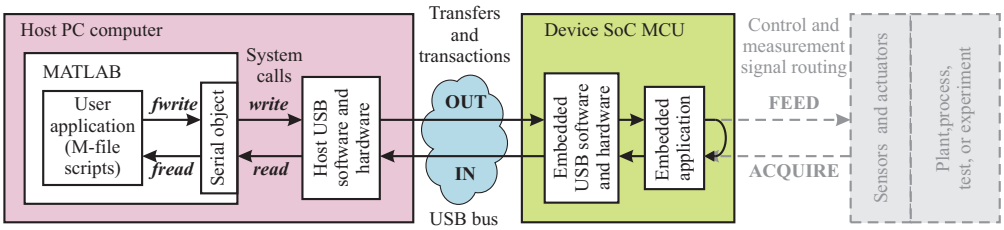

Fig. 2. Relations between user application and OS API function calls and USB bus transaction types.

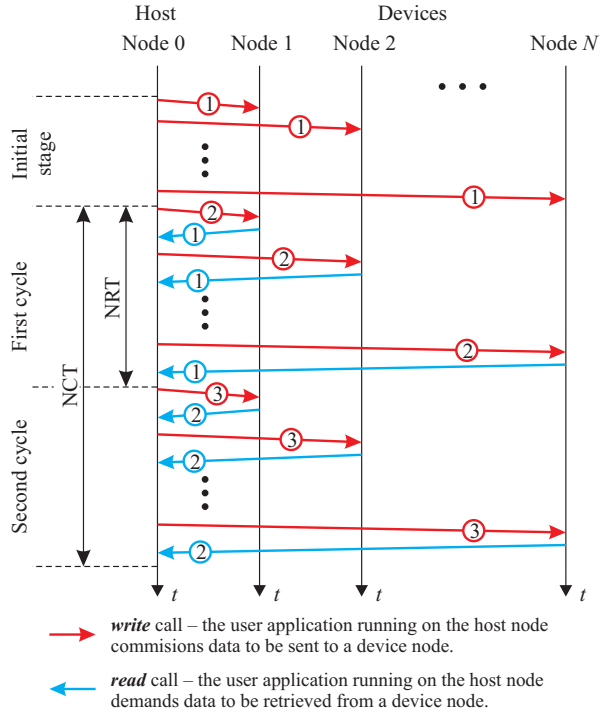

Fig. 4. Advanced interleaved schedule. The *network cycle time* (NCT) equals twice the *network repetition time* (NRT).

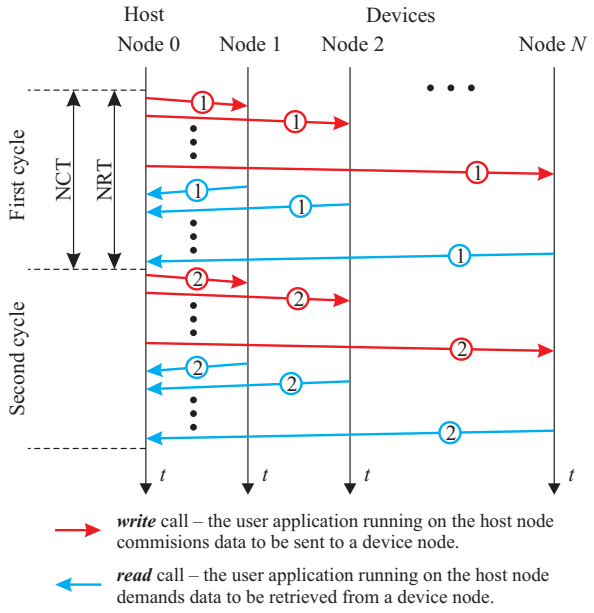

Fig. 5. Direct aggregated schedule. The *network cycle time* (NCT) is equal to the *network repetition time* (NRT).

and repeating the cycle. Thus, there is a sustained excess of writes over reads for each device. It can improve the communication performance by taking advantage of OS USB stack pipelining, buffering, and multithreading capabilities. A new measure called *network control time* (NCT) is introduced in Fig. 4. It is equal to the time elapsing between the beginning of a cycle where *write* operation are effected and the end of a cycle where corresponding *read* calls are completed (note numbers in circles on arrows in the figure). Because of the presence of the initial stage of the schedule, the NCT parameter equals twice the NRT in average. The *control* term in the NCT name alludes to the fact that in a closed-loop control application, NCT rather than NRT parameter influences the quality of control as it contributes to the net time delay in the loop.

C. Direct aggregated schedule

An important drawback of the schedule given in the previous section is that each response received from a device corresponds to last but one query instead of the last one. Hence, there is a one-step query–response shift or delay. Should it be unacceptable for a particular application, one may choose an alternative approach shown in Fig. 5. There is no special initial stage. In every regular cycle the host *aggregates* all write and all read operations in two separate groups, with all writes executed before all reads. That approach provides the stack with an additional time reserve for collection of device replies and does not introduce any shift in messages exchange order.

D. Advanced aggregated schedule.

A combination of *advancing* and *aggregation* techniques is presented in Fig. 6 where the last proposed polling scheme is explained. There is an initial stage comprising *write* calls only while all consecutive cycles start with aggregated writes succeeded by grouped reads. One may expect this schedule to provide further performance improvement by a synergy effect.

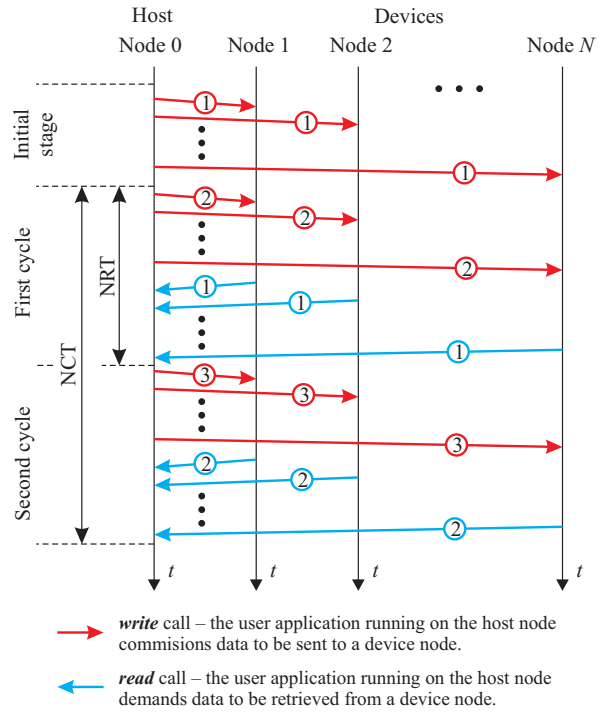

Fig. 6. Advanced aggregated schedule. The *network cycle time* (NCT) equals twice the *network repetition time* (NRT).

IV. Experimental results

A. Test conditions and performance measures

A lot of tests have been conducted for various experimental conditions gathered in Tab. II. Four different polling schedules, proposed in the previous sections, have been investigated in turn. Device nodes number N as well as the data length SIN for a single IN transfer (*read* call) have been varied, while the OUT transaction size SOUT (*write* operation) has been kept constant. A long data series of 10 000 samples have been collected for each experiment in order to compute several statistical performance measures. Four such quantities are used to compare performances of individual scheduling policies, based on network timing or throughput characteristics (see Tab. III). Timing is characterised by NRT and NCT parameters defined in the previous section. They are computed on the host side based on timestamps added to transferred data by device nodes employing hardware peripheral timers. Throughput corresponding to data transferred by IN transactions (*read* operations) is characterised by two related measures: *total network stream* (TNS) and *stream per node* (SPN), satisfying the equation $\mathrm{TNS} = N \times \mathrm{SPN}$ (as long as mean values are considered) where N is the number of active device nodes. For all four quantities their average values (avg) have been computed. For timing related NCT parameter its standard deviation (std) has been also determined. Time series and histograms of timing parameters obtained in selected experiments are presented in the next subsection in Fig. 7–10. Statistics computed from all tests results are gathered in Tab. IV. Discussion of results is also provided. The amount

Network performance measures

timing	NRT, ms	network repetition time
	NCT, ms	network control time
throughput	TNS, kB/s	total network stream
	SPN, kB/s	stream per node

of data presented in the table may seem to be intimidating for the reader. However, authors decided to include all results because they share a view expressed in [21]: *It is understood that real time systems are not tested with a single analysis that pronounces them correct. Testing of real time systems is a proof by exhaustion.*

B. Presentation and discussion of experimental results

Fig. 7 presents time series and histograms of the NCT parameter obtained for the *direct interleaved schedule* in an experiment with four active device nodes and IN transfer size of $\mathrm{SIN} = 100\,\mathrm{B}$. For a direct schedule, $\mathrm{NCT} = \mathrm{NRT}$ equality holds. The average (avg) NCT value is equal to 38 ms (see Tab. IV) and approximately matches performances observed by other authors for USB systems with a single device [7]. Minimum (min) and standard deviation (std) of NCT equal 11 ms and 21 ms, respectively. Large discrepancy between avg and min value as well as large std/avg ratio reveals a large room for improvement, since the min value estimates the best case scenario. From Tab. IV one can deduce that NCT is approximately proportional to the device nodes number N. That seems to be a natural behaviour for the schedule that executes two-way data exchange witch every devices in turn and does not employ any kind of parallelism. A relation between SIN and NCT is approximately affine with a considerable y-intercept and relatively small slope (NCT increases merely by 60% for SIN increasing over 160 times). It suggests that software components rather than a physical data exchange channel form a communication bottleneck and again suggests a potential for performance improvement by an appropriate polling schedule selection. The TNS is roughly proportional to SIN and almost independent on N. It shows the advantage of using large size transfers and reveals that the available throughput is equally shared by all device nodes.

Time series of NCT and NRT as well as NCT histograms for the *advanced interleaved schedule*, $N = 4$, and $\mathrm{SIN} = 100\,\mathrm{B}$

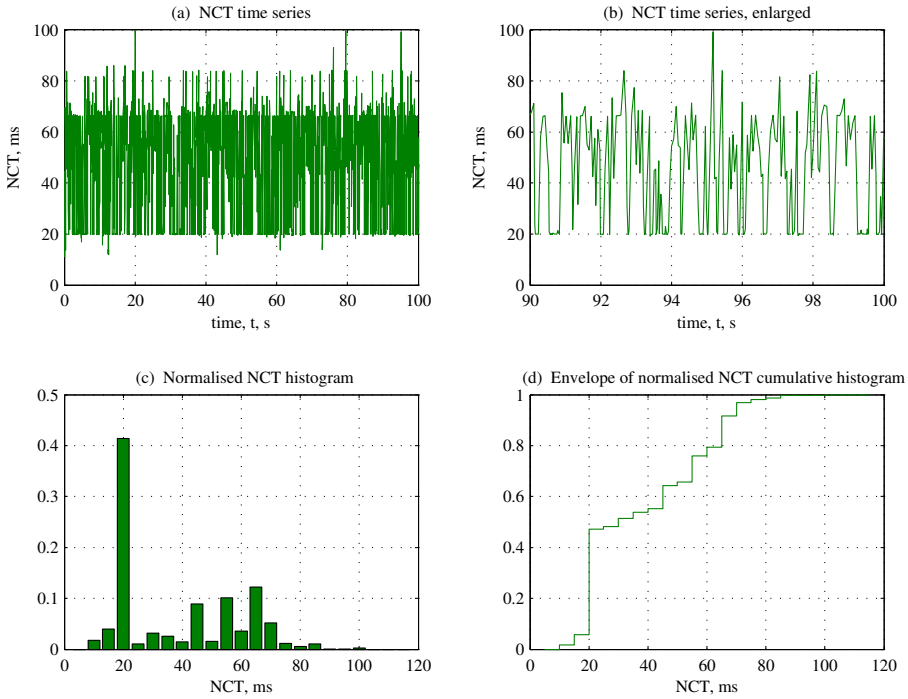

Fig. 7. Results of an experiment for the *direct interleaved schedule* with $N = 4$ active nodes and IN transfer size of 100 B. Time series and histograms of the *network control time* (NCT) parameter.

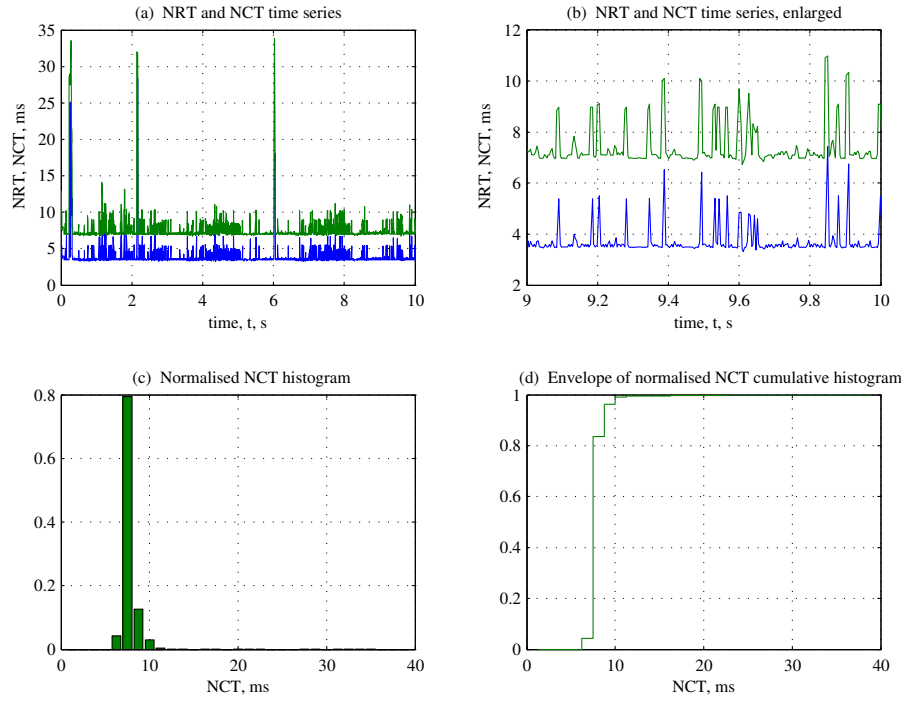

Fig. 8. Results of an experiment for the *advanced interleaved schedule* with $N = 4$ active nodes and IN transfer size of 100 B. Time series and histograms of *network repetition time* (NRT, blue) and *network control time* (NCT, green) parameters.

are presented in Fig. 8. Timing and throughput statistics for various conditions are gathered in Tab. IV. An enormous performance improvement can be observed compared to the *direct interleaved* scheme. The NCT is reduced five times from $38\mathrm{ms}$ to $7.5\mathrm{ms}$. The NRT reduction is even more impressive – about ten times from $38\mathrm{ms}$ to $3.7\mathrm{ms}$. Consequently, both TNS and SPN increase tenfold from $10\,\mathrm{kB/s}$ to $110\,\mathrm{kB/s}$ and from $2.6\,\mathrm{kB/s}$ to $27\,\mathrm{kB/s}$, respectively. The huge improvement is achieved exclusively by introduction of the initial, preparatory stage at the beginning of the cyclic polling schedule (compare Fig. 3 and 4). The one-step shift (and resulting time delay) introduced by the *advancing* technique is by far compensated by the timing performance improvement, revealed by the considerable reduction in both NCT and NRT measures. One can observe that the performance gain is more prominent for small SIN values. Apparently, when the data stream increase, the hardware limitations play more and more important role and diminish benefits brought by the polling scheme modification.

Results for the *direct aggregated schedule* are presented in Fig. 9 and in Tab. IV. For $N = 4$ and $\mathrm{SIN} = 100\,\mathrm{B}$, NCT and NRT become reduced over 6 times (from $38\,\mathrm{ms}$ to $6\,\mathrm{ms}$) compared to the *direct interleaved schedule* while TNS and SPN increase about 6.5 times (from $10\,\mathrm{kB/s}$ to $67\,\mathrm{kB/s}$ and from $2.6\,\mathrm{kB/s}$ to $17\,\mathrm{kB/s}$, respectively). Comparison of two improved polling schemes, the *advanced interleaved schedule* and the *direct aggregated schedule*, reveals that the former performs generally better as long as NRT, TNS, and SPN mean values are considered. However, for the average NCT, the latter scheme shows advantage for most N and SIN combinations. Consequently, for data acquisition systems, the *advanced interleaved schedule* is the preferred one while for the closed-loop control systems the choice should be made based of the number of nodes and IN transfers sizes.

Results of experiments for the *advanced aggregated schedule* are shown in Fig. 10 and in Tab. IV. They reveal a large improvement compared to the *direct interleaved* scheme. On the other hand, the table shows that the performance of this combined schedule is comparable to that obtained for the *advanced interleaved* one. Apparently, the *advancing* approach takes advantage of USB stack pipelinign, multithreading, and parallel computing capabilities to an extent that cannot be further intensified by incorporation of the aggregating technique.

C. Sporadic timing spikes

One can observe sporadic spikes on NCT and NRT time series presented in Fig. 7–10. They are several times higher than the average value of the considered timing parameter. They may result from an occasional lengthy or prolonged preemption of the USB stack or the user application by an unrelated time-consuming task, like hard disk servicing routine. One can expect such behavious since the Windows 7 is not a real-time OS. For a production system such a lack of determinism would be probably a prohibiting factor. For rapid prototyping purposes, however, it may be acceptable, since is far outweighed by development and testing benefits brought by RCP engineering tools like MATLAB or LabVIEW hosted by general-purpose OS-es.

V. Conclusions

The solution presented in the paper is intended for prototype rather than production systems and mainly for rapid prototyping approach. It allows to obtain high performance of a USB-based network despite the application of standard USB stack available in a general-purpose operating system. The dramatic communication improvement is achieved by employment of an appropriately modified read and write function call schedule on the user application side. It takes advantage of a multithreading, parallel computing, buffering and pipelining in the USB stack drivers to streamline the data exchange processes and improve data rate as well as timing characteristics. In a production real-time system designed for data acquisition or distributed control, one may expect protocol stacks to be adapted to the intended applications. That leaves less space for improvement with methods like those proposed in the paper.

All results included in the article have been obtained for a multinode system with several USB devices. However, some proposed methods and schedules can be used as well for a system comprising a single device communicating with a single host. Application of the advancing technique for such a system have been presented in authors' previous work [9].

The paper proves effectiveness of advancing and aggregating techniques in case of a network based on the USB bus technology. However, the authors expect that similar approaches may succeed also for other communication networks and protocols, provided that they make use of a similar software architecture.

The methods given in the article can be beneficial mainly for data acquisition systems, where data throughput maximization rather than closed loop latency (delay) minimization is the main objective. However, to a limited extent, they can also be employed in closed loop control applications as in some cases they also allow reduction of the round trip delay.

Information Technology for Management, Business & Society

IT4MBS is a FedCSIS conference area aiming at integrating and creating synergy between FedCSIS events that thematically subscribe to the disciplines of information technology and information systems. The IT4BMS area emphasizes the issues relevant to information technology and necessary for practical, everyday needs of business, other organizations and society at large. This area takes a sociotechnical view on information systems and relates also to ethical, social and political issues raised by information systems. Events that constitute IT4BMS are:

- AITM'18—16th Conference on Advanced Information Technologies for Management
- ISM'18—13th Conference on Information Systems Management
- KAM'18—24th Conference on Knowledge Acquisition and Management

16th Conference on Advanced Information Technologies for Management

WE are pleased to invite you to participate in the 16th edition of Conference on "Advanced Information Technologies for Management AITM'18". The main purpose of the conference is to provide a forum for researchers and practitioners to present and discuss the current issues of IT in business applications. There will be also the opportunity to demonstrate by the software houses and firms their solutions as well as achievements in management information systems.

TOPICS

- Concepts and methods of business informatics
- Business Process Management and Management Systems (BPM and BPMS)
- Management Information Systems (MIS)
- Enterprise information systems (ERP, CRM, SCM, etc.)
- Business Intelligence methods and tools
- Strategies and methodologies of IT implementation
- IT projects & IT projects management
- IT governance, efficiency and effectiveness
- Decision Support Systems and data mining
- Intelligence and mobile IT
- Cloud computing, SOA, Web services
- Agent-based systems
- Business-oriented ontologies, topic maps
- Knowledge-based and intelligent systems in management

EVENT CHAIRS

- **Andres, Frederic,** National Institute of Informatics, Tokyo, Japan
- **Dudycz, Helena,** Wrocław University of Economics, Poland
- **Dyczkowski, Mirosław,** Wrocław University of Economics, Poland
- **Hunka, Frantisek,** University of Ostrava, Czech Republic
- **Korczak, Jerzy,** International University of Logistics and Transport, Wrocław, Poland

PROGRAM COMMITTEE

- **Abramowicz, Witold,** Poznan University of Economics, Poland
- **Ahlemann, Frederik,** University of Duisburg-Essen, Germany
- **Atemezing, Ghislain,** Mondeca, Paris, France
- **Cortesi, Agostino,** Università Ca' Foscari, Venezia, Italy
- **Czarnacka-Chrobot, Beata,** Warsaw School of Economics, Poland
- **De, Suparna,** University of Surrey, Guildford, United Kingdom
- **Dufourd, Jean-François,** University of Strasbourg, France
- **Franczyk, Bogdan,** University of Leipzig, Germany
- **Januszewski, Arkadiusz,** University of Science and Technology in Bydgoszcz, Poland
- **Kannan, Rajkumar,** Bishop Heber College (Autonomous), Tiruchirappalli, India
- **Kersten, Grzegorz,** Concordia University, Montreal, Canada
- **Kowalczyk, Ryszard,** Swinburne University of Technology, Melbourne, Australia
- **Kozak, Karol,** TUD, Germany
- **Krótkiewicz, Marek,** Wroclaw University of Science and Technology, Poland
- **Leyh, Christian,** University of Technology, Dresden, Germany
- **Ligęza, Antoni,** AGH University of Science and Technology, Poland
- **Ludwig, André,** Kühne Logistics University, Germany
- **Magoni, Damien,** University of Bordeaux – LaBRI, France
- **Michalak, Krzysztof,** Wroclaw University of Economics, Poland
- **Owoc, Mieczyslaw,** Wroclaw University of Economics, Poland

Attribute Selection with Filter and Wrapper: An Application on Incident Management Process

Claudio A. L. do Amaral, Marcelo Fantinato, Sarajane Marques Peres
Graduate Program in Information Systems, Universidade de São Paulo, Brazil
{claudio.amaral, m.fantinato, sarajane}@usp.br

***Abstract*—Few approaches allow assertive estimates for ticket completion time in incident management. The accuracy level of prediction models depends on how useful the used attributes are. Moreover, to effectively use computational resources, a canonical attribute subset must be used. This paper proposes two automated attribute selection methods to build prediction model. A filter method and two wrapper search techniques were combined with annotated transition systems to automate attribute selectors applied to a real-life incident management process. The results show that the wrapper method surpassed human experts' decision making.**

***Index Terms*—process mining; attribute selection; incident management; ITIL; annotated transition system.**

I. Introduction

IN Information Technology (IT), optimization is sought by adopting frameworks such as the Information Technology Infrastructure Library (ITIL) [1]. ITIL covers several IT service management processes, including incident management [2], which is responsible for correcting failures and restoring the normal service operation, as soon as possible, minimizing the impact on business [1]. One of the most relevant monitoring indicators related to this process is the completion time for incident resolution (a.k.a. 'ticket completion time') [2].

Assertive and reliable estimates for completion time is still challenging [3]. A common reason for poor estimates is to conduct predictions based only on a naive and superficial abstraction of the actual process being performed. Fortunately, many companies are using process-aware information systems and recording events about the activities executed. The large amount of data recorded in event logs can be explored in detail through different process mining techniques, which allow to infer a more realistic process model [4]. For example, representing the process as an Annotated Transition System (ATS) allows to estimate the process completion time based on statistics aggregated into the process model [5]. To achieve a proper ATS model representing an incident management process, both the event log and a set of descriptive attributes need to be considered. However, depending on management context, the number of descriptive attributes that may be associated with process instances can be large and complex enough to render unfeasible *(i)* the use of all descriptive attributes, which could generate inefficient ATSs to predict completion time as well as *(ii)* a non-automated decision making about which attributes should be considered to build the ATS. Therefore, two concerns should be considered when building a proper process model: not all attributes are necessarily useful and much computational resource may be required. Thus, a canonical subset of descriptive attributes must be selected; i.e., an ideal minimum subset of descriptive attributes that minimizes the computational cost and contains the maximum information relevant to build the model.

This paper proposes to apply two classic methods of attribute selection to automatically determine the canonical subset of descriptive attributes. The filter [6] and wrapper [7] methods have been applied to an event log obtained from a real-world enterprise incident management system. For the experiments, ATSs were created using attribute subsets selected by human experts in addition to the two automated methods. The results show that the proposed automated methods surpass human experts in selecting attributes for prediction using the ATS built based on the selected attributes, having wrapper surpassed filter. The remainder of this paper presents: background, related work, proposed solution, experiments and results, and conclusion and future work.

II. Background

The transition systems used in process mining was proposed by Aalst *et al*. [8] and then extended with annotations to describe statistical data that allow predicting the completion time of a process instance [5]. To create the ATS, each state is annotated with data collected from all traces that have visited it [5]. For time analysis, for example, data about the completion time of the instances related to each earlier trace is used. The data are aggregated in each state producing statistics such as average time, standard deviation, median time etc. Two of the proposed strategies are applied here: *maximal horizon* and *representation*, including per *sequence*, *multiset* and *set* [5].

Attribute selection is essential to build a model capable of predicting ticket completion time, by deciding which features to describe the concept to be learned and how to combine them [9]. Methods for selecting attributes are typically classified as filters, wrappers and embedded [6]. In this paper, a filter method based on correlation analysis was applied. Each attribute is individually evaluated based on its correlation with the target attribute (i.e., the ticket completion time). Moreover, two well-known search techniques were applied: hill-climbing and best-first search [7]; having ATSs as the learning model and Mean Absolute Percentage Error (MAPE) [10], [11] as the metric to evaluate the learning model accuracy.

III. Related Work

The proposal presented in this paper is based on the extension of transition systems with annotations, which was originally proposed by Aalst, Schonenberg and Song [5], to predict completion time of running traces. According to them, ATSs include alternatives for state representation, allowing to address overfitting and underfitting in prediction tasks. They concluded that their prediction approach overcomes simple heuristic approaches. Other authors, as Polato *et al*. [12], extended ATS to solve the same task by combining the probability of occurrence of activities with a regression model.

In addition to transition systems, Petri nets have also been used as a technique for prediction work. Rogge-Solti, Vana and Mendling [13] introduced time series Petri net models, making it possible to handle the analysis of temporal aspects of processes. Hinka *et al*. [14], Evermann, Rehse and Fettke [15] and Tax *et al*. [16] presented approaches closer to the study presented in this paper. Tax *et al.* [16] presented a comparison of their approach with ATSs used as predictor and concluded that they obtain more accurate predictions except for instances with a reduced number of events. Approaches were assessed with cross-validation and prediction accuracy metrics: Mean Squared Error (MSE), Mean Absolute Error (MAE) and Mean Absolute Percentage Error (MAPE) [10].

Although with different strategies addressing completion time prediction, there is a lack of concern on choosing the input log configuration for the predictor induction. A preprocessing work for attribute selection, as proposed in this paper, has the potential to improve results of the related work.

IV. Proposed Solution

When an incident occurs, it is identified and reported by a caller. Afterwards, a primary expectation is to know the incident completion time. The usual estimates follow ITIL best practices, which are based on some specific incident attributes such as urgency, category etc. This approach is fairly general and inaccurate since it aggregates a large number of different situations and common target completion times. As the process evolves from early stage to initial support and investigation, some attributes are updated and new ones are added. Depending on the system used, it can usually lead to a number close to 100 attributes. There is an open issue related to providing assertive estimates on incident completion time that is not adequately solved by simple statistical methods. Incident management systems store descriptive information of process instances and audit information about the history of updates of the process in progress. The combination of both types of information allows executing a detailed step-by-step process evaluation and hence deriving estimates for each event.

The problem addressed here lies in such a scenario, where, one needs to discover an attribute subset that allows generating a model capable of minimizing the prediction error of the incident completion time during the process of its resolution. The process starts with a sequence of actions to build the enriched event log used to induce the prediction models. After that, it is possible to apply the three attribute selection methods explored in this paper: *(i)* expert-driven selection, *(ii)* filter with ranking and *(iii)* wrappers with the hill-climbing and best-first search techniques. The search is performed in the context of our attribute selection strategy. In these algorithms, there is a construction function to build an ATS and the evaluation function of the ATS. They use, respectively, a training log excerpt and a testing log excerpt, which represent disjoint subsets of the original event log generated in a cross-validation procedure. After that, the evaluation function is applied and returns the MAPE for the ATS under evaluation. The minimization function applied to the ATS evaluation returns the index of the model that produces the lowest MAPE when applied to the testing log. As final result, it is returned the ATS with lowest MAPE in the set of ATSs under evaluation.

For all the selection methods, ATS is applied as the prediction model responsible for generating the estimates of the incident completion times, including to act as a state evaluator in the wrapper search spaces. For practical purposes, the basic idea is that ATS can be generated from an attribute subset which adequately describes the currently completed incidents. From this point, ATS can be applied to predict the completion time of new incidents while they are running.

V. Experiments and Results

This section presents the used event log, experiments setup and execution details, and results obtained. A cross-validation method with 5 folds was applied to the enriched event log to build the prediction models. The ATS accuracy is given by the average MAPE of test folds in terms of mean and median of incident completion time. In addition, the ATS completeness (or non-fitting) was evaluated as the accounting of how many event records do not have a corresponding state in ATS.

A. Enriched Event Log

An enriched event log of the incident management process was extracted from an instance of the platform used by an IT company (Table I). Information was anonymised for privacy reasons. This enriched event log is composed by information gathered from the audit system and the relational model of the platform. A preprocessing step filtered out noise and sorted audit records in a sequence compatible with event log format.

Some statistical data on the enriched event log is shown in Table II. A well-defined behavior for the incident management process is observed, as most incidents (75%) go up to 7 updates, 50% up to 5 updates and on average 6 updates are needed to close incidents. However, there are outliers, with 58 as the maximum number of updates for one incident. Regarding time, the behavior resembles an exponential distribution.

B. Experiments Setup and Results

For the three experiments conducted, the ATSs parameters were: an enriched event log was randomly sampled by creating two subsets with 8,000 (A) and 24,000 (B) incidents, having $A \subset B$. The maximum horizon parameter values used were: 1 – case with the last event per incident trace; 3, 5, 6 and 7 – most frequent behaviors in this incident process (statistic ‘by incident’ in Table II); ‘infinite’ – uses all events in trace.

TABLE I
INCIDENT ENRICHED EVENT LOG EXCERPT

TABLE II
ENRICHED EVENT LOG STATISTICS: DISTRIBUTIONS BY INCIDENT/DAY

	1st Quart.	2nd Quart.	3rd Quart.	Max.	Mean	Std. Dev.
By incident	3	5	7	58	6	3.67
By day	0.01	0.40	5.29	336.21	6.67	21.20

1) Experiment #1 – Expert-Driven Selection: first, attribute selection was driven by data about the domain held by human experts. According to ITIL best practices, in the first stage of incident management process, the caller should provide the initial information, which is complemented by the service desk agent, especially with information related to the incident category and priority. Additional information (i.e, textual descriptions) is also provided to help the support agents; its use is out of the scope of this work. Based on these practices, *incident_state*, *category* and *priority* were considered the most adequate attributes to define the process model in ATS: *incident_state* reports the stage at which the incident is; *category* indicates the type of service the incident belongs; and *priority* determines the focus requested by business. In this scenario, using event log sample with 24,000 incidents and varying the horizon and state representation parameters, 18 ATSs were generated and used as completion time predictor. The best results were obtained with horizon 3, state representation *sequence* and are shown in Table III.

TABLE III
EXPERIMENTS – AVERAGE PREDICTION RESULTS. BEST ATTRIBUTE SUBSETS SELECTED BY SPECIALIST, FILTER AND WRAPPER. LOG SAMPLE: 24,000 INCIDENTS. METRIC: MAPE. NF = % OF NON-FITTING INCIDENTS. BOLD: BEST RESULTS ON EACH EXPERIMENT.

Max	Set			Multiset			Sequence		
Horiz	*Mean*	*Median*	*NF*	*Mean*	*Median*	*NF*	*Mean*	*Median*	*NF*
Experiment #1 – Attribute subset: *{incident_state, category, priority}*									
3	106.93	77.46	0.98	91.35	75.87	1.23	**72.36**	**63.66**	**1.38**
Experiment #2 – Attribute subset: *{caller, assigned_to}*									
5	90.73	76.30	33.31	**69.69**	**57.85**	**35.67**	80.97	69.10	35.73
Experiment #3 –Attribute subset: *{incident_state, location}*									
5	**50.45**	**24.49**	**1.11**	41.90	29.35	2.30	35.09	27.28	2.74

2) Experiment #2 – Filter with Ranking: second, attribute selection was driven by filter using a ranking strategy. This approach follows consolidated concepts of specialized literature [6], [7], [9]. In this paper, ranking was applied as preprocessing, as suggested by Kohavi and John [7], to create a baseline for attribute selection, regardless of the prediction model in use. It was created through a variance analysis by correlating the independent variables (i.e., descriptive attributes) and the dependent variable (i.e., attribute 'closed', prediction target attribute). Since most of descriptive attributes are categorical, the statistic η^2 (Eta squared) was applied, as explained by Richardson [17]. As a design decision, the 15 attributes with the highest correlation were selected to compose the ranking. The variance analysis was carried out on the entire enriched event log. The attributes and correlation scores are listed in Table IV. Using ranking results filter was executed by combining the attributes as follows: *{Caller (1^{st})}*; *{Caller (1^{st}), Assigned to (2^{nd})}*; ...; *{Caller (1^{st}), Assigned to (2^{nd}), ..., Knowledge (15^{th})}*. For this scenario, 18 ATSs were generated for each attribute subset. In the second part, the best two result sets obtained in the first part where chosen to generate new sets of ATSs, however, using event log sample with 24,000 incidents (best results in Table III). The prediction results with the ranked attribute subsets were slightly worse than those obtained in the experiment #1. Analyzing the results, it is noticed that, resource-related attributes impair the generation of the prediction model, i.e., they do not reflect the process behavior with the same fidelity as the control attributes do. Particularly regarding to non-fitting, a possible explanation for these poor results could be the frequent changes in the values of the human resources assigned to solve different incidents.

TABLE IV
THE 15 DESCRIPTIVE ATTRIBUTES WITH THE HIGHEST CORRELATION WITH THE DEPENDENT VARIABLE AND THE RESPECTIVE η VALUES.

Ord	Attribute	η	Ord	Attribute	η	Ord	Attribute	η
1^{st}	Caller	0.54	6^{th}	Incident state	0.32	11^{th}	Created by	0.21
2^{nd}	Assigned to	0.37	7^{th}	Subcategory	0.32	12^{th}	Opened by	0.20
3^{rd}	Assig. group	0.35	8^{th}	Category	0.27	13^{th}	Location	0.14
4^{th}	Symptom	0.33	9^{th}	Active	0.25	14^{th}	Made SLA	0.14
5^{th}	Sys upd. by	0.33	10^{th}	Priority conf.	0.24	15^{th}	Knowledge	0.12

3) Experiment #3 – Wrappers with Hill-Climbing and Best-First: lastly, the attribute selection was driven by wrapper using a forward selection mode[1], with the hill-climbing and best-first search techniques [7]. The search space is composed by all possible combinations of the 15 attributes pre-selected by the filter with ranking strategy, i.e., attributes listed in Table IV. Since each combination represents a state in such a space, whose quality measure is calculated as the predictive power achieved by the ATS generated with the attribute subset associated with this model[2], an exhaustive search procedure is unfeasible and hence the use of a heuristic search procedures is justified. Wrapper was carried out on the enriched event log sample with 8,000 incidents. For the best-first search technique, the maximum number of expansion movements with no improvement was set to 15. Both search techniques selected this same best attribute subset: *{incident_state, location}*. Despite the high agreement between them, this can be highlighted: with hill-climbing, the stopping criterion was reached after the third expansion movement and 42 states of the search space were explored; using best-first, 17 expansion movements were done and 172 states of the search space were

[1]In the forward selection, the search start point is a singleton attribute subset to which a new attribute is incorporated at each new step in the search.

[2]The search space had $2^{15} = 32,768$ states, taking the 18 ATSs generated for each state, the range of the horizon and state representation parameters.

explored. The best results were obtained with horizon 7 and state representation *set*; however, the results obtained with the other state representations for the same horizon were very good as well. These results are significantly better than those obtained by the filter and expert-driven selections. Overall, the low non-fitting results are promising. As a second part of experiment #3, a new set of ATSs was generated using as parameters those of best results and enriched event log sample with 24,000 incidents. The best results (Table III) were obtained with maximum horizon set to 5 and overcome those obtained in the previous experiments. The MAPE results are less than half of those measures obtained by the expert-driven selection, keeping non-fitting values at the lowest level.

C. Analysis of Results

When analyzing the results, it is verified that the strategies expert-driven and filter with ranking allow us building models with a similar predictive power. However, when checking the model non-fitting capabilities, differences (1.38% and 35.67%, respectively) are observed between them for the best results. Such differences were caused due to the different process perspectives represented by the attribute subset used in each case. For the former, the ATS generation was driven by incident descriptive attributes recommended by the ITIL best practices suggested by human experts for incident clustering and routing; then, the resulting model was able to accurately represent the process. For the latter, the set of attributes automatically selected to build the ATS represents organizational and resource perspectives of the incident management process. In this case, the ATS captured the way that teams (i.e., people) act to support user requests and became highly specialized and incapable of generalizing the real process behavior. This phenomenon happens because the attributes selected represent information that presumably changes frequently (i.e, 'caller' and 'technical people' in charge of the incident). The MAPE results obtained for the experiment #1 were compared to those obtained for the experiment #2, using the paired Wilcoxon statistical test. This test showed that there is no statistical difference among the distributions of the MAPE values, seeing that, with $p_{value} = 0.3125$, it is not possible to reject the null hypothesis for equal distributions.

The wrapper-based experiment achieved an average MAPE measure (24.49) that is 38.47% of the average MAPE achieved in the expert-driven experiment. The model non-fitting continued in an even lowest level (1.11%) as that obtained in the first one. The paired Wilcoxon statistical test was applied to compare the MAPE results obtained for the experiment #1 with those obtained for the experiment #3. The null hypothesis for equal distributions can be rejected with $p_{value} = 0.0312$. This result allows to affirm that the attribute selection obtained with wrapper is better than the expert's choice.

The attribute subset selected by wrapper is the union of expert knowledge with an organizational perspective, which produced a completion time predictor with high accuracy and low non-fitting rates. Moreover, it was very similar with results obtained with the hill-climbing and best-first search techniques. This behavior has already been observed in experiments executed by Kohavi and John [7], in which, for different types of datasets, additional search effort did not produce better results.

VI. Conclusion and Future Work

Wrapper made it possible to select a set of attributes that supported a significant improvement in the accuracy of the ATS to be used as a prediction model when compared to both filter and expert knowledge. Furthermore, such search process pointed out that the maximum horizon and different types of state representations have a high influence on the prediction model results. This approach has the potential to be used as a useful preprocessing step prior to the application of other prediction methods, in addition to the ATS method used here.

As next steps, it is necessary to verify the influence of outliers throughout the process (search and prediction performance), since the results obtained in the experiments presented some variation degree. The use of other search methods such as genetic algorithms or other induction algorithms such as neural networks and the combination of the best models of ATSs with other regression models are points to be explored.

***Abstract*—The main objective of this article is to compare of the utility of the multi-criteria TOPSIS method with scoring method and scoring method with preferences. The data was taken from Poland banking sphere in 2017. e-Banking websites were assessed from the point of view of an individual client. e-Banking helps to strengthen the bank's position in a competitive market environment; therefore, the high quality of a website frequently plays a decisive role in the perception of a bank as an organization. In the research the authors have used a scoring method, a scoring method with preferences and – in order to verify the correctness of the results and compare them – the TOPSIS method. An additional problem which appeared in the course of the study was the questions of whether the sophisticated multi-criteria methods produce better quality results than simple methods based on a scoring evaluation. Subsequently, on the basis of the obtained findings, the authors have carried out comprehensive and multi-dimensional analyses and presented the conclusions and recommendations drawn on the basis of the aforementioned analyses. The authors' contribution to the research was specifying the criteria for the evaluation of the websites as the main indicators of the perception of the quality of websites, identifying the best e-banking websites and formulating conclusions that may become a starting point for creating an effective quality management systems of e-banking services.**

I. Introduction

THE importance of electronic banking in Poland is evidenced by the constant pace of its development. In relation to the fourth quarter of 2016 the number of individual clients who have potential access to account increased in relation to the fourth quarter of 2017 by over 7%, reaching 35,512 million users (92% of the population), where the number of active individual clients rose by more than 3.5%, reaching the level of 15,889 million (45% of the population) [9]. It is the fastest growing banking sector – nothing seems to interfere with these positive trends. Over the last ten years, the number of customers has increased by more than 25 million. Thus, it is the sphere, the development of which should be carefully examined and analysed.

The problems related to the functioning of websites, in particular, access to e-banking services, are widely discussed in the literature on the subject, and there is no single formula which would allow their unambiguous assessment and the improvement of their quality. Numerous analyses also do not indicate what effect they have on the development of banking in the countries where they are being examined. There is an ongoing process of searching for the method which would best reflect the tendencies in this sphere and at the same time would be most convenient from the point of view of its users. Literature review shows that bank websites may be analysed from the point of view of their usability (site map, address catalogue) [2], functionality (search, navigation, content) [19], interactivity (accessibility and responsiveness) [14], [18] visualization (colour scheme, background, graphics, text) [7], reliability [1], cost-effectiveness (costs of purchase, transport, the difference in prices in traditional and online shops) [3].

Most of the evaluation methods of e-banking websites are traditional scoring methods based on specific criteria sets, evaluated according to a fixed scale. Among the criteria which are most frequently applied there are technical and functional criteria. Many of them contain factors which may be evaluated in a highly subjective way: text clarity, the attractiveness of the colour scheme, images and photos, the speed of finding specific functions and using them) etc. In addition, some users do not treat particular criteria sets in an equivalent way. On the other hand, there are also numerous problems with determining preferences and relations between them. These problems – according to relevant literature on the subject – are solved by multi-criteria methods. However, the question arises whether indeed their more complicated use may in some way be compensated for when compared to the ease and convenience in using simple methods. The authors will attempt to address this question in the article.

II. Description of the research method and the sample

The research in this paper has been conducted using the authors' own criteria sets used for electronic access to accounts of particular banks. The criteria sets were applied since 2006 and they were created on the basis of relevant literature and verified following consultations with the experts. The evaluation criteria were established during an internet discussion conducted with the participation of scientists and researchers representing leading universities dealing with electronic banking in Poland, based on the literature on the subject. At the moment of economic crisis of 2008, a set of anti-crisis criteria, i.e. the selected measures which – in the experts' opinion – were supposed to counteract the potential effects

of the banking crisis [15] - was added to the set of evaluation criteria used to assess the access to banking services. The second modification took place in 2017 where the authors verified the correctness, comprehensibility and importance of the se-lected criteria for the users with the participation of 244 respondents. Finally, after this verification and consideration of users' comments, the criteria adopted in the studies into the evaluation of banking websites were divided into three main groups: economic criteria, technical, visualisation and security criteria, anti-crisis measures. The respondents evaluated their preferences with regard to criteria groups as well as individual criteria. Specific criteria with preferences calculated as an arithmetic mean of the scores, motivation and justification of their choice are presented in details in [16].

Among the groups, the most important set were economic criteria which obtained on average a 62% score (including the most important criterion – account maintenance PLN/month (average: checking and savings account) – nearly 8%), subsequently, technical and security criteria – on average 32% (the most important security measures 6%) as well as anti-crisis measures, on average - 6%.

The presented study constitutes the next stage of the research carried out systematically from 2006 whose primary objective is to evaluate the factors which impact the quality of websites that provide access to individual accounts in banks. Frequently, it is the quality of the website which turns out to be decisive in retaining and acquiring new customers. It is important to notice that the present ranking evaluating the quality of e-banking websites includes also economic factors which are the specific reflection of the current bank policy. In order to evaluate particular criteria in the banks which were selected by the clients, the authors used a standardised, simplified Likert scale [10], in which lack of a particular quality is represented by the value equal to zero, its complete fulfilment is equal to one, average fulfilment of the feature – 0.5 and intermediary values such as good fulfilment is equal to 0.75; and sufficient fulfilment amounts to 0.25.

The study has been conducted with the initial application of a simple scoring method and a scoring method with preferences. In the simple scoring method, the authors measure the distance from the maximum value which can be obtained (according to the adopted scale). It concerns the value of the measure of the criterion and in the sense of a distance, it is the same when we measure the distance from the first and second criterion and vice versa. However, the relationship between individual criteria is not determined. Assigning the preference scale, which adds up to the value of 100%, to particular criteria (or criteria groups) can be regarded as such a measure. The normalised linear preference scale determines the participation of particular criteria in the final score. It is important to indicate that scoring methods are seen as subjective evaluation methods, even though their subjectivity appears to be limited together with the number of the interviewed respondents and the application of a preference scale. Despite their drawbacks, these methods are commonly applied and their scores are easy to interpret. The methods which are believed to be more objective, for example, AHP method [11], Promethee II, Electre I and III method, the TOPSIS method and other solutions are rather complex to use and sometimes it is difficult to interpret their findings. The authors' experience, mainly related to the application of AHP method used to evaluate websites, points to the fact that the completion of survey questionnaires is very complicated from the perspective of the respondents participating in the studies. As a result, this may lead to ill-considered and random assessments, and the final scores may frequently be determined by the order of particular criteria. In order to eliminate such prob-lems, the authors have devised their own evaluation method – a conversion method. The data which are used in calculations are collected in the form of the same input tables as in the case of a scoring method. This method combines the simplicity and unambiguity of a scoring method with the precision of relational methods. It consists in establishing the relations of each criterion in relation to other criteria, based on averaged distances from the potential maximum value previously established on the basis of a scoring method.

Based on the above assumptions, in December 2017, the authors have conducted the research into the quality of the e-banking websites of the banks which are most popular among individual clients in Poland. The sample of the study covered 721 respondents. Among them, there were 83 (nearly 12% of the population) people holding and evaluating two accounts in two different banks, 38 respondents (5%) having and assessing three accounts in three different banks. In total, the survey participants carried out 1002 evaluations of 28 banking websites. Among the 28 websites, seven responses concerned one bank, none of them was complete and correct, and thus the authors used 21 banks in further analyses. Correct responses were provided by 290 individuals (40% of the respondents), out of which 16 (almost 6%) people evaluated two websites, and four participants (over 1%) assessed three of them. In total, there were 334 fully and correctly completed evaluations of banking websites (33% of all completed survey questionnaires). The participants were 19-50 years old students from randomly selected students groups. More than 98% of respondents were 18-25 years old, which could have influenced the results of the survey (15.6% of the population in Poland are potential clients of e-banking, including over 50% of active clients in 2016). Among the survey participants, there were 72% of women and 28% of men. The majority (55%) described themselves as working students, 45% as students. Most people (26%) stated that their place of birth was a town below 50,000 inhabitants, almost the same number of respondents - cities with more than 500,000 residents, and 23% - villages.

The greatest number of electronic access accounts was indicated in the case of the clients of mBank (15%), then iPKO PKO BP S.A. (13%) and Millenium (12%). The smallest shares in the examined group were clients holding accounts in: BGŻ Optima and Orange Finance (each approximately 1%). The spread between the smallest and the largest share of electronic access to accounts in particular banks in the entire sample amounts to 14%. Only in six out of twenty-one banks,

the participation of clients was above the average amounting to 5%.

III. Comparative analysis of internet access to accounts in electronic banking with the application of a scoring method

In the analysis with the application of a scoring method, the authors used input tables, where each of the clients evaluated bank offers concerning the selected e-banking services and the fees related to using bank accounts which can be managed via the Internet. Next, on the basis of the completed surveys, the authors created one summary table of averaged criteria evaluations generated by the users. On this basis, it was possible to carry out analyses and discuss the obtained findings. There occurred a great discrepancy in the evaluations of the analysed banks. In 2017 it amounted to nearly 13 percentage points (as compared to 2.25 percentage points in 2008), which confirms the thesis that the period of crisis in 2008 increased the radicalism of the evaluations and increased the requirements with regard to tools providing access to account. The best in the ranking were: Orange Finanse (81.80%) and Bank Millenium S.A. (80.12%). The next positions were taken by ING Bank Śląski and Raiffeisen Bank. Interestingly, the first place was taken by a mobile bank which was created on the basis of the cooperation between the most innovative bank, i.e. mBank (taking the fifth position in the ranking) and one of the largest mobile operators, namely, Orange, on the basis of mBank experience. The worst in the ranking were: Bank Pocztowy S.A. and Credit Agricole Polska S.A.. The first thirteen banks in the ranking obtained the scores which were above the average amounting to 76.77%.

In the analysed banks, the transfer to a bank where we hold an account is evaluated as average (over 87%) and to a different bank (over 84%). The service of issuing a debit card is evaluated at a slightly lower level (over 83%), similarly to many different access channels (over 82%). The exceptionally low interest rates on deposits and relatively high-interest rates on credits in the analysed banks obtained the lowest scores (approximately 64% of the maxi-mum possible scores). It emerges that the spread between the highest and the lowest scores was relatively high and amounted to nearly 24 percentage points. The scores recorded in the case of the average interest rate of current and savings accounts were alarmingly low and amounted to 67-69%, which undoubtedly does not motivate the users to save money. The discrepancy be-tween the lowest and the highest scores was relatively high and amounted to nearly 24 percentage points. In total, thirteen evaluation criteria were above the average equal to 76.77%, and only ten were below it. It may appear that the respondents generally have a high opinion of the bank websites since all the criteria were rated above the 50% of the maximum score. However, since websites in Poland strongly compete with each other for many years, the scores should not be seen as satisfactory. The first of the banks in this year's ranking was a new player in the electronic banking market which gained its position owing to banking application for smartphones and tablets. In recent years, however, the highest scores were recorded in the case of the banks holding an established position in traditional internet banking such as ING Bank Śląski S.A., Bank BPH or BZ WBK. Among the first ten positions, there were banks such as Millenium and Getin Bank, as well as the banks which started to implement electronic banking and which have their loyal customers, especially those falling in the middle-age range. The high – fourth position was taken by Raiffeisen Bank, which probably resulted from the introduction of numerous modernizations and innovations carried out in recent years and an ongoing advertising campaign.

IV. Comparative analysis of electronic access to the account in e-banking with the application of the scoring method with preferences

One of the methods which allow for limiting the specific subjectivity of the experts' and users' evaluations in the scoring method is applying unitary preferences with regard to particular criteria or criteria groups. In the study, the authors divided the criteria into three groups: economic, technical and anti-crisis measures. The fourth group adopted in the study was created according to the preferences of the clients indicated in the research preceding the analyses. In this variant the criteria are as follows: economic criteria are preferred in 62%, technological in 32% and anti-crisis factors only in 6%. For each of the remaining groups, the authors adopted a variant with a group of dominating criteria: economic criteria (70% for economic criteria and 15% in the case of each of the remaining ones), technological, visualisation and security criteria (70% for technological, visualisation and security criteria, 15% for each the remaining ones), anti-crisis criteria (70% for anti-crisis criteria, and 15% for each of the remaining ones).

In the first case – of economic preferences – the three leading positions are taken by Orange Finance in the first place, Raiffeisen Bank (which moved from the fourth position), and Nest Bank (which moved from the tenth place). In the technical, visualisation and security variant, the first position is also taken by Orange Finance, mBank moved to the second place, and ING Bank Śląski is next. In the variant connected with the anti-crisis measures the second place is taken by Raiffeisen Bank, and Bank Millenium ranks next. In the last variant – the users' variant – the first place is still occupied by Orange Finance, and subsequent positions are taken by Bank Millenium and Raiffeisen Bank. The results of the rankings with particular types of preferences have significantly changed the order in the ranking and have shown the advantage of particular characteristics in the considered banks.

V. Verification of the ranking of internet access to an e-banking account with the application of the TOPSIS method

The theoretical assumptions of the TOPSIS method are presented below. In order to evaluate 21 most popular e-banking websites in Poland in 2017 (A1, . . . , A21), the authors used the set of 20 criteria which were adopted by the users

(C1, . . . , C20).
With the use of the MCDA (Multi-Criteria Decision Analysis) selection frameworks provided in [4], [5], [6] the authors chose the TOPSIS method to perform the empirical research. The obtained closeness coefficient CC_i is the score value produced by the TOPSIS method and is used to construct the ranking of alternatives (see table 1).

To carry out an analysis based on the TOPSIS method, the authors used the input tables where each of the clients evaluated the bank offers related to selected e-banking services and fees connected with using bank accounts which can be managed via the Internet. Subsequently, on the basis of the completed survey questionnaires, they created one summary table of the averaged criteria evaluations generated by the users. On this basis, the authors were able to carry out relevant analyses and discuss the obtained scores.
In the empirical study, 21 banks (A1 – A21) were evaluated with the use of 20 criteria (C1 – C20). The constructed decision matrix is presented in Table 1. The preference direction for all the criteria was set to maximum. In the first step of the research, a ranking was created based on the weights obtained with the use of normalized means of all users opinions. The obtained ranking is presented in table 2. The analysis of the ranking allows to observe, that the leading alternative A19 (Raiffeisen Bank Polska SA) obtained approximately four times more score than the worst alternative A4 - Bank Pocztowy SA - (0.6406 compared to 0.1578). On the other hand, the second and third alternative in the rank (A16 - Orange Finance - and A2 - Bank Millennium SA - respectively) obtained only slightly less score (0.6337 and 0.6096) than the leading alternative. The average score was 0.4703. Twelve alternatives obtained more than average score and nine alternatives scored worse than average.
Subsequently, the authors studied how the ranking would change if the weights of the criteria were not taken into account. Therefore, in the second step of the research, each criterion obtained an equal score. The produced ranking is presented in table 2. Again, the alternative A19 (Raiffeisen Bank Polska SA) took the first position in the ranking, and the alternative A4 (Bank Pocztowy SA) the last one. However, the alternatives A16 and A2 switched places in the new ranking. The analysis of the table 2 allows to note that as much as 7 alternatives remained unchanged: A19, A17, A7, A20, A6, A9, A4. On the other hand, the alternative A15 (Nest Bank) underwent the most significant change, from position 4 to 9.

The results of the calculations presented in table 2 show that the use of the TOPSIS method produces basically similar results with regard to the ranking as using the scoring method. This confirms the thesis that if the initial set is not greatly diversified, then the application of the simpler method is comparable to the use of more complex methods (here: the multi-criteria TOPSIS method), and it does not require any additional complicated calculations. The interpretation of the findings is also equally possible and convenient. At least – this represents a greater possibility to differentiate the input data in order to examine different hypotheses concerning the distribution of preferences between the criteria of particular groups.
If we compare the scores obtained in the scoring method and the TOPSIS method without the consideration of weight differentiation (carried out with the participation of the research sample), then – as indicated previously, the scores concerning the positions in the ranking are similar, despite the differences in the presentation standard (in the scoring method, the point of reference is the maximum possible level of the quality). Nevertheless, the differences in the rankings are really small. In 21 banks – for equal weights – they occur only in ten cases, and the greatest difference for Raiffeisen Bank amounts to the change of three positions. Fourteen differences (out of 21) occur when comparing the version with preferences. The biggest difference (four places) is recorded in the case of BGŻ Optima. In total, the differences are not as great as those in the case of comparison with the conversion method or the AHP method. In general, apart from the spectacular advancement of Raiffeisen Bank, or the lower position of BGŻ Optima, the differences are on average, the move of one place in the ranking. For equal weights, there is a considerable difference in the spread in the ranking for the TOPSIS method – more than 34% and simultaneously, twenty percentage points smaller (less than 10%) for the scoring method. Even greater differences between the high-est and the lowest values are indicated in the case of the version with preferences – for the TOPSIS method amounting to over 34%, for the scoring method to less than 4%.

VI. Conclusions

The presented analysis has shown the diversity of the opinions of individual clients on the usability of e-banking websites, in particular, their views concerning the selection and use of websites to meet the daily needs of users related to banking services. At this point, it is important to indicate that the demand is high and greatly diversified. At the end of 2017 in Poland there were 32.6 million of e-banking clients, including 14.7 million of active customers (at least one contact with checking and savings account per month) [12], including 8.9 million of clients using mobile devices to contact the bank (website or application) [13], including 2.2 million users of strictly mobile banking (only via a smartphone application) [8]. Even in 2017, we dealt mainly with the first trend, yet the bank analysts predict that this year the remaining trends will be taking a dominating position.
In this paper, the authors have not differentiated the clients with regards to the devices they use and the tools by means of which they contact their banks. Nevertheless, they evaluated them from the point of view of the device which made it possible to communicate with the bank. The evaluation of the devices allowed drawing the following main conclusions:

- it appears that mobile access to banking services is the most important phenomenon in the electronic banking market. This is evidenced by the position of Orange Finance in this ranking.

A15	Nest Bank	58.38%	4	0.5419	9	0.3203	6	77.81%	10
A16	Orange Finance	63.37%	2	0.62	3	0.3318	1	81.80%	1
A17	PKO Bank Polski SA (iPKO)	50.67%	11	0.5236	11	0.3129	12	77.98%	9
A18	PKO Bank Polski SA (INTELIGO)	41.78%	14	0.3768	15	0.3018	16	74.14%	17
A19	Raiffeisen Bank Polska SA	64.06%	1	0,6375	1	0.3244	3	79.82%	4
A20	T-Mobile Usługi Bankowe	36.74%	16	0.3721	16	0.3027	15	74.61%	15
A21	Volkswagen Bank Polska SA	55.76%	6	0.5769	7	0.3217	4	79.18%	7

- the position of Credit Agricole Bank Polska has significantly decreased in relation to other rankings, and the bank, when compared to previous rankings, lost its position among the top ten banks which obtained the best scores, similarly to T-Mobile Usługi Bankowe,
- the vast majority of active bank clients (62%) believe that economic criteria, i.e. the first three positions among all the most frequently used services are the most significant criteria in the evaluation of internet access to banking,
- however, more and more people admit that they are inclined to consider the ease of access to mobile banking (nearly 80%) and the number of access channels (82%) when selecting a given website,
- the issues related to anti-crisis measures also fell below the average (73%), and it emerges that users slowly start to forget about the crisis of 2008,
- the scale of inactive clients (approximately 55% appears to be alarmingly large in relation to those customers who can potentially use electronic banking. It is true that a few years ago the estimates did not exceed 20%, but the pace of increase in the customer activity in this field is still very slow.

The increasing diversification of banking services necessitates new approaches to the use of tools to assess their suitability and usability for the clients. The calculations obtained in the study carried out with the use of the scoring method and the TOPSIS method create the initial basis for such comparisons. Taking into consideration the basic features of these methods one can conclude that generally the obtained findings are largely similar. Therefore, the general conclusion is that in the case of large sets of homogeneous, uniform data both of these methods seem to be equivalent, and in the analyses it is recommended to use the simplest possible methods because they offer greater possibilities of "manual" analyses. The basic features which are characteristic of both methods are presented in table 3.

The fact that starting from last year, the long-awaited discrimination between banking services via mobile devices and mobile banking induces the authors to conduct thorough analyses of the "strictly" mobile banking carried out by means of the applications running on smartphones and tablets. The diversity in the sphere of banks operating independently, or in alliances with mobile operators also necessitates the consideration of the justification of making a separate evaluation of e-banking, e-banking used via mobile devices and mobile banking. The problem consists in the fact that clients who use mobile devices are not always fully aware that connecting to a website using a mobile device is not mobile banking. The second problem is that in the course of the previously conducted studies [17], clients claimed that they only engage

TABLE III
COMPARATIVE CHARACTERISTICS OF THE POSSIBILITIES TO USE THE SCORING METHOD AND THE TOPSIS METHOD; SOURCE: THE AUTHORS' OWN WORK

Criterion	Scoring method	TOPSIS method
Method	Simple method with the possibility to apply user preferences	Multi-criteria method with equal weights and calculated preferences
Obtaining input data	Easy	Easy
Initial data processing	Easy	Easy
Computing method	Easy	Relatively more difficult
Interpretation of the findings	Easy	Easy
Criterion	Scoring method TOPSIS	method
Extended analyses	Easy	Relatively more difficult

in low-value transaction when using a smartphone (by means of a website or application), and the remaining operations are carried out by means of personal and desktop computers, frequently not noticing or recording which of these transactions are conducted by means of applications. Thus, this area requires continuous and ongoing research in the field.

***Abstract*—The aim of this article is to execute a comparative analysis of services and distribution platforms used to purchase computer games. The article is a continuation of research focused on the popularity, use and impact of games on the behavior of a prominent population and analysis of the typical e-shops with games. For the analysis it was chosen the four most common amongst students computer game services and platforms simultaneously found in the first hundreds of searches in Google. CAWI analyzes were used for nine groups of features: transparency, site navigation, quality of information, product search quality, advertising, the quality of the order processing, way of visualization and product promotion from the customer's perspective. Platform analysis was carried out according to: installation package support, application design, search engine quality, transparency, product presentation and security. A qualitative study was conducted to select a sample of selected students using the point method and the point method with preferences to evaluate the distinctive features of the services. A group of over seven hundred randomly selected people from the university was examined. This approach was based on the structure of the article consisting of the presentation of the research hypothesis, the description of the methodology and the research sample, and the analysis of the results and their discussion together with the resulting conclusions. The results of the work may be used by the owners of computer distribution services or platforms and website designers.**

I. Introduction

THE MAIN objective of this study is to analyse the quality of selected Internet platforms of distributors of computer games. This is the fifth of the series of studies carried out among the representatives of academic youth concerning the possibilities of using computer games in education, entertainment, sport, etc. This time the study focuses on the potential distribution platforms providing access to various types of games. The digital distribution of computer games is considered by the authors to be a method of disseminating products consisting in making installation files or a code required to run the application via the Internet available to the player by the publisher. Generally, it is carried out with the application of a platform which is designed especially for this purpose and which provides support in the process of sale and after-sales customer service.

The study considers the data provided by GamesIndustry.biz and a report on the global gaming market in 2017 [1]. According to the published data, the value of the entire gaming market in 2017 amounted to 116 billion dollars, which represents an increase of 10.7% in relation to 2016. Mobile devices whose share in the total value amounted to 42% (an increase by 23% in relation to 2016) were the dominant platform. The income from games running on personal computers and consoles presented a very similar tendency, and it amounted to 27% and 31%, respectively [1-2]. Thus, it is a market which is developing, and thus it appears to be the research field which deserves further analyses. It is worth noting that the share of the digital platforms used for distribution of computer games in the entire market amounts to around 92% [3]. In the literature, one may point to the sources which evaluate the influence of the digital gaming platforms on the players [4] or on the natural environment [5], however, there is no comparative assessment of particular platforms from the point of view of users.

The conducted analysis is designed to determine the most important features of websites and platforms distributing computer games as well as motivations of individuals visiting the websites and making purchases.

II. The assumptions of the research methodology

Four platforms were selected for the above-described comparative analysis: GOG (CD Projekt – Poland, (https://www.gog.com)), Origin - (Electronic Arts Inc.- USA, (https://www.origin.com)), Steam (Valve Corporation – USA, (https://store.steampowered.com)) and Uplay (Ubisoft Entertainment – France, (https://store.ubi.com)). The rationale for choosing these platforms was their greatest recognition in Poland and popularity of use (segment leaders) and the diversity with regard to the location of owners. This has been supplemented and verified by an additional analysis of the frequency of the emergence of individual platforms in the first hundred Google search results and the results of the initial part of the survey distributed among students.

The analysis has been divided into four parts: the frequency of the use of games, devices and platforms, payments; comparative analysis of websites of distributors; comparative analysis of installed applications (platforms) and comments.

The analysis of the selected websites was conducted according to a set of thirty-seven indicators, divided into nine

groups which were verified in previous research [6-7]: website clarity; website support; information quality; the quality of the product search engine; advertising on the site; quality of the ordering process; the method of product distribution; presentation of the product and promotions. The third part of the research was the analysis of final digital distribution applications for PCs with Windows. The applications of the same distributors which were analysed in the first part of the research, namely Valve Corporation (Steam), Electronic Arts Inc. (Origin), Ubisoft Entertainment (Uplay) and CD Projekt (GOG Galaxy), were selected for analysis. The installation of Windows 10 on a virtual machine using VirtualBox 5.0 was used for the analysis. Six groups of parameters were analysed containing in total such criteria as: installation package, the appearance of the application, search engine, transparency, product presentation and security.

Under the circumstances of a dynamic and complex market environment as well as high innovation and competitiveness of solutions, the following questions arise: what characteristics and form should the software of websites and internet platforms adopt to increase their attractiveness to the client? which of the sets of attributes and functionality of these sites seem the most important?

Answers to these questions can be provided by means of a thorough analysis of the requirements of users of online platforms. The quantitative and qualitative research into users' opinions is needed for this purpose, and the study should examine, on the one hand, the use of software and, on the other, the websites which are the sources of its acquisition. Taking into account the fact that there are few and random studies regarding this sphere, both in national literature [8] as well as foreign sources [9-11], the research was based on the authors' own approach consisting of the following steps: selection of the test group, constructing an online survey characterizing websites and distribution platforms from the client's point of view, verification of the survey based on the test group, selection of the most important assessment criteria from the client's point of view, identification of the most important factors influencing the behaviour of the users of websites and distribution platforms and making the revised survey available again on the Internet, along with the dissemination of information about the possibility of its completion, analysis and discussion of the findings, drawing conclusions from research and design recommendations for growing platforms.

The simplified, standardized scoring method of R. Likert [12] was used for the assessment of each specified criterion. On this scale, each criterion was evaluated as follows: 0.00 - the criterion is not implemented, 0.25 - the criterion is implemented on a minimal, sufficient level, 0.50 - the criterion is implemented on the medium level, 0.75 - the criterion implementation level is good, 1.00 - full implementation of the criterion.

The selection of online gaming stores was made based on the analysis of the frequency of the first hundred of Google search results, after entering the keywords: *witryny dystrybutorów gier* (computer games websites) and *platformy dystrybutorów gier* (platforms of computer games distributors). This list has been verified by taking into account the opinions of students who frequently and intensely play computer games via digital platforms. The research was carried out in November 2017, on a sample of 713 randomly selected members of the academic community. 549 people completed the survey (over 77% of respondents), where - after a thorough analysis - 368 survey participants provided complete answers regarding the selected four platforms, which constitutes 67% of the respondents. 33% of the sample uses other platforms than the four websites selected for the present analysis.

The online survey was made available on the servers of the Faculty of Management at the University of Warsaw. The sample included the representatives of the academic community, students of all types of studies at two universities: the University of Warsaw and the Vistula Academy of Finance and Business, who were interested in completing the online survey. The study was carried out in two stages. The first stage concerned the evaluation regarding which of the distribution platforms are the most popular among students, which assessment criteria are the most suitable for the evaluation of distributors' websites and which should be applied to evaluate the applications of the selected Internet platforms. In the second stage, the services and selected applications were analysed according to user-defined criteria for the four previously mentioned online platforms. The survey was completed correctly by 368 respondents, evaluating only those websites they were familiar with out of the four websites considered in the study. Some of them rated two (55 people) or three websites (26 people). This resulted in a total of 446 observations. GOG was rated by 116 people, Origin by 121 respondents, Uplay by 108 and Steam by 103 individuals. Among the survey participants, there were 72.5% of women and 27.45% of men. The average age of respondents was 20.6 years, which was typical for BA and BSc students, mainly with secondary education (over 94%). Over 42% of respondents were non-working students, and almost 58% were working students. Almost 30% of respondents declared coming from the city of over 100,000 residents, over 26% from cities with 11-100 thousand inhabitants, and over 43% from villages or towns up to 10,000 residents.

III. Analysis and discussion of the findings concerning computer game distributors

The questionnaire was divided into three parts: an introductory part comprising eight questions, an analytical part (37 questions about websites and 6 questions regarding the application), a field of opinions, comments and recommendations of users, as well as a data sheet describing the test sample.

A. Introductory information

In order to analyse the obtained data, the scoring method was applied. Each of the respondents assessed individual

criteria in a subjective way. The assessments were then added together, structured and averaged, followed by a reference to the maximum possible assessment of each indicator, both in the cross-section of websites/applications and the criteria for the respondents evaluating them. From the authors' experience, the findings obtained with the application of comparative analyses of websites by scoring method are just as valuable as those received in the case of more sophisticated methods (AHP/ANP, Electre, Promethee and others) [13].

The first question concerned the moment when people using distribution platforms started playing computer games. Nearly 53% of respondents said that they started playing computer games in primary school, more than 12% in preschool age, almost 11% have been playing games from middle school, high school and college, and 24% did not play computer games at all. Among the gamers, almost 47% play games occasionally (once or twice a month), nearly 21% several times a week, 15% of the share - several times a month, more than 10% very rarely - several times a year, and more than 7% play computer games daily. After specifying this question, it turned out that 59% of the sample spend less than an hour a week playing computer games, and 16% play only 1-2 hours a week. Thirty percent of gamers use only a smartphone for their games, over 23% a PC or a desktop computer, 19% use a PC and a notebook, over 20% use a console or a portable console, and 8% - a tablet.

The next question concerned PC and console platforms where students have their accounts. Over 25% have an account on the Origin platform, over 21% on Steam, almost 10% on GOG and Uplay, and the remaining 33% of the share on the Windows Store, Xbox Games Store, Battle.net , PlayStation Store and Nintendo eShop.

Over 53% describe themselves as experienced players (many years of experience and a wide range of games they played), 9% believe that they are advanced players (they play almost every day, different games on different equipment at least from elementary school, 15% claim that they are casual players (novices or people playing only occasionally, e.g. once a month or every three months), and 23% do not play at all.

The students play mainly games that are free of charge - 74%, they do not spend any money on it. Of the remaining 26%, 13% of this share spend up to PLN 20, and only a little over 1% of the respondents spend over PLN 100.

B. Analysis of the findings concerning websites

Analyses of the findings concerning the evaluation of websites of the selected computer game distributors were made in two cross-sections: according to the websites and according to the evaluation criteria. The first cross-section was created by averaging the scores obtained for all specified criteria. The assessment for the detailed criterion was calculated as its percentage share in the potential maximum score that could be obtained during the implementation of a given criterion. All websites included in the ranking have achieved ratings exceeding 50% of the maximum possible score, so it emerges that the clients are generally satisfied with the services they offer. The average assessment in the respondents' opinions is close to 67%. Among the analysed websites, Steam received the highest rating with over 68%, the lowest rating was indicated in the case of GOG Galaxy - almost 66%. Thus the spread of results is in the range of 3%, which is very low value with regard to websites. The leading position in the case of Steam was caused by the highest score obtained for such groups of criteria as: product distribution, website clarity, the quality of product search and ordering process quality - where the average rating of these four criteria was 72%. The lowest rating of the GOG Galaxy website resulted from the highest rating in three categories: on-page ads, information quality and website navigation, with an average of these three criteria equal to 63%. Origin, where product presentation received the highest scores and Uplay (the best promotions) have taken the middle positions. The Steam service was the only website which ranked above the average; however, the difference amounted to less than 2 percentage points. The rating of the remaining websites was slightly below average.

Out of all nine groups of criteria, the highest scores were assigned to the product presentation (76.63%), the quality of the ordering process (72.05%) and the quality of the product search engine (69.67%). This demonstrates the pragmatism of website designers, who first of all pay attention to the most important factors from the point of view of sales that may encourage the clients to visit the website again. The lowest scores were recorded in the case of quality of advertising presented on the website (55.02%), information quality (61.51%) and promotion (64.08%). This is an interesting phenomenon, which shows that there is a growing dissatisfaction (compared to previous surveys of websites) with the excessive and redundant advertising on the website. The discrepancy between ratings is very large in this case, reaching 23 percentage points. The scores which are above average (which amounts to 66.74%) were recorded in the case of four groups of criteria – i.e. the above-mentioned factors listed in the three positions, as well as the criterion described as website navigation (67.15%). More detailed analysis will be present in extended version of the article.

C. Comparative analysis of platforms

Analyses of the evaluation results of the installed applications of the selected computer game distributors were also made in two cross-sections: according to websites and according to the evaluation criteria. The first of them was based on the average calculated for each distribution platform based on detailed assessments. The calculation indicates the absolute domination of the Steam application, expressed by the five highest average ratings in five categories of criteria, out of all six possible. In the opinion of respondents, only in the group of the product presentation (i.e. information about products and tools), the GOG Galaxy application gained the advantage of 3 percentage points. At the same time, it is a group of criteria with the highest average

assessment (74.02%). The lowest score (67.98%) on all platforms was assigned to the installation package (size and ease of access and ways of its distribution). The difference between the maximum and minimum scores amounts to 6 percentage points. Only the Steam platform with its results is above the average of all results. The lowest score was obtained in the case of the GOG Galaxy platform with the result of 69.93% by 4 percentage points less than Steam. The scores of Origin and Uplay platforms were only about one percent higher.

The order of the groups of detailed criteria determined the ranking order. The average for Steam was 73.72%. This was mainly due to the high search engine rating (in terms of usability and mode of operation), the appearance of the application, the layout of the elements, scalability to the screen size, clarity and readability (presentation of notifications and messages and the ease of finding information on the menu). The evaluations of Origin (70.95%) and Uplay (70.55%) are only slightly lower. The presentation method and the quality of the search engine received high scores, the worst scores were assigned to the installation package in each of the selected applications. Apart from this feature, the scores below the average (amounting to 71.23%) were indicated in the case of security – i.e. securing payments and access to purchased products.

For this study, the installation files of applications were downloaded directly from the distributors' websites in the November 2017, bypassing intermediaries. The application designed for the Windows platform was evaluated because all platforms operate on this operating system. Uplay has no alternative to other operating systems, while other platforms also have Mac installations, and Steam also distributes installations on Linux. All installation files were easily accessible from the manufacturer's website.

All platform applications require an active account. Each of them offers the opportunity to work offline, and the ability to add games from outside the platform. The installation process on all platforms proceeded in a similar manner and was not complicated. The most consistent and simplified installation process occurs on the Origin platform. It should also be noted that the installation is usually performed once.

IV. Analysis of the findings with the application of a scoring method with preferences and the discussion of the findings

One of the methods limiting the subjectivity of the experts' evaluations of users in the case of a scoring method (apart from the prior averaging of scores) is the application of unitary preferences, to particular criteria or selected criteria sets. In this study, the authors divided the criteria into three groups which are important or particular categories of users: novice – this category of a user is characterised by the interest in what he or she may evaluate at first sight, as well as the ease of obtaining a product and making a payment; gamer – a person who perceives a game as entertainment, frequently first plays games which are available free of charge on their smartphone, the switches to PC or console games; professional – a person who plays very frequently (every day), is passionate about playing games, plays all the latest games and is ready to pay for using them, plays professionally and can even earn money on the activity, etc. (he or she is mainly interested in the functional aspects: the presentation of the product, the quality of information (the amount of information on a website, the possibility and manner in which one may ask questions, ease of access to information), the quality of the product search engine (the number of modifications, the number of filters, accuracy of answers, clarity of the scores). For each group, the authors adopted one variant with a group of dominating criteria: novice (70% for technological aspects, 15% for the remaining ones); gamer (70% for service-related criteria, 15% for the remaining ones); professional (70% for functional criteria, 15% for the remaining ones).

Assigning preferences to particular groups of criteria resulted in slight changes in the rankings. The greatest changes could be observed in the case of the novice category in the case of games where Uplay platform moved from the last place to the second position in the ranking. In the remaining cases, the authors only recorded the reduction of the distance in relation to the previous experiment. Small differences confirm that despite the significant differences with regard to the strategy of the development of the examined platforms, there emerges a specific standardization of the product/services ranges offered to clients. The summary of the positive features of the ranking points to the dominating position of the Steam platform. Only in the variant of an e-gamer, the scores obtained for the Steam and Origin platforms were above the average, and in the case of a gamer only Steam platform reaches the scores beyond average, in the case of the novice, such scores were obtained for Steam and Uplay platforms.

V. Conclusions and recommendations

The conducted survey studies, supplemented with the opinions and comments of clients of computer games shops (the original wording of the respondents' opinions was retained), lead to the following conclusions: the majority of users are satisfied with the appearance and functioning of the websites distributing computer games, which is evidenced (mostly) by high scores (above 50%) of the specified criteria and their average values, both in the case of the selection of the examined companies as well as the evaluation criteria sets; the respondents emphasise the fact that in the case of the analysed websites they pay particular attention to the website features which allow them to easily obtain information on the content of the game (product information – 83% on average, and the information clarity – over 78%), as well as to find out whether they will be able to use all the functionalities of the game (hardware requirements - over 78%), ease of registration and payment (registration method and payment options – over 72% of approval), the lowest scores were obtained in the case of the excessive and intrusive advertising on the website (over 43%), despite the fact

that these are mainly advertisements aimed at self-promotion; Due to the fact that most of the individuals using the platforms consider themselves to be gamers, or even advanced gamers (65% in total), they are not interested in the manner and possibility to ask questions (51% and 56% respectively), as well as restrictions for unregistered users. Majority of the platforms is not designed for novices; clients value the simplicity and clarity of the analysed websites and the scores as well as the ease and intuitiveness of navigation, including the product search, the website selling computer games needs to be easy and clear to use, and a client cannot have any problem finding what he or she needs; the respondents pay attention to an important role of visualisation in attracting customers to computer games shops, simultaneously being aware of the fact that an excessive number of graphic elements may disturb visitors in making a selection and purchase,

At present, Steam is a world leader in the category of computer games distribution, and its high score in this study confirms its position and the awareness of the market where it operates. The lower scores indicated in the case of other platforms may be explained with the fact that it is targeting a rather narrow group of recipients, who do not mind certain shortcomings with regard to the website since they are satisfied with the high quality of the final product they purchase. Origin and GOG have a modern look and very good tools to communicate with the user. The design of the Ubisoft website appears to be obsolete, and thus it may be seen as unattractive. Moreover, another disadvantage of Ubisoft is the lack of consistency with regard to the naming of the website and the application which is installed on a PC to use the purchased games.

One of the limitations of the study was undoubtedly focusing on only four distribution platforms. These are the leading platforms on the market, and in total they constitute – according to statistics - approximately 70-80% of the market share.

The diversity of the opinions concerning the computer games websites causes some difficulties with regard to generalizing the evaluations. In the case of platforms offering games from independent designers there emerge various phenomena (such as “fake games”) [14], which may negatively affect the rating of a particular platform. Despite the high popularity of this type of websites, the similarity of their evaluations to the evaluations of internet shops in other areas of business [15]. Thus, it may be stated that there occurs a specific standardisation of views on how the website should look like. On the other hand, it gives also the idea on the discrepancy between the users’ expectations and the projects of their creators. Moreover, one may conclude that the traditional principles of designing websites are still up-to-date and applicable.

***Abstract*— Industrial administrators are promoting approaches to improve energy efficiency and developing smart homes and appliances. Development of green technology requires accurate models. Real-time Measurement and Verification (M&V) procedure is used to quantify energy performance. It is conducted through short-term on-site measurements and engineering calculation. The period of this procedure lasts for several months or up to a year so the failure to immediately detect abnormal energy efficiency decreases energy performance so timely correction of appliances will be unable and the opportunity to adjust or repair them will be missed. In this study, a cloud computing platform is established to measure the washing machine energy consumption parameters and calculate energy savings which consist of load sensors and fuzzy control. Time-series data are transmitted to the cloud environment through the network and saved in databases. On this platform, for constructing accurate models, integration of the particle swarm optimization (PSO), M&V methodologies and multivariate regression analysis are used. After uploading energy consumption data directly, pre-installation energy baseline model is created and post-installation real-time energy performance calculation is obtained. Observing fluctuations of washing machine energy consumptions provides real-time monitoring or correction of the operating performance of the appliance or system and then good energy performance can be obtained. The aim of this study is to gain real-time and long-term energy performance information and automatic calculations of energy savings on washing machines. Using this cloud platform for home appliances could help the manufacturers to promote energy efficiency programs on smart appliances.**

I. Introduction

Energy consumed in buildings consists of residential and commercial end-users and accounts for 20.1% of the total delivered energy consumed worldwide. Energy performance is evaluated through measurement and verification (M&V) procedures under the Tradable White Certificate, Clean Development Mechanism, Demand-Side Management, Energy Service Companies (ESCO) and Energy-Saving Performance Contracting [1]. M&V procedures have become an important key in the energy efficiency policies. Related works were conducted. Bertoldi, et al. [2] standardized contracts and M&V procedures based on the results of reviews and analysis of ESCO industries in the Europe and help end-users understand the M&V procedures. International performance measurement and verification protocol has been used by many countries. This protocol describes M&V concepts and methodologies to determine energy savings for energy conservation measures (ECM) s in residential buildings and industrial processes. For M&V of energy savings in building energy management projects, the American Society of heating, refrigerating an air-conditioning Engineers Guideline 14 is used [3]. This guide contains M&V concepts and methodologies to calculate energy and water savings in residential, commercial and industrial buildings. Different methods are applied to various energy conservation measures to calculate the baseline model and energy saving. Many M&V studies have been conducted. Lee [4] proposed an accurate model for energy savings calculation by long-term monitoring and assumed this model for individual cases because actual lighting conditions may differ from data, which provided by clients, and this difference makes errors in energy saving calculations. Dong, et al. [5] presented a baseline model for energy consumption in buildings by using regression analysis and considered different parameters for the baseline model which included outdoor dry-bulb temperature, relative humidity, and global solar radiation. They used statistical indicators such as coefficient of determination (R2) and the coefficient of variation of the real-time-square error (CVRMSE) to verify the accuracy of the baseline model. Related works show that regression analysis methods are used for constructing M&V baseline models to evaluate the performance of energy conservation measures accurately. PSO algorithm creates more accurate models than the least error squares techniques.

In this study, a cloud computing platform for real-time measurement and verification of energy saving performance is created based on the M&V methodology and integrating of PSO algorithm, java programming language, and cloud computing techniques. While baseline models are applied automatically for pre-installation and real-time energy saving performance is calculated automatically after post-installation, the cloud computing platform reduces the time

and cost of M&V and increases the accuracy of energy saving calculations.

A. Measurement and Verification Procedure

Non-profit Efficiency Valuation Organization (EVO) proposed the International Performance Measurement and Verification Protocol (IPMVP) which explains how to determine baseline data and calculate energy savings. Baseline data should be established because energy consumption in the pre-installation period (i.e., baseline period) cannot be measured by instruments after energy conservation measures (ECM) have been implemented [6]. Therefore, adjustments (A) to the baseline data are required to determine the energy consumption of the equipment and systems during the baseline period (BP) and the energy consumption during the post-installation period (reporting period (RP)) under the same operating conditions [7] The amount of savings (S) can be calculated as shown in (1).

$$S = (BP - RP) \pm A \tag{1}$$

There are four options, A through D, for M&V procedure. In option A, only key parameter will be measured. But in option B all parameters will be measured. A and B options can be used when evaluating the performance of a single conservation measure. Energy consumption parameters will be measured for pre-installation and post-installation. Statistical methods or engineering calculations are used for evaluating the energy performance [8]. In option C, energy conservation measure is calculated by analyzing energy bills and statistical methods. In option D, first energy savings are calculated by specialized software and energy consumption for pre-installation and post-installation in simulated. Then the energy bill data are used to correct the simulation models. C and D options are used for evaluating energy conservation measures in whole buildings or in situations where measurements are difficult.

B. Particle swarm Optimization

PSO is a probability-based optimization technique that was developed by Eberhart and Kennedy [9] and inspired by the social behavior of birds or fish in finding food. It is assumed that a group of birds are randomly searched for food in a region, while food is only available in one part of the search area [10]. In PSO, each answer is a bird in the search area called the particle. Each particle has a fitness value obtained by the objective function. The bird that is closer to food is more desirable [11]. Steps of PSO algorithm and Equation of it are as follow:

$$V_i^{k+1} = W \times V_i^k + L_1 \times r_1\left(Pbest_i^k - X_i^k\right) + L_2 \times r_2\left(Gbest_i^k - X_i^k\right) \tag{2}$$

$$X_i^{k+1} = X_i^k + V_i^{k+1} \tag{3}$$

(1) First, a position and velocity is randomly considered for each particle in N-dimensional space.

(2) Next, an objective function is used to determine the fitness value for each particle.

(3) The fitness value is compared to the current best value for each particle (Pbest) and then the particle velocity is adjusted to improve the fitness value in the next iteration.

(4) A comparison between Pbest and the current best value for group (Gbest) is conducted, if Pbest is greater than the Gbest, then Gbest will be adjusted. The velocity and position of each particle are then adjusted based on Gbest for the next iteration.

(5) Each particle's velocity and position are updated using (2) and (3) as shown in Table II.

II. Cloud Computing Platform for M&V of Real-Time Energy Performance

The architecture of cloud computing platform contains three layers: first is the on-site measurement layer, second is the cloud computing layer and the last one is the user layer.

(1) *On-site measurement layer:* Energy consumption and other energy parameters are stored in storage devices and then all collected data are transmitted to the cloud computing platform via the internet.

(2) *Cloud computing layer:* All calculations are conducted in this layer, including creating files, receiving data, transmitting data, filtering data, sorting data, executing PSO algorithm operations, constructing baseline equations and energy savings calculations. In this cloud computing platform, the Google App Engine (GAE) is used as the cloud-based server. For displaying the results on graphs and curves and calculating energy savings automatically, web pages are created dynamically in hyper markup language (HTML) or JavaScript.

(3) *User layer:* In this layer, users can communicate with the cloud platform via their computers and follow the energy consumption fluctuations of any appliance at any time interval and on the curves, and also finds abnormal patterns, so they become aware of the critical issues of the appliance.

III. Software Architecture

Software architecture of this cloud platform contains PSORun (server), PSORun (client) and the Data Upload Program which are described as follow:

- *PSORun (server):* this program includes four subprograms and established on the GAE platform.
  1) *ProjectServiceImpl.java:* the functions of this program include project creation, project storage, project deletion and PSO operations. Which conducted by this primary program.
  2) *File Upload.java:* when pre-installation baseline data are uploaded and cloud computing results are returned, this program is called and executed.
  3) *DoGet and DoPost are hypertext transfer protocol requests:* DoGet protocol retrieves and

transmit data from the server to users and DoPost transmit data from the user to the server.

- *PSORun (client):* web page creation

Projectlist.java: this program is an interface which can be divided into two subprograms:

1) projectList-Savingview.java: is the interface for energy savings calculations
2) ProjectList-Manage.java: is the interface for managing projects.

- *Data Upload Program*: this program uploads post-installation data in a fixed format to the cloud platform for calculating energy savings.

IV. Constructing the Baseline Model Using PSO

Users can determine the number of independent variables in baseline regression model using cloud computing platform. In this study four energy consumption parameters (i.e. four independent variables) are used in the baseline regression model. The pre-installation energy consumption is assumed as P and the measurement of the four independent variables are considered as X, Y, V and Z. the PSO algorithm is applied to determine the coefficient of each independent variable (C_0- C_{14}) [1].

$$P = f(X, Y, V, Z) \tag{4}$$

$$P = C_0 + C_1 \times X + C_2 \times X^2 + C_3 \times Y + C_4 \times Y^2 + C_5 \times V + C_6 \times V^2 + C_7 \times Z + C_8 \times Z^2 + C_9 \times X \times Y + C_{10} \times Y \times V + C_{11} \times V \times Z + C_{12} \times X \times Z + C_{13} \times X \times V + C_{14} \times Y \times Z \tag{5}$$

In this process, the cloud computing platform first filters the pre-installation data using a regression analysis while retains data with less than 10% errors for dependent variables. Then, PSO regression analysis is used to determine the coefficients of independent variables to complete the baseline model. Further, the filtered independent variable data can be used as the upper and lower limits for post-installation data filtering, therefore users can be assured that the ranges of the baseline model and uploaded data are matched and the energy savings are calculated accurately. PSO algorithm includes the number of particles, number of iterations, inertia weight (w), cognitive learning factor (L_1), social learning factor (L_2), maximum particle velocity (Vmax), minimum particle velocity (Vmin), maximum particle position (Xmax), minimum particle position (Xmin), random numbers (r_1 and r_2) and convergence condition (Z_minAvg) which can be defined by the user. When the PSO algorithm determines that the convergence condition has been satisfied, the calculations will be determined. The convergence condition in this study is the relative error of dependent variable in (6).

$$Z = \sum_1^n \frac{depend\ variable - depend\ variable\ pso}{depend\ variable} \times 100 \tag{6}$$

V. Energy Saving Calculations

Energy saving calculations require uploading post-installation data to the cloud platform and a corresponding pre-installation project ID and URL should be entered like a data file name and file path. Inputting post-installation energy consumption values to the pre-installation baseline model yields the pre-installation energy consumption with the same conditions. Energy performance is obtained by subtracting the post-installation value from the pre-installation value (1).

While the post-installation data are uploaded to the cloud platform, a data filtering function is used to allow the appropriate data range to be set, so energy savings will be calculated accurately. In this cloud computing platform, energy performance information including average energy savings (KW), total kilowatt-hours savings (KWh), average percentage of energy savings, and energy cost saving are calculated.

In addition, constructing a time interval calculating function allow users to set a time interval so they can monitor fluctuations in the pre-installation energy consumption (Padjusted) and post-installation energy consumption (Pmeasured) on a graph and users can select a time point over the curve to see the associated data record and gain the results online.

VI. Case Study

The M&V cloud computing platform is used to assess the energy conservation for the washing machine. This platform automatically calculates the energy consumption, energy savings, and the energy cost savings. In addition, this system displays the results on the web pages and allows users to monitor the energy savings and energy performance and whenever the efficiency of the washing machine comes down, it warns the users, for example, washing their laundries in proper time or change the filter of machine. According to (4) and (5) five parameters, wash load (L_w), the amount of water (W_q), the temperature to be reached (T_f), energy consumption (P_e) and spin speed (V_s), are selected and shown in (7). First, the project ID, project name, and PSO parameters Table II were entered into the real-time energy performance M&V cloud computing platform. Next, pre-installation energy consumption data are uploaded for calculations. Cognitive Learning Factor is a broad theory that explains thinking and differing mental processes and how they are influenced by internal and external factors in order to produce learning in individuals. Social Learning Factor (Bandura) Bandura's Social Learning Theory posits that people learn from one another, via observation, imitation, and modeling. The theory has often been called a bridge between behaviorist and cognitive learning theories because it encompasses attention, memory, and motivation. Then the PSO algorithm is applied to determine the coefficients of these independent variables (C_0-C_{14}) and the construction of the baseline model is

complete and the message ‘‘true” was displayed for the field ‘‘computations completed”.

$$P_e = C_0 + C_1 \times L_w + C_2 \times L_w^2 + C_3 \times W_q + C_4 \times W_q^2 + C_5 \times T_f + C_6 \times T_f^2 + C_7 \times V_s + C_8 \times V_s^2 + C_9 \times L_w \times W_q + C_{10} \times W_q \times T_f + C_{11} \times T_f \times V_s + C_{12} \times L_w \times V_s + C_{13} \times L_w \times T_f + C_{14} \times W_q \times V_s \quad (7)$$

After the post-installation data for energy consumption and other energy parameters are uploaded to the cloud computing platform for the real-time M&V of the energy performance, the calculations indicates the energy savings accumulated over 11.5 h. Specifically, the average energy savings is 20.3 KW, the total kilowatt-hours saved is 2.8 KWh, the average percentage of energy savings is 25%, and energy cost savings was $523 as shown in Table I.

TABLE I.
THE POST-INSTALLATION ENERGY SAVINGS FOR THE WASHING MACHINE

Average energy savings(KW)	20.3KW
Total kilowatt-hours savings	2.8 KWh
Average percentage of energy savings	25%
Energy cost saving	523$

TABLE II.
PSO PARAMETERS VALUE

Interia weight (W)	0.4
Social learning factor (L2)	2
Minimum particle velocity (Vmin)	-5
Minimum particle position (Xmin)	-20
Maximum number of iterations	10,000
Cognitive learning factor(L1)	2
Maximum particle velocity (Vmax)	5
Maximum particle position (Xmax)	20
Number of particles	300
Convergence condition (Z_minAVG)	0.1

VII. CONCLUSION

Over the past few years, the energy efficiency and the market penetration of efficient washing machines has increased. Key parameters of washing machines are their energy and water consumption (full and partial loads), spin-drying efficiency and supply for hot fill. There are many washing machine features which make sense concerning energy efficiency containing load-auto sensor, automatic temperature control, automatic dispensers, spin speeds, fuzzy control and all water washing machines. The key parameters of washing machines can be achieved by these features. Observing fluctuations of the washing machine energy consumptions on a curve can help the users monitor the appliance operations and gain information about the energy consumption, a view of calculating energy savings and detect abnormal functioning. In this study a washing machine is considered with four independent variables including wash load, the amount of water, temperature to be reached, speed of spin and energy consumption for heating, mechanical actions, and pumping. A cloud computing platform for the M&V of the real-time energy performance that integrates the M&V methodology, PSO, and multivariate regression analysis modeling is conducted on the GAE cloud platform. The M&V cloud platform use uploaded real-time energy consumption data and create pre-installation baseline model and post-installation real-time energy performance calculation. When independent variables are uploaded onto the platform, a baseline regression model can be established and the energy performance can be calculated then the results will be displayed on the web page. Therefore, whenever energy consumption rises or energy savings decrease, the system alerts and suggests that the relevant problem be corrected for example the system suggests that the filter should be changed or declares the time inappropriate. This procedure can be used for evaluating energy performance accurately.

Comparative Analysis of Big Data Analytics and BI Projects

Gloria J. Miller
SKEMA Business School
Lille, France
Email: gloriajean.gloria@skema.edu

Abstract—Decision support systems such as big data, business intelligence (BI), and analytics offer firms capabilities to generate new revenue sources, increase productivity and outputs, and improve competitiveness. However, the field is crowded with terminology that makes it difficult to establish reasonable project scopes and to staff and manage projects. This study clarifies the terminology around the data science, computation social science, big data, business intelligence, and analytics and describes their meaning relative to decision support projects. For BI and big data projects, it identifies the critical success factors, empirically classifies the project scopes, and investigates the similarities and differences between the project types. This comparative analysis provides unique insights into the factors and criteria that influence BI and big data project success. These results should inform project sponsors and project managers of the contingency factors to consider when preparing project charters and plans.

Index terms: Big data analytics, data science, business intelligence (BI), project success factors

I. Introduction

DATA Science and computational social science are emerging interdisciplinary fields that overlap in content with big data, business intelligence (BI), and analytics. As more data have become available on the internet, social media, and other source organizations have begun to collect it in growing volumes, new business models and algorithms are emerging, and data sales have become potential revenue sources [3]. Despite the increased attention to big data, the critical success factors for decision support projects have received little attention in the project management literature. Decision support projects are implementation projects that deliver data, analytical models, analytical competence, or all three, for unstructured decision-making and problem-solving. They include subspecialties such as big data, advanced analytics, business intelligence, or artificial intelligence. Without insights into the project's critical success factors, it can be challenging for project sponsors and managers to establish a reasonable project strategy and to achieve the desired benefits efficiently.

The emerging status of these fields means that terminology is not standardized. Scant research exists about the application and scientific and commercial implications of these domains to project management. There is little understanding of the impacts of those differences in transitioning organizations in order to benefit from those scientific areas and data platforms. This paper empirically investigates the critical success factors for decision support projects and provides a comparative analysis of big data and BI projects. This comparative analysis provides unique and previously unpublished results on the structural factors that contribute to decision support project success. The findings of this study add to technology and project management practices. In particular, it provides in-depth insights into what factors influence big data and BI project success. It provides information on the similarities and differences with regard to the criteria for measuring success. These results should inform project sponsors and project managers of the contingency factors to consider when preparing project charters and plans.

II. Literature Review

A. Business Intelligence

Business intelligence is used to refer to technology, processes, and software used to transform raw data into intelligence for computer-aided decision-making. The BI process includes the collection, evaluation, analysis, and storage of data and the production and dissemination of intelligence [6]. Davenport and Harris [7, p. 7] define analytics as a sub-category of BI that includes "*the extensive use of data, statistical and quantitative analysis, explanatory and predictive models, and fact-based management to drive decisions and actions.*" Otherwise, the term analytics is not standardized in literature.

B. Big Data

As data volumes have grown and computing requirements have increased, technologies and tools used to manage, manipulate, and understand data have evolved [8, 9]. On the one hand, there is a consensus that "Big Data" refers to the attributes of data——velocity, variety, validity, and volume—— and on the other hand, it refers to innovative technologies and processes that allow for the use of data in novel ways [3].

C. Data Science

Data science is an interdisciplinary field that includes data analysis, statistics, data mining, and models; it has the goal to transform data into knowledge by finding patterns and trends in the data [8, 10]. The terminology originated as a role description for a single person who could act as a Business

This work forms part of a research project on "Decision Support Project: Project Success and Organizational Performance" conducted by the author.

Analyst, Statistician, Engineer, or Research Scientist [8]. Davenport and Patil [10] popularized the data scientist's role in their "Harvard Business Review" article; they described it as "a high-ranking professional with the training and curiosity to make discoveries in the world of big data" [10, p. 72].

D. Computational Social Science

Computational social science refers to revealing patterns related to group and individual behavior. It is based on the emergence of scientific research methods that can leverage big datasets [11]. Computational intelligence refers to approaches where algorithms intimate human information processes and reasoning [12].

E. Project Success Factors

Projects are a form of temporary organization for introducing changes and transitions into organizations. The transition is the change or transformation expected as a consequence of the temporary organization's tasks. Project success refers to the project delivering its expected output and achieving its intended objective [13, 14]. Success criteria and success factors are the main elements of success. Success criteria are used to judge the outcome of the project, and success factors influence the likelihood of achieving a successful outcome. That is, the success criteria determine measures or indicators for success, while the success factors refer to the circumstances, conditions, and events that support the project in achieving its objectives [13, 14].

F. Summary

There is significant overlap in the implementation processes and technologies used between big data, analytics, BI, decision science, and computational social science. We can summarize the terminology as follows for further use in this paper. BI, big data, and computational social science have similar technical processes and techniques but differ in use cases. BI focuses on the platforms, architectures, and tools for the provision of data and intelligence and has an enterprise orientation. Big data seeks use cases to monetize data directly through its sale or indirectly through data-driven business models or algorithms. Computational social science has a scientific research focus. Its use case focuses on leveraging big datasets for learning. Data science refers to the responsibilities of the people who use BI, big data, or analytical techniques; it describes a role or job.

III. Research Methodology

The research used a web-based survey with quantitative methods to collect data on decision support projects and to explore the difference between BI and big data analytics' project characteristics. The measurement items and composite variables are based on a review of the literature and quantitative analysis conducted by [15]. The survey collected the data over a ten-week period (September 2017 to December 2017) from a single informant. Project managers, team members, and sponsors from completed decision support projects were asked to take the survey. The responses were checked for scope, completeness, consistency, ambiguity, missing data, extreme responses, outliers, and leverage. Validity checks for common method bias, response bias, and reliability were conducted. No bias was found, and the data were considered to be reliable and valid.

The survey sample was comprised of 82 usable responses as follows: 76% of the respondents have a master's degree or higher; 38% perform IT roles; 18% are from a project management office; 48% are project or program managers; 5% agile coaches; 22% project team members; and 5% are project sponsors. The organizations sponsoring the projects were mostly publicly traded (51%) and were large, with more than 249 employees (83%) and US$50 million in revenue (78%). They are spread throughout 22 different industries and 24 countries. The majority of the participants were from Europe (74%).

Latent Class Analysis (LCA) was used to classify the types of projects. Descriptive statistics, mean ranking, Wilcoxon score, and correlation analysis were used to explore the characteristics, establish the validity and reliability, and explain the relationship between the variables.

IV. Construct Operationalize

Project critical success areas based on [1] and decision support success systems factors were used to formulate the measurement instrument. Table I includes an abbreviated description of the measurement items. Most of the items are based on a five-point Likert scale (1 = Not at all; 5 = To a great extent). To ensure completeness of data, "Don't know" or "Not Applicable" (N/A) was added to the Likert scale. Items that used different scales are described in the relevant sections.

A. Project Mission

The project mission represents the clarity of goals and directions [1]. The following deliverables proposed by [7] as valuable components of analytics projects were used in the analysis to define the project strategy and classify the project types: *Proprietary algorithms* or business models, *new data* that was not previously available in the company, deliverables embedded into *distinctive business processes*, and data science or *analytic competence*. The measurement instrument did not directly ask a question on the project's objectives. Thus, the organizational impacts of the project were used as proxies for defining the business strategy and vision. The impacts include the *cost* and effort-saving or increases in productivity, increases in *revenue,* and *strategic benefits* such as providing new and reusable learning or improving forecast and prediction accuracy.

B. Top Management Support

Top management support is needed to authorize the project and to provide the resources and authority to execute the project [1]. User contribution is divided into user participation and user involvement [17]. *Participation* represents an active role in the development process and *involvement* represents the importance and personal relevance an individual places on the system or project. Top management support was measured based on top management and senior management involvement.

C. Project Schedule/Plan

The project plan represents the steps needed to reach the project goal [1]. The Shenhar and Dvir [18] project classification model was used to define the attributes of the project. The three levels of *Technological uncertainty* refer to the degree to which the company is using a technology it has never used before: no, some, almost all, or all new technology. *Complexity* is described on three levels: assembly, system, and array. *Pace* describes the sense of urgency and the four levels are: regular, facts/competitive, time-critical, and blitz. Product *novelty* represents the uncertainty of the project goals and in the market: derivative, platform, and breakthrough.

D. Client Consultation

Client consultation involves engaging the internal and external stakeholders to give them the opportunity to air their views, influence the project plans, and know what has been decided [13]. Top management, senior manager, and business user involvement were evaluated using their participation in *steering* (establishing criteria), *directing* (steering and solving conflicts), *acceptance* (evaluating outcomes), and *participation* in projects tasks, specifically setting requirements and building models.

E. Personnel

Competency attributes were used to evaluate the specialized skills required for the staff [2, 8, 10]. The items measure the effort required to deliver quality services during the project for competencies highlighted by Debortoli, Müller and Vom Brocke [19] as being relevant to BI and big data, including *technical*, *business*, *data*, and *analytical* competence. The *data scientist* item considers the involvement of an analytically competent person or persons on the team.

F. Client Acceptance

Lucas Jr [20] suggests that the decision-making style of the users is a factor in their ability to comprehend and accept the results of decision support systems. Thus, *system use* is a measure of client acceptance. System use covers the mandatory and voluntary use as a measure of system success [21]. Top management and senior management participation include their usages of system results in *decision-making* or decision-making and *acting* on the results.

G. Technical Tasks

Success factors for technical tasks are addressed from multiple perspectives such as data sources and IT infrastructure, which includes the availability and quality of data, as well as the heterogeneity and sophistication of IT infrastructure [2]. New and existing items previously used in the DeLone and McLean (2003) [22] information systems success model were used to create factors by [15] and used to evaluate the technical tasks.

H. Monitoring and Feedback, Communication, Troubleshooting

The project manager and team members, the organization, and the external environment are four interrelated groups of project success factors [1, 23]. *Project management competency* is a quality measure for change management, planning, or agile competency [19]. Other environmental factors evaluated include: project demographics, budget, duration, number of departments involved, number of organizations involved, and team size. Organizational demographics include revenue, number of employees, market share position, and revenue position.

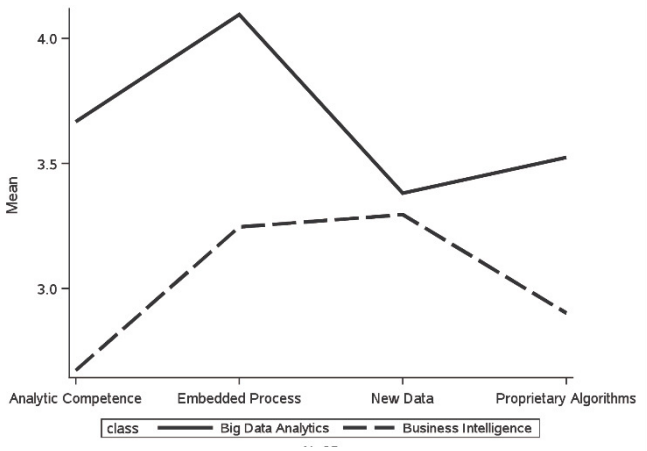

Fig. 1. Two-Cluster Model Structure

V. ANALYSIS

The latent class clustering technique was used to identify the homogeneous clusters. The dimensions were modeled in RStudio 1.0.153 using poLCA for the analysis. The four items for the BI/BD strategy in Table I were specified as indicators in the models. The two-cluster model was selected, given that it had the lowest Bayesian Information Criterion (BIC) measures and highest maximum likelihood. Fig. 1 includes the mean distribution for the two-cluster solution. The delivery of algorithms and analytic competency provide the most differentiation between clusters. Thus, each cluster has a strong differentiating feature. Cluster 1 was named Big Data Analytics and Cluster 2 was named Business Intelligence.

SAS Studio Release: 3.6 (Basic Edition) was used to perform the mean score ranking. The means were computed and ranked. The Wilcoxon test was used to compare the means of variables between the two classes of projects and to provide the significance of the comparison. The mean ranking and Wilcoxon score and significance for the variables for the two project classes are shown in Table I. The Wilcoxon scores with a p-value of less than 0.05 indicate that there are significant differences in the project types. The rank indicates the relative position—equated to importance—of the item for that project type.

VI. RESULTS

The 13 items for project attributes and demographics were not significant and are excluded from Table I for space reasons. Next, many of the results were expected. Specifically, *analytic competence* is ranked higher for big data analytics than for BI. Innovative technologies such as MapReduce- and Apache Hadoop-based systems exist specifically to process significant amounts of data and store

structured and unstructured data such as text, sound, images, video, etc. [9]. Thus, *data variety* was more highly associated with big data analytics, as expected. However, an unexpected result was that *data quality* was higher for big data analytics than BI. Given the *novelty* of big data analytics and its innovative uses, it is unusual that data quality would rank higher. Perhaps it can be explained by the big data solutions being used for the monetization of data. Monetizing big data means being able to process or derive intelligence from data that results in additional revenue from the sale, use, or reuse of the data or intelligence [3]. However, the organizational performance measures for revenue, costs, and strategy were not significantly different. The empirical results suggest BI and big data projects are differentiated based on analytics competence, providing models or algorithms. However, both project types have a similar level of technology uncertainty and pace. Next, while top management contribution is a critical success factor for all type of projects, senior managers and business users are significantly more involved in big data projects than they are in BI projects. The reason is elusive as the organizational performance measures do not differ significantly. However, the newness of the expected outcome, the technical, data, and analytical competence of the team, the data quality and variety, and the performance of the technical infrastructure are significant success factors for big data analytics.

VII. Conclusions

The practical implication is that sponsors and project managers should use this information to plan projects and to establish success criteria. First, based upon the literature review, it establishes the contingency factors for BI and big data analytic projects. That is, the measurement items offer a guide for defining the infrastructure, personnel, technical tasks, and governance for a project. For example, data privacy would be a critical factor in projects that produce proprietary algorithms and embed them in the business process. Thus, the project should include a specialist and activities for following data protection and privacy regulations. Consequently, the items can be used to facilitate discussions to assign accountable persons and human and financial resources to the project goals. The second area for using the results is to formulate success criteria that can be measured and monitored during the project. For example, measures could be defined around important aspects of service quality. This study contributes by adding clarity to BI and big data analytic project differences. The results of this study are not generalizable beyond decision support projects, and the findings are limited due to the small sample size.

***Abstract*—Security has become an important concern with the development of large scale distributed and heterogeneous multi-agent systems (MAS). One of the main problems in addressing security during the development of MAS is that security is often an afterthought. The cost involved to patch existing systems against vulnerabilities and attacks after deployment is high. If developers and designers can spend some quality time investigating security aspects before beginning to code then this cost can be reduced significantly. Also, using formal methods to specify the complex behavior of large scale software systems has resulted in reliable software systems. This research effort was focused on using formal methods early in the development lifecycle to specify security requirements for MAS. New solutions are emerging to fix security related issues, but how much thought gets in during the early phases of development in terms of security needs to be answered. In this paper, analysis of security requirements for MAS, existing solutions to secure MAS, and the use of formal methods to specify security requirements has been studied. Descartes – Agent, a formal specification language for specifying agent systems has been taken into study to model the security requirements of MAS early on in the development process. Functional specifications of MAS are modelled along with the non-functional security requirements using the Descartes – Agent specification language. A case study example is used to illustrate the specification of security requirements in MAS using the Descartes – Agent.**

***Index Terms*—multi-agent systems, security requirements, formal methods, Descartes - Agent**

I. Introduction

MAS are a set of software agents that work together to solve problems that are beyond the individual capacity of a single software agent. MAS are a comparably new software paradigm, which has been accepted widely in several application sectors that involve large and complex tasks. The autonomous, pro-active and dynamic problem solving characteristics of MAS have recently caught the attention of several application areas, such as: banking, transportation, e-business, and healthcare. In all these mentioned services, it is imperative that security must be assured. These services will face serious deployment issues if the security requirements are not being enforced. This approach is possible by considering the agent properties and the security aspects that relate with those specific properties.

The use of MAS in open, distributed, and heterogeneous applications, however may cause problems with security issues which in turn may affect the success of the various applications. Security in MAS is an upcoming field in a well-established field of study, such as security in networks, P2P, and web services communication. Hence, this paper analyzes the basic security concepts required to be applied to security of MAS.

This paper includes a review of the past and present work related to the security issues of MAS. Also, the research effort has studied the existing security technologies used as solutions to address the security issues of MAS. Mobile agents, host security, agent communication, and delegation are some of the current security technologies that are used to address security issues [1].

The need for systematic and secure system development has increased the use of formal methods. The following are some of the specific characteristics of using formal methods to specify secure software systems [5]:

- enable reasoning from logical/mathematical specifications of the behaviors of computing devices
- offer accurate proofs, so that all system behaviors meet desirable properties
- crucial for security goals
- rule out a range of attacks
- provide guidance for gapless construction and
- always use models.

Implementing formal methods in various areas such as verification of hardware system, embedded systems, analysis and testing of software has improved the quality of computer systems. There is a forecast that formal methods can bring similar improvement in the security of software systems. Formal methods have been associated with security

applications for a while [15], thereby offering new techniques for security goals across a wider range of components. Without the implementation of formal methods, security will always remain weak. In this paper, one such formal method has been used to specify the security requirements of MAS.

Wing, in her paper, has stated that security always had played a vital role in the development of formal methods in the 70s and early 80s [7]. There are a few questions that might arise regarding the formal methods. Has the scenario changed? Are the formal methods now ready to have a significant role in the production of more secure systems? The answer is yes, formal methods now play an important role in security systems. In this paper, limitations of formal methods, summary of the results on how model checking and theorem proving tools were discussed. Also, the challenges and opportunities for formal methods in analyzing the security of systems, beyond the protocol level are also elaborated. Formal methods need integration with 1) other methods that address issues on formalization (analysis must include several factors such as risk, hazard, fault, and intrusion detection) and 2) into the entire software development lifecycle (such as during requirements analysis, testing, and simulation). Finally, there is a necessity to introduce the human factor (cannot be ignored), which in principle is part of the system's environment. Research conducted on modeling of human behavior, human-computer interaction, and management of processes and organizations can all aggregate the formal nature of research on formal methods.

The remainder of this paper is structured as follows:
Section 2 discusses the existing work related to security issues in MAS, security solutions to MAS, and the use of formal specification to specify security requirements in MAS. Section 3 discusses the earlier extensions done to the Descartes specification language to specify agent systems. Section 4 discusses the security framework developed in this research effort to specify the security requirement of MAS using Descartes – Agent. Section 5 provides a case study example that illustrates the application of the developed security framework with an e-commerce application. Section 6 discusses the lessons learnt and Section 7 summarizes the paper with a brief discussion of future work.

II. Related Work

Jung, et. al [2] surveyed existing research efforts that exist related to security in MAS, with a special focus on access control and trust/reputation. The paper concluded that security of agent based environments is critical. In spite of several efforts, many problems still remain and appear to be challenging with the continuous development of new technologies that are developed.

The research described in the research paper [3] identified the various security issues encountered by MAS. In order to assure MAS security, the paper examined the following: 1) basic concepts of security in computing, 2) characteristics of agents and MAS that introduce new threats, and 3) different strategies to prevent attacks. However, despite the similarities, security in MAS has specific requirements which need the autonomy, mobility, and other agent features that are not usually found in most conventional systems.

A model (based on the concepts and models regarding agent's role and communications) is presented [4] for securing MAS. The model provides an adequate way to ensure the security requirements and design are combined with system functionalities during the development process. The proposed model also incorporates the general security requirements at the agent and system levels. The paper has considered and addressed several system level threats, such as 1) corrupted mobile agents attack the main system host, 2) fake agent, 3) insecure communication among the platforms, and 4) agent level threats. The research work has attempted to extend the Gaia methodology with the security model. Further research work is needed in order to provide developers with security solutions for MAS based on the Gaia methodology.

A secure-critical system is difficult to develop and there are several known research issues regarding the security weaknesses in many sectors. Hence, a good methodology to support secure systems development is immediately needed. The research paper [6] presents the aim to assist the difficult task of developing security-critical systems using an approach of the Unified Modeling Language. The extension UMLsec of UML [6] (that allows expressing security relevant information within the diagrams) in a system specification is described in this paper. The UMLsec is defined in the form of a UML profile using the standard UML extension mechanisms. In particular, the related constraints provide criteria to classify the security aspects of a system design, by attributing to the formal semantics of a simplified fragment of UML. Formal evaluation is possible since the behavioral parts of UMLsec are considered with formal semantics. Hence, even the security experts who undertake a formal evaluation for certification purposes also may benefit from the possibility of using a specification language that may be more adaptable than some conventional formal methods.

Even though security has a major role in the development of MAS, security requirements are usually considered after the design of a system. The main reason is because of the fact that agent oriented software engineering methodologies have not unified security concerns throughout their developing stages. Mouratidis and Giorgini [12, 20] in their paper, introduce extensions to the Tropos methodology to enable them to model security concerns throughout the entire development process. This paper also describes the new concepts and modeling activities getting integrated to the current stages of Tropos. Tropos is characterized by the following three key aspects.

- deals with all the phases of a system development, adopting a uniform and homogeneous way,
- attends to the early requirements (emphasizing the need to understand organizational goals), and
- builds a model of the system that is refined and extended from a conceptual level to executable level, by a sequence of transformational steps.

The Tropos methodology includes five main software development stages, such as early and late requirements analysis, architectural design, detailed design, and implementation. In order to extend Tropos with security related concepts, factors such as security concepts and security modeling activities are detailed in the paper. A real life case study from the health and social care sector is used to illustrate the approach using Single Assessment Process (eSAP) system.

MAS have become a promising architectural approach for constructing Internet-based applications. Recent research work in software architecture have resulted in the necessity to truly define languages for designing and formalizing agent architectures and more specifically secure ones. This paper describes the basic fundamentals for an architectural description language (ADL) to specify secure MAS. Mouratidis, et al. [13] in their paper introduce a set of system design primitives that is conceptualized with the Z specification language to build secure MAS architectures. The main concepts of SKwyRL-ADL, including the security aspects, are described in this paper. The Z specification language is used to describe SKwyRLADL concepts. Z is widely used as a formal specification language as it is clear, concise and easy to learn. The three sub-models of SKwyRLADL: agent model, security model, and architectural model are detailed in this paper. The concept is applied on an e-commerce example to illustrate the research effort. The illustration involves the description of formally specified architectural aspects, such as interfaces, knowledge bases, security objectives, security mechanisms, and plans of the e-Media system.

III. Background

The Descartes specification language, developed by Urban [10] was designed to be used throughout the software life cycle. The relationship between the input and the output of a system is functionally specified when using this specification language. Descartes defines the input data and output data and then relates them in such a way that output data becomes a function of input data. The data structuring methods used with this language are known as Hoare trees. These Hoare trees use three structuring methods namely direct product, discriminated union, and sequence.

Direct product provides for the concatenation of sets of elements. Discriminated union provides for the selection of one element out of a set of elements. A plus sign (+) is used to denote discriminated union. Sequence represents zero or more repetitions of a set of elements. Sequence is indicated by an asterisk (*) suffixed to the node name.

By definition of Hoare trees, a sequence node is followed by a sub node. A single node can accommodate a sequence of direct product or a sequence of discriminated union. In the Descartes specification language, a literal is any string that is enclosed within single quotes. Consider the following example,

agent

‘autonomous_agent’ wherein autonomous_agent is a literal.

The Descartes specification language was extended in 2013 by Subburaj [11] for specifying complex agent systems. The extensions made to the Descartes specification language follows a top-down modular development allowing for the decomposition and incremental development of large agent systems. Six new concepts were added to Descartes for specifying and validating agent software systems. The added concepts were: (1) agent construct; (2) agent goal; (3) agent attributes; (4) agent roles; (5) agent plans; and (6) communication protocol.

Agent systems consist of multiple autonomous agents. Each of the agents has a specific goal to achieve and a set of actions to perform in order to achieve a goal. The agent construct in an agent system is used to define the behavior of an agent, including the goal, different roles, type of events, the plans, and the knowledge base. Each agent in an agent system has a structure. The notion of declaring an agent can be compared to the identification of objects in an object oriented methodology. The declaration of an agent module is pre-pended with a unary “agent” reserved word. Consider the following example,

agent AGENT_MODLUE_NAME_(INPUT)

Every agent has a goal of achieving a certain state or task. For example, imagine an agent that would start running with a goal of cleaning a house. The initial goal of such an agent is to clean the house and perform actions accordingly to achieve the goal statement. In Descartes - Agent, the agent goal is specified by using a new primitive, “goal”, added to the Descartes syntax. An agent goal is an important attribute to be specified in an agent system. The plans that are executed by an agent solely depend upon the goal defined for a specific agent.

The agent roles are used to identify the key roles in an agent system. The notion and description of role models has been adopted from the Gaia methodology [8].

One of the most important aspects of agents is that they act autonomously to achieve their goals. This characteristic of agents to act autonomously in an environment is realized through the plans part in an agent system. The plans consist of a sequence of actions that an agent will take when a corresponding event occurs. The first part of the plan specified the list of events that trigger the execution of a specific plan by the agent. The second part context describes the contexts when the plan is applicable. The context part is

used to specify the current beliefs of the agent system. This part consists of a set of rules that can be specified with respect to specific agents. The context part also communicates with the knowledge/belief component in the agent framework to update and reads agent specific rules. The next extension is the reserved keyword "plans" used to specify the agent plans. The keyword triggered_events is used to list the triggered events. The keyword context is used to specify the agent specific rules and belief. The keyword method is used to specify the list of actions to be taken. In order to specify the context of the plan, new logical primitives were added to Descartes - Agent.

The knowledge/belief base in an agent system contains the knowledge that the agent has about itself and its environment. An agent's plan reads and modifies the knowledge/beliefs base. The knowledge/belief base consists of logical rules that are known initially before the agent starts to execute the plans. Also, based upon the execution of plans by the agents in the agent systems, the knowledge/belief base gets updated according to a current belief. In the Descartes - Agent processor, the knowledge/belief base was implemented as a separate component. The processor before executing the agent plans and also after executing the agent plans will access the knowledge/belief component to take appropriate decisions.

The last extension to Descartes - Agent for specifying agent systems is the communication protocol. Agents interact with other agents in the agent system and also with the environment to realize agent goals. The communication protocol in the extended Descartes is set up by the name tag (in upper case letters) of the calling agent module within parentheses followed by a period and the name of the relevant message within parentheses followed by the "^" symbol and then the name tag (in upper case letters) of the called agent module within parentheses.

IV. Specifying Security Requirements Using The Descartes – Agent

A. MAS properties

Wooldridge and Jennings [15] software agents come with the following properties:

Autonomy: An agent has its own goal and the ability to operate without any human intervention; more importantly, agent has control over its own state and can regulate its own functioning without outside assistance.

Sociability: An agent is capable of interacting with other agents and humans using an agent communication language. This approach allows an agent to seek and provide services.

Reactivity: An agent is capable of perceiving and acting on its close environment. The agent can respond to changes that occur in its surroundings.

Pro-activeness: Agents are not only capable of responding to the stimulus from their surroundings, but are also capable of exhibiting a goal-oriented behavior by taking initiatives.

In addition, there are some other characteristics, such as situadeness, mobility, rationality, veracity, and benevolence. Situadeness means agents are capable of sensing a special condition based on the inputs received from the environment.

Table I.
Agent properties and associated security concerns

Agent property	Description	Security concerns
Situatedness	If the agent gets to sense the input from its local host, then problems are less. But, instead if the information is coming from the Internet then there comes the problem of trust.	Trust, authentication, and integrity
Autonomy	Malicious agents can intrude without any request from humans or other agents.	Authorization
Social Ability	Enabling secure communications among agents and between humans and agents.	Confidentiality, integrity, availability, accountability, and non-repudiation
Mobility	By being able to self-migrate from one platform to other platforms, agents are prone to a number of security attacks.	Authentication, confidentiality, integrity, privacy, and faulty tolerance Damage, DoS, breach of privacy or theft, harassment, social engineering, event-triggered attack, compound attacks, masquerading, unauthorized access, copy-and-reply, and repudiation
Cooperation	Many agents cooperatively working together to access resources and internal status of other agents. This leads to security concerns.	Authentication and authorization

The term software agents covers a wide range of more specific agent types. Etzioni and Weld [16] and Franklin and

Graesser [17] provide a list of attributes that each agent must possess to a lesser or greater degree. The software agent attributes are as follows:

"Reactivity: the ability to selectively sense and act

Autonomy: goal-directedness, proactive and self-starting behavior

Collaborative behavior: can work in concert with other agents to achieve a common goal

Communication ability: the ability to communicate with persons and other agents with language more resembling humanlike "speech acts" than typical symbol-level program-to-program protocols

Inferential capability: can act on abstract task specification using prior knowledge of general goals and preferred methods to achieve flexibility;

Temporal continuity: persistence of identity and state over long periods of time

Personality: the capability of manifesting the attributes of a "believable" character such as emotion

Adaptivity: being able to learn and improve with experience

Mobility: being able to migrate in a self-directed way from one host platform to another."

B. Security requirements in MAS

The autonomous, pro-active, and dynamic nature of software agents thought proven to solve challenging problems, also comes with security concerns. Often, these security aspects get unnoticed until the deployment of the end-deliverables. Patching the security flaws after deployment has always resulted in high costs.

From the above properties, it is evident that software agents operate in an open environment and are free to interact with their surroundings to achieve their goal. This openness gives rise to a number of security and trust issues. Some of the commonly occurring security problems with agent based systems [2] are: confidentiality, integrity, availability, accountability, and non-repudiation.

Based on agent characteristics, there [2, 12] have been presented a list of security requirements of the MAS. Table I associates agent characteristics with their associated security problems.

C. Descartes – Agent Security Specifications

Among the list of security concerns listed above, in this paper we focus on two concerns namely: access control and confidentiality.

To provide access control there are two steps involved: first is to provide authentication to a group of agents enabling them to establish their true identity and then authorization that allows us to define the type of access privileges each agent obtains.

Every agent has a goal of achieving a certain state or task. In the secure agent framework specified by using the primitive, "goal" being prepended by a "!" symbol. With the specification of the secure agents, the goal is enclosed within a * symbol denoting the goal of secure agents.

Figures 1 and 2 illustrate the Descartes – Agent framework for specifying MAS and the Descartes – Agent secure framework for specifying MAS.

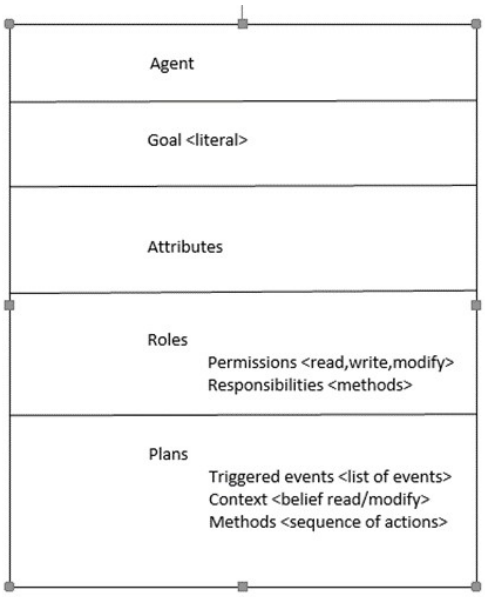

Fig 1. The Descartes – Agent framework for MAS

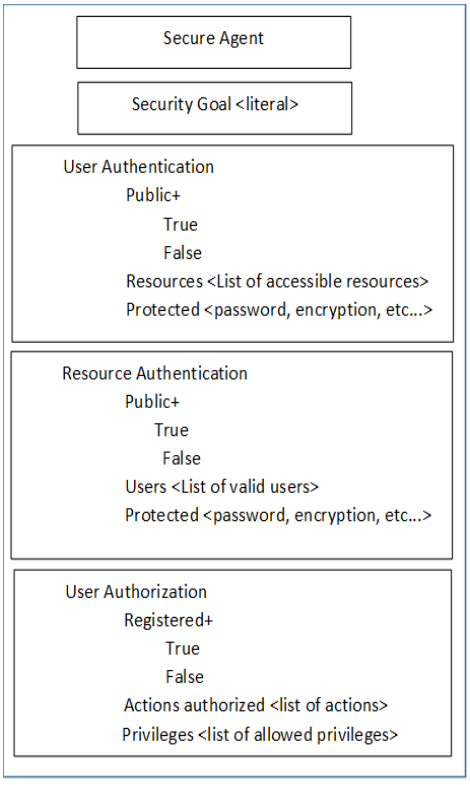

Fig 2. The Descartes – Agent security framework for MAS

1) Formally specifying authentication requirements for software agents

The authentication block in the security framework specified in the above Figure, is decomposed as user authentication and resource authentication. Within the user authentication, the node named public is a discriminated union meaning the public attribute can either be true or false. Resources in a secure agent system define the different types of resources that the secure agent can access. The protected attribute defines the method of authentication used by that user. There can be unique credentials such as passwords, encrypted passwords, and public-key-infrastructure schemes. The resource block is the same as the user except that there is a list of users that are given permission to access particular resources. Figure 3 illustrates the specification of the authentication requirement using Descartes – Agent.

```
agent TRANSACTION_AGENT
goal
   *! To successfully complete a secure transaction *
user1
   public+
        true
        false
      users
        files
            'list of files that can accessed'
          servers
            'list of servers that user1 can talk to'
      protected
          password*
            alphanumericstring

resource1
   public+
        true
        false
      resources
        users
            'list of users that can this resource'
      protected
         password*
            alphanumericstring
```

Fig 3. Authentication example using secure Descartes - Agent

2) Formally specifying authorization requirements for software agents

The user authorization block specified in the secure agent framework consists of three parts: registered, actions authorized, and privileges. The first part of the user authorization block specifies whether the user is a registered user or not. The second part of the authorization block allows one to specify all the actions that an authorized user can perform. The third part allows for the specification of all the privileges or access rights to specific resources. In order to specify the access privileges of users, new logical primitives were added to Descartes - Agent. Figure 5 illustrates the specification of an authorization requirement using Descartes – Agent. Figure 4, lists the newly added authorization primitives.

(<userx>)_HAS_READ_PERMISSIONS_TO (<resourcex>) – user X has read permission to access a specific resource

(<userx>)_HAS_WRITE_PERMISSIONS_TO (<resourcex>) – user X has write permission with a specific resource

(<userx>)_HAS_APPEND_PERMISSIONS_TO (<resourcex>) – user X has append permission with a specific resource

(<userx>)_HAS_EXECUTE_PERMISSIONS_TO (<resourcex>) – user X has execute permission with a specific

Fig 4. Authorization primitives

```

            'confirm_the_completion_of_a_transaction'
        privileges
              (USER2)_HAS_WRITE_PERMISSIONS_TO
              (TRASACTION_RECORD)
              (USER2)_HAS_EXECUTE_PERMISSIONS_
              TO_(COMMIT_QUERY)
```

Fig 5. Authorization example using secure Descartes – Agent

3) Design and Implementation

The secure Descartes – Agent specifications discussed in Section IV can be transferred into UML design and then into implementation code. AGENT UML [22][23], an extension of Unified Modeling Language (UML) was proposed to facilitate developers with a smooth agent development process. The extended Descartes has already been specified using AUML in [21]. The extended Descartes – Agent security requirements can be specified using use case, sequence, and communication protocol diagrams. For instance, a sequence diagram in AUML is a diagram that describe sequence of messages between agents that exchange messages through protocols. These diagrams define the different agent roles, constraints, and the messages that are ordered according to a time axis. Sequence diagrams use the following basic components along with other components to describe a communication pattern between agents: agents and agent roles, agent lifelines and thread of interaction, connectors, messages, and conditions on messages. Authentication and

authorization requirements can be enforced via protocols every time a message transfer occurs between the agents. Since the Descartes specifications are in an executable form, with formal specification constructs close to that of programming, implementation of these Descartes – agent specifications can be done in any high-level programming language. With Descartes – Agent specifications, the transition from specification to design and then to implementation happens seamlessly.

V. Case Study Example

MAS are used to provide efficient e-commerce solutions, but different security related issues are associated with the agent solutions of e-commerce applications. A case study example of a real time MAS for e-commerce applications [19] is described for illustrating the security framework introduced in this research effort. The real time multi-agent architecture for an e-commerce application consists of four different types of agents namely: UserAgent, QuotingAgent, TrendWatchingAgent, and BuySellAgent.

The main goal of the USER_AGENT is to determine the user requirements such as the risk level, amount of money to spend, and the market sector preferences. The USER_AGENT specifies the quality threshold to ensure if the actual stock price lies within the threshold value [9]. Security requirements associated with this user agent requires authentication, authorization, and confidentiality. The following Descartes – Agent specification adds the security requirements discussed in Section IV.B to the USER_AGENT. Figure 6 illustrates the specification of USER_AGENT that includes authentication and confidentially security requirements.

VI. Lessons Learnt

Following were the lessons learnt out of this research effort. Security is a major issue when it comes to addressing requirements for MAS. The existing Descartes - Agent specification language constructs along with few newly added ones were successfully used to specify the security specifications of MAS. Case study examples similar to but not limited to the one described in the paper can be used to illustrate the extensions made to the Descartes - Agent specification language. The formal executable specification demonstrated the possibility of converting the security specification into design and then into implementation.

Some of the drawbacks identified out of this research effort are as follows: general framework for understanding the security requirements of MAS is not available; automated design and code generation techniques from the formal specification languages used to specify secure MAS is also scarce in the literature; efficient ways to rank and specify security requirements according to importance is not adequately discussed.

         (USER_AGENT)_HAS_EXECUTE_PE
         ESHOLD_QUERY)
```

Fig 6. Case study example using secure Descartes - Agent

VII. Summary and Future Work

A security framework that allows developers to formally specify the security requirements of MAS has been discussed in this paper. The security framework has been built as a part of the Descartes – Agent formal specification language. The key point on the developed security framework is that it can be applied early on in the development process of MAS. The identification of these security requirements early during the development of agent systems reduces the security patching cost involved with MAS development. One of the main benefits of using Descartes – Agent is that it allows partial specifications to be developed and executed. This feature allows one to specify security requirements with a high-level of abstraction.

Three important security issues with MAS, namely authentication, authorization, and confidentiality, were taken into study. The security framework built in this research effort allows for the specifications of security requirements that would implement these security solutions in MAS. The challenging aspect of incorporating a formal executable specification language to specify security requirements for MAS has been accomplished in this research effort. A case study example has also been discussed to illustrate the use of the security framework built in this research effort. The case study discussed in this paper serves as a basis for formally specifying security requirements for MAS and can be applied to different applications in similar fields.

As future work, the security framework developed will be extended to provide solutions to other security issues, such as trust, integrity, availability, accountability, and non-repudiation. Extending the security framework to enforce security with distributed MAS will be a future challenging effort.

An Approach to Transforming Requirements into Evaluable UI Design for Contextual Practice - A Design Science Research Perspective

Matthias Walter
Chair of Information Systems, esp. IS in Manufacturing and Commerce, Technische Universität Dresden
Dresden, Germany
matthias.walter3@tu-dresden.de

***Abstract*—We contribute a methodical approach in the context of IS design science research to develop UI prototypes for evaluations in practice-oriented research. Based on previous research on improving IS support for early product cost optimization, we present and discuss our methodical approach to derive UI prototypes based on an evaluated requirements model. The objective of the outlined approach comprising different steps is to derive a clickable UI prototype that is feasible for further artifact evaluation within institutional environments. Together with experts from the practice of software engineering we iterated through the working steps of the elaborated approach to determine its feasibility to derive a prototype and moreover, generate visual examples for each step to improve the approach's comprehensibility. In addition to the description of the approach itself we point to significant hurdles that have arisen with the application of it in order to generate learnings for other research projects.**

I. Motivation

In times of globalization, demand rises for agility, innovation, and quality. Furthermore, shortened product life cycles and an amplified variety of product models have increased pressure on product manufacturers [1], [2]. In order to keep up with the global competition as such, optimizing product costs throughout a product's life cycle has become a major driver for economic success. To ensure the long-lasting economic success of products in the upcoming decades, organizations have been attempting to optimize product costs for the overall product life cycle. This is especially true for the discrete manufacturing industry, where products like cars, trucks, airplanes, and high-tech machinery are assembled out of thousands of globally sourced components [1].

Figure 1 describes the cost situation in the life cycle of such products. Surprisingly, 90% of all product costs are determined before production starts – and, thus, in the phase of product development. Linking this fact to the idea of product cost optimization to ensure economic success, it becomes obvious that product development phases offer the most potential to optimize product costs. Despite this immense potential, there is a lack of information system (IS) support for product cost optimization during product development [3], [4], [5].

In our long-term research project, we aim to improve IS support for product cost optimization during product development and, therefore, aid the industry in making use of the cost optimization potential. Due to the practical relevance of the research problem and the demand for new IS approaches within the industry [4], [5], we initiated a research project together with the software corporation SAP SE. The resulting research collaboration, which includes various international companies, is framed by a design science research (DSR) approach [6]. First, we worked out a detailed problem identification together with companies among the discrete manufacturing industry [4], [5]. To overcome the identified problems, we elaborated major implementation challenges and requirements, which were further transferred into a requirements model [1]. After an industry evaluation of the requirements model [1], we now aim to design possible solutions to improve the support of IS for early product cost optimization and, thus, use the potential of product development phases (Figure 1).

In order to exploit the full potential of our industry research collaboration, it is recommended to evaluate DSR artifacts in their natural setting [7]. For this purpose, it is necessary to elaborate instantiations of potential problem solutions that can be evaluated by industry experts in practice. The question is: how can this be done?

Although DSR is generally gaining popularity in IS research [8], there are only a few research contributions that provide guidance for the design of at least partially instantiated artifacts in the context of DSR [9]. Further literature analyses have shown that the majority of the designed artifacts in DSR research are of type method or model [8] and can, therefore, only provide limited guidance for our practice-oriented approach to design potential solutions. In addition, the need to develop further research methods that immerse researchers in practice environments has been highlighted in the literature [10].

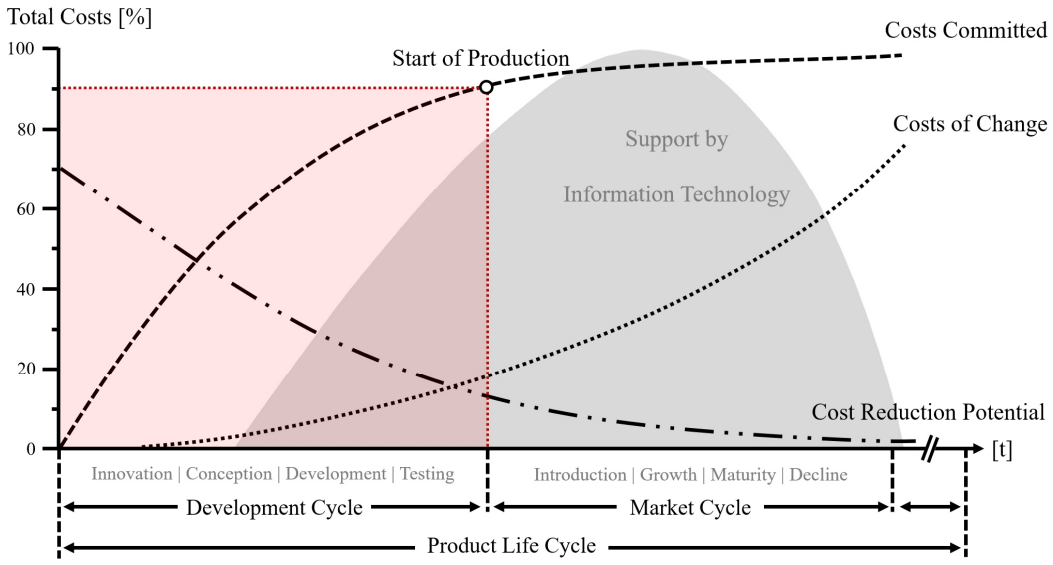

Fig. 1 Cost commitments and reduction potential along product life cycle [4], [11]

To improve this area of research, we would like to depict and discuss a methodical approach to develop user interface (UI) prototypes based on validated requirements. This approach has helped us in our industry collaboration research project, because such prototypes can be evaluated intuitively by experts without requiring a dedicated theoretical knowledge base. In addition, the development of UI prototypes requires considerably less efforts than regular software-based prototypes. Driven by the question of how to elaborate such evaluable UI designs, we focus the following research questions:

RQ1: Based on the elaborated requirements model, what could a methodical approach look like to transform requirements into UI prototypes that are suitable for iterative practical evaluations?

RQ2: What are the challenges of such an approach, and how can possible hurdles be mitigated?

To answer these research questions, we briefly introduce the research project and the research results to date. We then explain the elaborated approach to develop the UI prototype and explain the individual working steps in detail with the support of visual examples. The paper concludes with a discussion of results and an elaboration of lessons learned based on the application of this approach in the context of our research project, including possible pitfalls to provide valuable insights for other researchers.

II. Background

Though there are IS available that aim at supporting product cost calculation during product development [12], a lack of functionality and the demand for enhancements has been identified [3]. Building on this, in our initial research steps, we identified missing support for early product cost optimization and the resulting drawbacks for the industry [4], [5]. To establish a substantiated foundation for further research activities in a DSR context [13], we elaborated and evaluated a requirements model with experts from international companies within the discrete manufacturing industry [1]. Moreover, we identified major implementation challenges that have an impact on the solution acceptance in the industry and, therefore, will have an impact on the current phase of our research: solution design.

In theory, the DSR artifact design and development process is described as a rather individual and creative engineering process [9], [14]. Though there are general approaches available in the literature describing this process, the lack of guidance for artifact design in IS literature is evident [9].

Seeking such processual guidance for developing a potential solution, we had to consider an important circumstance in our research domain: Product cost optimization measures are derived in a rather unpredictable context based on deliberations of various stakeholders (e.g., product developers, production process engineers, production planers, cost controllers, and purchasers) and their collaboration [4]. Such deliberations do not follow best-practice patterns, but originate from an evolving knowledge-base along the product development phase, and therefore, result in dynamic, context-driven product cost optimization processes. Such processes can be classified as one type of emergent knowledge processes, as argued in our requirements elaboration [1].

Hence, potential solutions must support dynamically changing processes with a bandwidth of deliberations and tradeoffs based on complex, evolving expert knowledge bases within the organization, which is exclusive to product development [15].

Fig. 2 Degree of process specification [1], [16]

With this justificatory knowledge in mind, developing potential solutions becomes a challenge: First of all, it is important to determine the right degree of process support for experts using the IS without being too restrictive to limit their capabilities while carrying out product cost optimization across their organization. In addition, following the argumentation in [7] and [16], the developed solutions must be evaluated in the specific environment of their application. In our case, this requires an evaluation where business experts try to use our prototypes as support for their product cost optimization processes.

Due to the strong tie of our research problem to an organizational context, it is necessary to reflect whether the DSR methods to develop such a UI prototype fit our research context. This is especially important since it has been revealed that DSR methods consider organizational intervention to be of lesser importance [17]. In contrast to this, [10] argued to further develop specific methods aiming at the co-constitutional character of user contexts and institutional environments.

Such co-constitutional aspects can be approached in multiple ways. [18] criticized the strong sequencing of DSR, which separates developing artifacts from evaluating artifacts. To overcome this separation, action design research (ADR) has been recommended as a DSR method to closely link development to evaluation [18]. Further recommend-dations have been proposed in the literature [19]. Based on a comparative analysis of DSR with the constructive research approach, [19] highlighted the potential to improve DSR methods by developing best practices for collaborative development.

Beyond the DSR discourse, it is worth examining how IS prototypes are being used in practice. One area of regular prototype development and evaluation is agile software development (e.g., rapid prototyping) [20]. One specific example within the area of development research is mockup-driven development [21]. This approach makes use of UI prototypes (mockups) to receive early and continuous feedback to guide modeling and, thus, align further application development. This coincides with the intention for ADR as a method [18] to combine development and evaluation of artifacts into iterative steps.

We would like to take advantage of the experiences that have been made with mockup-driven development approaches to build a bridge between our scientific research and the evaluating group of practitioners. By this attempt, we intend to enable business experts within the discrete manufacturing industry to quickly grasp core intentions of our prototypes without preceding knowledge transfer. Furthermore, less effort would be exerted to create UI mockups instead of software prototypes, allowing shorter artifact iterations. The use of UI prototypes as a feasible option for DSR artifact evaluation has already been shown in other DSR projects [22].

III. Methodical Approach

The purpose of this paper is to draft and discuss a processual approach to develop evaluable UI prototypes to enhance practical research collaborations. This practical research collaboration is important for the problem solution, as product costing has a strong focus on expert knowledge [5], [23]. Moreover, industrial practice is the most important source of information for cost optimization projects [24]. Therefore, the access to knowledge from practitioner communities is fundamental for our research [1]. At the same time, such knowledge ensures that our research is relevant to practice [25].

Within our long-term design science research project, we elaborated and evaluated a requirements model [1] that included 30 detailed requirements in combination with implementation challenges on the basis of industry expert interviews and focus groups. In addition, the knowledge exchange with domain experts helped us to gain a holistic understanding of applied product cost optimization processes among different companies in an applied environment [5]. This was essential to develop a rather abstract approach – with respect to emergent circumstances toward the degree of process specification (see Background) – toward early product cost optimization, which has been agreed upon by industry experts (Figure 3).

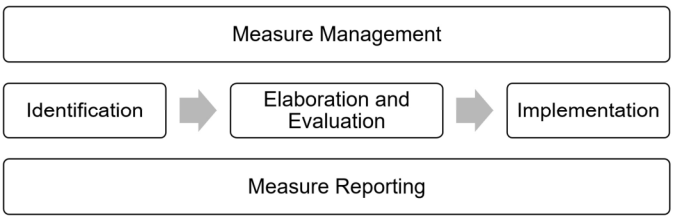

Fig. 3 Approach to support early product cost optimization [1]

As this approach provides support for the maturation of individual optimization measures (e.g., make-or-buy decisions, evaluation of alternative product concept or production processes, or optimization of logistic costs) [1], [5], our UI prototype development should be guided by such scenarios in which optimization measures mature from their identification through evaluation to implementation.

Therefore, we initiated our prototype development with the derivation of example optimization processes (Figure 4). These process descriptions were then used to deduce different user scenarios, each representing one step within the exemplary optimization process. Such a user scenario

describes the sequence of working tasks from the perspective of a specific expert user involved in the optimization processes (e.g., product cost controller, purchaser, engineer).

Such user scenarios are designed in a way that they consider aspects of the previously evaluated requirements. This is important because we used these scenarios for a focus group with five UI experts from our research partner SAP SE who were not familiar with our research domain of product cost optimization. Since the UI experts were not familiar with the industry processes, we were able to validate and adjust our user scenarios in terms of comprehensibility. After the establishment of a common understanding, it was the task of the UI experts to transfer the user scenarios independently into UI drafts without further assistance. This was done using a paper-based approach.

Afterwards, each UI expert presented his UI drafts for each user scenario to the whole group. During this presentation, each focus group participant was encouraged to provide feedback for the different UI drafts. This feedback was helpful for us to then transfer the various paper-based designs into a digital "best-of-breed" UI prototype combining the most valuable concepts. This prototype was created with Balsamiq mockup software [26], which allows individual UI screens (and their elements) to be linked into a "clickable UI prototype."

As the last step of this development approach, we internally evaluated the clickable UI prototype first against our user scenarios and example processes, and later against the evaluated requirements in detail. This iteration allowed us to adjust the prototype design and the user scenarios.

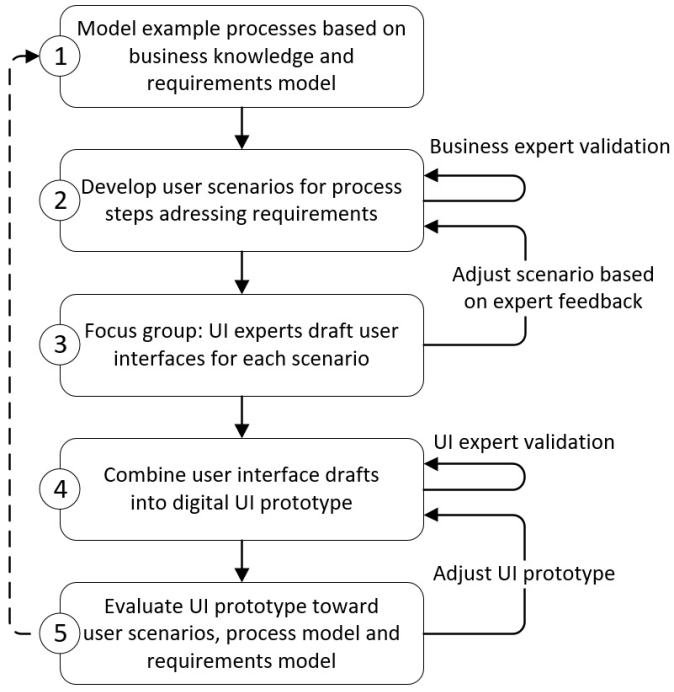

Fig. 4 Approach to transform requirements into UI prototype

This iterative approach to design a rather mature clickable UI prototype is necessary, because practitioners within the industry are usually limited toward their buy-in into research activities (especially timewise) [27]. For this reason, it makes sense to integrate these important knowledge resources in less granular and well-prepared research increments, being feasible for practice-oriented evaluation to maintain collaboration motivation.

In the next section, we will discuss the single steps of the development approach in detail and support them with examples from our research project.

IV. Process Details

A. Processes Modeling (1) and User Scenario Design (2)

According to [10], the process of designing a DSR artifact always has its point of departure in the current world. This is especially true for our practical problem of lacking IS support during early product cost optimization. Therefore, we first established an understanding of relevant optimization approaches [5] and transformed these into exemplary process flows. We started with a rather informal descriptive approach, and later used model-based approaches to establish a basis for a collective understanding among the stakeholders. In detail, we modeled the exemplary process flows with BPMN 2.0 (Business Process Model and Notation) [28].

Due to the emergent process characteristics of our research domain, process modeling is a challenge (see Background). This is because of emergent process adaptions in practice that can neither be foreseen nor fully defined by us; yet, at the same time, it is immanent that there is no chance to reach full process coverage. Therefore, we decided to transform those optimization approaches into process models, which have been evaluated as the most relevant for early product cost optimization within the discrete manufacturing industry (Table 1) [5].

Table I.
TOP 5 Optimization Approaches (Rating Scale 0 - Not Important to 10 - Very Important) [5]

Optimization Approach	Avg. Rating
Make-or-buy analysis	7.83
Material price optimization	7.78
Alternative concept and product designs	7.33
Alternative production plants	7.29
Alternative reference components, assemblies, materials, and recipe ingredients	7.06

It is important to emphasize that this set of modeled exemplary processes does not claim to be complete. Nevertheless, it provides valuable insights into where and

how the support of practitioners needs to be improved with IS.

Furthermore, process modeling helped us to identify the various process stakeholders. By differentiating between different user roles and their individual tasks within the optimization process, we were able to identify each business expert's contribution to mature a cost optimization measure from a vague idea to its implementation into a cost calculation. Building on this, we derived specific user scenarios, each representing one step within the modeled optimization process. These user scenarios form a descriptive sequence of granular working tasks from the perspective of the specific user role. These user scenarios were then enriched by transforming evaluated requirements into dedicated user actions along the processual working tasks. This was done similarly to the approach of formulating user stories in agile software development to describe functional requirements [29].

User scenario: Create a new proposal for a make-or-buy analysis for a specific component in your product

The cross-functional "cost-optimization workshop" for the development of product "Pump P-100" is in progress. You have identified a target cost deviation for the component "Casing" in your current cost calculation. Together with experts from different specialties, like purchasing, engineering, and production planning, you have identified and discussed potential optimization measures. As product cost controller, Peter, it is your task to initiate the most promising optimization measure "Make-or-buy analysis for component Casing" for further evaluation.

To do so, the following working steps must be accomplished:

- Create the measure for component "Casing" in your costing structure.
- Create an achievement plan for the measure. The cost calculation of "Pump P-100" is part of a customer quotation and, therefore, must be done by 2017-11-30.
- In order to reach the target costs, the measure must achieve savings of 300€. This targeted impact was agreed on during the cost optimization workshop. Maintain this targeted impact for the measure to enable further evaluations.
- Assign the responsibility for next evaluation steps to user Joe from purchasing department.

Fig. 5 User scenario to create a new optimization measure

Figure 5 shows a rather simple scenario from the beginning of the optimization process for a measure of type "make-or-buy analysis" (Table 1) that is being used in our prototype development. The scenario is written from the perspective of the product cost controller – who is responsible for the management of cost optimization measures at most companies [4] – and addresses requirements from our evaluated requirements model in [1]. For example, we approach the requirement toward a functionality that supports "Target costing" during the identification of an optimization measure ("Identification," Figure 3). In addition, we address requirements from the area of measure management ("Measure Management," Figure 3). In detail, this is the basic requirement of a centralized platform to manage the optimization measure among cost calculation projects, the assignment of responsibilities, the ability to create achievement plans, and the need to link the measure to components in existing cost calculations. To prioritize requirements toward our prototype, the requirements were not only validated toward their general relevance, but were prioritized on a scale from 0 (not important) to 10 (very important). Table 2 shows selected requirements and their evaluation results.

TABLE II.
EXCERPT OF EVALUATED REQUIREMENTS FROM REQUIREMENTS MODEL [1]

	Avg. Rating	Std. Dev.
Measure Management		
Collect cost-optimization measures	7.78	1.72
Select measures for […], and cost items	8.06	1.43
Define responsibilities	6.78	2.44
Create achievement plans	7.06	2.29
Estimate measure impact	8.29	1.45
Measure Identification		
Target costing	8.72	1.45

The user scenario in Figure 5 implies that there is an IS for performing early product cost calculation in place which our prototype can integrate with (see Background). As identified in previous research, this is not always the case in practice [4]. Nonetheless, the elaborated implementation challenges in previous research demand an integrated approach to ensure artifact acceptance by the end-users [1]. Moreover, this scenario implication seems to be valid because such IS are available on the market [12], although their functionality cannot cover all requirements among the discrete manufacturing industry [5].

Moreover, we introduced avatars for each user role (Figure 5) in our optimization processes. Through this idea adopted from a gamification concept for agile software development [30], we aim at making the descriptive, mostly text-based user scenarios, more attractive to people being involved in our prototype development and evaluation process (e.g., UI experts or evaluating domain experts). In addition, this should improve transparency about available user roles and their dedicated tasks in practical environments. These avatars remained consistent among the different optimization scenarios and the prototype development iterations (Table 1).

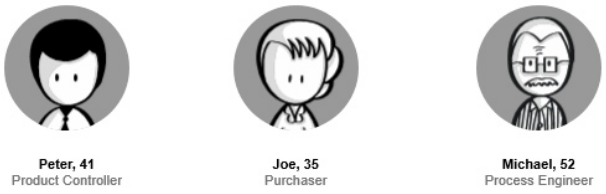

Fig. 6 Avatars that were used for the make-or-buy optimization process

B. Focus Groups with UI Experts (3)

The elaborated user scenarios build the foundation for the next step in our prototype development process. In contrast to software engineering practice where mockups are being used to enrich descriptive requirements [31], our research focuses on the derivation of design principles to improve IS support for emergent cost-optimization processes. Therefore, we decided to use the process of transforming requirements into visual mockups as an initial step to identify possible success criteria and design principles to support ex-post evaluations [32].

Due to our research collaboration with SAP SE, we had the chance to involve experts for user interfaces design in business software from SAP Innovation Center Network [33]. In a focus group involving five senior experts, who have focused on UI conception and development, with more than 7 years of work experience each, we firstly introduced the research topic driven by our problem identification [4]. Afterwards, we introduced the research approach (Figure 4) and stated the objective to create UI drafts aiming at the task fulfillment described in the set of user scenarios. As the last step of our introduction, we outlined the selected optimization process based on our BPMN models with the support of user role avatars.

Since the role of creativity to suggest solutions was highlighted in [9], we chose a pure paper-based approach to initially draft UI proposals. Nevertheless, this deliberation was not made without intention: Research has shown that paper-based approaches have certain advantages over digital prototyping approaches. Paper-based prototypes are particularly preferable when different design solutions need to be negotiated and stakeholder feedback is considered important [34]. Since we planned to have open feedback discussions among experts and, moreover, wanted to combine different solutions into a "best-of-breed" UI prototype later in the process, the paper-based approach seemed more valuable from a research perspective.

To create the UI drafts, we iterated through the optimization process based on the user scenarios as an iteration increment. The user scenario was presented to the focus group following the opportunity to clarify questions regarding its comprehensibility. By challenging the comprehensibility with the experts, we were able to further enhance the user scenarios. After reaching a collective understanding of the user scenario, the experts were asked to draft the UI individually. To underpin our claim to exemplary action, selected results of this focus group session are presented in Figure 7.

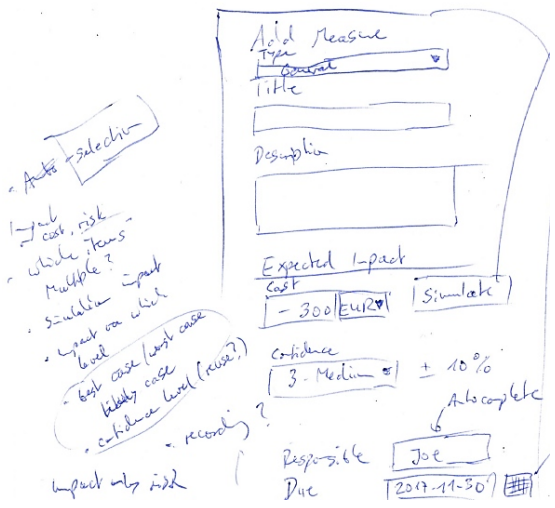

Fig. 7 Paper-based draft implementing user scenario from Figure 5

At the end of each iteration cycle, each focus group participant presented his UI draft for the specific user scenario, supported by an argumentation for the chosen UI concept. Afterwards, focus group members could provide feedback and clarify open questions. In total, we derived 47 individual, paper-based UI screen proposals for the optimization process of type "make-or-buy analysis" distributed over two separate sessions with a total duration of five working hours. The challenge in the following development step is to combine the various drafts to an evaluable prototype.

C. Development (4) and Validation (5) of a UI prototype

To transform the various paper-based UI drafts into a UI prototype that is suitable for evaluation with industry experts, we combined the most promising (also, in regard to UI expert feedback during the focus group session) drafts into digital mockups. As mentioned earlier (see Development Approach), we used the dedicated mockup software Balsamiq [26] to create a digital UI prototype.

Such a digital UI prototype consists of multiple mockups, each representing a certain UI screen (Figure 8). The major advantage of such a digital prototype over a paper-based prototype is the ability to link the different mockups (UI screens and their elements, such as buttons or text fields) to each other. The result is a UI prototype that a user can click through similarly to a real, implemented prototype.

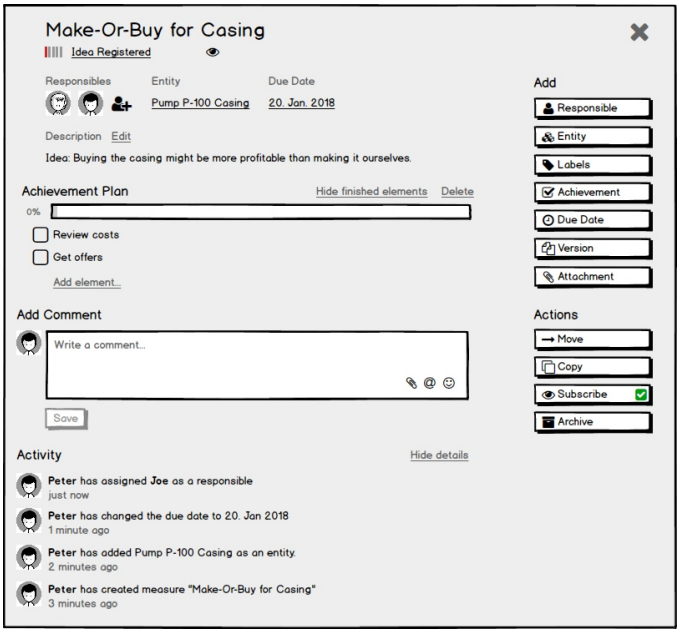

Fig. 8 UI mockup for user scenario from Figure 5

As was to be expected, not all expert UI drafts could be combined with each other. This was not due to specific UI elements or their arrangement in screens, but rather in terms of different conceptual approaches to address user scenarios. With the help of the digital UI prototype, we can easily exchange a series of UI screens to provide alternative concepts for parallel evaluation. This is extremely helpful to simulate different approaches toward process support (see *Background*).

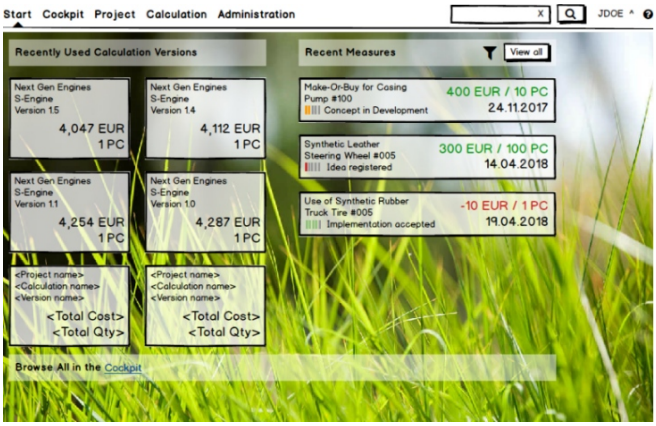

Fig. 9 Mockup of SAP Product Lifecycle's homescreen extended by functionality toward early product cost optimization

To stress the argumentation of [10] once more (see *Processes Modeling (1) and User Scenario Design (2)*) and, thus, enable an evaluation in institutional environments, we designed the clickable UI prototype to integrate with mockups of SAP Product Lifecycle Costing (Figure 9) [35]. This software is a dedicated solution to support early product cost calculation (see *Background*) and is one possible software solution available on the market that could be integrated with our UI prototype [12]. At the same time, this visual integration was necessary to address one of our elaborated implementation challenges demanding an integrated approach for optimization measure management [1].

The further development of this clickable UI prototype is linked to its internal evaluation. This internal evaluation uses three previously elaborated elements for evaluation: process models, user scenarios, and the requirements model, including a requirement description (Figure 10). Initially, we verified that the prototype addressed the tasks outlined in the user scenarios. Furthermore, we checked whether the prototype implemented by the user scenarios still corresponded to the requirements description in the validated requirements model. Finally, the prototype's click sequence needed to support the order of the tasks according to the process models.

Define responsibilities

Due to highly interdisciplinary activities, measures' responsibilities, such as functional organizations or individual task owners, must be distinctly assigned to each measure. It ensures clear organizational responsibilities for the cross-functional optimization processes.

Create achievement plans

Due to time pressure during product development, product cost optimization must be accomplished in time. Therefore, measures must contain either due dates or product development-related gates, enabling ongoing reporting.

Fig. 10 Exemplary descriptions for the evaluated requirements (Table 2) [1]

After the successful internal evaluation, we completed the development of the UI prototype that is intended for further evaluation by domain experts. This evaluation is planned in two parts: First, we let domain experts, such as consultants, product owners, and solution owners for product costing solutions, from our research partner SAP SE do the evaluation. Based on their feedback, we iterate through the outlined development process (Figure 4) once more. Business experts from the industry will then take over further evaluation.

V. Lessons Learned

In addition to the outline of our approach to transform requirements into a UI prototype, we want to contribute lessons learned from the application of this approach for our research project. Although the approach with its examples from our research project seems easy to implement, there are still some hurdles to overcome. We want to show these in the following, as they can also be relevant for other researchers in similar research contexts.

During the focus group sessions with UI experts (see Focus Groups with UI Experts (3)) we underestimated the duration of the iterations per user scenario. Looking back,

the time required for each scenario can be estimated to be one hour. Contrary to our expectations, the initial scenario explanation with subsequent questions toward comprehensibility was very time-consuming. This was mainly due to the UI expert's lack of knowledge in the specific research domain of early product cost optimization and its application in practice. Due to the unexpected delay, we had to schedule a second appointment with the UI experts to finish the draft of the optimization process of type "make-or-buy" (see Processes Modeling (1) and User Scenario Design (2)). Due to time constraints, we had to consult another UI expert and, thus, employed initial ramp up efforts once more. In order to counter such timing problems early, sufficient time should be planned for the appointments.

From our perspective, there is a chance to speed up the drafting process. Our assumption of providing the user scenarios for each step of the process in terms of process comprehensibility led to a certain redundancy across several user scenarios (e.g., different user roles were accessing the collection of optimization measures in a similar way). By removing such redundant scenarios and, moreover, focusing on less self-explaining scenarios (e.g., the cockpit screen, Figure 9), we could have been more efficient without losing relevant findings for our research problem (see Background).

For the next prototype development, we aim at a focus group approach that further enhances the creativity of involved UI experts. Though our idea of a paper-based approach was appropriate in our research context to develop potential approaches solving identified problems, we strongly believe that user scenarios provide too much guidance to elaborate ground-breaking findings. Nonetheless, the approach to draw paper-based prototypes is less time-consuming than drafting digital prototypes with dedicated software (See Development (4) and Validation (5) of a UI prototype).

In general, the approach to aim at such "clickable UI prototype" for evaluation is valuable for us. Instead of the need to implement a full-stack prototype, which, in addition, could have been limited by the extensibility options of available product costing software (see Processes Modeling (1) and User Scenario Design (2)), we could efficiently iterate through the development process to further enhance the prototype. This would simplify the testing and evaluation of several solutions in parallel. It would also motivate stakeholders to participate in the research (e.g., with new ideas or concepts), as development and its output would be progressing rapidly.

In addition, it should be mentioned that difficulties may arise when deriving and interpreting the process models and their user scenarios from the industry context into the research context. Therefore, we highly recommend evaluating the single process step results (Figure 4), like process models or user scenarios with domain experts to prevent the derivation of (partly) incorrect scenarios. To easily communicate and evaluate such results, model-based approaches like BPMN 2.0 (see Processes Modeling (1) and User Scenario Design (2)) should be used to establish a collective understanding for all stakeholders.

Furthermore, it must be ensured that the transfer of research domain content to the UI experts has been successful. Though we thoroughly introduced our research domain, including the core of our problem identification [4], [5] and the approach to derive a UI prototype (Figure 4), multiple questions for each scenario were raised. This was time consuming, but necessary for a collective understanding. The transfer from paper-based UI drafts and their underlying conceptual ideas to the digital UI prototype involves similar transition difficulties, which we recommend verifying with UI expert consultations, at least briefly, after the mockups have been created.

VI. Discussion

First, the question must be asked regarding whether the outlined approach is a valid contribution to practice-oriented DSR since we utilize a variety of well-established elements and approaches from software engineering (e.g., paper-based prototypes or mockup-driven development). According to [14], the development of tentative designs to solve identified problems is a rather pedestrian process in which no novelty beyond the state-of-art is required. Rather, the novelty should be part of the solution design itself. Following this argumentation, we do not state the UI prototype development approach as our research artifact, but as a valuable contribution to the research community.

This is especially true because, for example, the rare process guidance for artifact design has been criticized [9]. In detail, recent literature reviews have indicated only a small amount of DSR dealing with the development of software-based artifacts [8]. This is underpinned by [10], who requested methods to enable IS researchers to become immersed into institutional environments. As our approach results in UI prototypes for evaluation in practical contexts, we are convinced that it is a valuable and engaging approach toward practice-oriented DSR for all stakeholders.

What is indeed beneficial for our contextual prototyping are insights from works on action design research (ADR) as proposed in the context of DSR [18]. The interference with ADR and, therefore, the strong practical context opens room for discussions about the methodological rigor of our proposal to design a potential solution for further evaluation in the context of our problem to improve IS support for early product cost optimization. As argued by [36], there are certain conflicts in the discipline of IS research when it comes to the influence of methodical rigor. With this

contribution, we want to respond to and later solve a practical problem, which IS routine problem solving [37] has failed to address for many decades [3], [4], [5], [23], and now must be tackled by IS research.

Though we have not yet demonstrated the capability of the results to solve our identified problem [4], [5] as recommended by [6], the sole idea of designing an evaluable UI prototype has advanced our research project. The iterative validations and adjustments during the execution helped us to sharpen the understanding of the research; furthermore, the approach enabled new and improved existing collaborations with research stakeholders. According to [38], participation has the potential to enrich descriptions of the research process as well as increase the understanding of the artifact and its instantiation. Though the participation of experts in our approach led to unexpected efforts (see Lessons Learned), we can confirm and highly recommend a broad participation – especially if it concerns participants from other disciplines. Hence, the presented approach provides thought-provoking impulses and prevents tunnel vision among researchers.

This links to the contextual nature of our UI prototype for future evaluation. Earlier in this paper, we highlighted the emergent character of product cost optimization processes and the need to provide a context-integrative solution (see Background). The integration into the context of an industry application was possible and, thus, addresses one major implementation challenge to improve IS support in early product cost optimization [1]. Moreover, the evaluation of such UI prototype in practical contexts has already been shown in other research projects [22]. Therefore, we are convinced that the presented approach can contribute to finding answers to the research questions associated with our long-term research project. In addition, the concept to design the prototype iteratively improves result quality and, hence, helps to better use the already difficult-to-reach experts within the industry.

However, researchers who want to adapt this approach for their research must bear in mind that some hurdles may arise, especially regarding the transitions between the individual steps of the approach (Figure 4):

- Derivation of misguiding processes and user scenarios
- Knowledge transfer to UI experts regarding the research domain and the objective to think beyond boundaries
- Transformation of UI drafts back into the research domain-oriented context

To avoid such issues, validation and participation are key contributions to successfully derive a ready-to-evaluate UI prototype.

VII. Conclusion

Overall, we outlined our approach to develop a clickable UI prototype based on an evaluated requirements model with 30 individual requirements in the context of our long-term research project. This research project follows a DSR process recommendation [6] to improve early product cost optimization in the discrete manufacturing industry. In conjunction with this practical problem and its emergent character [1], we need to design and propose a IS solution that can be evaluated in the context of institutional environments as part of an iterative evaluation. This evaluation is part of the next research step in our long-term project, and has started with the UI prototype derived out of the outlined approach.

The approach of transforming requirements into a UI prototype has proven its value for us: Well-established techniques and state-of-the-art approaches from the software engineering discipline helped to improve research quality and strengthen relations with stakeholders with reasonable development efforts (compared to software-based prototypes). The collaboration with and the contribution of UI experts to our research were especially appreciated.

Moreover, we address the evident need within the literature to provide further guidance for the design phase of DSR. To provide meaningful guidance to IS researchers, the presented approach is enriched with examples and increments from our research project. In addition, the *Lessons Learned* section should help to adopt the process more easily. By this, we hope to further encourage researchers in practice-oriented research, and, at the same time, motivate experts among industry to join scientific research projects to solve relevant problems.

Applying the recommendation from [6] to our research project, we further concentrate on the improvement of our UI prototype and its ability to solve the problem identified in [4] and [5]. This prototype improvement is mainly driven by iterative evaluations of experts from the industry.

***Abstract*— This study aims to advance information society research and practice by examining and understanding the information and communication technologies (ICT) adoption in government units in the context of the sustainable information society (SIS). A quantitative approach was employed to identify the levels of ICT adoption and sustainability in government units as well as investigate the correlation between the ICT adoption and sustainability. The survey questionnaires were used and data collected from Polish government units were analyzed. The research findings reveal that there are significant statistical differences between the lowest level of information culture and the highest one, namely the levels of ICT management and ICT outlay. Moreover, such differences are also identified between the lowest level of ecological sustainability and higher levels of economic, socio-cultural, and political sustainability. Finally, it is investigated that the ICT quality and information culture have a significant impact on sustainability in government units, whereas the ICT outlay and ICT management do not have such an impact.**

I. Introduction

The sustainable information society (SIS) is a new phase of information society development in which information and communication technologies (ICT) are becoming key enablers of sustainability [1]-[10]. Some areas, where the information society, sustainable development, and ICT come together, are identified and described in many studies [11-17]. All in all, the SIS is a multidimensional concept comprising environmental, economic, cultural, social, and political issues. Society stakeholders, mainly within government units, households, and public administration, could strongly affect the above issues by adopting ICT [10].

In general terms, ICT potential can be approached from two angles: ICT as an industry and ICT as a tool, and viewed as an inherent aspect for the SIS development [10]. As an industry, ICT have become a major economic driver in the hardware, software, telecommunications, and consulting services sectors. ICT as a tool can be used to transform and improve business, everyday life of people, and public governance.

ICT used as a tool to revolutionize public administration is examined in this study. Some researchers identified ICT as one of the most important tools in building sustainable government practices. ICT are expected to have a significant impact on enhancing public information and service provided for all SIS stakeholders and improving the liability and functioning of the government units [18], as well as the transparency and responsiveness of government units [19]. It is contended that ICT enable government units to improve productivity, support innovation, reduce costs, increase the effectiveness of services, and enhance the efficiency of government decision-making [7], [14], [17], [20]. Moreover, the ICT adoption in government units can yield benefits in environmental preservation by increasing energy efficiency and equipment utilization [4] as well as it can influence social development by making information and services available to all stakeholders at a faster rate [7]. All these possibilities make ICT enablers of sustainability in several respects, i.e. environmental protection (ecological sustainability), economic growth (economic sustainability), socio-cultural development (socio-cultural sustainability), and governance (political sustainability) [7], [10].

Ziemba [21], [22], [23] merely proposed a SIS model composed of the ICT adoption and sustainability, and evaluated the contribution of ICT adoption to sustainability in Polish enterprises. Following an extensive review of the literature, it can be stated that it did not uncover any deep studies identifying levels of ICT adoption and sustainability in government units nor there were any findings that interpret how the ICT adoption in government units improves sustainability. Moreover, there is a lack of research on the SIS and correlations between the ICT adoption and sustainability in less developed European countries, which are called transition economies, i.e. the former Eastern Bloc countries, which, since the early 1990s, have been undergoing transition from the command economy model to the free market model [24].

Thus, the motivation for the research is to address this under-investigated topic. The focus of this research is therefore to explore the ICT adoption and sustainability in government units. Its purposes are to identify the levels of ICT adoption and sustainability in government units, and to investigate the impact of ICT adoption on improving sustainability.

The paper is organized as follows. The next section reviews the theoretical foundation for this work and poses research questions. Subsequently, the employed research methods are discussed. The later sections describe the research findings and conclusions.

II. Theoretical Background And Research Question

A. ICT adoption

ICT are defined as a diverse set of software and hardware, to perform together various functions of information creation, storing, processing, preservation and delivery, in a growing diversity of ways [25]. They cover computers, the Internet, and mobile technologies, and mainly applications that can be used to support government units' performance and their relations with the SIS stakeholders. Based on Ross's & Vitale's study [26], the adoption of ICT is defined as ICT design, implementation, stabilization, and continuous improvement. It embraces the whole spectrum of activities from the period when government units justify the need for adopting ICT until the period when government units experience the full potential of ICT and derive benefits from them.

Based on a stream of research, Ziemba [27] advanced a model of SIS in which the ICT adoption construct is composed of four sub-constructs: ICT outlay (Out), information culture (Cul), ICT management (Man), and ICT quality (Qua). A detailed analysis allows for specifying primary variables which can be used to measure identified sub-constructs and the ICT adoption as a whole. These variables are presented in Table 1. The sub-construct of ICT outlay includes the government units' financial capabilities and expenditure on the ICT adoption, as well as funding from the European funds. The information culture sub-construct embraces digital and socio-cultural competences of government units' employees and managers, constant improvement of these competences, personal mastery and creativity of employees, and incentive systems encouraging employees to adopt ICT. The ICT management sub-construct comprises the alignment between information society strategy and ICT adoption, top management support for ICT projects, as well as the adoption of newest management concepts and standard ICT solutions developed at the national level. It also includes the implementation of legal regulations associated with the ICT adoption, regulations on ICT and information security and protection. The ICT quality sub-construct consists of the quality, interoperability, and security of back- and front-office information systems, quality of hardware, maturity of e-public services, and the adoption of electronic document management system, electronic delivery box, as well as ERP and BI systems. The construct asserted that the four sub-constructs were interrelated and critical to the design of the ICT adoption in government units in the context of the SIS.

B. Sustainability

The definition of sustainable development employed throughout this paper relates to a development in which the

Source: own elaboration.

needs of present generations are met without compromising the chances of future generations to meet their own needs [28]. According to Schauer [7], sustainable development has four dimensions which are ecological, social, economic, and cultural sustainability. Fuchs's [29] conceptualization of sustainability in the information society resonates with the Schauer's approach. He examined five dimensions of sustainability, i.e. ecological sustainability (enhancement of the natural environment), technological sustainability (usability of technologies), economic sustainability (wealth for all), political sustainability (participation), and cultural sustainability (wisdom). It is therefore expected that sustainability within government units comprises four kinds of sustainability: ecological, economic, socio-culture, and political. Such an approach was verified and confirmed by Ziemba [27].

Regarding government units, the ecological sustainability (Ecl) is the ability of government units to maintain rates of renewable resource harvest, pollution creation, and non-renewable resource depletion by means of conservation and proper use of air, water, and land resources [30], [31]. Economic sustainability (Eco) means that the government units gain competitive edge, reduce costs, organize work in a better and more efficient way, increase the number and maturity of public services delivered electronically, and boost government shareholders' value by adopting sustainable practices and improved public decision-making [14], [15], [31]. Socio-cultural sustainability (Soc) is based on the socio-cultural aspects that need to be sustained, e.g. trust, common meaning, diversity, capacity for learning and capacity for self-organization [28]. It is seen as dependent on social networks, making community contributions, creating a sense of place and offering community stability and security [32]. Political sustainability (Pol) rests on the basic values of democracy and partnership relations between government units and other SIS stakeholders. It is related to government openness, transparency and responsiveness, as well as democratic public decision-making [32], [33], [34]. Table 1 presents the description of all specified sustainability sub-constructs and variables measuring them.

C. The impact of ICT adoption on sustainability

Some studies show that ICT adoption affects sustainability. Schauer [7] stated that ICT contribute to ecological, social, cultural, and economic sustainability. Hilty and others [35] asserted that ICT can facilitate sustainability by creating the kind of economic activity that harmonizes nature with human and social welfare in the long term. Johnston [36] referred to the ICT impact on sustainability, pointing out to the need for greater investment in more effective public services and public administration as well as more active promotion of 'eco-efficient' technologies and their use.

In general, ICT for ecological sustainability comprises sustainability in ICT and sustainability by ICT [4]. Sustainability in ICT is related to greater sustainability of ICT goods and services over their whole life cycle, which is achieved by limiting energy and material flows connected with them. Then, sustainability by ICT manifests itself by creating, enabling, and encouraging sustainable patterns of production and consumption by means of ICT. ICT are crucial driving force in achieving durable, harmonious and flexible economic benefits in government units [31], [37]. The adoption of ICT can improve their efficiency and effectiveness. ICT are bound to play an increasingly prominent role in enabling socio-cultural sustainability, e.g. they can increase employment, facilitate learning and work, promote culture, reduce social exclusion [38]. ICT are used to deliver public services electronically to SIS stakeholders [38], [39]. The work by Grunwald [40] pointed out that ICT can play an important role in supporting cooperation, networking and partnership relations between government units and households. Furthermore, ICT can also allow for strengthening democracy by their adoption for improving political transparency and citizen's participation in democratic decision-making [39].

D. Research questions

Motivated by these above concerns, the SIS is a multidimensional concept encompassing two constructs: the ICT adoption and sustainability, as well as correlations between them. The sustainability construct composed of ecological, economic, socio-cultural, and political sustainability can be strongly influenced by the ICT adoption that encompasses ICT outlay, information culture, ICT management, and ICT quality.

In other study Ziemba [41] assessed the quality of the two constructs by examining the construct reliability [42], convergent and discriminant validity [43], [44]. The following measures were calculated: the loadings of each item of each component, composite reliability (CR) of all sub-constructs, average variance extracted (AVE) of all sub-constructs, Cronabch's Alpha of all sub-constructs**,** correlations between the sub-constructs, the square root of AVE for each component. Overall, the results successfully established the reliability, convergent validity, and discriminant validity of the proposed constructs and their sub-constructs [41].

The present study focuses on addressing the following research question:

RQ1: What is the level of ICT adoption in Polish government units?

RQ2: What is the level of sustainability in Polish government units?

RQ3: Does the ICT adoption influence sustainability in Polish government units?

III. Research Methodology

A. Research instrument

The Likert-type instrument (a questionnaire) was developed. The task of respondents was to assess the primary variables describing:

- The four sub-constructs of the ICT adoption construct, i.e. the ICT outlay (Out), information culture (Cul), ICT management (Man), and ICT quality (Qua) (Table 1). The respondents answered the question: *Using a scale of 1 to 5, state to what extent do you agree that the following situations and phenomena result in the efficient and effective ICT adoption in your government unit?* The scale's descriptions were: 5 – strongly agree, 4 – rather agree, 3 – neither agree nor disagree, 2 – rather disagree, 1 – strongly disagree; and
- The four sub-constructs of the sustainability construct, i.e. ecological (Ecl), economic (Eco), socio-cultural (Soc), and political sustainability (Pol) (Table 1). The respondents answered the question: *Using a scale of 1 to 5, evaluate the following benefits for your government units resulting from the efficient and effective ICT adoption?* The scale's descriptions were: 5 – strongly large, 4 – rather large, 3 – neither large nor disagree, 2 – rather small, 1 – strongly small.

B. Research subjects and procedures

In April 2016, the pilot study was conducted to verify the draft of survey questionnaire. Seven experts participated in the pilot study, i.e. five researchers from an information society and business informatics, and two employees of the Silesian Centre of Information Society in Katowice (ŚCSI). ŚCSI is a government unit that is responsible for information society development in the Silesian Province in Poland. Finishing touches were put into the questionnaire, especially of a formal and technical nature. No substantive amendments were required.

The study examined government units from the Silesian Province in Poland. The region was chosen due to its continuous and creative transformations related to restructuring and reducing the role of heavy industry in the development of research and science, supporting innovation, using *know-how* and transferring new technologies, as well as increasing importance of services. In response to the changing socio-economic and technological environment intensive work on the development of the information society has been carried out in the region for several years. In the next development strategies of the information society it was and is assumed that the potential of the region, especially in the design, provision and use of advanced information and communication technologies will be increased [ŚCSI]. All this means that the results of this research can be reflected in innovative efforts to build a SIS in the region and, at the same time, constitute *a modus operandi* for other regions throughout the country and in other countries.

Selecting a sample is a fundamental element of a positivistic study [45]. A random sample was used for statistical consideration to provide representative data. A survey questionnaire was submitted to all 185 government units in the Silesian Province.

The subjects were advised that their participation in completing the survey was voluntary. At the same time, they were assured anonymity and guaranteed that their responses would be kept confidential.

C. Data collection

Having applied the Computer Assisted Web Interview and employed the ŚCSI platform, the survey questionnaire was uploaded to the website. The data were collected between 30 May 2016 and 15 July 2016. After screening the responses and excluding outliers, there was a final sample of 118 usable, correct, and complete responses. It means that 64% of all government units from the Silesian Province completed their responses fairly, in all respects. The sample ensured that the error margin for the 95% confidence interval was 5%.

Table 2 provides details about government units' size, and their participation in SKEAP project. This project was carried out by the municipal and district authorities of the Silesian Province in 2005-2008. The project's result was the Electronic Communication System for Public Administration called SEKAP [46]. It enables government units to provide e-public services at different levels of maturity to all society stakeholders. It could be presumed that these government units which participated in SEKAP more skillfully entered into the ICT adoption than those which did not.

TABLE II.
ANALYSIS OF GOVERNMENT UNITS' PROFILES (N=118)

Characteristics	Frequency	Percentage
Number of employees		
less than 50 (small)	51	43.22%
50 and above (large)	67	56.78%
SEKAP partner		
yes	91	77.12%
no	27	22.88%

Source: own elaboration.

D. Data analysis

The data were stored in Microsoft Excel format and subsequently analyzed using Statistica package and Microsoft Excel in two stages. The first stage assessed the levels of the ICT adoption and sustainability, and the second

stage examined the significance of construct correlations and provided regression analysis.

In the first stage, the descriptive statistical analysis was employed to describe the levels of the ICT adoption and sustainability in government units. The following statistics were calculated: mean, median (MDN), first quartile (Q25), third quartile (Q75), mode, variance (VAR), standard deviation (SD), coefficient of variation (CV), skewness (SK), and coefficient of kurtosis (CK). Further, the analysis of variance (Anova Kruskala-Wallisa) was used to determine if there were statistically significant differences between distributions of scores for the ICT adoption and sustainability sub-constructs. Additionally, the Pearson Chi-square test of independence was employed to determine whether there is an association between the sub-constructs of ICT adoption/sustainability, and the size/the SEKAP participation of government units (i.e. whether the sub-constructs and the size are independent or related as well as the sub-constructs and the participation of government units are independent or related).

In the second stage, the correlation and regression analysis [47] were used to estimate the correlations between a dependent variable (sustainability and its various kinds) and one or more independent variables (ICT outlay, information culture, ICT management, and ICT quality). The coefficient of determination, denoted R^2 and advanced R^2, determines the productiveness of the proposed theoretical model. Falk and Miller [47] recommended that R^2 values should be equal to or greater than 0.10 in order to be deemed adequate for the variance explained of a particular endogenous sub-construct.

IV. Research Findings

A. The level of ICT adoption in government units

In order to answer the research question *RQ1: What is the level of ICT adoption in Polish government units?*, a detailed descriptive analysis was conducted. The results are presented in Table 3.

It has been found that the average levels of ICT adoption sub-constructs ranged from 3.29 to 3.62 (on a 5-point scale from 1.00 to 5.00). Median values were in the range between 3.22 and 3.67. On average, the level of ICT management was the highest, followed by the level of ICT outlay. The level of information culture was the lowest. The levels of the ICT adoption sub-constructs were above their average levels in most government units.

TABLE III.
THE LEVELS OF ICT ADOPTION AND SUSTAINABILITY IN GOVERNMENT UNITS

Sub-constructs	Mean	Q25	MDN	Q75	VAR	SD	CV in %	SK	CK
ICT adoption sub-constructs									
Out	3.50	3.00	3.67	4.00	0.68	0.82	23.50	-0.38	-0.20
Cul	3.29	2.89	3.22	3.89	0.41	0.64	19.46	-0.27	-0.33
Man	3.62	3.27	3.59	4.09	0.29	0.54	14.99	-0.35	0.09
Qua	3.45	3.09	3.55	3.82	0.25	0.50	14.38	-0.21	-0.59
Sustainability sub-constructs									
Ecl	2.83	2.50	3.00	3.00	0.63	0.79	27.98	0.06	0.91
Eco	3.13	2.71	3.14	3.57	0.46	0.68	21.70	-0.25	0.17
Soc	3.15	2.75	3.25	3.50	0.43	0.66	20.88	-0.64	0.70
Pol	3.19	3.00	3.00	4.00	0.60	0.77	24.21	0.06	-0.17

Source: own elaboration.

The values of h-Kruskala-Wallisa H(3, N=472)=17.861 and p=0.001) and Chi-square statistic (Chi-square=10.112, df=3, p=0.018), and finally *post-hoc* analysis confirmed significant differences between the distribution of scores for the information culture and the distributions of scores for the ICT management (p=0.000) and ICT outlay (p =0.024). In addition, the Pearson Chi-square test of independence (α=0.05) allowed for indicating that there were not statistically significant relations between the size of government units and the levels of ICT outlay, information culture, ICT management, and ICT quality. Such a relation was also not confirmed between the SEKAP participation of government units and the levels of all ICT adoption sub-constructs within them.

B. The level of sustainability in government units

In order to answer the research question *RQ2: What is the level of sustainability in Polish government units?*, a detailed descriptive analysis was conducted. The results are presented in Table 3.

It has been found that the average levels of sustainability sub-constructs ranged from 2.83 to 3.19 (on a 5-point scale from 1.00 to 5.00). Median values were in the range between 3.00 and 3.25. On average, the level of political sustainability was the highest, followed by socio-cultural sustainability. The level of ecological sustainability was the lowest. The levels of economic and socio-cultural sustainability were above their average levels in most government units, whereas the levels of ecological and political – below their average levels.

The values of h-Kruskala-Wallisa (H(3, N=472)=20.256, p=0.000) and (Chi-square=43.034, df=3, p=0.000), and finally *post-hoc* analysis confirmed significant differences between the distributions of scores for ecological sustainability and the distributions of scores for economic (p=0.003), socio-cultural (p=0.001, and political (p=0.002) sustainability. In addition, the Pearson Chi-square test of independence (α=0.05) allowed for indicating that there was statistically significant relation between socio-cultural sustainability and the size of government, as well the SEKAP participation of government units. The average level of socio-cultural sustainability was higher in small government units and in those government units which were not a SEKAP partner.

C. The contribution of ICT adoption to sustainability

Table 4 shows the results of the correlations between:

- the ICT adoption sub-constructs and the sub-constructs of sustainability; and
- the ICT adoption sub-constructs and the total sustainability construct (Y).

TABLE IV.
CORRELATIONS AMONG SUB-CONSTRUCTS OF ICT ADOPTION AND TOTAL SUSTAINABILITY AND ITS SUB-CONSTRUCTS

Sub-constructs	Ecl	Eco	Soc	Pol	Y
Out	0.055 p=0.553	0.146 p=0.115	0.192	0.064 p=0.494	0.154 p=0.960
Cul	0.174 p=0.059	0.416	0.467	0.338	0.446
Man	0.157 p=0.089	0.467	0.439	0.371	0.467
Qua	0.208	0.542	0.406	0.321	0.498

Source: own elaboration.

The correlation coefficients for the sub-constructs of ICT adoption and the sub-constructs of sustainability were significantly different from zero (p=0.000 < 0.05=α), with the exception of one correlation between the ICT outlay and ecological (p=0.553), economic (p=0.115), and political (p = 0.494) sustainability, between information culture and ecological sustainability (p=0.059), as well as between the ICT management and ecological sustainability (p=0.089). In other cases there was a positive linear correlation. In addition, the three sub-constructs of the ICT adoption construct, i.e. the ICT quality, information culture, and ICT management had a significant association with the total sustainability construct (Y). Such an association was not indicated between the ICT outlay and total sustainability (p=0.960).

The correlations analysis was sought into the linear regression. In the first and second steps of building the regression model, the following results were established. For the sub-constructs of ICT outlay (p=0.125) and ICT management (p=205), p-values were higher than the accepted level of significance (α=0.05). There is not enough evidence at the 0.05 significance level to conclude that there is a linear relationship between the level of ICT outlay and the level of sustainability as well as between the level of ICT management and the level of sustainability in the examined population. Therefore, these sub-constructs were removed from the regression model and then the correct model was received (Table 5).

TABLE V.
CORRELATIONS AMONG COMPONENTS OF ICT ADOPTION AND THE TOTAL SUSTAINABILITY AND ITS COMPONENTS

Sub-constructs	Standardized coefficients		Unstandardized coefficients		t(115)	Signif. p
	Beta	Stand. error	Beta	Stand. error		
R=0.552; R^2=0.305; Adv.R^2=0.293 (F(2.115)=25.247; p<0.0000);Standard error of estimation:0.504;N=118						
Constant			0.726	0.342	2.121	0.036
Cul	0.272	0.088	0.255	0.083	3.083	0.003
Qua	0.370	0.088	0.448	0.107	4.200	0.000

Source: own elaboration.

Two sub-constructs of the ICT adoption construct, i.e. the ICT quality and information culture explained 31% of the variance in sustainability (F2.115=25.247; p<0.0000). These sub-constructs predicted sustainability significantly well. The examination of coefficients indicated that the sub-constructs had a positive significant impact on sustainability. The effect of ICT quality was stronger than of the information culture.

Then, the relationship between the ICT adoption and sustainability may be written:

$$\hat{Y} = 0.726 + 0.255*Cul + 0.448*Qua$$

where:
$\hat{Y}$p – the theoretical level of sustainability in government units, including ecological, economic, socio-cultural, and political sustainability;
Cul – the level of information culture in government units;
Qua – the level of ICT quality in government units.

Generally, the estimated model is correct and there is no reason to reject it. It allows for understanding of the ICT adoption contribution to sustainability in government units. It gives an answer to the question – whether the growth in

levels of ICT outlay, information culture, ICT management, and ICT quality in government units determines an increase in the level of sustainability of the information society. The above results successfully established the significant and positive contribution of information culture and ICT quality to sustainability. Such a contribution was not confirmed between the ICT outlay and sustainability and between ICT management and sustainability.

V. Conclusions

A. Research contribution

This work contributes to existing research on the SIS, in particular the contribution of ICT adoption to sustainability by:

- indicating and describing the level of ICT adoption in government units, especially the levels of ICT outlay, information culture, ICT management, and ICT quality;
- indicating and describing the level of sustainability in government units, especially the levels of ecological, economic, socio-cultural, and political sustainability; and
- investigating how the ICT adoption in government units, i.e. the ICT outlay, information culture, ICT management, and ICT quality contribute to sustainability comprising its four types, i.e. ecological, economic, socio-cultural, and political.

Firstly, this study indicated significant statistical differences in the level of information culture and the level of ICT management in the Polish surveyed government units. On average, ICT management was at the highest level, whereas the lowest level was specific to information culture, followed by the ICT quality. It means that government units should focus their efforts particularly on improving information culture and ICT quality. Based on the detailed analysis of primary variables, it can be pointed out that the ICT management in government units is rather the result of top-down regulations than the efficient management, e.g. through the implementation of modern management concepts already employed in business. There were also indicated no statistically significant relations between the size of government units and the levels of ICT outlay, information culture, ICT management, and ICT quality.

Secondly, the outcomes showed significant statistical differences in the level of ecological and the levels of economic, socio-cultural, and political sustainability in the Polish surveyed government units. On average, ecological sustainability was at the lowest level, whereas the highest level was specific to political sustainability. The levels of socio-cultural and economic were only minimally lower to the political sustainability. Generally, the levels of all kinds of sustainability are low. It means that government units reap insignificant ecological, economic, socio-cultural, and political benefits from adopting ICT.

Thirdly, it was indicated that the ICT quality and information culture significantly and positively contribute to sustainability in government units. However, the effect of the ICT quality was stronger than of information culture.

With regard to the presented results, it is reasonable to conclude that this study expands the existing research on the SIS provided by Schauer [7], Fuchs [1], [2], Hilty et al. [4], [5], Guillemette, Paré [14, [15], and Curry and Donnellan [12], [13] by presenting the levels of ICT adoption and sustainability as well as identifying how the ICT adoption influence sustainability. The research outputs are also complementary with findings related to the effect of ICT adoption on sustainability in enterprises [21], [22], [23] and households [48]. Summarizing up-to-date research findings, it can therefore be concluded that the ICT quality, ICT management, and information culture within enterprises and households have a significant impact on sustainability, whereas in government units only the ICT quality and information culture influence sustainability. In addition, the ICT outlay does not have any impact on sustainability both in enterprises, households, and government units. On average, the levels of ICT adoption and sustainability in government units were lower than such levels in enterprises and households.

B. Research implication for research and practice

The research findings of this study can be used by scholars to improve and expand the research on the SIS. Researchers may use the proposed methodology to do similar analyses with different sample groups in other countries, and many comparisons between different countries can be drawn. Moreover, the methodology constitutes a very comprehensive basis for identifying the levels of ICT adoption and sustainability, as well as the correlations between the two constructs, but researchers may develop, verify and improve this methodology and its implementation.

This study offers several implications for government units. They may find the results appealing and useful in enhancing the adoption of ICT, experiencing the full potential of ICT and deriving various benefits from the ICT adoption. The findings suggest some framework comprising various kinds of benefits like ecological, economic, socio-cultural, and political that can be obtained thanks to the ICT adoption. In addition, they recommend some guidelines on how to effectively and efficiently adopt ICT in order to obtain those benefits. It is evident from the findings that government units should pay utmost attention to the improvement of information culture and ICT quality. In particular, this research can be largely useful for the transition economies in Central and Eastern Europe. This is because the countries are similar with regard to analogous geopolitical situation, their joint history, traditions, culture and values, the quality of ICT infrastructure, as well as building democratic state structures and a free-market

economy, and participating in the European integration process.

All in all, the research results might provide a partial explanation to the issue of how government units can participate in the creation of sustainable development and sustainable information society.

C. Research limitations and future works

As with many other studies, this study has its limitations. First, the ICT adoption and sustainability constructs are new constructs that have yet to be further explored and exposed to repeated empirical validation. Second, the sample included Polish government units only, especially from the Silesian Province. The study sample precludes statistical generalization of the results from the Silesian government units to government units in other Polish provinces. After all, caution should be taken when generalizing the findings to other regions and countries. Finally, the research subjects were limited to government units and it is therefore only the viewpoint of government units toward the ICT adoption for achieving sustainability in the information society.

Additional research must be performed to better understand the SIS, the ICT adoption and sustainability construct, and the correlations between the ICT adoption and sustainability. First, further validation of the levels of ICT adoption and sustainability should be carried out for a larger sample comprising government units from different Polish provinces. Second, the methodology of the ICT adoption, sustainability, and SIS measurement should be explored in greater depth. A composite index for the SIS with sub-indexes of ICT adoption and sustainability in government units should be explored. In addition comparisons between government units and enterprises [21], [22], [23] may be made.

13th Conference on Information Systems Management

THIS event constitutes a forum for the exchange of ideas for practitioners and theorists working in the broad area of information systems management in organizations. The conference invites papers coming from two complimentary directions: management of information systems in an organization, and uses of information systems to empower managers. The conference is interested in all aspects of planning, organizing, resourcing, coordinating, controlling and leading the management function to ensure a smooth operation of information systems in an organization. Moreover, the papers that discuss the uses of information systems and information technology to automate or otherwise facilitate the management function are specifically welcome.

TOPICS

- Management of Information Systems in an Organization:
  - Modern IT project management methods
  - User-oriented project management methods
  - Business Process Management in project management
  - Managing global systems
  - Influence of Enterprise Architecture on management
  - Effectiveness of information systems
  - Efficiency of information systems
  - Security of information systems
  - Privacy consideration of information systems
  - Mobile digital platforms for information systems management
  - Cloud computing for information systems management
- Uses of Information Systems to Empower Managers
  - Achieving alignment of business and information technology
  - Assessing business value of information systems
  - Risk factors in information systems projects
  - IT governance
  - Sourcing, selecting and delivering information systems
  - Planning and organizing information systems
  - Staffing information systems
  - Coordinating information systems
  - Controlling and monitoring information systems
  - Formation of business policies for information systems
  - Portfolio management,
  - CIO and information systems management roles
- Information Systems for Sustainability
  - sustainable business models, financial sustainability, sustainable marketing
  - qualitative and quantitative approaches to digital sustainability
  - decision support methods for sustainable management

EVENT CHAIRS

***Abstract*— Location Based Services play an important role in decision-making processes, company activities or in any control and policy system in modern computer organizations. Usually LBS applications provide location-specific information only when user requests it. However, Supply Chain Management applications require to push geolocalized information directly to the user. The most discussed and requested application is *Geofencing*, which allows to determine the topological relation between a moving object and a set of delimited geographical areas. This paper describes the design of an innovative solution for implementing proactive location-based services suitable for application scenarios with strong time constraints, such as real-time systems, called Proactive Fast and Low Resource Geofencing Algorithm.**

I. Introduction

LOCATION-BASED services (LBS), software-level functionalities that use location data to control features, have recently become a hot topic for both consumer and industrial applications, evolving from simple synchronization-based service models to authenticated and complex tools thanks to advancements in telecommunication technologies and localization services.

Nowadays, Location Based Services are *crucial for many businesses*, as well as for government organizations, as they could play an important role in decision-making processes, company activities or in any control and policy system in modern computer organizations.

The majority of applications exploiting LBSs are based on the idea to present location-specific information in case the user asks for it. A relatively small amount of new applications act *proactively*, delivering *enter*, *exit* and *cross* geo-notifications directly to the end user. The most discussed and requested proactive LBS nowadays is *Geofencing*, which allows to determine the topological relation between a moving object and a set of delimited geographical areas.

This paper describes the design of a new *geofencing algorithm*, Proactive Fast and Low Resource Geofencing Algorithm (PFLGA) proposed as an innovative solution for implementing proactive location-based services suitable for application scenarios with strong time constraints, such as real-time systems. PFLGA is then exploited in a real application scenario to implement a geofencing service within the See Your Box system, an IT company offering Business-to-Business services which allow early detection of logistic issues happening in Supply Chain Management across several industry verticals.

In particular, PFLGA aims to resolve trajectory-based topological join queries to catch the occurrence of topological events, related to the movement of mobile IoT/M2M tracking devices, within strict time constraints, in the context of real-time supporting services for Supply Chain Management.

PFLGA proposes a centralized, thin-client solution to the geofencing problem, exploiting the GeoJSON format and tree-based index structures for the representation, collection and indexing of geospatial geometric shapes. These features allow the proposed solution to face two classical challenges of Geofencing: reducing the energy consumption at the mobile device, and allowing the matching process within the centralized solution to scale [1].

Classic geofencing solutions require the use of GPS locators continuously connected and therefore in need of continuous power supply.

Several different algorithms have been proposed in the technical literature for the implementation of geofencing functionalities and this section analyzes some of the latest and most interesting designs of the recent years. One of the main problem is the *point-in-polygon problem (PIP)*, which, in computational geometry, solves the question about the position of a point with respect to the boundary of a polygon in the same plane. The paper compares PFLGA with *Parallel In-memory Spatio-temporal TOpological joiN* (PISTON) [2], *Scan-Line Algorithm and Grid Compression (SLGC-1)* [3] and *Geofencing via Hybrid Hashing* [4]. The features and performance of PFLGA are far better than that of the algorithms mentioned above, making it a good solution for the Supply Chain Management context.

Section II examines location-based services, addressing their components, their technical characteristics, focusing on geofencing and route-matching services. Section III describes

This work was funded in part by University of Catania, Dip. Ingegneria Elettrica Elettronica Informatica (DIEEI), under DEDuCE project

features and requirements of the application scenario considered in this work, which relates to *Machine-to-Machine (M2M)* data processing systems based on infrastructure-assisted mobile devices, potentially exploitable in various areas such as Supply Chain Management, then considers many existing geofencing solutions, taken from the technical literature. Section IV deeply discuss PFLGA and one of its possible implementation and provides a comparison between the algorithm mentioned above and those existing geofencing designs which better fit with the service requirements of the considered application scenario. Section IV-B provides comparison both in terms of features and performance for achieving the geofencing result. Finally, conclusions and ideas for future developments are discussed in Section V.

II. Related Works

A. Location Based Service and Geofencing

A location-based service is a software-level service that uses location data to control features [5]. LBS is a part of virtually all control and policy systems which work in computers today [6] and can be used in a variety of contexts, such as healthcare [7], entertainment, indoor object localization and work. LBSs have rapidly evolved from simple synchronization-based service models to authenticated and complex tools for implementing virtually any location-based service model or facility, becoming crucial for many businesses, as well as for government organizations, as they could play an important role in any control and policy system in modern computer organizations.

Together with the Internet of Things (IoT) paradigm, it constitutes an enabling technology for advanced Machine-to-Machine services, useful for companies across diverse industries where often the efficiency plays an important role [8].

According to the definition given by the international Open Geospatial Consortium [5] a LBS is an intersection of three technologies:

1) wireless and mobile telecommunication technologies, which play an important role for the development of many new location-based services for both business and consumer applications, providing applications with an infrastructure able to manage the communications between mobile terminals and Providers of the service [5];
2) Geographic Information Systems (GIS) [9] that provide a strong framework to build database management systems and object extensions, to store and maintain geographical records to monitor the status and changing of the world's geography, and application software such as interactive maps and analysis instruments;
3) New Information and Communication Technologies (NICT), which encompass all those technologies and smart assets, with embedded processing and communication capabilities, which enable human actors to access, store, manipulate, transmit and share information wherever and whenever they want.

LBSs differ from the common Internet services because they must be aware of the context in which they are being used and they must adapt their contents' actions accordingly [5]. LBSs must be aware of any information that could be used to describe the context, such as a place, its features, the objects and people standing in it and anything that is relevant to the interaction between an user and the LBS application. Systems that can dynamically change their behavior according to the context are defined *context-sensitive or responsive*. Service adaption can take place at different levels, from the information level, where the information provided by the service is adapted according to the context, to the user interface and presentation level.

According to literature [10] LBSs can be classified in the following two categories:

- *Pull LBSs*, which deliver information directly requested from the user/customer. Pull LBSs can be further classified [5] in functional services, which facilitate the user in the acquisition of goods and services related with his/her position, and information services, which retrieve information about a specific subject depending on the user's position;
- *Push LBSs*, which deliver information not requested or indirectly requested from the user, although the user may have originally subscribed to the service at an earlier time. Push services are activated by events and are usually more complex to establish.

In the last years the attention moved from Pull LBSs to a more advanced, proactive type of location-based services, where environmental information is pushed to the user depending on the geographical position of a mobile device [11]. The most discussed and requested Push LBS in recent time is geofencing.

In this paper we focus on *Geofencing* that is is a location-based service which enables to detect and monitor when a mobile IoT/M2M device enters, leaves, crosses or bypasses a precise geographical area delimited by a virtual perimeter, called geofence [10], [12] providing alerts or notifications, usually referred to as *geo-notifications*. A geofence can be dynamically generated, like a circular area surrounding the current position of a mobile device, or can be made of a predefined set of boundaries, which may be arbitrarily drawn by the user or specific for a place or a building. Geofencing services can be classified, depending on the geographical references used to check device's position, in [13] *static* that checks the geographical position of a mobile device with respect to a fixed area, *dynamic* that operates according to the position of a mobile device with respect to a changing area and *peer-to-peer* that uses the geographical position of a mobile device with respect to other mobile devices.

A geofencing service can be characterized according to the following features [13]:

- *location accuracy*: geofencing accuracy is strictly related to the accuracy of the geographical position provided by the service used to track the location of the mobile device, either satellite/GPS or GSM-based.
- *Tracking Rate*: expresses the frequency at which the

device provides a location update to the server of the proactive LBS.
- *Device Speed*: the speed of a device determines the time period within which the device must provide a location update to be evaluated against eligible events.
- *Device Route*: the path a device takes across a geofenced area which affects the time period within which location update must occur.
- *Geo-notification delivery*: geo-notifications can be delivered to the user only once or every time the mobile device successfully enters, leaves, crosses or bypasses a geofenced area.

The spread of location-based services applied to IoT technologies, especially for mobile-based solutions, makes it necessary to add to the features listed above the *power efficiency*, since the signal is triggered by small, battery powered mobile devices.

The behavior of a moving mobile IoT/M2M device relative to a set of one or more geofences can be easily defined using the spatial predicates enter, leave, bypass and cross, proposed for the first time by Erwig, Schneider et al. in [14]. Whether a moving object enters, leaves, crosses or bypasses a given geofenced area can be determined by examining one or more segments of its trajectory, checking if they intersect with the before mentioned geofence and evaluating the intersections found. The whole process is often referred to as trajectory-based topological join query.

Trajectory-based topological join queries are really powerful instruments for spatiotemporal analysis, but they are also rather compute-intensive. For their resolution they require a description of the route traveled by the moving object, which could be expressed as a set of segments or as a polyline. This requirement raise the issue of how the route should be determined, which will be discussed later on when it comes to route-matching service.

B. Geofencing implementation

One of the most important component in a geofencing system is the Location Monitoring Unit (LMU), which is the component inside the geofencing system infrastructure which is responsible for location processing of the positions of a mobile device and for keeping the geofence scenarios secret. Technically, a geofencing system can be implemented in two different solutions [1]: mobile-based and centralized system.

In a mobile-based geofencing system, the device positioning, determined with satellite-GPS technology, together with the matching of the position with a set of geofences is executed at the mobile device. This type of geofencing systems represents a thick client solution which is mainly used in case a trustful position of nodes is needed, although it requires high battery consumption due to the geospatial processing executed at the mobile node.

In a centralized geofencing system, a mobile device is being tracked by the surrounding network infrastructure, while the matching of the retrieved position with a set of geofences is executed by the servers which make up the geofencing system infrastructure. Centralized geofencing systems represent thin client solutions [15] and have several advantages over mobile-based counterparts, such as:
- mobile devices get rid of the CPU-intensive geospatial processing necessary to determine the current state of a mobile client regarding the geofence scenarios.
- Centralized geofencing systems use network-based positioning methods within the infrastructure, such as satellite-GPS positioning or GSM Cell ID positioning, which relieve the mobile clients from the energy-draining positioning process.
- Since the LMU monitors all the mobile clients of the system, centralized systems allow for collaborative geofencing and monitoring of the current number of clients within a particular geofence.

On the other side, in centralized geofencing systems the communication between the LMU and mobile clients increases, accompanied by all the weaknesses of mobile communications like loss of connection, unpredictable latency and an energy consumption tightly depending on the location update frequency.

C. Geofencing challenges

Geofencing is associated with two main technical challenges: reducing the energy consumption at the mobile device, in particular within the mobile-based solution, and allowing the matching process within the centralized solution to scale [1]. The high energy consumption of the mobile device is mainly caused by the positioning modules (satellite-GPS or GSM-based) nodes are equipped with and, in case of mobile-based geofencing systems, by the geospatial processing necessary to determine node status.

As for the high energy consumption caused by the positioning modules inside the device, this is tackled by selecting the positioning method based on:
- accuracy need: satellite-GPS technologies allow for a more precise localization than GSM Cell ID technology;
- current environment: in case GSM signal doesn't reach the area the mobile device is currently in, positioning technique is switched to satellite-GPS;
- current position/speed towards a geofence: in case the mobile device is far from a geofence boundary, at a distance which is greater than a specific safety radius, then no location update is needed. Otherwise, if the mobile device is close to a geofence boundary, it will transmit periodic location updates to make the system check its position relative to the geofence.

In the context of geofencing systems, scalability is required in two dimensions [16]:
1) amount of geofences set by the user;
2) number of location updates processed per time unit (throughput).

To allow the customer using the geofencing system to store as many geofences as he wants, without compromising the efficiency of the service and aiming at the maximum scalability, geospatial objects need to be indexed using spatial indexes.

The use of spatial indexes allows to reduce greatly the time needed to resolve geospatial queries, which results in more location updates processed per time unit, which increases system scalability.

D. Route-matching

Intelligent Transport Systems (ITS) and Location-Based Services (LBS) require location information about mobile IoT/M2M telemetry devices. In the last few years Global Positioning System (GPS) has established itself as the major positioning technology for providing location data. This information can be used with spatial road network data to determine the spatial reference of device location via a process known as map-matching or route-matching [17].

Route-matching techniques integrate positioning data, coming from satellite-GPS or GSM positioning technologies, with spatial road network data to provide enhanced positioning capabilities, with the aim of identifying the most plausible route segment traveled by a mobile object between two or more location points [18] and determining the device location inside the calculated road segment [17].

The quality of the result returned by a map-matching service depends on:

- the quality of the spatial road map used by the algorithm, which must always been up to date and checked in-depth in order to identify and correct flaws in the available road network data;
- devices' sampling frequency, which in turn depends on the precision requirements of the localization service and on the performance of the transceiver the mobile device is equipped with. Since the positioning technology chosen for tracking the mobile device is characterized by a known measurement error the desired accuracy for the route-matching algorithm can be achieved by adjusting the sampling rate of the tracking service, according to the lens-shaped probability distribution function describing the sampling error, depicted in [19];
- the result of the initial map matching process, which selects a set of road segments falling within an error ellipse, representing the area in which the current position of the mobile device may be, according to the error of the localization service. In case the vehicle's initial position is further from roads junctions, the ellipse produced by the initial matching process won't contain any junction point nor shape point assuming the vehicle is outside of the known road network;
- the implementation of the route-matching service. The mobile-based approach requires high battery consumption, due to the route-matching algorithm executed at the mobile node whilst it reduces communications between the device and the central server. The centralized implementation relieves mobile devices of the CPU-intensive map-matching processing, although communications between devices and the server increase, accompanied by all the weaknesses of mobile communications, such as loss of connection, unpredictable latency and energy consumption.
- The route detail level required by the route-matching service application. Simplified routes are less accurate than fully detailed routes, but their computation time is lower .

E. Geofencing algorithms in literature

Custom virtual fences surrounding specific areas of interest have been used for more than a decade for on-line mapping applications, proximity-based digital coupon distribution and many other application software. Since its first appearance in research and technical literature, geofencing has evolved into a powerful geospatial analysis tool, becoming one of the most cutting-edge feature in application software and systems used in different fields.

Several different algorithms have been proposed in the technical literature for the implementation of geofencing functionalities and this section analyzes some of the latest and most interesting designs of the recent years.

One of the main problem is the *point-in-polygon problem (PIP)*, which, in computational geometry, solves the question about the position of a point with respect to the boundary of a polygon in the same plane. The PIP test finds application in areas dealing with geometrical data processing, such as computer graphics, computer vision, geographical information systems and many more. One of the first approach is the ray-casting algorithm, proposed in the early description of the point-in-polygon problem [20], but this method doesn't work in case the point is on the edge of the polygon.

Many of the discussed examples define simplified geofencing features by solving, with different approaches, the point-in-polygon test.

PISTON: Parallel In-memory Spatio-temporal TOpological joiN (PISTON) is a geofencing algorithm, designed by the research team of the Department of Computer Science of the University of Toronto, which implements a parallel, main memory, query execution infrastructure designed specifically to address spatiotemporal join [2]. PISTON, which was initially designed as an optimization of the INLJ2I geofencing algorithm, introduces a novel parallel, in-memory trajectory index I_R, designed to handle a high rate of location data updates, and a novel in-memory spatial index I_S, organized with a two level grid approach and specifically optimized for point-in-polygon test. PISTON delivers low query response times acceptable for real-time use-cases, even with large geofence datasets.

SLGC-1: Scan-Line Algorithm and Grid Compression (SLGC-1) is a geofencing algorithm, designed by the development team of the Software School of the Xiamen University of China to solve regional limited problems in Internet of Vehicles (IoV) systems with restricted time and storage requirements [3]. It works in two separate steps. In the preprocessing step the algorithm imposes a spherical grid on the geofence area in input, matching the shape of the real region, then a scan conversion algorithm is used to determine the location attribute

of each cell of the grid. Finally the grid is compressed using a QuadTree compression algorithm, which provides a memory-efficient index structure (storage requirements is less than O(n)) for the geofence area to analyze and calculates the Morton Code (MD code) to identify each node inside the QuadTree structure.

Geofencing via Hybrid Hashing: Geofencing via Hybrid Hashing was selected as one of the three best geofencing algorithms, out of the 29 submitted ones, proposed as a solution for the task posed by the ACM SIGSPATIAL GIS CUP 2013 contest [4]. It builds and updates the in-memory hash tables used to index polygons during system spare time, shifting some computation cost from the "point-in-polygon test" stage to non-time-critical processing stage [4]. taking advantage that, in typical geofencing applications, points position are changed much more frequently than those of polygons.

On the basis of the results obtained by testing the algorithm on the dataset provided for the ACM GIS CUP 2013 contest, the algorithm provides low response times with respect to many other algorithms.

III. Application Scenario

This section focuses on the application of geofencing algorithms in services related to Supply Chain Management (SCM), which involve the movement and storage of raw materials and unfinished products from the point of origin to the point of destination and/or consumption. SCM was traditionally driven by Enterprise Resource Planning systems, which provided plans and estimation regarding the different aspects of the business activity. In recent times, a quiet revolution has been taking place thanks to the use of Location-based technologies and innovative solutions to track and trace transportation equipment, materials and drivers across all the step of the supply chain [21]. LBSs allow the enterprise to dynamically tender and dispatch shipments in real time, divert a route because of weather conditions or a severe accident that is causing major delays in the transportation route, or transmit notification messages to the stakeholders whenever a shipment arrives at a warehouse [21] making the whole process more efficient and less expensive.

For all these reasons, location-based services can be considered a disruptive technology for the supply chain that will bring great opportunity for logistics innovation. The evolution in mobile telecommunication technology, together with the advances in electronics and the introduction of the IoT paradigm, has enabled the networking of portable wireless devices and wearable computers that can provide new types of usable knowledge to all the members and stakeholders of a globally dispersed supply chain [22].

These devices, equipped with sensors and actuators, exploit their connection capability to transmit to the Service Provider's servers, in a Machine-to-Machine communication, all the data regarding the status of the shipment which are important for the service's functioning.

The installation of M2M nodes in pallets, containers, vehicles and warehouses, along with new types of inference algorithms and techniques, will enable seamless, efficient, and transparent movement of raw materials and products through the global supply chain [22], allowing the business's customers to look at all the critical points of the chain.

M2M communication, together with geofencing, map-matching and localization services, represent the enabling technologies for developing and deploying a location-based service.

Developing a Location-Based Service, founded on M2M Communication, to support the Supply Chain Management raises several technical challenges, the most important are: geographical diversity and telecommunication coverage, location awareness, response time, accuracy of the result, power conservation, security and privacy, meet customer expectations.

Geographical diversity and telecommunication coverage: along their trip, from the moment goods are packaged for shipping to the moment they arrive at destination, containers and cargoes go to many places where GSM coverage is poor to non-existent. Thus, the use of dual mode GSM-satellite M2M devices is crucial to provide uninterrupted service to customers thus satellite communication is always available as a back-up technology to transmit the device's position. Furthermore, mathematical statistical interpolation may be used to fill the missing data.

Location awareness: in some application scenarios, such as air transport, the ability of the LBS to switch operative mode depending on devices' position could be an important feature both to meet customer needs and legislative restrictions (e.g. IATA restrictions on network-enabled electronic devices [23]).

Response time: the algorithm behind the LBS services should return the result of the computation within a specific deadline from the moment the packet, transmitted by the device, is received. This is important in order to guarantee the responsiveness of the application which uses the service, and is crucial for time-critical applications.

Accuracy of the result: the precision of devices' location depends on the hardware and software used in the mobile communication system, as well as on the positioning service [24]. The accuracy level requested to the Location-Based Service, both for position tracking or route-matching, influence the service's response time and varies depending on the application scenario in which the service will be used.

Power management: energy efficiency and power consumption are critical aspect when developing a LBS using battery-powered M2M devices. Containers and cargoes trips from source to destination may last 75 days in average, so the device attached to them should work properly for long period of time, often without the possibility to recharge the battery.

Security and privacy: customer concerns about security and privacy are another challenge for location-based technologies applied to Supply Chain Management. With regards to shipment security, it is desirable that the LBS integrates a priority function which immediately alerts the customer in case of illicit manipulation of the container holding the goods. On the other hand, the M2M devices should transmit the shipment status and location data using data security

instruments, such as cryptography, to keep them confidential and avoid interception of sensible information.

Finally, the developed services have to satisfy customers' expectations, in terms of expected results, perceived Quality of Service, reliability, availability and more importantly cost.

Among all available tools which contribute to the establishment of applications and systems for Supply Chain Management, geofencing plays an important role in the context detection of proactive applications, which can automatically adapt business and industrial operations to the geospatial context a user, or a mobile device, is currently in.

A. Geofencing service for SCM systems

Geofencing allows to detect and monitor the changing in the topological relation between a mobile device and a bounded geographical area (the geofence). The aforementioned topological relation can be expressed in terms of the spatio-temporal predicates enter, leave, cross and bypass, which are obtained as the result of trajectory-based topological join queries. These queries test the intersection between the whole or part of the trajectory of a moving object and a geofence, returning the spatio-temporal predicate describing their relationship based on the intersections found. These queries are really powerful instruments for geospatial analysis, but they are also computationally intensive.

This represents a challenge, as it requires to identify or construct the most efficient algorithm or method which, under the operating conditions of the specific system and application scenario, resolves geofencing problems, returning the result of trajectory-based topological join queries in a period of time that is acceptable for interactive, ad hoc geospatial analysis services.

The application scenario of the geofencing service proposed in this paper is that of IoT-based industrial services supporting Supply Chain Management and logistics for remote monitoring of goods and assets using mobile devices, smart cards, tags or similar technologies. This kind of services are placed in the context of Industry 4.0. In particular, the application scenario presented in this paper provides for a system using uniquely identifiable mobile objects, from here onwards called trackers, which transmit real-time location data with a precise, configurable frequency, which may change over time. The aforementioned system is centralized and thin-client, meaning that the trackers have limited resources and processing capabilities, in order to save battery power to provide a long-lasting monitoring service.

The geofencing service to be implemented should make it possible to detect whether one of the aforementioned mobile devices, capable of transmitting real-time location data to the system, enters, leaves or crosses one or more specific areas of interest, the geofences, and, whenever this occurs, it should notify the system of the event, depending on the specific service configuration assigned to the specific device. Each geofence should be statically defined by a geometric shape or by indicating a location identifier, such as an address. In order to reduce the processing within the tracker, all computing related to geofencing should be performed within server computers. Furthermore, to meet the real-time requirements, the geofencing routine must be non-blocking and the service must return a correct result within specific time constraints, often referred to as deadlines, failing which the result should be invalid.

In order to determine the topological relation between the moving object and the set of assigned geofences, the service should be coupled with a utility capable of reconstructing the path traveled by the device. In addition, if it is not possible to estimate all or part of the route traveled by the tracker, or in case a low level geospatial analysis is requested, the service should be able to work with the simpler geospatial data available at the time of the request. Following the reception of a notification from the geofencing service, the system should notify the user about the event and/or switch the device configuration depending on the event occurred.

According to the above features, the requirements of a good geofencing for SCM are:

- static, meaning that the spatio-temporal predicates are verified by checking the trajectory of the moving object with respect to fixed, bounded areas;
- geometric and symbolic addressed, so that the geofences could be defined with both geometric shapes or symbols, such as words and alphanumeric codes, which identifies precise locations;
- centralized, so that the matching between the trajectory of the moving object with the set of associated geofences is executed by the servers, which are the main part of the system;
- capable of operating effectively with different and variable location accuracy, tracking rate and device speed.

IV. Proactive Fast and Low Resource Geofencing Algorithm

In order to satisfy all the requirements discussed in the previous section, we propose a new geofencing design inspired by the ray-casting algorithm called Proactive Fast and Low Resource Geofencing Algorithm (PFLGA). The developed solution exploits geofences drawn over the WGS84 (or EPSG:4326) world geodetic coordinate system [25], which is a mathematical model of the Earth from a geometric, geodetic and gravitational point of view and is used by GPS navigation system and for aviation as a mandatory standard.

The proposed design provides every tracker for which geofencing service is enabled with a set of one or more geofences, i.e. geospatial objects, such as polygons and circles, whose boundaries are drawn over a specific geodetic coordinate system.

The data periodically transmitted by the tracker carries its geographical position, expressed in terms of latitude and longitude coordinates, enabling the location update for each tracker. These geographical points are used to determine the most plausible *path traveled* by the device between location

updates, exploiting route-matching services with different levels of detail. The *traveled path* is then used to determine the topological relation between the moving object and the set of geofences assigned to the shipment the device is attached to.

Although the algorithm is designed to determine the topological relation between a moving object and a set of geofences using its trajectory, it can also perform the geofence inclusion test using other geospatial objects, from a geographical location point to a single segment of the whole complex trajectory traveled by the tracker, depending on the available geospatial information regarding the moving object and the complexity required for the geofencing analysis. This allows the algorithm to be potentially applied to different use cases, from those which require an examination with low level of detail, in favor of a low query response time, to those that require a detailed geospatial analysis regardless of the query response time.

Since the application scenario in which the geofencing service will be used provides that each tracker can be assigned a set of one or more geofences, and the trajectory-based topological join queries are rather compute-intensive, it is important that data structures containing geospatial data support the retrieval of elements of an arbitrarily large size in an efficient way, therefore the proposed geofencing algorithm uses an in-memory, tree-based index structure for indexing the set of geofences assigned to each tracker for which the geofencing service is required. The insertion strategy for these structures has a computational complexity of $O(n)$, while the search operation has a computational complexity of $O(\log n)$, which permits a fast object retrieving in time critical applications.

The use of this kind of spatial index enables the application of an efficient filtering strategy on the set of geofences on which the intersection test with the trajectory will be performed.

PFLGA searches for any intersection between the route traveled by the tracker and progressively smaller bounding areas, called *Minimum Bounding Rectangles* (MBRs), which contain one or more geofences within them. In case the trajectory doesn't have any intersection with those bounding areas, the test ends without checking the set of geofences, otherwise the test continues with smaller bounding areas, until a precise geofence is found and tested.

PFLGA is based on the theory behind trajectory-based topological join queries. Given a set of geofences, bounded geographical areas represented as polygons or circular shapes, and the whole or a part of a trajectory defining the path traveled by the moving object, represented as a polyline geometric object, the algorithm verifies the existence of intersections between this polyline and the set of MBRs containing the geofences to be analyzed. If the polyline defining the trajectory intersects one or more MBRs, the algorithm performs the following steps on each geofence contained within the MBRs of interest:

- gets the previous position of the device and checks whether it was inside or outside the current geofence;
- calculates the intersections between the geofence and the trajectory traveled by the device, if there is any;
- analyzes the result obtained above and returns a composite topological predicate [19], which tells whether the object entered, crossed or left that precise delimited area.

This algorithm implies the a-priori construction of the in-memory, tree-based index, which will use a time interval proportional to the dimension of the set of geofences in exam (since the insertion algorithm for this tree-based index structure has a computational complexity of $O(n)$). Since the set of geofences is quite static and it is updated rarely, compared to the location of the moving object and its trajectory, the additional processing required for the index is bearable, especially if it is compared to the query processing speed up offered by the use of this index structure. The algorithm, whose possible implementation in pseudo-code is shown below, has a computational complexity of $O(\log n)$.

input : $\mathcal{F}$: set of geospatial objs making geo-fences
idx : index of the set of geofences
$route$: trajectory traveled by the object
output: $predicate$, position with respect to the fence

```
// list of FeatureIDs of the MBRs in
// the index intersecting the route
I = getIntersection(idx, route)
foreach pos ∈ I do
    prev_pos = getPrevPosition(route);
    // checks if the prev_pos was
    // inside the current MBR
    if (getIntersection(F[i],prev_pos)!=null) then
        wasInside = true;
    else
        wasInside = false;
    end
    Intersections = getIntersections(pos, route)
    if (wasInside) then
        if Intersections number is odd then
            the object left the fence
        else
            the object is still inside
        end
    else
        if Intersections is empty then
            the object is still outside
        else
            if Intersections number is odd then
                the object entered the fence
            else
                the object crossed the fence and it is
                outside
            end
        end
    end
end
```

Algorithm 1: PFLGA description

A. Comparison between geofencing algorithms

In order to verify the performance of the proposed geofencing algorithm, the developed solution is compared with other geospatial analysis algorithms which resolve the same geofencing problem.

First, the algorithms are compared on the basis of the set of features requested by the application scenario the proposed solution has been developed for. Subsequently, the developed design is tested using the same dataset and setup utilized for testing the performance of the other solutions considered in this comparison, which vary depending on the algorithm in exam.

All the features of PFLGA are used to study the similarities between the proposed design and the other geofencing solutions considered in the previous paragraph. Table I shows the comparison among the following features:

1) In-Memory Spatial Index (IMSP);
2) Spatio-Temporal Topological Join Predicates (STTJP);
3) Use of Trajectory-Filtering / Filtering Strategy (TFFS);
4) Geofencing via evaluation of point-in-polygon (PIP);
5) Geofencing via evaluation of spatial intersection with trajectory segments (SEGS);
6) Geofencing via evaluation of spatial intersection with complex trajectories (TRAJ).

TABLE I
COMPARISON OF FEATURES

	IMSP	STTJP	TFFS	PIP	SEGS	TRAJ
Hybrid Hashing	Yes	Yes	Yes	Yes		
SLGC-1	Yes		Yes	Yes		
PISTON	Yes	Yes	Yes		Yes	Yes
PFLGA	Yes	Yes	Yes	Yes	Yes	Yes

Next we compare the algorithms with respect to the benefits and/or their problems in the context of the application scenario the algorithm has been developed for.

Hybrid hashing: The Hybrid Hashing adopts a very efficient filtering strategy, based on the use of two in-memory hash tables, to reduce the time spent for the point-in-polygon test. Moreover, it builds or updates the in-memory hash tables for the geofences during system spare time, shifting some computation from the "point-in-polygon test" stage (which is often time critical) to non-time-critical processing stage. This algorithms shows a low response time. CONs. The main drawbacks are the high storage requirements, the time required for the construction and update of index and data structures for the geofences. Finally Hybrid Hashing is not able to return trajectory-based spatio-temporal topological join predicates.

SLGC-1: This algorithms uses QuadTree compression algorithm to store data regarding geofences, which reduces the amount of memory requested for the index structure, the complexity of the storage is less then $O(n)$ and the approach to geofencing is a simple and straightforward point-in-polygon based solution. Lastly the point-in-polygon test time does not increase with the number of edges of the analyzed geofence. As the previous algorithm, SLGC-1 is not able to return spatio-temporal topological join predicates, so the geospatial analysis is not deep.

PISTON: PISTON adopts a parallel in-memory indexing for trajectories and spatial geofences, which is a very scalable approach. Moreover, it evaluates the spatio-temporal topological join predicates with a sequence of topological relations that may hold between the trajectory of the moving object and the geofences at different time units, The trajectory index IR is optimized for high rate of location updates and can handle both coordinate-based and trajectory-based queries. PISTON adopts an efficient trajectory-filtering strategy and it is scalable due to its native multi-threaded setup. Main problems deal with the time required for the construction and update of the R-Tree index for the geofences, which is high, and the high memory requirements.

PFLGA: PFLGA adopts an in-memory, tree-based indexing for the spatial polygons representing the geofences of interest, the time required for the construction and update of the in-memory index for the geofences is low. Moreover, it adopts an efficient trajectory-filtering strategy which checks for intersections between the MBR of the analyzed trajectory and the MBRs inside the in-memory index and is able to return the trajectory-based spatio-temporal topological join predicates describing the relation between the moving object and each area in the set of geofences. Lastly, the algorithm can also evaluate the simple point-in-polygon test for the current position of the moving object if a simple geospatial analysis is requested. The main drawback is the response time of the trajectory-based topological join query, which is not the shortest among the other algorithms.

B. Performance Comparison

The performance of PFLGA is compared against the ones of the above discussed algorithms. In order to allow a fair comparison and avoid data dependencies, every test uses the same dataset used by the algorithm's author to determine the performance. The test has been executed on a laptop computer loaded with Intel Core i7 4720HQ CPU (Quad Core, 2.60 GHz up to 3.60 GHz) and 8 GB DDR3 RAM, running Linux Ubuntu 14.04 LTS using Apache Bench (also indicated as ab), a tool designed for benchmarking Apache installations and any HTTP server in general [26].

This section reports the dataset characteristics for each algorithms and the results in term of performance.

PISTON vs PFLGA: We used the following datasets to compare these algorithms:

1) Geofences Dataset: US TIGER® Texas Arealm, a real-world spatial-objects dataset which contains 6694 geofences drawn in the Texas area [52];
2) Trajectories Dataset: 10000 trajectories between couples of random location point inside the Texas area, generated according to the specifications in the PISTON paper [48].

The test requires the execution of a geospatial query for each of the trajectories contained in the dataset.

The following table compares the performance of PFLGA against PISTON [2].

TABLE II
PISTON VS. PFLGA

	PISTON	PFLGA
Average Spatial Index Creation Time (ms)	537000	860
Average Query Execution Time (ms)	340	330

Hybrid Hashing vs. PFLGA: For this performance test we used two datasets , according to the paper [4]. The first dataset is provided by the ACM Open GIS Cup 2013 [4], which includes two location point files and two polygons files, for this comparison we selected two of these files, one for each category:

1) Geofences Dataset: Poly10 file, which contains 32 instances of 10 different polygons;
2) Locations Dataset: Point500, which contains 39289 instances of 500 different points.

The test requires the execution of 10000 geospatial queries for each of the trajectories contained in the dataset, according to the experiment specification in the paper. The table III contains the result obtained at the end of the test. According with

TABLE III
HYBRID VS PFLGA

	Hybrid Hashing	Proposed
Average Spatial Index Creation Time (ms)	5	15
Average Query Execution Time (ms)	7	10

Hybrid Hashing's Authors we used another dataset constructed as follows:

1) Geofences Dataset: Poly-OSM1, which contains 200 instances of 20 different polygons, selected from the Land Polygon dataset.
2) Locations Dataset: Point-OSM1, which contains 80000 instances of location points randomly selected from the MBR area of each polygon.

The test requires the execution of 10000 geospatial queries for each of the trajectories contained in the dataset. Table IV shows the result obtained.

TABLE IV
HYBRID HASHING VS PFLGA

	Hybrid Hashing	PFLGA
Average Spatial Index Creation Time (ms)	40.9	45.0
Average Query Execution Time (ms)	76.0	46.0

SLGC-1 vs. PFLGA: The two datasets used for this performance comparison are constructed according to the SLGC-1 paper [3]. This geofences dataset contains 5 different polygons, respectively having 5, 10, 50, 100 and 223 vertexes, and a circular area. Each of these geospatial objects covers a geographical area almost equal to 4000 km^2, and Locations Dataset, 125000 different GPS location points limited in the geofences' areas. For each couple of GPS points a trajectory connecting them is calculated. The test requires the execution of a geospatial query for each of the trajectories contained in the dataset. Table V shows the results of the comparison.

TABLE V
SLGC-1 VS. PFLGA

	SLGC-1	PFLGA
Average Spatial Index Creation Time (ms)	19.0	1.5
Average Query Execution Time (ms)	3255	3

The comparison between PFLGA and the other solutions highlights the proposed algorithm has a wider set of features compared to the other solutions. In particular PFLGA is designed to perform the geofencing test with different geospatial objects, depending on the available information regarding the moving object, which offers a great flexibility depending on the use cases it is applied to. Moreover, in the inclusion test stage, PFLGA performances are comparable to, and in some case better than, those of the other designs, both in terms of average spatial index creation time, in the preprocessing stage, and average query execution time.

V. CONCLUSIONS

This work has described the design process of a geofencing algorithm to be used to implement proactive, context aware functionalities in Supply Chain Management systems with real-time requirements.

PFLGA has been extensively set side by side to other existing geofencing designs, presented in the last few years in technical literature. PFLGA shows more features and comparable performance to the other geofencing solutions, making it more flexible to the different service requirements which may occur depending on available data or service requests.

Subsequently, PFLGA has been implemented in a back end software module within See Your Box test environment. The algorithm has been tested using data collected by a set of trackers along their journeys on different routes in Europe, proving its correctness and its ability to provide the result of the requested analysis within precise time constraints. Then the algorithm has been implemented as a service within See Your Box system. As for future developments, there is still room for optimization of the search strategy inside the set of geofences assigned to a specific mobile device, referred to as the tracker. Upcoming implementations may adopt a new indexing structure for the set of geofences, in order to further reduce the computational complexity and the response time of the algorithm. Another great opportunity for improvement concerns the route-matching service. Route-matching is used to determine the most plausible route traveled by the tracker, given as input a set of geographical points, each of which is coupled with a timestamp, which is then exploited in the proposed algorithm to perform a topological analysis to catch the occurrence of precise events. The introduction or improvement of route selection strategies based on the timestamps of the collected geographical points, or on the estimation of the cruising speed of the device, would allow to increase the accuracy of the result offered by the route-matching service, which would bring great benefit to the

geofencing service in all those application scenarios within Supply Chain Management where the estimated trajectory traveled by the device represents a critical parameter (e.g. alert service in case of crossing a specific area not allowed by company policies).

***Abstract*—In this paper, specific practices are proposed for better managing Cyber-physical Sytems (CPS) projects, called CPS-PMBOK approach. CPS-PMBOK is based on the Project Management Institute's PMBOK body of knowledge. It is focused on the integration, scope, human resource and stakeholder knowledge areas; which were chosen considering a systematic literature review conducted to identify the main CPS challenges.**

I. Introduction

CYBER-physical Systems (CPS) refer to computational systems interacting with the physical world [1], [2]. CPS gained remarkable advances in science, such as medical surgery, autonomous vehicles, energy harvesting and smart buildings. A CPS is composed of a computing platform, the physical world, sensors and actuators [1], [2], [3]. CPS merge areas from embedded systems, mechanical engineering, software, among others [3]. CPS development projects tend to be large, complex and groundbreaking, with innovative technologies [1], [2], [4]. A usual feature is multidisciplinarity, which requires good team communication skills as CPS development merges computing and physical concepts. Collaboration among practitioners from different areas (such as software engineering, civil engineering, experimental physics or natural sciences) is needed to accomplish CPS developments [3], [4].

Project management practices aim to enhance the probability of success in a product or service development [5]. Success depends on organization, application area and project goals, and priorities may vary, including: finishing within planned time, meeting agreed scope, reaching satisfactory quality, or finishing in determined budget. Managing a project consists of controlling the development and providing all resources necessary for project execution, and it is a responsibility usually assigned to a project manager. Project management may be useful for many fields in most diverse applications, such as: medicine, civil engineering, software development, advertising campaigns etc. The Project Management Institute gathers best practices in the so-called Project Management Body of Knowledge (PMBOK) [6], which presents tools and techniques for a better management considering experts' knowledge. PMBOK organizes the best practices through five process groups (initiating, planning, executing, monitoring and controlling, and closing) and ten orthogonal knowledge areas (integration, scope, time, cost, quality, human resource, communications, risk, procurement, and stakeholder).

Considering the particularities of CPS projects and the need to manage them to reach their goals according to the success factors established, this paper addresses specific practices for better managing CPS projects. These specific practices are proposed as a PMBOK extension, called CPS-PMBOK. CPS-PMBOK is focused on the integration, scope, human resource and stakeholder knowledge areas. They were chosen considering a systematic literature review conducted to identify the main CPS challenges. Thus, we expect to improve both team communication skills and understanding of the project activities. The proposed practices are based on approaches previously presented in literature as well as the authors' background. We consider that a well-managed CPS project may increase physical world comprehension, modeling and interaction, enhancing the technological advances.

The remainder of this paper presents: related work and research method, the proposed approach, and conclusion.

II. Related Work and Research Method

Although PMBOK is a general-purpose guide, specific application areas, including CPS projects, may benefit from adapted or focused project management practices, which can better drive project activities and prevent common weaknesses [5]. Some authors propose, for example, new techniques for stakeholder management in civil engineering projects and in clinical research environments [7], [8]. Taking organizational structures differences, some works address concerns on stakeholders, scope, human resources, and communications for globally distributed projects [9], [10]. Other authors propose entire revisions of PMBOK processes, knowledge areas or other project management approach adaptations, but in a general way. One example extends the knowledge areas creating the new 'project sustainability management', dealing with reuse of lessons learned and standardization of project management practices within an organization [11].

To propose our PMBOK extension, we used results from a systematic literature review, conducted to link PMBOK's knowledge areas and the CPS development. We used various technical CPS-related terms to embrace as many primary studies as possible, such as: embedded systems, system of systems, sensors network, IoT, and automation and control.

The primary studies obtained were analyzed to find which knowledge areas were subject of study. A relevance score was applied based on the number of times that keywords related

to each area were mentioned. The outcomes are that scope, human resource and stakeholder were the areas with more issues studied. Considering the outcomes of this systematic review, our work proposes project management practices, focused on the CPS context for the scope, human resource and stakeholder knowledge areas. We also propose a generic practice related to the integration area.

These practices were found to manage scope in CPS projects: software and frameworks for requirements analysis, application of international standards, estimates based on use case points and hardware points, specific modeling languages for requirements elicitation and system architecture visualization, requirements review through peer reviewing and Scrum boards, development of design models, meetings with live demonstrations, and requirements lists and model-driven design [12], [13], [14], [15], [16], [17], [18], [19], [20], [21], [22], [23], [24], [25], [26], [27], [28], [29], [30], [31].

As for the project human resource, these practices were found to CPS projects: use of an expert and multidisciplinary team, statistical estimates and classification of familiarity of team members, training in specific development methods, such as goal- and model-driven and extreme programming, and skill-based human resource management [12], [14], [15], [32], [17], [33], [21], [22], [23], [26], [28], [27].

Finally, considering the project stakeholders, these practices were found as suggestions to address this knowledge area in CPS projects: identification of stakeholders and assignment of tasks following systematic algorithms and norms, assignment of stakeholders within the organization, involvement of stakeholders during the transition between development phases, and workshop meetings and constructive SoS integration model [12], [14], [15], [17], [21], [23], [24], [26], [28], [34].

To propose CPS-PMBOK, we further analyzed all the practices obtained in the primary studies to find practices still not covered by PMBOK and practices already covered but with suggested specializations. The final practices chosen are those most frequently found in the primary studies as well as aligned with the primary insights of the authors of this work.

III. The CPS-PMBOK Approach

CPS-PMBOK is composed of the original set of PMBOK best practices, extending it for CPS projects. The specialization address four PMBOK's areas. For each, one or more practices are proposed: *(a)* integration – characterization model (artifact); *(b)* scope – pre-elaborated requirements lists (technique), review requirements (process), process simulation (technique); *(c)* human resource – specialized team division (technique), cross-training (technique); *(d)* stakeholder – build technical trust (technique), dynamic follow-up strategies (technique).

A. Project Integration Management

The proposed practice 'characterization model' should be used as a brainstorm driver, to equalize the comprehension and familiarization with the system being developed. It should be produced as an output of the develop project chart process, which is part of the initiating process group; and it should be used as input by all processes that use the project charter also as input, i.e.: plan scope management, collect requirements, define scope, plan schedule management, plan cost management, plan risk management, and plan stakeholder management. During the brainstorming, participants should indicate levels for some characteristics, providing estimates about project size and technical challenges besides to discussions among team members. These characteristics are divided in: *(i)* CPS environment, representing the variables present in the CPS to be developed, such as how much limited tasks are required, communication with known group of devices, interaction with known group of people, and industrial standards or norms should be followed and *(ii)* CPS complexity, based on specific technological areas, such as mechanical structures, network, sensors, actuators, data storage, user interaction, legacy systems integration, and power energy systems.

B. Project Scope Management

In terms of scope, some processes present special challenges for CPS projects due to their highly innovative and dynamic aspects [35], [2], [4], [3]. In addition, the high complexity involved for modeling the physical world and its phenomena is another challenge source. CPS project managers and team should be able to constantly look for new requirements, bringing up changes in scope as soon as possible. As a result of this scenario and needs, two practices are proposed to the scope management, as presented in this section: pre-elaborated requirements lists and review requirements.

1) Pre-elaborated Requirements Lists Technique: to gather requirements, CPM-PMBOK includes a technique called pre-elaborated requirements lists to create reusable assets by gathering common requirements in CPS projects. This technique is proposed to be used within the collect requirements process, which is part of the planning process group.

2) Review Requirements Process: CPS development may lead to unexpected results and dynamic requirements [23]. Since such scope revisions and redefinitions are highly common in CPS projects, one of our specific practices is proposing an additional process to the scope knowledge area – review requirements – as part of the monitoring and controlling process group. Review requirements results in change requests similarly to performed by the control scope process, as described in PMBOK. The difference is that, in CPS-PMBOK, review requirements is a creation-focused process, considering less the already known requirements and revisiting the highest definitions of the project looking for new requirements. In PMBOK, the control scope process focuses on ensuring the accomplishment of the defined scope and, when needed, the appropriate processing of changes is made. In this new process, techniques to collect requirements already described in PMBOK are used, as meetings, surveys and interviews.

3) Process Simulation Technique: this technique is added in support of review requirements. Simulation tools to predict environment or conditions such as mechanical simulation, radiation diagrams and thermal dissipation are useful in review requirements and are part of process simulation. Other tools

to isolate part of the CPS, to validate models or equipment, such as hardware or software in the loop may be used.

C. Project Human Resource Management

Considering multidisciplinarity, human resources can be from different specialization areas, what increases the challenge of managing relationships and technical communication [33]. As a result, two additional techniques are proposed in CPS-PMBOK for human resource management: specialized team division and cross-training.

1) Specialized Team Division Technique: specialized team division is included in CPS-PMBOK to improve the development performance and avoid inappropriate assignment of tasks. The team should be split into subteams taking different application areas or project deliverables. Some works found in literature were used as a basis to propose it, including: the application of team division based on academic profiles, such as electrical engineering, computer engineering and information technology [22], [2]. This technique is proposed to be used within two processes: the plan human resource management process, which is part of the planning process group; and the acquire team process, which is part of the executing process group. We propose an initial suggestion for a specialized team division considering the context of CPS projects and taking into account the proposed characterization model in terms of CPS complexity. According to our suggestion, the sub-teams for a CPS projects could be: *(a)* mechanical design team – responsible for physical structures and mechanical packing; *(b)* hardware design team – responsible for processing platforms, sensors and actuators specification; *(c)* electrical design team – responsible for electrical project and drawings, besides power energy design; *(d)* network design team – responsible for communication protocols and technologies specification; *(e)* information system development team – responsible for software development; *(f)* other specialized teams – power bank development team, human-computer interface team, antenna design team, specific sensors team etc. Other options for specialized team division can be used according to specific project needs, based on the context of the system application. An alternative division is based on deliverables or partial results of the project, assigning a focused team for each logical deliverable part of the developed CPS system. A specialized team division may be used to support organizational or resource breakdown structures.

2) Cross-training Technique: cross-training is a practice briefly depicted in PMBOK, proposed to reduce impact when a team member leaves the project. It consists in allocating more than one resource to a task execution. For CPS projects, we propose that the cross-training should be always used to enable some team members acting as a communication bridge between different sub-teams by allocating a team member from a given area to perform a task of some other area. This technique is proposed to be used within the develop team process, which is part of the planning process group. Considering cross-training, a software engineer may sporadically follow a mechanical engineer's work with the purposed of understanding and even positively contributing with potential ideas and insights emerged from another outlook. Cross-training can be used as a facilitator in the identification and development of multidisciplinary practitioners.

D. Project Stakeholder Management

Project stakeholders in CPS projects are usually highly technical or very close to the system's final users. This occurs mainly in joint projects of research with universities, involving researchers and students. Also in industrial projects aiming to improve production performance, where many stakeholders are production leaders experts in many technologies of the area [4]. Consequently, two additional techniques are proposed in CPS-PMBOK for stakeholder management: build technical trust and dynamic follow-up strategies.

1) Build Technical Trust Technique: CPS projects tend to involve academic researchers or experts to support the development of CPS physical elements. They may represent technical stakeholders who know both the application and engineering areas. PMBOK describes a practice of trust building for stakeholder engagement management, showing that the company, team and the manager have competencies to accomplish project's requirements in time and cost. Accordingly, when involving technical stakeholders in CPS projects is to build technical trust between them and the team. In this context, CPS-PMBOK proposes a specialization of the trust building, adding the technical aspect to this practice. Build technical trust is proposed to be used within the manage stakeholder engagement process, which is part of the executing process group. Build technical trust means to pass technical confidence regarding project accomplishment conditions, considering the team and project manager. Accordingly, the team should get close to the stakeholders, mainly in situations in which the stakeholders are highly technical. For CPS-PMBOK, an internal expert or an external consultant should be put in charge of following up the project management activities allowing more technical stakeholders to be more comfortable with the project progress. This person has the role of translating technical stakeholders concerns. The technical trust may improve stakeholders' satisfaction due to their proximity and understanding of technical issues. Besides that, the developers may feel more comfortable as well, due to the understanding of terms and concerns provided by a expert or consultant.

2) Dynamic Follow-up Strategies Technique: some approaches found to improve communication with CPS projects' stakeholders are: face-to-face meetings to update the project status to stakeholders [23], stakeholders' participation in every last weekly follow-up meeting of development iterations [21], and weekly workshops for system demonstrating – to update stakeholders [24]. Most of these approaches are based on agile methods, which has the communication with stakeholders as one of their most important concerns. To meet the different levels of demand and satisfaction of stakeholders, we propose dynamic follow-up strategies as part of CPS-PMBOK. This technique is proposed to be used within two processes: the manage stakeholder engagement process, which is part of the

executing process group; and the control stakeholder engagement process, which is part of the monitoring and controlling process group. According to different aspects of a given specific CPS project, the project manager should adapt the follow-up strategy aiming to enhance stakeholder engagement and reach their expectations. The following suggested strategies are proposed: *(i)* during the project initiation and planning stages, which involve, for example, discovering of requirements and stakeholders, understanding of highly engaged stakeholders, and understanding of stakeholders' application area – regular face-to-face meetings should be adopted as follow-up strategy; *(ii)* during the project execution and monitoring stages, which involve, for example, resolution of requirements conflicts and alignment between technical demands from stakeholders and project documents – only sporadic participation of stakeholders could be included during planning and technical meetings; and *(iii)* during the closing stage, which involves, resource scarcity, time re-planning and stakeholder staff updating – the stakeholders should be able to follow up on the final results through workshops with live CPS demonstrations.

IV. Conclusion

This work proposed project management practices driven to CPS projects. The approach is based on PMI's PMBOK best practices and focused on integration, scope, human resource and stakeholder. CPS-PMBOK relies on the following requirements for CPS projects: multidisciplinary teams, high level of innovation and unpredictable requirements. Our challenge is to be able to evolve the proposed practices considering two needs that can be seen as antagonistic ones: on the one hand, being specific to the CPS project domain; but, on the other hand, being not too specific in order to allow adjustments as required for specific contexts and organizations.

***Abstract*—Value cocreation is gaining momentum as organizations' underlying business logic and encompasses tools and techniques for discovering new valuable and necessary artefacts to support inter-organizational and network-centric business activities. To cocreate value, organizations must talk to each other using a clear and easy to use language. In the course of the ValCoLa (Value Cocreation Language) project, we aim at elaborating such language. To that end, in previous work, we developed a value cocreation metamodel based on three dimensions: the nature of the value, the object concerned by the value and the method to cocreate value. In this paper, we first extend ArchiMate to the domain of value cocreation to provide our metamodel with a dedicated modeling language. Second, we illustrate the language with a case study from the financial sector.**

I. Introduction

Business collaboration is a process that requires a considerable examination of the jointly created value among the parties involved in these exchanges. Value cocreation (VCC) is a notion mostly associated to the paradigm of service-dominant logic (S-DL), rooted in the marketing theories and whose aim is to *jointly create value during business exchanges among two or more partners* [1], [2]. A first example of VCC between a company and its customers is PowerDrive, a Swedish manufacturer of hydraulic drive systems that cocreates value with three of its customers based on the collection and analysis of data from an existing remote monitoring system [3]. Another example is Starbucks that has developed an online community platform to allow its customers, around the globe, to suggest innovative ideas and to allow the most voted ones to be deployed in practices [4]. In those examples, but also in other ones like those reported in [17], VCC is made possible thanks to the interconnections between the involved parties' information systems (IS). Accordingly, depicting value cocreation processes is paramount for IS designers but also to support the communication between IS designers and developers. Therefore, in our previous work, we designed an abstract language (metamodel) to support VCC exchanges [16], [21], [22].

To construct this abstract language, we first observed that the creation of value is an integration of three dimensions [16]: the nature of the value (e.g., financial value, quality, and security [5]-[8]), the object concerned by the value (e.g., a service, a contract, and a database [9]-[11]) and the method used to create the value (e.g., model-based, by design, chunk [12]-[15]). We also observed that, in practice, each of these dimensions is expressed using a specific language and that none of them alone allows expressing all dimensions at once. This lack of shared language is a problem when IS designers want to communicate together, especially when there is a shift from a local creation of value to a cocreation of value in a network of organizations. Indeed, in this context, communication among the IS designers from each of the involved organizations is essential. Due to the different languages that may be used by the different organizations engaged in value cocreation, however, communication can become extremely complex.

To address this problem, our approach consisted in building a value creation metamodel that simultaneously captures and abstracts all the dimensions of value cocreation. By abstracting the value propositions (originating from each organizations of the network), our goal was *to support the IS designers* from those organizations to communicate with each other using a shared language, expressed by means of common elements, having the same semantic (definitions of the concepts), the same structure (associations between concepts) and the same syntax (modelling language). Practically, and as demonstrated in [16], while being instantiable with specific languages, the VCC metamodel is suited to play the role of binding element between the modelling languages (i.e., the language has been designed at an abstraction layer appropriated to be instantiated to various types of value, like the security or the quality).

In this paper, we have exploited an enterprise architecture (EA) model to express VCC using only one language. EA consists in approaches which enable illustrating the interrelations between a company's different layers and between its different aspects such as behavior, information, or people. EA metamodels provide views that are understandable by all the stakeholders and that allow making decisions and trace the impact of such decisions. Although the concept of value exists in some EA metamodels, this concept (and its relationship with other concepts), is not appropriate to express value cocreation. As a result, we acknowledge that existing EA metamodels are not dedicated to accurately model value cocreation. However, we consider that the EA metamodels

The research is supported by the National Research Fund, Luxembourg (http://www.fnr.lu) and the Swiss National Science Foundation, Switzerland (http://www.snf.ch), and financed by the ValCoLa (VCC Language) project.

provide a good basis for modelling VCC since they model the most significant concepts of a company's information systems. To reap the benefits of the enterprise architecture metamodel for value cocreation engineering and management, we have opted for focusing our research on integrating the value cocreation metamodel with the ArchiMate EA metamodel. We have decided to focus on ArchiMate because it does not address VCC at all yet and because it is an open standard published by The Open Group[1].

All along the paper, the usage of the ArchiMate extension to the value cocreation is illustrated with a case study related to knowledge-intensive business services in the financial sector [21]. This case study concerns the cocreation of value between a bank and a datacenter. The context is that because both organizations have been collaborating for a long time, the datacenter has good knowledge of the bank's information system. For that reason, the bank has decided to outsource the improvement of the privacy of the customers' data to the datacenter. Both have hence started to cooperate in designing the privacy improvement service of the customers and therefore the bank has agreed to give information about its information system (architecture, functions, etc.) to the datacenter. In turn, the datacenter enhances its offer of services and thereby stabilizes its own business. The enhancement is possible as a result of the bank's feedback.

In the following, we first present the state of the art in VCC as well as our previous work in VCC modeling in Section II. Then, we introduce ArchiMate, its language and its extension mechanisms in Section IIIa, b, and c, and we extend it for expressing value cocreation in Section III.d. The financial case study is presented in Section IV and consists in expressing VCC metamodel through ArchiMate extension. Finally, Section V discusses the results and proposes future works and Section VI concludes the paper.

II. State of the art and previous works

This section presents the state of the art related to VCC modeling using concrete syntax and more especially using the ArchiMate metamodel.

A. Litterature review

Value cocreation is a very old topic that has been incorporated by Vargo and Lusch in the notion of service-dominant logic [1, 2]. According to the authors, a service is the basis of all exchanges and focuses on the process of value creation rather than on the creation of tangible outputs. Against this backdrop, Vargo and Lusch further elaborate on the idea that value is derived and determined in use rather than in exchange, meaning that value is proposed by a service provider and is determined by a service beneficiary. Hence, the firm is in charge of the value-creation process and the customer is invited to join in as a co-creator [2].

For Grönroos [47], this interaction is defined through situations in which the customer and the provider are involved in each other's practices. Consequently, the context (social, physical, temporal, and/or spatial) determines the value-in-use experience of the user in terms of his individual or social environment [48].

Recently, Chew [49] has argued that, in the digital world, service innovation is focused on customer value creation. Chew proposes an integrated Service Innovation Method (iSIM) that allows analyzing the interrelationships between the design process elements, including the service system. The latter being defined as an IT/operations-led, cross-disciplinary endeavor. In IS literature, Blaschke et al. [50] propose a business-model-based management method encouraging cocreation interactions by reconciling value propositions, customer relationships, and interaction channels.

Gordijn et al. [51] explain that business modeling is not about process but about value exchange between different actors. Gordijn et al. propose e3value to design models that sustain the communication between business and IT groups, particularly in the context of the development of e-business systems. In [52], Weigand extends the e3value language to consider cocreation. He defines so-called value encounters, which consist in spaces where groups of actors interact to derive value from the groups' resources. In a similar way, Razo-Zapata et al. propose visual constructs to describe the VCC process [53]. These constructs are built on requirements from the service-dominant logic and software engineering communities.

B. The VCC metamodel

In this section, the metamodel of value creation in the field of IT-related business services is defined according to three dimensions: the nature of the value, the method of value creation, and the object concerned by the value.

Provided that this research is anchored in Design Science Research [19-20], its development has followed an iterative cycle. Only the last version of it is presented in this section. The first version was presented in the conference FedCSIS 2017 [16], the second version in LNBiP [21], and the last version in AINA 2018 [22]. This metamodel is elaborated based on the analysis of value related frameworks [5]-[8], of scientific literature [1], [2], [47], [51], [52] and on a performance evaluation methodology for decision support in industrial project proposed in [23]. The aim of this methodology is to propose a benefit-cost-value-risk based approach to help decision makers in evaluating performance at any stage of an industrial project.

In the next sub-sections, each dimension of the value is successively analyzed and presented. Moreover, concepts of our VCC metamodel are illustrated using the first part of the case study.

[1] http://www.opengroup.org/subjectareas/enterprise/archimate

1) Dimension 1: Nature of the value

To understand and model the nature of the value, first we have reviewed a set of frameworks addressing the different value natures in the field of IT, including security, quality, compliance, privacy, responsibility, and others. Based on this review, we have extracted the most meaningful concepts necessary to express this nature. For example, we have analyzed the information systems security risks management (ISSRM [24]) framework, which addresses the IS security (*Nature of the value*). This framework characterizes security through integrity, confidentiality, availability, non-repudiation, and accountability (i.e., *Value component* concept of the VCC metamodel). And the security concerns business assets of the company (*Objects* concept of the metamodel). Finally, based on a further review of the literature, our own definitions of the constitutive concepts of the dimension have been provided and the concept has been integrated in the nature of value metamodel (Fig. 1).

Basically, most of the analyzed reference frameworks focus on depicting the semantic of value following a given perspective being function of the beneficiary of the value. In practice, due to the quantity of heterogeneous value natures [32], clearly defining the semantic of this nature is laborious. However, we observe that, in the same transaction, two main perspectives of value nature emerge depending on the context: value at the provider's side vs. value at the customer's side. At the provider's side, the basic rationale for all organizations entering into dyadic exchange relationships is the value capture [33] from a service exchange. This can be in the form of value-in-exchange (e.g., money given by the client), or in the form of value-in-context. In that regard, it is worth noting that considering the provider in the context of the digital society expands this narrow meaning to the consideration of other value elements. An example of them are the information collected on the customers (e.g., analyzing customer data to support the creation of new offerings) which, afterwards, contributes to economic increase [34]. On the customer's side, value generated by a transaction never refers to money but consists in other wealth, which contributes in sustaining and supporting the customer's own business.

According to [23], value is described as the degree of satisfaction of a set of stakeholder expectations or needs, expressed by the level of appreciation associated to a number of performance indicators. Li [35] explains that value can be described by the relative worth, utility, or importance of something. Value increases when the customer's degree of satisfaction increases. The concept of value becomes different depending on the point of view (stakeholder). Accordingly, the *expected value* is the value that the stakeholder would like to get and the *perceived value* is the real value that a stakeholder can finally get. The degree of satisfaction is identified through the comparison of these two elements. According to Zeithaml, value implies some form of *assessment of benefits against sacrifices* [36].

In our analyzed case, at the bank's side, the privacy of the customers' data is a legal requirement that has to be fulfilled by each entity processing private information. Having this data privacy generates the benefit of being compliant with regulations, but it is also expensive because the bank needs to deploy an appropriate mechanism such as performing privacy impact assessment. At the datacenter's side, offering 24/7 data availability to the bank is a benefit to distinguish the datacenter from its competitors, but this offering is also costly because it requires a very robust infrastructure.

According to this review, the concepts that are relevant to the metamodel for the nature of the value are:

- **Value.** This concept is defined as a degree of worth of something [23, 35] and that improves the well-being of the beneficiary after it is delivered.
- **Nature of the value.** The nature of the value **defines** the value to be delivered. Table 1 shows that the nature of the value expresses a domain of interest related to which the value will be delivered (e.g., security of the IS, the cost of a transaction, or the privacy of personal data). In the case of the datacenter that archives the data of the bank customers, the nature of the value generated by the datacenter is the *availability* of the customer's data.
- **Value component**. This concept expresses the different elements that constitute the value (e.g., availability, confidentiality, portability, etc.). Hence, the value **aggregates** value components and these components may also, as a result, themselves be other **types of** value. Regarding the case study, one component of the availability is the *accessibility in real time*.
- **Object.** The object concerned by the value is the element from the information system that has significance and is necessary for a company to achieve its goal (e.g., software, process, data). From a modeling point of view, the value is associated to an object with a relation of type **concerns** or an objective to be achieved. In the case study, the object concerned by the value is the *customers' data.*
- **Measure.** The measure corresponds to a property on which calculations can be made for determining the amount of value expected from a value cocreation method. Measure can result from different factors impacting value. As stated by [23, 35], the value components are measured by means of estimation methods. Accordingly, there exist an association named **appraises** from the concept of measure to the concept of value, an association named **is function of** between the concept of measure and the type of value, and between the concept of measure and the object concerned by the value. The first expresses that the measure is characterized by the nature of the value and the second posits that the measure also depends on the object concerned by the value. According to [35], measure may integrate qualitative and quantitative elementary performance expressions.

Based on the above definitions, the nature of the value is modeled in Fig. 1.

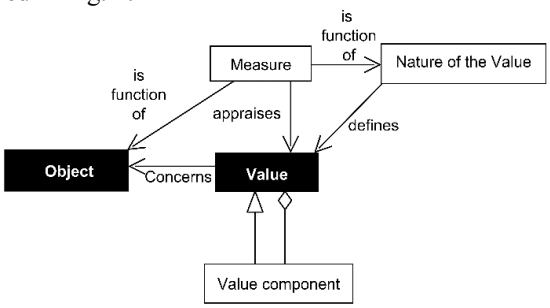

Fig. 1. Nature of the value metamodel

2) Dimension 2: Method of value creation

A method of value creation corresponds to a set of activities that contribute to the generation of value. Similar to the nature of the value, to depict the elements relevant for the creation of value, a set of IT-related frameworks on value creation methods have been reviewed. The analyzed methods include method by design [12], model driven [15], impact assessment [17], method chunk [14], risk-based [37], and process-based [38] approaches.

Traditionally, value is created through the exchange and use of goods and services [1]. Methods for value creation are the body of techniques and activities that use and generate resources [39]. These correspond, at the corporate level, to a bundle of approaches including the design of strategies, the integration of models, and the evaluation of results. By looking more closely at the analyzed methods, it has been observed that each has a dedicated goal, that they are composed of method elements, and that method elements are organized in a sequence of ordinated steps. For instance, by investigating the model-driven approach to interoperability, one can notice that it has for goal to improve interoperability of enterprises' information systems that it is composed of models, and that three steps are required for model-driven interoperability: model design, model integration, and model instantiation. Amongst the other methods reviewed, it is also interesting to highlight that one (method chunk) has for particular objective the creation of methods themselves, using, as chunk of existing methods as method elements, and as method steps the decomposition of existing methods into method chunks and the definition of new method chunks from scratch [14].

As a summary and according to this analysis, the concepts that construct the method of value creation are:

- **Method**. The method is a specific **type of** object that defines the means used by the stakeholder to **create** objects and value. A method is **composed** of a set of activities necessary to achieve a dedicated goal. In the same vein, Sein et al. [40] explain that the elementary quantitative value expressions (the value components) are aggregated by means of selected aggregation methods and quantitative weights to generate the overall value. An example of method used to create security of the IS consists for instance in performing a security risk assessment [24].
- **Activity**. The activity is an element of the method that corresponds to a unitary task (e.g., analysis, data collection, or report). The activities **compose** the method and are organized and coherently articulated with each other (e.g., if-then-else, process elements ordination, etc.). This relation is modeled using an iterative association of a type: activity **follows** activity. The articulation of activities corresponds to the aggregation from [16]. One particular type of activity consists in **generating** resources. For instance: *acquiring a backup tool, maintain the backup tool, etc.*
- **Stakeholder.** A stakeholder is a human, a machine or an organization that is involved in the creation of value at three levels. First, it **performs** the method that generates value (e.g., the risk manager performs a risk analysis); second, it **generates** resources used by the method; and third it **expresses** the value expected after the execution of the method. For example, the *datacenter* is the stakeholder that exploits the redundancy system and the *bank* expresses that it expects availability of the data.
- **Resource.** This element is **a type of** object from the IS that is generated by a stakeholder and that **is used by** an activity composing the value creation method. Resources are typically information and data (e.g., passenger location), but could also consist in computing resources, funding, manpower, etc. For instance, the *backup software* is the resource used by the exploitation of a redundancy system.

Based on the above definitions, the value creation method is modeled in Fig. 2.

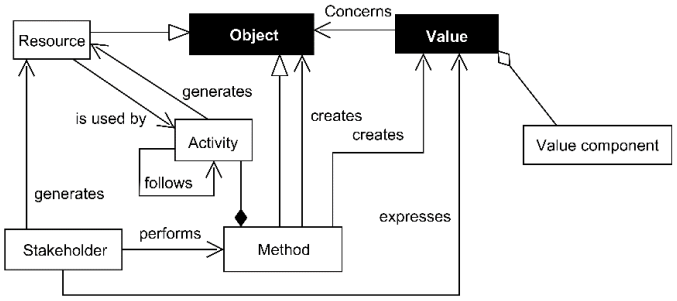

Fig. 2. Value creation method metamodel

3) Dimension 3: Object concerned by the value

The object concerned by the value corresponds to elements (e.g., information, process, tool, or actor) being part of an enterprise. These elements exist in a specific environment represented by the context. This context has an influence on the type and the amount of value associated with this object, for instance, a *customer's browsing history* is an object of a data type that has a particular pecuniary value for an airline travel agency that can estimate the value ascribed to a flight ticket for a customer. This value is calculated based on the number of times this flight ticket is viewed on the company's website by

the customer. At the opposite, this *customer's browsing history* is not an object of value on a drugstore website with fixed prices. Complementarily, it is also worth noting that the context has no impact on the nature of the value. For example, privacy in healthcare is defined in the same way with the same characteristics as in industry.

To collect and deal with the concepts that are necessary to model the object of value, it has been assumed that each sector such as manufacturing, finances, or healthcare, is associated with a specific information system. Each enterprise specific architecture models the objects composing this enterprise as well as the relationships between these objects, using a dedicated language.

Sector-specific information systems and enterprise architecture (EA) models and languages are good approaches here because they semantically define generic objects and sometimes concrete languages to express these objects. Numerous frameworks have been designed to model IS and EA of various sectors, e.g., Cimosa [41], ArchiMate® [42], DoDAF [43], and many others.Regarding the financial case study, the data of the bank's customers is the object concerned by the required privacy (generated by the bank) and concerned by the required availability (generated by the datacenter).

As a summary and according to this analysis, the concepts defining the context and the object concerned by the value are:

- **Information system**. The information system encompasses, and **is composed by,** the objects concerned by the value and the stakeholders that benefit from the value created.
- **Context**. The context represents the surrounding of the IS. It includes (1) the constraints on the system in which the value is created and (2) the definition of the borders of this system (e.g., the sector and the sector purpose of the business entity that is concerned by the IS, the rules and regulations related to the sector or the IS, the institutional arrangements, etc.). Accordingly, the context is associated to the information system with an association named characterizes. As stated in [23], the context also allows selecting the performance components […] necessary to define the scope of the performance evaluation problem. Hence, this selection defines a particular context, or viewpoint, for the evaluation of the value. To model this, the concept of context is associated to the measure with a relation named influence. Regarding the case study in the financial sector, the context is the financial regulation.

Based on the above definitions, the object concerned by the value is modeled in Fig. 3.

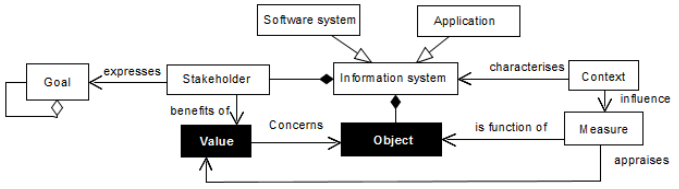

Fig. 3. Object concerned by the value metamodel

III. ARCHIMATE EXTENSION

In this section, we extend ArchiMate language to the VCC domain. Therefore, first we introduce ArchiMate's metamodel, language and extension mechanisms, and finally present the extended ArchiMate to VCC.

A. Introduction to ArchiMate

ArchiMate is a modeling language built on a thorough metamodel for enterprise architecture. It is used by IT architects to design static business and IT views and their links in enterprise architecture endeavors [42]. ArchiMate allows reducing the complexity and proposes means to model and thus better understand the enterprise, and the interconnections and interdependency between the processes, the people, the information, and the systems. Consequently, one objective of ArchiMate is to provide pictures of each enterprise architecture aspects such as the organisational structure, the business processes, the information processing system or the infrastructure. It permits to ensure uniform semantics of the instantiated models but it is not really appropriate to enable quantitative analysis.

One of the underlying assumptions of ArchiMate is to support enterprise architecture for the creation of business value. Relying on ArchiMate's metamodel, each business value is generated by business processes that are supported by applications and infrastructures.

ArchiMate's core is structured in three horizontal layers: the business layer, the application layer and the technology layer. All three layers are built with the same type of concepts and associations. They are structured according to three aspects (vertical layers). The first aspect concerns the active structure elements, which are defined as *entities that are capable of performing behaviour,* e.g., a role or an actor. The second aspect concerns the behavioural elements, which are defined as *units of activity performed by one or more active structure elements*, e.g., a process or a function. The last aspect addresses passive structure elements, which are defined as *objects on which behaviour is performed*, e.g., a contract or an object. ArchiMate metamodel is presented in Figure 4.

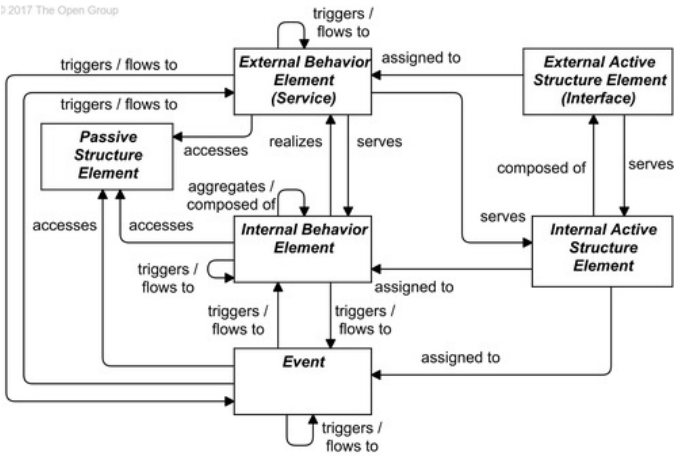

Fig. 4. ArchiMate metamodel (extracted from [10])

B. ArchiMate language

ArchiMate uses a syntax based on symbols and colors, related to the vertical and horizontal layers. Table I provides a sample of ArchiMate elements, definitions and symbols that we later use in the mapping and integration of both metamodels (i.e., ArchiMate's and our previously outlined metamodels).

TABLE I. SAMPLE OF ARCHIMATE SYMBOLS

ArchiMate 3.0 metamodel	Definition	ArchiMate 3.0 metamodel element symbol
Value	Value represents the relative worth, utility, or importance of a core element or an outcome.	Meaning	The knowledge or expertise present in, or the interpretation given to, a core element in a particular context	Assessment	An assessment represents the result of an analysis of the state of affairs of the enterprise with respect to some driver.	Business function	A business function is a collection of business behavior based on a chosen set of criteria (typically required business resources and/or competencies), closely aligned to an organization, but not necessarily explicitly governed by the organization	
Business process	A business process represents a sequence of business behaviors that achieves a specific outcome such as a defined set of products or business services	
Business actor	A business actor is a business entity that is capable of performing behavior	
Resource	A resource represents an asset owned or controlled by an individual or organization	
Capability	A capability represents an ability that an active structure element, such as an organization, person, or system, possesses	
Driver	An external or internal condition that motivates an organization to define its goals and implement the changes necessary to achieve them	

C. ArchiMate extension mechanismes

ArchiMate extension is achieved by integrating its metamodel with the metamodel of the domain that extends it. According to [44], the integration of two metamodels requires resolving three types of heterogeneities: syntactic, semantic and structural. For our integration, only the semantic and the structural heterogeneities have been addressed. In effect, the syntactic heterogeneity aims at analyzing the difference between the serializations of the metamodel. As explained by [45], it addresses technical heterogeneity such as hardware platforms and operating systems, or access methods, or it addresses the interface heterogeneity such as the one which exists if different components are accessible through different access languages. The structural heterogeneity exists when the same metamodel concepts are modelled differently by each metamodel primitives. This structural heterogeneity has been addressed together with the analysis of the conceptual mapping and the definition of the integration rules. Finally, the semantic heterogeneity represents differences in the meaning of the considered metamodel' elements and must be addressed through elements mapping and integration rules. Regarding the mappings, three situations are possible: no mapping, a mapping of a type 1:1, and a mapping of a type n:m (n concepts from one metamodel are mapped with m concepts from the other).

After defining the mapping, the concepts can be integrated in a single metamodel using both ArchiMate' extensions mechanisms: the addition of attribute as well as the specialization [46]. Concretely, if no mappings are detected, the concept from extension domain is added in the ArchiMate using the first extension mechanism, which consists of adding an attribute to an existing concept. If a 1:1 mapping exists without conflict between two concepts, both concepts are merged in a unique one. The resultant concept is added into the integrated metamodel, and this concept keeps the name of the ArchiMate concept. If a mapping of type 1:1 with conflict exists between two concepts, this means that one concept from one metamodel is richer or poorer than a concept from the other metamodel and in this case, both concepts are added in the integrated metamodel using the second extension mechanism of ArchiMate i.e., the stereotype (specialization) (e.g.: [56]).

D. ArchiMate extension to VCC

In this section, the ArchiMate extension mechanisms have been applied to the field of VCC. Table II explains the mapping between elements from the VCC and from the ArchiMate metamodels. Nine VCC elements (as outlined in section B) are mapped with ArchiMate elements (as outlined in section C) and only one VCC element (i.e., the **value component**) has no corresponding ArchiMate element. In effect, although the **value component** from the VCC metamodel could have been mapped to the **value** from the ArchiMate metamodel, we have preferred to keep the semantic difference amongst the **elements of value** and the **value component** from the VCC metamodel in the ArchiMate metamodel. Accordingly, the integration rule that we have exploited to integrate the **value components** with the ArchiMate metamodel is the addition of attribute, and as a result, we have considered that the **value component** is an attribute of the **value**.

Another integration rule that we have used is the merge, i.e., the concept of **value** from the VCC metamodel has been merge with the concept of **value** from the ArchiMate metamodel. This is due the fact that both concepts are defined somewhat equivalently, respectively: *as the degree of worth that concerns something* [which] *improves the well-being of the beneficiary after it is delivered* (VCC metamodel) and as *the relative worth, utility, or importance of a core element or an outcome* (ArchiMate metamodel).

TABLE II. VCC-ARCHIMATE EXTENSION MAPPING

VCC elements	ArchiMate elements	Mapping	Integration rule	Integrated element
Value	Value	1-1	Merge	Value
Nature of the value	Meaning	1-1	Specialization	<<Nature of the value>>
Value component	-	-	Addition of attribute	<<Value>>, Value component: description
Object	Business, Application and Technology layers	1-n	Generalization	Business, Application and Technology layers
Measure	Assessment	1-1	Specialization	<<Measure>>
Activity	Business function	1-1	Specialization	<<Activity>>
Method	Business Process	1-1	Specialization	<<Method>>
Stakeholder	Business actor	1-1	Specialization	<<Stakeholder>>
Resource	Resource and Capability	1-2	Generalization	Resource
Information system	Business, Application and Technology layers	1-n	Generalization	Information system
Context	Driver	1-n	Generalization	Context

We considered four concepts of the VCC metamodel as specialization of concepts from ArchiMate: **nature of the value**, **measure**, **method**, and **stakeholder** in VCC are respectively specialization of **meaning**, **assessment**, **business function** and **business actor** in ArchiMate. For instance, the method is defined as *a property on which calculations can be made for determining the amount of value expected from a value creation method* in VCC metamodel and by *the result of an analysis of the state of affairs of the enterprise with respect to some driver* in ArchiMate metamodel. The second definition is hence more general than the first.

Finally, we considered four concepts of the VCC metamodel as generalization of concepts from ArchiMate: **Object**, **Resource**, **Information system** and **context** in VCC are respectively generalization of elements from the **Business, Application and Technology layers**, **Resource and Capability**, **Business, Application and Technology layers**, and **Motivation** in ArchiMate.

According to the ArchiMate semantic, the VCC concepts may be expressed using the corresponding symbols, as illustrated in Table II

IV. CASE STUDY

The case study presented in the introduction section is illustrated using UML at Figure 5. This figure demonstrates that without an appropriate visual language, the UML model are hardly exploitable by business people having to design new business activity and to co-create new value.

At Figure 6, which model the same case, we illustrate that using the ArchiMate extension provides a much more understandable presentation of our case in terms of clarity and readability.

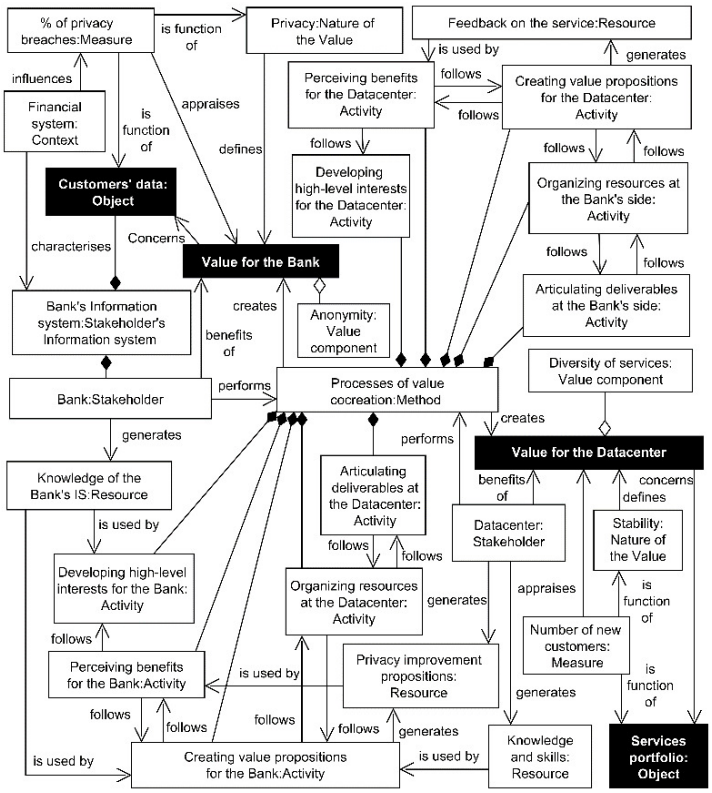

Fig. 5. Value creation perspectives

The advantages are the following:

1. The elements expressed in the model are classified using a code of colors, i.e., **business concepts** are in yellow, **resources** are in orange, **value** related concepts are in purple. These are mainly specialization from the **motivation extension** of ArchiMate, which means that the cocreation of value is something that may be perceived in addition to the **information system** and that motivates the design of elements of this IS.
2. Elements on the figure may also more easily be geometrically organized, e.g. **activity of value cocreation** is on the right-side and **value related elements** are on the left side.
3. Concept reading is facilitate using the shape of the symbols. For instance, **value elements** are rapidly detectable on the model because they are in oval. The **nature of this value** is also easily differentiated because it is presented as clouds.
4. The last advantage is that using ArchiMate also allows us to take advantage of the relationships between concepts semantic. For instance, a task that accesses a resource is illustrated using a dotted line, the association between the activity or the actor that generates the resource is illustrated in dash line, and the generic association is illustrated using a plain line. To improve the semantic of the association, we have specialized it, e.g., the association between the context and the information system has been specialized so that the context <<**characterize**>> the information system.

V. Discussions and Future Works

A. ArchiMate extension

Although ArchiMate extension has already been achieved in many areas such as security [55] and risk management [55], our study conducts such extension in the new field of value cocreation. Concretely, such extension effort resulted in the improved readability of the cocreation instances of the value cocreation metamodel and that all ambiguities have been removed regarding the conceptual semantic.

On the other hand, the most challenging issue is that ArchiMate must be adopted as a common language beforehand, and that all organizations involved in the cocreation have to understand the meaning of the symbol and the language structure, but also that they agree to invest in the usage of the framework.

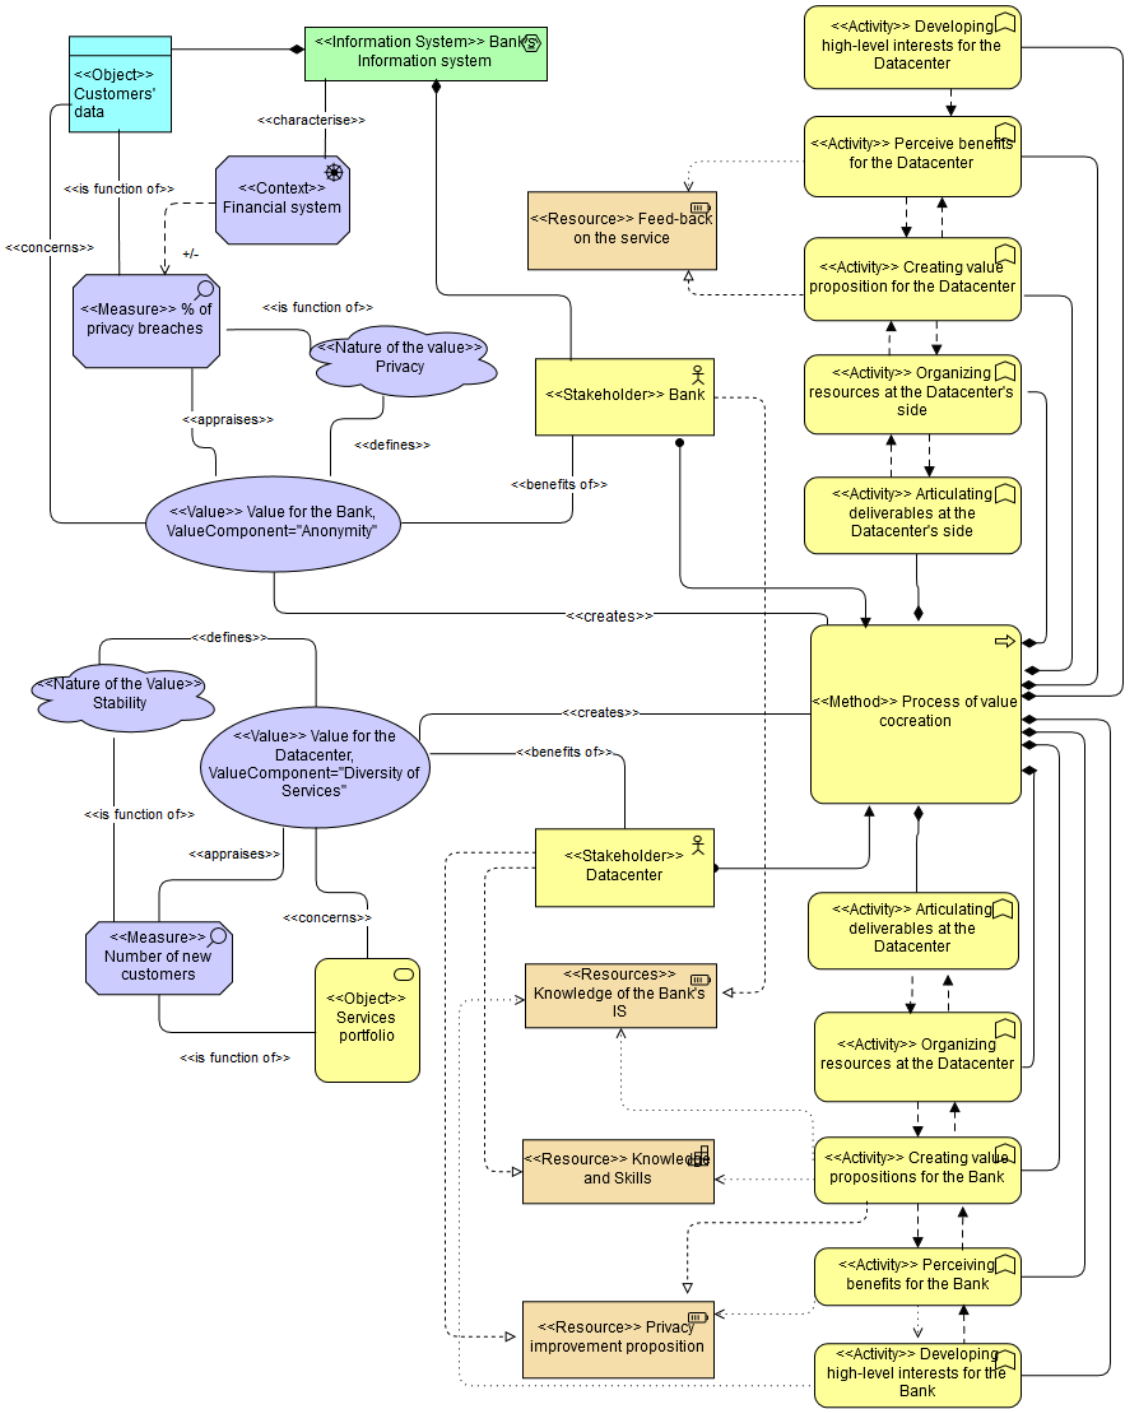

Fig. 6. Value cocreation expressed with ArchiMate

B. *Value perspectives*

ArchiMate has been extended for the field of value cocreation. However, more perspective may be addressed in that VCC domain, such as those illustrated in figure 7:

- The creation of value. This is the most basic but important one. It addresses the method used to valuate an object of the IS, e.g., a privacy impact assessment method that improves the privacy of a database, or a process based method that contributes to the repeatability of the incident management activity of a company. Accordingly, in this first perspective the creation of value is generally expressed based on the three following dimensions: the nature of the value, the object concerned by this value, and the method that creates the value. Preliminary work related to the modeling of the value with ArchiMate were achieved in [54].
- **The method of value creation**. The second perspective considers that the creation of value is a value per se for the company. Hence, the method of value creation may be view as a type of value creation. Example of contribution in this perspective is the method chunk [14] which consists in a type of method of value creation, which in turn, contributes to making an object of the company better off.
- **The value cocreation.** As explained in this paper, the creation of value results sometime to a collaboration between a provider and a client. For instance, a consultant that improves the security of its client's information system collaborates with the client to access the IS architecture, to analyze the value of the business assets to be protected, and to understand the threats. Hence, when a customer collaborates with a provider to generate value, we are in the perspective of value cocreation.
- **The method of value cocreation.** Similar to value creation, the value cocreation may also be perceived as a type of value being cocreated by more than one actor. For instance, a provider and a customer who collaborate for a long time and who analyze, together, how they could cogenerate new value for each other's businesses (like in the case of PowerDrive [3]). Example of processes to support this cocreation mechanism are proposed in [18].

In frames 1 and 3, the (co)created value concerns the creation of value of a concrete nature (e.g. security, privacy, quality,…) and therefore corresponds to a type of value that already has a benefit for company. The value created in both frames 1 and 3 also concerns a concrete object of the IS or of the company. We thus advocate that the value created in both frames corresponds to value-in-use [28].

In frames 2 and 4, we postulate that the created value is the method of value(co)creation itself. This method of value (co)creation is necessary before (co)creating concrete value. In frames 1 and 3 this method is transformed in value-in-use when it is used to (co)create value of a concrete nature. In the frame 4, the value proposition (defined by one actor) is proposed to another actor, which accepts it or not. If accepted, this proposition of value cocreation is transformed in value-in-use when the concrete value is realized through a collaboration among the actors involved.

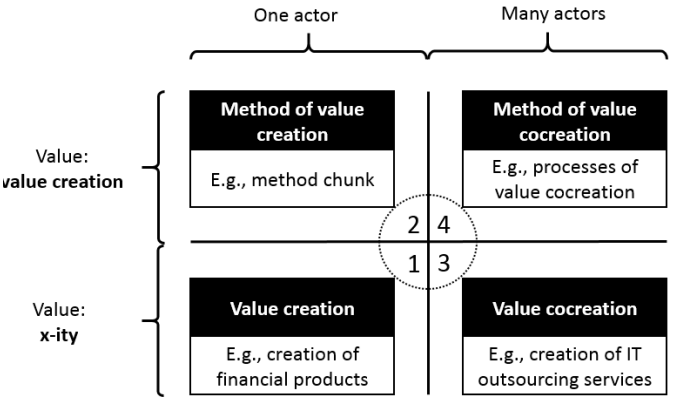

Fig. 7. Value creation perspectives

Provided the similarities among the four perspectives, we claim that perspectives 2, 3 and 4 are specializations of perspective 1. Accordingly, we claim that designing one language for many value creation perspectives is redundant and that our language designed to express the cocreation of value could be specialized to express all perspectives. Therefore, we plan for specializing the ArchiMate extension for the VCC to the four perspectives and validate the expressiveness of these specialization in our future works.

VI. CONCLUSION

This paper has defined a concrete value cocreation language based on the VCC metamodel previously presented in [16, 21, 22]. To define this language, we have extended ArchiMate using its extension mechanism, to know: the specialization and the addition of attributes as explained in [46]. Finally, we have demonstrated the usability of the language with a case in the financial domain.

Abstract — **The main aim of the proposed research is to identify factors that create an environment conducive to successful Business Process Management (BPM) adoption. Factors predicting successful BPM adoption have been identified within the TOE (Technology-Organization-Environment) framework using a literature review and methodology for constructing conceptual frameworks. The following factors are proposed: top management support for previous projects of organizational change, complexity of BPM system and notation, satisfaction with existing systems, business-IT alignment level, perceived strategic benefits of using BPM, extent of coordination, organizational readiness, performance measurement, culture conducive to organizational change, and, perceived environmental pressure. Study results have the potential to fill the research gap by contributing to the development of a theoretical model of BPM adoption that has not been proposed in studies thus far. In practical aspects, the proposed study can influence the understanding of the factors predicting successful BPM adoption.**

I. Introduction

THE main aim of the proposed research is to identify factors that create an environment receptive for Business Process Management (BPM) adoption and allow the prediction of successful adoption and use of this management concept.

BPM has been developing for over 25 years in Information Systems (IS) research [17], [14] and also in management practice [44]. BPM combines the identification, modeling, automation, implementation, control, measurement and improvement of business processes to support organizational goals and increase its effectiveness and efficiency [39]. In each of these BPM areas there are a number of studies, which, however, lack a coherent, theoretical adoption model [23], [16]. This evident gap in BPM research and expected contribution for theory and practice are the main motivations for this proposed study.

The term "adoption", in the context of this research, is defined as the use and acceptance of BPM assumptions in an organization relating to: process-based organizational structures, employee communication, process documentation, process execution, use of IT tools to support implementation and control of processes, performance measurement, process ownership, and taking into account customer requirements [33]. The level of organization involvement in BPM initiatives and programs determines process maturity, i.e., the higher the process maturity of an organization, the higher the level of BPM adoption. However, we can examine closer process maturity only when the organization decides to adopt BPM and starts the first associated initiatives and programs. In the proposed study, we identify technological, organizational and environmental conditions that are conducive to the successful adoption of BPM before the decision on this adoption is taken. Therefore, the BPM adoption model refers to factors that are predictors of the successful use and acceptance of BPM and are conducive to the development of BPM maturity.

BPM adoption factors, to the best of our knowledge, have not been identified thus far. Therefore, they need initially to be understood and they merit in the first step systematic literature review and qualitative approach [43], [20]. Thus, this research aims at the identification of the initial list of BPM adoption factors, based on a systematic literature review on BPM Critical Success Factors and of a methodology of qualitative research for constructing conceptual frameworks by Jabareen [20]. To group BPM adoption factors the TOE (Technology-Organization-Environment) framework was used as one of the most recognized concepts for innovative solutions adoption on the organizational level [41], [4]. The proposed study is an indispensable basis for the initial formulation of research hypotheses for the BPM adoption model.

The BPM adoption model should elucidate what factors predict successful BPM use in an organization, and, as a model to develop a theory, it should provide predictability based on clearly defined assumptions and be precise and falsifiable [37]. These reasons led to the proposed use of the TOE. The TOE framework was introduced by Tornatzky and Fleischer in 1990 [41] to indicate widespread theoretical

This work was supported by the Polish National Science Centre, Poland, Grant No. 2017/27/B/HS4/01734

perspective on factors influencing business innovation in organizations. This framework explains how a technological, organizational, and environmental context influences the adoption and implementation of innovations [41], [4].

BPM as a driver of organizational innovation [36, pp. 3-15] enables the development and implementation of process innovations [32], [40]. Previous research on BPM indicates that not only are resources within an organization important for BPM adoption, but also in the broadly understood context and external environment [44]. There is also strong evidence-based research showing a relationship between Information Systems (and general Information Technology) and BPM in organizations [1], [22], [27], [13]. These arguments led to the use of the TOE framework within a technological, organizational, and environmental context as the theoretical lens of BPM adoption's determinants.

Thus, to realize the main aim of the proposed research three research questions are formulated in this study:

RQ1: Which technological factors are conducive to successful BPM adoption?

RQ2: Which organizational factors are conducive to successful BPM adoption?

RQ3: Which environmental factors are conducive to successful BPM adoption?

This paper will be organized as follows: firstly, the literature underlying the BPM adoption will be presented, followed by a literature review on BPM Critical Success Factors (CSFs) and the factors identified in the research using the TOE framework. Next, the research methodology and obtained results will be presented. Finally, a discussion, contribution, and direction of future research will be also proposed.

II. BACKGROUND

Adoption of BPM

The topic of BPM is widely explored in empirical research [17] and used in organizations primarily to increase organizational effectiveness, prepare organizations to implement IT systems and increase customer satisfaction [29], [42]. One common definition of BPM is proposed in [39, p. 87]: "Business Process Management (BPM) is a discipline involving any combination of modeling, automation, execution, control, measurement, and optimization of business activity flows in applicable combination to support enterprise goals, spanning organizational and system boundaries, and involving employees, customers, and partners within and beyond the enterprise boundaries". This definition was created as a result of a broad discussion of the researchers of the phenomenon and practitioners of BPM implementation, and because it covers both, the BPM technological context (BPM as a technology) and the business context (BPM as a management discipline), it is considered the most comprehensive [39, pp. 87-88].

Despite the great popularity of process-based management concepts and the benefits they bring, BPM is still not adopted as a practice in many organizations, particularly in those of the public sector. It is unclear what causes this lack of acceptance [42]. Moreover the term "adoption" in the context of BPM is seldom used in literature, although it seems to be analogous to the area of Enterprise Resource Planning (ERP)

systems research [13]. This is particularly notable if we wish to explore factors that can explain the use and acceptance of BPM assumptions in an organization [12], [16].

Previous BPM adoption studies that have used the "adoption" term have focused on success factors or single, selected aspects of BPM implementations and applications. Hribar and Mendling [16] in quantitative research analyzed the role of organizational culture for the successful adoption of BPM. According to this study organizational culture influences the success of BPM adoption. Moreover, this research includes an analysis of the types of organizational culture and indicates which culture types to a greater extent contribute to the success of BPM adoption and the resulting increased performance.

Malinova and Mendling [23] in their qualitative research proposed a conceptual framework for the adoption of BPM indicating possible causes of adoption, action and implementation strategies, and the anticipated effects of this adoption. However, there is no measuring instrument in the study, so it cannot serve as a model for adoption in accordance with the principles of modeling in organizational science [37]. Eikebrokk, Iden, Olsen and Opdahl [12] applied a similar approach to the analysis of factors that influence the acceptance and use of process modeling in organizations: a process modeling acceptance model was developed and tested empirically using survey data from companies.

In general, research on BPM devotes much more attention to BPM after the adoption decision. Studies on the entire BPM life cycle and studies examining different aspects of BPM maturity are definitely dominant. In addition to the afore mentioned studies of the type of culture as a predictor of successful BPM adoption [16] and research on the acceptance of BPM tools [12], literature sources on BPM prediction are virtually non-existent.

BPM Critical Success Factors

In the context of the successful adoption of BPM there have been several studies on critical success factors (CSFs) [3], [5], [7], [11], [31], [38], [42]. Researchers used different terms for identical factors frequently critical to the success of BPM. These terms include: matching processes to organizational strategies, selecting appropriate project management and management methods, supporting top management, using the right information technology, and building a BPM-driven organizational culture.

All these factors are important for understanding the factors behind a successful BPM adoption. However, the adoption model should provide predictability based on clearly defined assumptions and be precise and falsifiable [37]. A BPM adoption model should explain which factors are positive or negative predictors of BPM adoption. For this reason, a review of critical success factors diagnosed after BPM (ex-post) adoption may be a starting point to consider which of these factors can be predicted earlier. For example, if top management support is a BPM critical success factor, then this factor probably also occurred in other organizational change projects implemented in the organization. If top management did not support other projects, it can be assumed that it will not support BPM initiatives and programs. Thus, the review of BPM CSFs studies is the first step to diagnosing prediction factors and for the development of a BPM adoption model, which is missing in BPM research. Table I. presents a summary of a literature review on BPM CSFs.

TOE as a Conceptual Framework for BPM Adoption

To identify and group BPM adoption factors in an organization the TOE framework is applied. The technological context of the TOE concerns the availability of internal and external technologies and new technologies relevant to the organization; the organizational context describes the characteristics of the organization such as communication processes and internal resources; the environmental context refers to the environmental conditions in which the organization operates, e.g. nature and/or strength of competitors and government regulations [25], [4].

The TOE framework takes into account the three aforementioned perspectives important for the adoption of new solutions, and have therefore been chosen as the theoretical basis in various areas of IS research such as cloud computing adoption [2], [6], e-business adoption [25], enterprise resource planning systems (ERP) adoption [26] and e-government assimilation [28]. In BPM research, the TOE framework was used to study BPM software adoption [15]. In order to identify contextual factors a literature review on TOE

TABLE II.
FACTORS AFFECTING INNOVATION'S ADOPTION BASED ON TOE FRAMEWORK

	Factors in research using the TOE framework	Source
Technological Context	Complexity, Compatibility, Satisfaction with existing systems, Technology Competence, Technology readiness, Technology integration. framework applications and on success factors of BPM implementations was conducted. Table II. provides an overview of the factors using in the research with TOE framework. The factors are grouped according to the technological, organizational and environmental context. Factors are listed according to the name under which they occur in the research. However, some names have the same meaning.

III. Research process and Methodology

To identify the TOE factors that allow us to predict successful BPM adoption we used the methodology for constructing conceptual framework by Jabareen [20]. There are two main reasons why we have chosen this methodology. Firstly, this methodology defines framework as an integrated set of factors that enable the theoretical explanation of the studied phenomenon. Thus, according to this definition, the chosen methodology can be used for the preliminary identification of factors. Secondly, it is a methodology of qualitative research that can be based on literature review research, this being the initial step of every researcher as the necessary basis for developing new knowledge and systematizing the existing one [43], [20]. Moreover, the literature review creates a foundation for the development of new models and theories [43], and this is the main aim of proposed research: to create a foundation for the BPM adoption model.

Jabareen's methodology for building conceptual frameworks from existent multidisciplinary literature is a process of theorization [20]. According to the chosen research procedure, we have used in this study the following research steps presented on Figure 1. In the first step of our research process we collected, mapped, and read the literature sources. Our data sources search included literature on BPM in general, especially BPM critical success factors. The literature regarding the current applications of the TOE framework in the research on the adoption of new innovative solutions was also crucial.

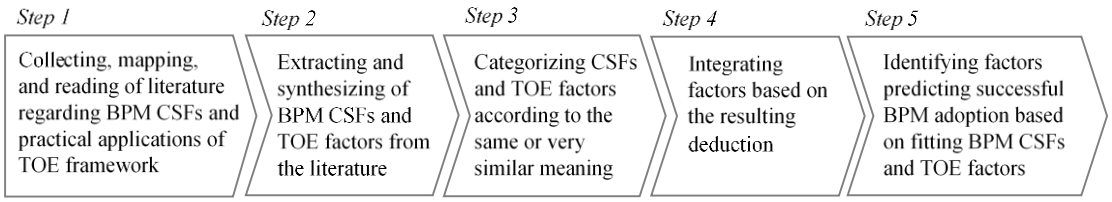

Fig. 1 Research process to identify initial list of factors predicting successful BPM adoption

In the second step of our research process (Fig. 1), we reviewed and synthesized the critical success factors for BPM, as presented in Table I. Also, the factors used in the TOE studies were collected and grouped by technological, organizational, and, environmental context. Findings of this research step are included in Table II.

In the next, third step, we categorized the factors found in the literature, both BPM CSFs and those used in the TOE applications according to the same or very similar meaning. Results of this investigation present first and second column in Table III. In the next, key stage of the study (step 4 on Fig. 1), as a result of the subsequent deduction, we combined factors of the same meaning, while reducing their number. For example, the key success factor of strategic alignment shows that the organization can indicate the impact of processes on the implementation of strategic objectives. Thus, this factor allows an assessment of the expected costs and benefits of BPM implementation. Factors matching the concept in the framework of the TOE are: perceived benefits, perceived costs, perceived barriers. These factors can all be measured with the help of a factor "perceived strategic benefits of using BPM". This approach allows us to identify in the fifth step an initial list of factors predicting successful BPM adoption. This approach resulted from the most common objective for literature review being a combination of past literature aiming at "formulating general statements that characterize multiple specific instances of research, methods, theories, or practices" [10, p. 4].

IV. Results and Discussion

Technological Context of BPM Adoption

Technological factors of BPM adoption can refer to the information technologies that are dedicated to modeling, analysis, simulation, automation, and process management in general. "Complexity", defined as "the degree to which an innovation is perceived as relatively difficult to understand and use" [34, p. 257] is considered as one of the fundamental factors that adversely affect adoption in many past IT adoption studies [30], [19]. Based on results of the BPM software adoption study [15], we suggest the same relationship for BPM in general, i.e. that the complexity of a BPM system and notation has a negative effect on the BPM adoption.

The adoption of BPM can also be affected by other relationships between processes and information technology (IT), such as Business-IT alignment [22], [42] or the adoption of ERP systems, where a process-driven approach is commonly used in system implementations [27], [13]. Reference [9] note that the satisfaction level with existing IT systems plays a significant role in the shaping of motivations to change. Satisfaction with existing processes that are automated in ERP systems, or, satisfaction with service delivery processes through IT, may discourage organizational

TABLE III.
FITTING OF BPM CSFS AND TOE FACTORS

BPM CSFs	TOE factors	TOE factors for BPM
Top management support, Management involvement, Leadership	Top management support	Top management support for previous projects of organizational change
Information technology, Development of service-oriented business applications and adapting the IT infrastructure, IS support	Complexity / Compatibility Satisfaction with existing systems Technology competence / readiness / integration	Complexity of BPM system and notation Satisfaction with existing systems Business-IT alignment level
Strategic alignment, Alignment of processes to organizational goals	Perceived benefits / costs / barriers / Financial commitment	Perceived strategic benefits of using BPM
Governance, Clearly defined process owners, Appointment of process owners	Extent of coordination	Extent of coordination
Methods, Methodology	Organizational readiness	Organizational readiness
Project management, Change Management, Ability to implement the proposed changes	Organizational readiness	Organizational readiness
Performance measurement, Measurement and control		Performance measurement
People, Level of employee's specialization, Training and empowerment of employees, Motivated employees	Employees knowledge	Culture conducive to organizational changes
Culture, Communication, Teamwork, Social Networks		Culture conducive to organizational changes
	Perceived environmental pressure / market uncertainty / Regulatory policy and support	Perceived environmental pressure

changes. Thus, the next technological factor concerns the Business-IT alignment level: the higher the technological factor the more positive the impact on BPM adoption. However, satisfaction with existing systems has a negative effect on the BPM adoption. The more an organization is satisfied with its systems, the less it wants to change the processes to which it is accustomed.

Organizational Context of BPM Adoption

The TOE organizational context refers to the characteristics, structures, processes, and resources of an organization that may constrain or facilitate the adoption of innovation [9], [19]. The first factor takes into consideration the perceived strategic benefits of BPM. Awareness of benefits such as efficiency, effectiveness, and agility [35] can be a basic driver of a decision to adopt. Therefore, the hypothesis is formulated as follows: perceived benefits of using BPM have a positive effect on the BPM adoption.

Top management support is one of the most commonly mentioned CSFs, not only for BPM, but also for all organizational change projects. Effective decisions, monitoring and promoting acceptance of the project, and general change of management from the top, are crucial for a successful BPM adoption [1], [3]. The supporting role of top management in the previous change projects can be also a positive predictor for BPM adoption. Therefore, top management support has a positive effect on BPM adoption.

Organizational readiness is defined in research on innovation adoption as "the availability of the needed organizational resources for adoption" [18, p. 467], [2], [19]. Of particular importance is the perceived assessment by managers on the financial resources held by the organization and the organizational competence to undertake the adoption. This viewpoint confirms studies on BPM CSFs [3], [31]. The following statement is therefore suggested: organizational readiness has a positive effect on BPM adoption.

Coordination mechanisms can take the form of "processes, roles, or structural arrangements […] as teams, informal linking roles, like those of change agents" [8], [28]. This factor seems highly important in the context of the development of BPM governance that establishes appropriate and transparent roles and responsibilities for BPM [11]. The resulting factor is the extent of coordination. The use of a coordination mechanism can have a positive effect on BPM adoption.

Performance measurement does not exist in previous studies using the TOE framework. However, the need to measure the effectiveness of the organization and its processes, and the inclusion of process performance measurement for continuous process improvement, are essential to the high level of BPM adoption and organizational maturity [31], [42]. The need for performance measurement results from strategic considerations and fosters the adoption of BPM. This result in the identification of the factor investigating the use of performance measurement, what can have a positive effect on BPM adoption.

Factors regarding organizational culture have not been mentioned so far in research using the TOE framework.

Probably because it was difficult to measure the impact of this factor in the context of adopting new technologies and innovations. However, in the area of BPM research there are strong arguments in the work of Hribar and Mendling [16] indicating the type of organizational culture that creates an environment for BPM. The results of these tests will allow to build an appropriate measurement instrument and thus to include the cultural factor in the BPM adoption model. BPM's adoption is very strongly linked to cultural and human aspects [11], [16] and so we believe that this factor must be included in the model.

Environmental Context of BPM Adoption

BPM adoption can be the result of pressure exerted on an enterprise by its environment or external circumstances. Pressure can be exerted by business partners, competitors or government policies [21], [14]. A study of McCormack and Johnson [24] indicates that BPM maturity in a least advanced organization determines the level of cooperation and adaptation of inter-organizational processes. External conditions can also force the adoption of BPM in an organization, when, for example, the improvement and development of internal processes is forced upon it as the result of feedback from customers and suppliers [14], [38], [7]. In summary, perceived environmental pressure can have a positive effect on BPM adoption.

V. Conclusion

In this research we explored the factors that create environments receptive or unreceptive to BPM adoption and use. Factors have been identified within the TOE framework and grouped by the technological, organizational and environmental context.

The method of literature review and its qualitative analysis was used to identify factors. Table IV. presents the results of the study. As indicated in the title, this research paper presents initial steps for BPM model development. A review of prior literature and identifying of preliminary list of factors that can predict successful BPM adoption creates a foundation for future research and facilitates theory and model development.

The identified list of factors is the foundation for the BPM adoption model which has not been proposed in studies so far.

VI. Future Research

The initial identification of BPM adoption factors presented in this research is the basis for the development of the adoption model. However, as such factors have not yet been investigated, further studies are needed to verify the initial proposed list of factors. Subsequent research should be of qualitative and quantitative research. In order to verify factors derived from the literature review and perhaps adding new ones, a multiple case study method could be applied. This multiple case study analysis is considered the most suitable in examining organizations that adopted BPM within the real-life context. We plan to use a qualitative study with the aim of developing relevant hypotheses for future quantitative research on the phenomena. Thus, to develop BPM adoption model we plan further research aims: to examine identified factors in a qualitative study, and then formulate and test research hypothesis based on qualitative research. To develop a model to explain BPM adoption is our target aim.

Table IV.
BPM Adoption Factors Based on TOE Framework

	TOE factors for BPM adoption
Technological Context	Complexity of BPM system and notation Satisfaction with existing systems Business-IT alignment level
Organizational Context	Top management support for previous projects of organizational change Perceived strategic benefits of using BPM Extent of coordination Organizational readiness Performance measurement Culture conducive to organizational changes
Environmental Context	Perceived environmental pressure

VII. Contribution

The results of the proposed research could contribute to the development of a consistent theoretical model that would include the various factors influencing the successful adoption of BPM and thus contribute to the theory development. The methodological approach utilizing the TOE framework as the basis of the adoption model is novel in BPM research.

The proposed initial list of BPM adoption factors may provide the foundation for further research. This list can be developed and modified using other data sources and types of research mentioned in the section about future research.

The exploration of BPM adoption factors can contribute to the development of both individuals and entire organizations, and in both the public and private sectors. For individual employees and managers, it will be possible to raise awareness of BPM and identify gaps in competency delaying the adoption of BPM. At an organizational level, the model will help streamline organizational planning and resource development in all areas of the TOE framework. Knowledge about factors influencing successful BPM adoption can help predict the effects of BPM application in organizations that are less mature. A high level of BPM adoption allows an increase in the efficiency of processes carried out for citizens in the public and customers in the private sector, thus benefiting a country as a whole.

***Abstract*—The process of sustainable supplier selection is crucial to a company's business continuity. Distortions in poorly chosen suppliers can lead to an impediment or even complete downtime of the company's operations. The paper proposes a new unique approach in which classical MCDA paradigm is extended with aspects of temporal evaluation and various temporal aggregation strategies are provided. The partial MCDA evaluations are performed with three MCDA methods – AHP, TOPSIS and COMET – to allow for hierarchical structuring of the decision problem, creation of a reference model and avoiding rank reversal. The proposed approach is verified on a case study with an actual company and its supplier selection from a group of 30 potential suppliers.**

I. Introduction

SINCE the very beginning of the supply chain thinking, it has been understood that the selection of a proper supplier is the pillar of developing a competitive supply chain [1]. It is a strategic decision, which can considerably affect the company's competitive advantage [2]. The consequences of such decision can be intensified even further if a company plans expansion to new markets. A successful selection of decent suppliers can positively affect the company productivity and effectiveness, as well as decrease the operational costs [3]. Moreover, an apt arrangement of a supply base is crucial for effective and efficient materials and products logistics. Therefore, such selection directly affects the company's business continuity [2].

Integrated relationships between supply chain partners drive the supply chain efficiency, however, if over-dependence occurs, it might lead to propagation and amplification of various disruptions [4]. There are multiple works studying the negative effects of incompleteness or negligence of the supplier evaluation processes. In the early studies, Meade pointed out that wrong selection of suppliers can have negative effects on multiple processes within an organization [5], whereas the subsequent works expanded the negative consequences over the full integrated supply chain (Supply Chain Management - SCM) [6]. Moreover, Chan points out that the negligence of the process of suppliers evaluation can lead not only to disruptions in the supply chain process, but also to ceasing the primary operations of a company at all [6].

The development of the Internet and ICT (Information and Communication Technologies) lead to a considerable increase of the data processing efficiency. As a result, an on-going monitoring and evaluation of suppliers was made possible. Moreover, nowadays, such evaluation can easily be performed repeatedly over a span of time. The development of modern smart management information systems allowed the evaluation of suppliers on a temporal level, thus opening new research areas. From the methodological and practical points of view, an on-going monitoring – as opposed to a one-time evaluation – of the quality of services and products supplied by the company's key supply partners becomes an interesting research problem. Such evaluation takes into account an important, yet often overlooked, aspect of the appraisal changeability in time. For example, the businesses such as e-commerce websites can have as much as 30% of raise or loss in transactions count between the busy December and slow summer holiday months [7]. On the other hand, for the farming industry the summer months are the peak of the fruit picking season and the companies are looking for additional outsourcing suppliers to cope with the increased amount of work [8].

Over the span of the last two decades, the studies about environment protection have been increasingly gaining importance in the world [9]. The increased environmental awareness has lead to pressures from various stakeholders [10] for the companies to realize the significance of incorporating the green practices into their daily operations [11]. Therefore, the evaluation criteria used in the previous decades [2] needed to be expanded to support the evaluation of the green supply chain management (GSCM) practices [10], [12].

Multi-criteria decision analysis (MCDA) methods have been successfully applied in such evaluation problems to find "good" (but not optimal) solutions. However, the exclusive use of an MCDA method provides the "here and now" evaluation of the suppliers, yet it does not take into account the temporal validity of the aggregated data and the partial evaluations. The authors attempted to address this problem in their prior work (see [13]). However, the evaluations obtained with the most popular MCDA methods may be not fully reliable, because many of them are prone to the rank

reversal phenomenon, which means that introduction of a new supplier to the evaluation process can reverse the ranks of the other, unrelated, suppliers. Therefore, the authors expand their approach presented in [13] and their contribution in this paper is to provide a framework for dynamic MCDA-based sustainable supplier selection, which takes into account the temporal aspects, the hierarchical structure of the decision problem, as well as it studies the full space of the decision problem, thus preventing the rank-reversal phenomenon. In practical terms, the introduction of the temporal aspects to the MCDA-based evaluation means introduction of a set of time-anchored MCDA-based models and providing the mechanisms of their aggregation according to the DM's needs.

The rest of this paper is organized as follows. In section 2 a literature review regarding the current state of art is provided. Section three presents the methodological framework. An empirical research and its results are presented in section four. The conclusions and future work directions are presented in section 5.

II. Literature Review

The supplier selection is a process of a significant strategic importance for all the parties involved. The literature analysis provides a wide spectre of theoretical solutions and practical studies where the authors evaluate and select the suppliers in the supply chain. A numerous set of studies has been performed in the areas of electronics industry [10], [11], automotive [9], [15], [16], manufacturing [18], or food supply chain [17], [20] to name just a few.

Nowadays, due to the increased awareness of the environmental issues, the sustainable supplier development has become a necessity, as companies increasingly compete on the ground of having green supply chain capabilities [9]. Many companies struggle with the eco-friendly supplier selection, yet the advancements in the green supply chain management practice strategies can help in this selection [11]. The literature review of the research methodologies shows that the evaluation process is performed with the use of numerous analytical methods. A profound discussion of the approaches can be found in [21]. It can be also noted, that MCDA methods are becoming increasingly popular in such type of applications. Moreover, in some studies fuzzy variants of the crisp MCDA methods, as well as hybrid solutions are used.

Table I presents some of the recent applications of the MCDA methods in sustainable supplier selection. Kannan et al. [10] used the fuzzy TOPSIS method on a set of criteria based on green supply chain management (GSCM) practices to select green suppliers for a Brazilian electronics company. Similarly, Uppala et al. [11] used a hybrid approach of fuzzy AHP and fuzzy TOPSIS to select green suppliers for an Indian electronics company. For the same kind of industry in Taiwan, Chateterjee et al. [12] used a hybrid set of DEMATEL, ANP and MAIRCA methods with 15 criteria in 5 dimensions. Razaei et al. [2] used BWM (the Best-Worst Method) to evaluate 34 suppliers in edible oils industry for a company seeking to expand to a new country, whereas Banaeian et al. [17] used the fuzzy variants of TOPSIS, VIKOR and GRA for a green supplier selection for an actual company from agri-food sector in Iran. Akman [9] used VIKOR and fuzzy c-means clustering to evaluate 198 automotive industry suppliers in Turkey, based on 4 performance and 9 green criteria. Govindan et al. [20] used a mixture of Fuzzy TOPSIS, Fuzzy AHP and Fuzzy SAW for green supplier selection and order allocation in a low-carbon paper industry in India. A more comprehensive literature review of MCDA methods usage for the green supplier evaluation and selection can be found in [22], [23].

It is important to note, however, that the aforementioned MCDA-based approaches produce an assessment based on criteria measurements collected for a single moment in time. In case of the supplier selection problem, it is often required to consider the variability of each suppliers' evaluations in time. There have been some efforts to extend the MCDA methods to provide the ability to aggregate measurements and evaluations collected over a period of time. Banamar and De Smet [24] extended the PROMETHEE II method to allow temporal evaluations. Sahin and Mohamed [25] introduced a Spatial Temporal Decision framework, based upon a combination of System Dynamics modelling, Geographical Information Systems modeling and multi-criteria analyses of stakeholders' views with the use of the AHP method. Zhu and Hipel [26] used multiple stages grey target decision making method for vendor evaluation of a commercial airplane in China. Arasteh et al. [27] used the Goal Programming MCDA method to consider a 6-project portfolio over five investment periods and compared the use of their model in fuzzy and crisp scenarios. Last, but not least, a framework extending the TOPSIS method capabilities to evaluate and select green suppliers based on temporal analysis has been constructed [28], [13]. However, the latter approach still did not take into account the hierarchical structure of the decision problem, nor the rank reversal problem. Thus, the performed literature review allows to observe an interesting research gap of the sustainable suppliers selection problem which would simultaneously take into account the decision problem hierarchical structure, temporal aspects of the evaluation as well as protect the produced outcome from the rank reversal phenomenon.

III. Methodological Framework

The selection of a sustainable supplier in the Green Supplier Chain Management is a complex problem that requires a proper approach. The popular MCDA-based approaches are not without shortcomings. They are based on the classic MCDA paradigm, where constancy of all the elements of the decision support process is assumed. It should be noted, however, that the process of sustainable supplier evaluation requires taking into account its characteristics - its hierarchical structure as well as changeability of the appraisal elements in time. Based on the above, the authors propose using a complementary approach based on precise mapping of the structure of the decision problem (derived from AHP), building a supplier reference model (TOPSIS), as well as minimizing

TABLE I
MCDA METHODS APPLICATION IN THE SUSTAINABLE SUPPLIER SELECTION PROBLEM

the shortcomings of the two methods by incorporating the COMET method. Moreover, the characteristics of the sustainable supplier evaluation process requires taking into account the variable effect of each supplier appraisal in a period of time. Therefore, the authors propose using time-conditioned evaluation aggregation strategies. The framework is visually presented on Fig. 1 and is described in detail in the following subsections.

A. MCDA Foundations of the Proposed Framework

The problem of sustainable supplier selection is a multi-criteria problem, since it requires to take into consideration multiple, not only performance but also environmental, criteria. For example, Rezaei et al. [2] provided a list of 23 supplier selection criteria most utilised in the periods 1966-1990 and 1990-2001, and combined them with 15 modern environmental criteria. However, such a vast set of criteria makes the evaluation difficult to perform. Therefore, in the proposed approach we utilise the AHP method to organize the evaluation criteria in a hierarchy (see subsection III-B).

The AHP method produces a ranking of suppliers with the percentage score of the DM's preference of each supplier over the others. However, in the problem of sustainable supplier evaluation it would be beneficial not only to know how much one supplier is preferred over its competition, but also to compare such supplier with a potential ideal supplier. Therefore, the proposed framework utilizes the TOPSIS method to compute a potential ideal and anti-ideal supplier (see subsection III-C).

Unfortunately, neither the AHP nor the TOPSIS method are resistant to the rank reversal phenomenon. Therefore, in the last step of the MCDA analysis of the suppliers, the proposed approach explores the complete space of the decision problem criteria values, thus providing a universal solution immune to rank reversal (see subsection III-D).

Last, but not least, the outputs of the aforementioned three MCDA components of the framework constitute the input to the temporal aggregation (see subsection III-E).

B. Hierarchical Structure of the Sustainable Supplier Selection Problem

The Analytical Hierarchy Process (AHP) by Saaty [30] is one of the best known and most widely used MCDA approaches. It is built on three main principles [31]: construction of a hierarchy, setting priorities and logical consistency. The decision problem is decomposed and structured into a hierarchy of sub-objectives, attributes, criteria and alternatives. In case of the proposed approach, the hierarchy of criteria is presented in Table II. Subsequently, the decision maker (DM) uses a pairwise comparison mechanism to determine the relative priority of each element at each level of the hierarchy. When comparing the elements of the hierarchy, a scale of $1-9$ is used to indicate the degree of preference of one element over the other. In case an element is less preferred, a reciprocal value is used, i.e. $\frac{1}{9}-1$.

The comparison results are stored in the pairwise comparison matrix, and the weights of individual elements are obtained. Each element of the matrix represents the dominance of an element in the column on the left over an element in the row on top. If the element on the left column is less important than the element in the row on top, a reciprocal value is inserted. The elements on the diagonal of the matrix are always

TABLE II
EVALUATION CRITERIA GROUPED INTO CRITERIA, SUBCRITERIA AND SECOND LEVEL SUBCRITERIA

Criteria	Subcriteria	2 Level Subcriteria	Ref
Cost		Product costs, Total supply cost which impact on final product, Financial cost, Operating expenditure, After-sales costs, Sunk/loss cost/customer dissatisfaction, Suppliers production pauses	[6], [9], [10], [14], [28], [13]
Quality		Product quality, Quality of Service, Warranty, Quality system certificate of the supplier, Quality assurance, Conformance quality, Quality image, Vendor specific, Quality manual, Documentation control, Archive of quality records, Receiving Inspection, Calibration control, Non-conforming material control system, Corrective and preventive action system, Audit mechanism	[9], [11], [16], [13]
Logistics		Choice of transportation, Reliability of quality, Delivery flexibility, Serious delivery delay rate, Compliance delivery with quantity, Supplier Stock Management, Technology Level, Capability of R & D, Order fulfill rate, Capability of Product Development, Procurement, Return forecast for each client, Warehouse management, IT management, Confirmed fill rate, Total order cycle time, System flexibility index, Integration technologies level, Increment in market share	[6], [29], [21], [28]
Social		The interests and rights of employee, The interests and the right of shareholders, Information disclosure, Expose nonfinancial information, Respect for the policy, Discrimination in employment, Child labor	[9], [11], [18], [19], [28], [13]
Profile		Customer base, Performance history, Production facility and capacity, Facility location, The number of working years in this sector, References, Communication capability, The number of personnel, Education status of the personnel, Machine capacity and capability, Manufacturing technology, Facilities manufacturing capacity, Technical capability, Manufacturing planning capability, Handling and packaging capability	[6], [17], [18], [13]
Green	Innovation	Green Technology Capabilities, Green Process/Production Planning, Recycling Product Design, Renewable Product Design, Green R & D Project, Redesign of Product	[9], [29], [14], [18], [28]
	Environment protection	Environment Efficiency, Eco-design, Environment Protection System Certification, Environmental Protection policies/plans	[29], [11], [12], [19], [28], [13]
	Environment Management	Production of material ecologically efficient, Eco-design requirements for energy using products, Level of restriction of hazardous substance in the production process, Compliance with the local regulation and policies	[29], [14], [15], [28]
	Pollution control	Air Emissions, Waste water, Pollution Control Capability, Pollution Reduction Capability	[9], [12], [19], [28]
	Hazardous Substance Management	Management of hazardous substances in the production procedure, Prevention of mixed material, Process Auditing, Warehouse Management, Inventory of Hazardous Substance	[29], [15], [22], [13]
	Image	Ratio of green customers to total customers, Green customers market share, Stakeholders relationship, Green materials coding and recording	[9], [11], [18], [28], [13]
	Product	Recycle, Green Packaging, Cost of Component Disposal, Green Production, Reuse, Re-Manufacture, Disposal	[6], [12], [20], [22], [28]
	Materials	Materials used in the supplied components that reduce the impact on natural resources, Ability to alter process and product for reducing the impact on natural resources	[29], [15], [19], [28], [13]

equal to 1. Therefore, a total of $n(n-1)/2$ comparisons needs to be performed. The procedure is repeated on all subsystems of the hierarchy. Sometimes, the DM's judgments can be inconsistent. However, in the AHP method, the inconsistency can be considered a tolerable error in measurement, as long as it does not exceed 10%.

C. Positive-Ideal and Negative-Ideal Supplier

The TOPSIS method (Technique for Order Performance by Similarity to Ideal Solution) utilized in the proposed approach, is a popular MCDA decision-making technique, originally developed by Hwang and Yoon [32], based on the idea to compare relative the distances between the alternatives and the ideal (PIS, positive ideal solution) and anti-ideal solutions (NIS, negative ideal solution). The best alternative should be as close as possible to the PIS, and, at the same time, as far as possible from the NIS.

The algorithm of the TOPSIS method comprises of six stages. In the first of them, the decision maker (DM) is required to choose m alternatives and n criteria for use in solving the problem, which are used to build the decision matrix $D[x_{ij}]$. The rows of the matrix represent alternatives and the columns represent criteria. The x_{ij} element is a representation of the decision attribute of the ith alternative regarding the jth criterion:

$$D[x_{ij}] = \begin{pmatrix} x_{11} & x_{12} & x_{13} & ... & x_{1n} \\ x_{21} & x_{22} & x_{23} & ... & x_{2n} \\ x_{31} & x_{32} & x_{33} & ... & x_{3n} \\ ... & ... & ... & ... & ... \\ x_{m1} & x_{m2} & x_{m3} & ... & x_{mn} \end{pmatrix} \quad (1)$$

The second step of the procedure is the decision matrix normalization. Each decision attribute is normalized separately for each criterion. The following formulae are used to normalize benefit and cost criteria respectively:

$$r_{ij} = \frac{x_{ij} - min_i(x_{ij})}{max_i(x_{ij}) - min_i(x_{ij})} \quad (2)$$

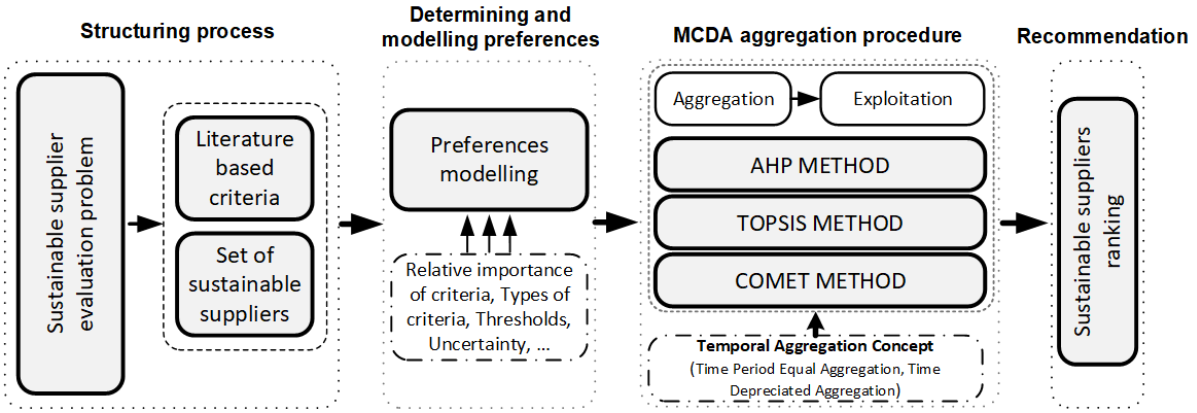

Fig. 1. Visual illustration of the proposed approach

$$r_{ij} = \frac{max_i(x_{ij}) - x_{ij}}{max_i(x_{ij}) - min_i(x_{ij})} \tag{3}$$

In the third step of the procedure, a weighted normalized decision matrix is created with the following formula:

$$v_{ij} = w_j \cdot r_{ij} \tag{4}$$

The PIS (V_J^+) and NIS (V_J^-) are obtained in the fourth step:

$$V_j^+ = \{v_1^+, v_2^+, v_3^+, \ldots, v_n^+\} \tag{5}$$

$$V_j^- = \{v_1^-, v_2^-, v_3^-, \ldots, v_n^-\} \tag{6}$$

In the fifth step, the Euclidean distances between the alternatives and PIS and NIS are computed:

$$D_i^+ = \sqrt{\sum_{j=1}^{n}(v_{ij} - v_j^+)^2} \tag{7}$$

$$D_i^- = \sqrt{\sum_{j=1}^{n}(v_{ij} - v_j^-)^2} \tag{8}$$

In the last step of the algorithm, the relative closeness of the alternative to the ideal solution is calculated:

$$CC_i = \frac{D_i^-}{D_i^- + D_i^+} \tag{9}$$

Based on the CCi values, the final ranking of alternatives is created. In case of the proposed approach, the CCi value of each supplier allows to understand how far it is from a potential ideal supplier.

D. Prevention of the Rank Reversal Phenomenon

The proposed approach utilizes the Characteristic Objects METhod (COMET) [33] for exploring the complete space of possible solutions. The COMET method is based on the fuzzy sets theory and instead of comparing alternatives, as it is in AHP and TOPSIS, characteristic objects are created and compared in it, in order to create a linguistic rule base. Each evaluated alternative is subsequently scored in a defuzzification process. It is important to note, that due to the fact that a complete space of possible solutions of the decision problem has been explored by the comparisons of the problem's characteristic objects, introduction of a new supplier to the analysis will not change the evaluations of the remaining suppliers.

In the first step of the COMET procedure, the expert determines the dimensionality of the problem by selecting r criteria, $C_1, C_2, ..., C_r$. Then, a set of fuzzy numbers is selected for each criterion C_i, e.g. $\{\tilde{C}_{i1}, \tilde{C}_{i2}, ..., \tilde{C}_{ic_i}\}$ (10):

$$\begin{aligned} C_1 &= \{\tilde{C}_{11}, \tilde{C}_{12}, \ldots, \tilde{C}_{1c_1}\} \\ C_1 &= \{\tilde{C}_{21}, \tilde{C}_{22}, \ldots, \tilde{C}_{2c_2}\} \\ &\ldots \\ C_r &= \{\tilde{C}_{r1}, \tilde{C}_{r2}, \ldots, \tilde{C}_{rc_r}\} \end{aligned} \tag{10}$$

where $c_1, c_2, \ldots, c_r$ are the ordinals of the fuzzy numbers for all criteria.

In the second step, characteristic objects (CO) are obtained as a Cartesian product of the fuzzy numbers' cores of all the criteria (11):

$$CO = C(C_1) \times C(C_2) \times \ldots \times C(C_r) \tag{11}$$

As a result, an ordered set of all CO is obtained (12):

$$\begin{aligned} CO_1 &= C(\tilde{C}_{11}), C(\tilde{C}_{21}), ..., C(\tilde{C}_{r1}) \\ CO_2 &= C(\tilde{C}_{11}), C(\tilde{C}_{21}), ..., C(\tilde{C}_{r2}) \\ &\ldots \\ CO_t &= C(\tilde{C}_{1c_1}), C(\tilde{C}_{2c_2}), ..., C(\tilde{C}_{rc_r}) \end{aligned} \tag{12}$$

where t is the count of COs and is equal to (13):

$$t = \prod_{i=1}^{r} c_i \tag{13}$$

In the third step of the procedure, the expert determines the Matrix of Expert Judgment (MEJ) by comparing the COs pairwise. The matrix is presented below:

$$MEJ = \begin{pmatrix} \alpha_{11} & \alpha_{12} & .... & \alpha_{1t} \\ \alpha_{21} & \alpha_{22} & ... & \alpha_{2t} \\ ... & ... & ... & ... \\ \alpha_{t1} & \alpha_{t2} & ... & \alpha_{tt} \end{pmatrix} \tag{14}$$

where α_{ij} is the result of comparing CO_i and CO_j by the expert. The function f_{exp} denotes the mental judgment function of the expert. It depends solely on the knowledge of the expert. The expert's preferences can be presented as (15):

$$\alpha_{ij} = \begin{cases} 0.0, & f_{exp}(CO_i) < f_{exp}(CO_j) \\ 0.5, & f_{exp}(CO_i) = f_{exp}(CO_j) \\ 1.0, & f_{exp}(CO_i) > f_{exp}(CO_j) \end{cases} \tag{15}$$

After the MEJ matrix is prepared, a vertical vector of the Summed Judgments (SJ) is obtained as follows (16).

$$SJ_i = \sum_{j=1}^{t} \alpha_{ij} \tag{16}$$

Finally, the values of preference are approximated for each characteristic object. Correspondingly, a vertical vector P is obtained, where the $i-th$ row contains the approximate value of preference for CO_i.

Then, in the fourth step, each characteristic object and its value of preference is converted to a fuzzy rule as follows (17):

$$IF \quad C(\tilde{C}_{1i}) \quad AND \quad C(\tilde{C}_{2i}) \quad AND \quad ... \quad THEN \quad P_i \tag{17}$$

Thus, a complete fuzzy rule base is obtained.

Eventually, in the final step, each alternative is presented as a set of crisp numbers, e.g., $A_i = \{a_{1i}, a_{2i}, ..., a_{ri}\}$. This set corresponds to the criteria $C_1, C_2, ..., C_r$. Mamdani's fuzzy inference method is used to compute the preference of the $i-th$ alternative.

E. Temporal Aggregation of the Supplier Evaluation Results

The classic MCDA procedure requires both the alternatives and criteria to be constant [34], [35]. However, if criteria measurements are collected over a span of time, the ones closest to the time of the evaluation are intuitively the most valid. By all means, the criteria measurements from all periods can be aggregated using for example fuzzy sets theory and fuzzy numbers. However, it would affect the accuracy of the evaluation method input data and, consequently, could lead to oversimplifying the model and reducing the quality of the decision support. Therefore, in the proposed approach, instead of aggregating the input data, the DM should perform a temporal aggregation of the outcomes produced by evaluations produced in each period.

The temporal aggregation concept is based on the construction of a general utility function with an additional attribute called *forgetting*. Two possible types of forgetting strategies can be used:

TPEA
: Time Period Equal Aggregation – the impact of individual ratings on the final outcome of the assessment is balanced;

TDA
: Time Depreciated Aggregation – along with increasing distance of the historical data to the current period, its significance is being diminished.

Regardless of the forgetting strategies chosen, the general utility of a supplier can be obtained with the formula:

$$V(a^i) = \sum_{k=1}^{n} S_{ik} \cdot p(t_k) \tag{18}$$

where $V(a^i)$ denotes the general utility for the ith supplier on the basis of all n periods taken into consideration, S_{ik} means the utility of the ith supplier in period k and $p(t_k)$ means the significance of data for the k period in time t, based on the selected forgetting strategy. S_{ik} is determined in the previous step by the AHP, TOPSIS and COMET methods.

IV. Empirical Research

The proposed approach was empirically verified on a real company. A set of thirty suppliers of the company were selected for the research. The suppliers for the research were selected based on the yearly and monthly turnover. The criteria for the study were chosen as a result of a thorough literature review and are presented in Table II. The companies' performances in some of the criteria, such as time to confirm delivery, delivery time, delivery on-time, complaints, turnover, cost of transport, terms of payment and currency were fetched automatically from ERP systems, whereas for criteria where automation was not possible, surveys and expert judgment were utilized.

The obtained measurements of each criterion were normalized and mapped according to the Likert scale. In the next step, the AHP, TOPSIS and COMET methods were used to obtain the utility values of each supplier for each period. Eventually, temporal aggregation was performed based on five strategies TPEA, TDA1, TDA2, TDA3 and TDA4, which are illustrated in Table III and Fig 2.

In case of the TPEA strategy, the $p(t_k)$ value is always equal 1. In case of TDA1, TDA2 and TDA3 the forgetting

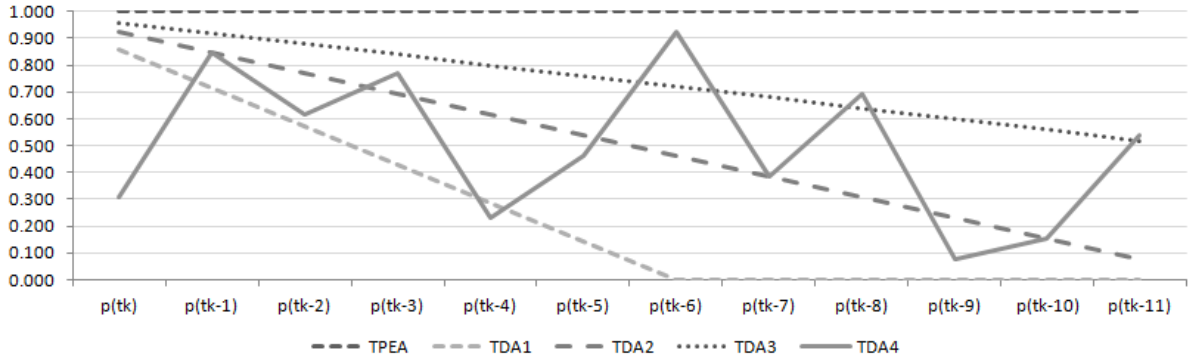

Fig. 2. Forgetting functions for TPEA, TDA1, TDA2, TDA3 and TDA4 strategies

TABLE III
FORGETTING FUNCTION PARAMETERS FOR TPEA, TDA1, TDA2, TDA3 AND TDA4 STRATEGIES

Aggregation	p(tk)	p(tk-1)	p(tk-2)	p(tk-3)	p(tk-4)	p(tk-5)	p(tk-6)	p(tk-7)	p(tk-8)	p(tk-9)	p(tk-10)	p(tk-11)
TPEA	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000	1.000
TDA1	0.857	0.714	0.571	0.429	0.286	0.143	0.000	0.000	0.000	0.000	0.000	0.000
TDA2	0.923	0.846	0.769	0.692	0.615	0.538	0.462	0.385	0.308	0.231	0.154	0.077
TDA3	0.960	0.920	0.880	0.840	0.800	0.760	0.720	0.680	0.640	0.600	0.560	0.520
TDA4	0.308	0.846	0.615	0.769	0.231	0.462	0.923	0.385	0.692	0.077	0.154	0.538

function is spread over 6, 12 and 24 months respectively. In case of TDA4, the value of the forgetting function depends on the supplies turnover.

The results of the temporal evaluation of the suppliers based on the AHP, TOPSIS and COMET methods partial evaluations are presented in Tables IV, V and VI respectively. For the reasons of brevity, the number of suppliers presented in the paper was limited to twelve.

As it can be noticed from the analysis of Fig. 3, all obtained rankings are highly correlated. A higher correlation can be observed between the rankings produced by the same method. However, the rankings obtained based on the AHP or TOPSIS methods are more correlated than any of these methods with the COMET method. This is caused by the fact that the COMET method explores the complete space of the decision problem, whereas the AHP and TOPSIS methods operate locally on the provided alternatives (suppliers).

The analysis of the temporal evaluation of the suppliers based on the three MCDA methods allowed to observe that depending on the aggregation strategy and the MCDA method used, the ranks of the suppliers vary slightly. However, it was noticed that the supplier A12 appeared on the majority of the rankings within the group of the best 5 suppliers.

V. CONCLUSIONS

The process of sustainable supplier selection is crucial to the companies' business continuity. Distortions in invalidly chosen suppliers can lead to a considerable impediment or even to a complete cease of company's operations. The current research focus is double-track. The first track focuses on the evaluation methods development. The second one focuses on the sustainability factors of the green cities, taking into account not only greening, but also human well being. While many prior studies focused on evaluation of suppliers based on performance and environmental criteria, the approach presented in this paper extended them with the following authors' contributions:

- possibility to organize the evaluation criteria into a multi-level hierarchy for better manageability of the decision problem;
- possibility to obtain a potential positive-ideal and negative-ideal supplier description and evaluation of the actual suppliers in relation to those two test cases;
- possibility to comprehensively explore the complete space of solutions of the sustainable supplier selection decision problem, thus preventing reversals in the produced rankings;
- possibility of temporal aggregation of the rankings obtained over a span of time with various forgetting strategies.

Compared to study [13], the performed research clearly shows that usage of a single hierarchical MCDA method in the process of sustainable supplier selection might not always be sufficient if the exploration of the complete space of the selection problem solutions or potential positive-ideal and negative-ideal supplier descriptions are needed.

Abstract*—As information technology (IT) in private and public organizations continues to gain importance, information system outsourcing (ISO) has become a critical component of corporate strategy for many institutions. Consequently, a substantial amount of research has investigated topics around ISO decisions and outcomes. However, despite decades of ISO research, analyses that focus on information system (IS) backsourcing remain scarce. Therefore, in this paper, we share the results of a systematic literature analysis of papers that consider IS backsourcing. Within our paper, IS backsourcing is integrated into the wider research landscape of ISO. Finally, our study clearly identifies the need for further and more extensive research on IS backsourcing. The high dissatisfaction and failure of outsourcing arrangements should not be ignored. Both sourcing decisions and existing outsourcing arrangements must be analysed carefully and in the long term to ensure the success of the company.

I. Introduction

Information system outsourcing (ISO) has become a common alternative to running in-house information technology (IT) operations and development activities across company and national borders. Looking at the ever-growing range of IT services that are available in the global outsourcing market, companies can purchase not only small development and hosting services but also entire business process and infrastructure solutions. Thus, information system outsourcing (ISO) / information technology outsourcing (ITO) has become a well-established field of research. Typical research topics evolved from ISO motivations and success factors in the 1990s to the relationship between vendor and client in the 2000s to modern forms of sourcing in approximately 2008 [1].

ISO/ITO are backed by many drivers: optimized cost situation (mainly through high labour cost differences), access to highly qualified staff, access to new markets, high flexibility and technical feasibility. These factors weigh even more heavily if the company-owned IT department experiences a lack of competence, high costs or a lack of attention because it does not belong to the core business [2].

What seems like an ideal solution comes with a variety of risks and problems. These range from global client risks, which include the state of the labour market and the infrastructure in the provider's country, to local client risks, such as cultural differences, different time zones, language problems, knowledge transfer and technical skills, which hamper the quality of the cooperation [3]. Further risk factors are, for example, interest conflicts, low product or service quality, high turnover rates on the provider-side, additional work and extra costs for the client and technology-related risks [4]. Referring to practice-oriented studies, many of the stated risks have become problems [5]. This argument is also supported by surveys that report that 50% of analysed offshore outsourcing contracts that are signed by North American companies failed to meet their expectations [5], 30 to 50% of the companies that are involved in offshore outsourcing had cancelled their contracts [6], and 20% of those outsourcing contracts are cancelled in the first year [7].

One of several alternatives for a company that is facing those problems is to terminate its relationship with the vendor and relocate its IT services. Therefore, this paper will focus on backsourcing as one type of relocation. IS backsourcing in the IS literature is generally defined as the process of recalling operations back in-house after they have been outsourced [8]. The practice of IS backsourcing has been only briefly discussed in the scientific literature, compared to the growing literature on ISO/ITO [9]–[11]. This is surprising when examining some of the numerous prominent cases, where banks such as *JP Morgan Chase* and *Bank One* prematurely terminated their multi-billion-dollar ITO contracts to pull those services back in-house [12]. Such cases highlight the practical relevance of IS backsourcing. To address the knowledge void that surrounds this phenomenon, it is necessary to analyse the state of the academic literature on IS backsourcing, to answer the most important question, namely, "*Why backsource IT services?*", and determine what is known about the transition process to answer the question "*How can IT services be backsourced?*".

Therefore, the main objective of our paper is to identify drivers for IS backsourcing and factors that influence the transition phase in the existing academic literature. To fulfil this objective, we conducted a systematic literature analysis.

This work was not supported by any organization

With this analysis, we aim at answering two research questions:

- *What are drivers for companies to backsource their IT services?*
- *How do companies backsource their IT services?*

To obtain an initial answer to these questions, the paper is structured as follows: First, we present a short overview of our methodology. Next, as the main focus of our paper, we describe in detail the findings of our literature analysis. Then, we conclude with a discussion and summary of our results and identify aspects for future research.

II. Research Approach

A. Literature Review

To obtain a general overview of the body of IS backsourcing research, we followed the guidelines of [13], in which a five-step approach for conducting IS literature reviews is provided. In the first step, we defined the review scope, backed by a taxonomy of literature reviews that were developed by [14]. In steps 2 and 3, relevant working definitions (for a common understanding of the used search terms) and the search process (sources and the selection criteria for the literature) are described. The definition of analysis and synthesis is assigned to the fourth step, including a categorization referring to [12], [15]. The final step is composed of summarization of key findings and specification of a research agenda.

As an initial step, we examined IS journals and IS conference proceedings using the databases *AIS Electronic Library*, *EBSCOhost Business Source Complete*, *Emerald Insight*, *IEEE Xplore* and *ScienceDirect*. We conducted electronic searches of *titles*, *keywords* and *abstracts* for the following search term*: ["backsourc*" OR "backshor*" OR "reshor*" OR "insourc*"]*. Furthermore, we performed a second search on the following search term: *[("offshor*" OR "outsourc*") AND "fail*"]*. With these searches, we identified 290 publications. After analysing each article's abstract and keywords, and/or the full article when necessary, we excluded 220 articles that were duplicates or did not appear to be concerned with or relevant to our research focus. As a third analysing step, by reading the abstracts of the remaining 70 papers, we selected only 15 papers for deeper review. In the last step, five additional publications were identified through backward and forward search (as suggested by [16]). Table 2 in the Appendix gives an overview of the 20 publications that elaborate a consolidated view of the current field of IS backsourcing. In the remainder of this article, we focus on these papers.

B. Literature Analysis and Synthesis Framework

For the analysis and synthesis of the relevant literature, the analytical framework of [4] is partially considered, which refers to the perspectives *research focus* and *research approach*.

Research Focus: Dibbern et al. [2] developed a five-stage model of ISO. These five stages are divided into two main phases: *the decision process* and *the implementation*. The decision process contains the following questions and stages: ***Stage Decision*****:** (1) Why does an organization consider outsourcing? (e.g., drivers, antecedents), (2) What is outsourced? (e.g., functions, organizations) and (3) Which choices are made? (e.g., with a decision model or guideline); ***Stage Implementation*****:** (4) How is outsourcing carried out? (e.g., selecting vendors, transition of knowledge) and (5) What are the outcomes of outsourcing? (e.g., experience, lessons learned). Since backsourcing is a major decision in an organization, the adoption of this stage model appears appropriate. Thereby, our paper focusses on the two main stages by reducing the decision process to the "**WHY**" stage and the implementation to the "**HOW**" stage. This limitation is backed not only by the foci of most of the IS backsourcing literature, which instead examines the antecedents of backsourcing, but also by the similarity of the transition process in outsourcing and backsourcing in terms of influencing factors (see [17]).

Research Approach: Referring to the view on research approaches of [2], the identified literature was analysed and we differentiated between empirical and non-empirical approaches. Thereafter, the epistemology within the approaches was determined by following [4]. **Empirical approaches** contain the following types of epistemology: *interpretivism*, *positivism* and *descriptivism*, whereas **non-empirical approaches** can be distinguished between *conceptual* and *mathematical methods*.

III. Findings

As a result of the literature analysis and synthesis, this section outlines the determinants for backsourcing IT services and the factors that influence the transition phase. Working definitions are specified in the first part, followed by a descriptive analysis of the findings and their methodologies. Subsequently, the drivers and transition process influencers for IS backsourcing are analysed and synthesized.

A. Conceptual Background

Prior to identifying the drivers for outsourcing failure and relocating IT services from an offshore location to the home country, various working definitions must be clarified. As backsourcing is a type of general sourcing in the academic literature, both IS and manufacturing definitions could be applied. Especially in manufacturing literature, multiple synonyms are used, such as *back-shoring*, *reshoring*, *back-sourcing* and *de-internationalization* (see [18]). In IS research, mainly the terms *backsourcing* and *insourcing* are being used. Table 1 presents an overview of existing definitions.

A comparative analysis of the definitions that are found in both the IS and manufacturing literature (see Table 1)

reveals several characteristics of the relocation of manufacturing or IT services back to the home country of the company: **(a)** the relocation is the reverse decision with respect to a previous offshoring process, **(b)** the relocation does not necessarily involve repatriation or the closure of all of a company's offshore activities or plants **and (c)** a difference between the ownership modes can be identified (backshoring and backsourcing).

Referring to [4], in which a framework was specified for classifying the characteristics of the term offshoring, almost all characteristics can be assumed to be parallel to backsourcing. Only the category *Distance* may be left out, since the destination for the backshoring action is usually the domestic country of the company by definition. Thus, the focus lies on three characteristics (see [2], [4], [19]):

- **Ownership** (What property model shall be used?),
- **Function** (What IS services shall be backshored?) and
- **Degree** (To what extent shall IS services be backshored?).

These characteristics can be further divided into internal, external, partial, selective and total.

(1) Ownership: As opposed to offshoring, where the action begins in the home country of the company, backsourcing starts in the country to where the services have already been located. Hence, several reshoring alternatives are possible. Company **internal** IS services can generally be reshored to captive organizational units that are still located in foreign countries (in-house reshoring following [20]). They can also be reshored to **partially** owned companies (e.g., joint ventures or strategic alliances, following [10], [21]) or **externally** owned companies (near-/ offshore outsourcing, following [22]).

(2) Function: Strasser and Westner [23] determined that most studies do not specify which IS services are transferred, as often only general terms such as *information system development activities* and *IS functions* are stated. By clustering these terms, three groups of activities are defined: *infrastructure services*, *application development services* and *business process services* ([4], [21]).

(3) Degree: Here, distinctions between **total** and **selective** reshoring can be made ([21], [24], [25]). Contrary to the case of total offshoring, total reshoring of previously outsourced or offshored services is realistic.

This paper will focus on backsourcing as one case of relocating IS services. As the drivers for relocating IS services to the home country of a company will be investigated, backshoring, which is used primarily in the manufacturing reshoring literature, will be considered as well. This paper follows the initial definition of backsourcing of [26]: "[…] backsourcing, where companies who initially outsourced their IT decide to bring it back in-house." For the remainder of our review, further specifications were set to avoid ambiguities in the stated characteristics of reshoring: The backsourced IS services are considered to be integrated into the company-internal organization, which is located in the home country of the company. Only internal functions are backsourced entirely.

B. Applied Research Methodologies

The selected conference and journal publications regarding IS backsourcing can be divided into *non-empirical* (conceptual or mathematical) and *empirical* (interpretive, descriptive or positivist) papers. Mathematical modelling papers were not found. An overview on who used which approach can be found in Table 2 in the Appendix.

The **non-empirical conceptual** research papers include issues and perspectives that are related to the phenomenon of IS backshoring. Akoka and Comyn-Wattiau [27] designed a framework for understanding "Why to backsource IT" by defining rational and irrational factors. Another framework for understanding the decision to backsource IT was created by [28], who regarded the reasons for IT backsourcing not only as a problem-solving strategy but also as an internally or externally motivated opportunity for stability and growth. Another backsourcing decision model was constructed by [29], in which a decision process is designed by integrating knowledge from the research literature and expert interviews.

TABLE I.
OVERVIEW OF TYPES OF RESHORING

Concept	Definition	References
Backshoring	"Re-concentration of parts of production from own foreign locations as well as from foreign suppliers to the domestic production site of the company" [30]	[30]–[32]
Backsourcing	"[...] where companies who initially outsourced their IT decide to bring it back in-house." [26] "Production return relocation from an [...] external entity" [31]	[26], [31], [33]
De-internatio-nalisation	"Any voluntary or forced action that reduces a company's engagement in or exposure to current cross border activities" [34]	[34]–[36]
Insourcing	"Insourcing is the practice of evaluating the outsourcing option, but confirming the continued use of internal IT resources to achieve the same objectives of outsourcing" [11]	[11]
Reshoring	"Moving manufacturing back to the country of its parent company" [37]	[20], [37]

Moreover, McLaughlin and Peppard [9] integrated backsourcing into an end-to-end sourcing model, which means that backsourcing is one of several alternatives of sourcing options. Finally, Beardsell [38] tried to determine whether backsourcing improves the firm's innovative capability by integrating a broad range of theories.

Many **empirical interpretivist** research papers were identified, which were mostly based on real case studies. Butler et al. [17] conducted six semi-structured interviews in a company that recently backsourced its whole IT department to identify parallels between backsourcing and outsourcing. A similar approach was taken by several authors ([12], [33], [39], [40]), who examined antecedents for IS backsourcing, not only based on interviews but also by analysing external media publications. This method was extended by [41]–[44], in which internal company data, such as presentations and e-mails, were considered in the analysis of determinants that have led to the failure of ISO arrangements.

Several **empirical positivist** research papers were identified [10], [28], [45]. They interviewed over 250 employees from various companies in field studies on the success and failure factors for ITO and identified reasons why companies backsource.

Bhagwatwar et al. [46] used an **empirical descriptive** approach to analyse two case studies and developed best-practices for the success of an IS backsourcing arrangement in terms of knowledge re-integration based on their observations.

C. Why-Stage: Backsourcing drivers

Comparing the foci of the relevant IS backsourcing literature in this paper with those of selected papers in IS offshoring literature reviews ([1], [4], [23]), striking differences are observed. While the IT offshoring literature focusses on multiple dimensions, such as *distance* (onshore, nearshore, offshore), *function* (infrastructure, application, etc.), *degree* (selective, total), *perspective* (vendor, customer, consultant) and the *stages* of why, how, what and which to offshore, the IS backsourcing literature is very limited in its research perspectives. This underlines the weak pervasion of the subject matter from a research point of view.

Regarding the analysed papers, multiple types of classifications are proposed. Veltri [47] classified backsourcing drivers into *costs*, *uncertainty and risk*, *goal conflict* and *opportunism*. Wong [44] categorized his findings into *strategic factors*, *power and politics*, *outsourcing expectation gaps* and *changes in vendor organization*. A very general classification was made by Wong in 2008 [40], who categorized his findings into **(1)** *outsourcing expectation gaps*, **(2)** *internal organizational changes* and **(3)** *external environmental changes*. Driven by the content analysis of the selected publications, the categorization and sub-categorization by [40] are most suitable due to the broad variety of the obtained results.

In the following, expectation gaps are stated, followed by internal organizational changes and external environmental changes. A comparison of the results with **(a)** *the results to the ISO* and **(b)** *manufacturing backshoring* literature is performed afterwards.

(1) Backsourcing drivers through expectation gaps: The most commonly mentioned factor for moving IS services back among the selected research papers is *unsatisfying service quality* (mentioned in eleven of the papers). In particular, concrete factors are *low product and service quality*, *poor communication*, *lower productivity*, *poor commitment of the vendor* and a *lack of transparency*. An additional striking factor is *cultural differences*, which is reflected into *different understandings of hierarchy*, *punctuality, acknowledging mistakes*, and *accuracy and responsibility over tasks*. In addition, *knowledge mismatch*, which describes a lack of business and technology knowledge, and *process comprehension and experience* might lead to inefficiencies in collaboration. Independent from possible mismatches through differences of any kind, *opportunistic behaviour* must be considered as well, since the vendor has latitude, for example, in appointing key personnel to specific positions, which he might use to further his interests.

Furthermore, *cost aspects* are found to be of higher relevance, specifically unrealized cost savings through agency costs, transaction costs, hiring and retaining costs, lost performance and uncertainty costs. Through these categories, it becomes clear that cost and service quality are both highly considered in decisions on outsourcing and backsourcing IS services [26].

Losing control over the vendor's activities is also considered a central driver for backsourcing regarding possible principal-agent problems, such as inefficiencies through incorrect working directions and, especially, insecurity issues for sensitive information. From a strategic point of view, *failing to achieve defined outsourcing goals* is one of the most striking arguments for backsourcing. Additional drivers are *uncertainties regarding objectives*, *performance measurements* and *missing measures for low performance or failure*.

Lastly, an important factor for IS backsourcing is *missing access to latest technologies*, which refers not only to state-of-the-art soft- and hardware technologies but also to highly educated human and knowledge capital, which might lead to deficiencies in communication and cooperation and, finally, lower competitiveness.

(2) Backsourcing drivers through internal or external changes: From a company-internal organizational point of view, backsourcing can result from trivial causes, such as *changes of the (top) management*, *changes of the role of IT in the company* or *general changes in the strategic direction*. The last two factors go hand in hand due to the rising relevance of IT in the operations and strategies of

companies, especially in times of digitalization of assets and products. Deduced from this, outsourcing can also occur for reasons of business model changes, organizational changes in structures (e.g., through acquisitions, mergers, or divestments) or simply through a shift or lack of top executive support.

(3) External environmental changes: Comparatively few factors were identified regarding IT backsourcing. Those factors mostly refer to *changes in the vendor's strategy or organization* or, from an economic perspective, *uncertainties in demand and supply through economic ups and down*s. A link to the *technology factor* can also be made, meaning that disruptive technologies might lead to new markets, which again might lead to new business models and environments that require new sourcing considerations.

(a) Comparison to ISO literature: The most frequently identified drivers for ISO are of financial and strategic nature ([2], [4], [23]). These primarily include cost reduction, wealth maximization by leveraging cost savings, access and proximity to highly skilled employees and markets, focus on core competencies and higher flexibility and technical feasibility [4]. Comparing the most striking motivations of both fields, except for the cost factor, a relatively small number of matchings occur. Considering the reviewed determinants for consideration of ISO as a sourcing option by [23], who specify factors such as advanced technology access, chance for organizational changes and higher innovativeness, similar results dominate.

However, both phenomena contribute to the success of an organization via reconsideration of the business strategy and adaption to the business environment. Additional matchings can be identified when the stated risks for ISO are compared to the drivers for IS backsourcing. Gonzalez et al. [3] addressed risks for the client from different aspects, such as economic (e.g., unemployment rates, poor infrastructure), local (e.g., differences in culture, mentality, language and knowledge transfer or legal problems) and managerial risks (e.g., low quality, additional effort, hidden costs). A striking matching regarding the results of the review is the risk of impacting (internal and external) customer relationships, which is rarely stated in the ISO literature. In their analysis, Butler et al. [17] stated that backsourcing cannot be viewed as "outsourcing in reverse", which can be confirmed in this part of the analysis.

(b) Comparison to manufacturing backshoring literature: For this comparison, two existing systematic literature reviews were used ([15], [48]), which resulted in 22 and 20 selected publications for reshoring manufacturing. Although those reviews are similar in their analysed literature and period, different methods of categorizing the drivers for reshoring manufacturing were used.

Stentoft et al. [15] synthesized and summarized their findings from the reshoring-company perspective. The following aspects were considered: *cost*, *quality*, *time and flexibility*, *access to skills and knowledge*, *risks*, *market* and *other factors* (e.g., incentives from governments and change of a company's strategy).

On the other side, Wiesmann et al. [48] considered an economic perspective by selecting the following driver categories: *global competitive dynamics*, *host and home country*, *supply chain and firm specifics*.

However, the disparity between the manufacturing reviews makes a direct comparison with the findings of our analysis difficult. Therefore, a differentiated comparison appears appropriate. On an enterprise level, the major difference between the IS service and manufacturing business seems to be the subject matter of the backsourcing arrangement: intangible vs. tangible assets, whereas in IS backsourcing, the aspects of cost and quality are considered factors that influence the collaboration between client and vendor; those factors refer more to asset and logistical costs and product quality on the manufacturing-side. Linked to the relevance of collaboration in IS, related factors, such as cultural differences and communication as well as project management, are of high importance. In terms of control, only a few factors are specified in the manufacturing literature. One reason might be the deeper integration of IS services in the company, since IS services are being used by employees abroad whereas manufacturing functions as its own entity for the most part. This stresses the relevance of IS in terms of operations and strategy (see [2]). This goes hand in hand with the high relevance of designing well-conceived contracts for facing all types of contingencies. Lastly, the IS backsourcing literature concentrates on the company layer and considers changes in strategy, management and structure as possible drivers.

In contrast, the characteristic of tangibility influences most of the arguments that are stated in the review of [15], such as production and delivery reliability, supply chain risks and the value of "Made in X"-brandings. These points emphasize that operational artefacts, especially employees, products and the production process, are of interest in the analysis of manufacturing backshoring factors. A variety of parallels and similarities can be detected. As an example, delivery reliability can be found in IS services as well in terms of system and service availability. Both fields face unplanned efforts in terms of transaction costs, miscalculations and high employee turnover rates. In addition, the access to state-of-the-art technologies, the lack of trust and commitment and the risk of theft of intellectual property are factors that are considered as drivers for backsourcing in both IS and manufacturing.

From an economic point of view, Wiesmann et al. [48] conducted a more differentiated review than we did in our analysis by including the categories that are mentioned above. While our paper identifies backsourcing drivers that come from external sources, Wiesmann et al. [48] amplified the influence of political, economic and structural

circumstances, specifying, for example, changes in the international and national economy, political risks, access to qualified personnel, the increasing degree of automation and international differences between productivity rates and work morale among staff. Due to their business character, these arguments can also be considered for the IS field. Competition for resources, sustainability and environmental aspects and difficulties in estimating supply and demand volumes appear to fit into the manufacturing area at first glance but touch the IS area indirectly as well (see [28], [47]).

D. How-Stage: Re-transition process

Comparing our findings in the IS backsourcing literature with those in the ISO literature, the infancy of IS backsourcing becomes visible only in the "how"-stage. Whereas backsourcing results in three publications (two in IS backsourcing), Dibbern et al. [2] identified 36 papers, Wiener et al. [4] considered six papers and Strasser and Westner [23] 13 papers. One reason for this difference is the maturity of ISO research. Furthermore, the limitations, which were mentioned at the beginning of this section, have to be considered, since factors such as supplier selection play an important role in the "how"-stage and might lead to the higher number of findings. Research in the "how"-stage, if narrowed down to IS backshoring literature, is comprised of four areas:

(1) transfer and management of knowledge,
(2) project management needs and challenges,
(3) the relevance of relationship management and
(4) hiring or re-hiring strategies.

(1) Transfer and management of knowledge: As IS services are more integrated into a company's infrastructure than isolated manufacturing activities, a delimitation is difficult to make ([2]). Thus, the transfer of knowledge in an IS backsourcing arrangement must be structured and accurate, due to multiple barriers, such as business requirements, geography or distance, limitations of information and communication technologies, language and problems with sharing beliefs and cultural norms ([46]). Adapting and modifying the approach in Strasser and Westner's [23] systematic literature review on ISO, this section can be divided into *knowledge transfer factors* and *knowledge processes and roles*.

Knowledge transfer factors: Most IS backsourcing and a wide range of ISO studies examine the knowledge transfer process between the client and the vendor and identify central factors that influence this process positively or negatively. As an example, in reviewing two case studies of IS backsourcing, Bhagwatwar et al. [46] argued that high transparency and the willingness to cooperate lead to positive impacts on the transfer, while neglecting the communication and the integration of the employees into the transition process lead to negative impacts. The scope of knowledge, in terms of product specifications and processes, and an environment of clear instructions play a crucial role in transferring concrete knowledge from one entity to another. Indirect influencers are formal factors, such as the level of knowledge on each side, organizational characteristics, and additional efforts for privacy preservation of company-internal data.

Knowledge processes and roles: The knowledge transfer process can be divided into different types and can therefore be explained in different process models (see [49]–[51]). It becomes clear that various types of knowledge exist; hence, different transfer methods should be applied. A prior step to the transfer is to enable the process by sensitizing affected employees on the client and vendor sides to prepare the cooperation and communication on an organizational level. Wang et al. [52] developed a process of boundary formation and spanning activities and defined the role of a boundary spanner, who navigates and negotiates existing boundaries. A second role, namely, the bridge system engineer, is defined. This role is to help minimize all types of issues regarding knowledge gaps and make the client staff aware of cultural differences between the client and the vendor (see [53], [54]).

In their literature review, Strasser and Westner [23] extended Wiener et al.'s [4] findings by identifying additional organizational practices that influence the knowledge transfer. In particular, the relevance of intermediaries and learning activities for successful knowledge transfer was determined. Comparing these findings with the existing IS backsourcing literature, most of the factors that are specified in the ITO literature are also identified but only briefly analysed.

(2) Project management challenges: Adapting and modifying Wiener et al.'s [4] results, the project management challenges for ISO can be divided into three categories: *cultural differences*, *distances* and *psychological contract*. Referring to the definition and characteristics of IS backsourcing, these categories can be applied in this research area as well. In the lessons that they learned from two case studies, Bhagwatwar et al. [46] emphasize the relevance of a guided re-integration process, backed by a backsourcing project team and plan. This team ideally consists of not only executives, managers and technical staff but also the mentioned bridge system engineers. The most obvious tasks of the team are to relay decisions of the vendor to all relevant parties, pay attention to existing and defined security policies and perform the business continuity planning [46]. In addition, it is an unobvious but crucial challenge to lay the groundwork for working and collaborating by defining milestones and responsibilities and overseeing deadlines and costs [4]. On an unconscious level, the project team is responsible for handling upcoming challenges in terms of providing platforms and methods for overcoming any mentality, language or communication barriers that might

hamper the collaboration between the client and the vendor. Coordinating cultural groups over a geographical distance in different time zones while integrating all relevant stakeholders increases the difficulty of the task of project management in IS backsourcing.

(3) Relationship management: As knowledge transfer can be considered the main task and project management the main tool in the "how"-stage, effective relationship management involves an enabler and a facilitator for both aspects. According to [23], relationship management can be divided into *relationship management factors*, *relationship management practices and strategies* and *client and supplier middle-management capabilities and roles*.

Relationship management factors: Since a relationship exists between the client and the vendor, the similarity of factors between IS backsourcing and ISO seems obvious. Primarily, the interests of both client and vendor must be considered since different and possibly hidden motivations drive the engagement on either side [55]. On a more operational and interpersonal level, various aspects have an impact on the relationship management. While trust and the motivation for collaboration lead to a successful relation [56], missing commitment of senior management and weak employee identification influence the relationship negatively [46]. In addition, the various aspects of distance play a role in managing relationships, parallel to the challenges in project management. Since any type of backsourcing has the characteristic of finality, short-term activities seem appropriate, whereas ISO also focusses on establishing long-term strategic partnerships.

Relationship management practices and strategies: Since two organizationally and culturally different groups are in contact, specific practices and strategies appear to be necessary for a collaboration. Abbott and Jones [57] developed a framework for obtaining a better understanding of complex cross-cultural practices and processes. Based on their interviews, Mehta and Mehta [58] emphasized the need for investments in the vendor relationship to minimize the client's risk of relationship breakdown. Such investments may be face-to-face contacts or interactions and the motivation of both the vendor's and the client's employees [59]. In case of a deterioration of the relationship, for example, due a lack of team identity or blockages of communication, Mathew [60], Zimmermann [61] and Butler et al. [17] suggested contingency plans and risk mitigation strategies, such as accelerating the transition.

Client and supplier middle management capabilities and roles: Surprisingly, scant research has been published on middle managers, who execute the outsourcing on an operational level and report to the top management [2]. Willcocks and Griffiths [62] identified the capabilities and roles of middle management for both client and vendor that ensure the effectiveness of an outsourcing arrangement. To clarify the difference from the project management approach that was mentioned earlier, middle managers are domain experts, behaviour managers or governance specialists who are directly confronted with upcoming problems from the operational side. In contrast, project managers are responsible for general organizational issues regarding the project. However, overlaps in roles and tasks exist.

(4) Hiring and re-hiring strategies: Parallel to ISO and manufacturing backshoring research, information on handling human resource capacities is lacking. This phenomenon might occur in ISO, since hiring new staff is an issue of the vendor. Bhagwatwar et al. [46] stressed the relevance of having a strategy for re-transferring existing employees and hiring new employees. Backsourcing without the needed manpower is impossible, which makes it necessary to consider the availability and the need to transfer or hire staff in advance. This need is emphasized by the fact that running in-house IT functions requires people with expertise. The hiring and training of highly skilled staff and service quality assurance are time and cost issues that also must be considered in the backsourcing decision [17].

Comparison to ISO and manufacturing literature: While [2] focused more on conceptualizing and building a relationship between client and vendor, Wiener et al.'s [4] review examined the challenges of offshore relationships, including risk mitigation techniques and success factors. Strasser and Westner [23] extended these findings by specifying a range of factors that emphasize the relevance of communication and commitment of all stakeholders. In addition, they identified additional research fields regarding the role and capabilities of middle management, cross-cultural and organizational learning processes and offshoring attitudes and resulting behaviours that influence relationship management of offshoring initiatives. In their study, Butler et al. [17] stressed the importance of relationship management in terms of investing in the relationship to enable a smooth knowledge transfer and avoid a relationship breakdown during the transition.

IV. Discussion and Conclusions

This literature review presents a consolidated view of the current IS backsourcing field of study and is the first of its kind. Twenty publications critically reflect the state of research of the period between 2003 and 2016. In this article, the current state of the IS backsourcing research stream was reviewed and analysed. By partially referring to the analytical framework of [4], the perspectives of research focus and research approach were adapted. With the help of this modified framework, a common understanding of basic terms and, thus, the basis for the analysis of prior academic IS backsourcing literature was enabled. According to an analysis of the findings, the chosen framework appears to be appropriate and encourages further research in the field along the framework perspectives.

A. Current State of Research

With its first mention in the 2000s, IS backsourcing became a field of interest in the upcoming years. Most of the papers that address the IS backsourcing phenomenon were published between 2003 and 2010, whereas only a few publications that investigated failed outsourcing arrangements appeared from 2014 to 2016. According to the main path analysis by [1], who analysed ISO research from 1992 to 2013, IS backsourcing is only mentioned as an alternative among IS sourcing possibilities.

In total, 20 papers were identified in our literature analysis, which were published between 2003 and 2016 and consisted of eleven conference papers from nine conferences and nine journal papers in nine journals (see Table 2 in the Appendix). With the literature review at hand, one overarching finding becomes immediately apparent. Backsourcing research is in a stage of infancy. This finding is based solely on the number of publications and the foci of the papers compared to the ISO research field; such as in [23], in which the authors were able to identify and analyse 95 articles that were published from 2009 to 2013 for their literature review on ISO. However, with other reviews emerging (e.g., see [63]) the topic of backsourcing seems to gain momentum.

B. Research Focus

The findings demonstrate that the focus of research is the decision process, especially the drivers for enterprises to backsource their IT services (16 papers). Most of those findings address the concrete IS backsourcing subject, whereas three articles instead investigate failures of outsourcing arrangements. Thus, currently, it seems to be the most mature branch of the IS backsourcing research stream. One reason for this domination might be related to how backsourcing is viewed. Initially viewed as a solution for poor service quality and unmet expectations, backsourcing has become a strategy for change and innovation over time. In analysing the first large wave of publications on ISO, Dibbern et al. [2] encountered a similar domination.

Unlike the literature reviews on ISO, few articles focus on the "how" question, which refers to the implementation of the IT services back to the home country of the company. In drawing parallels to other research fields, influencing factors could be found indirectly and partially matched to findings in the IS backsourcing field due to the similarity of various characteristics of transition processes. Accordingly, future research should further address the implementation aspect of the re-implementation stage of IS backsourcing.

According to the search results, a stronger focus should be laid on the implementation phase, to determine what influences the transition phase and what outcomes can be expected. Distinctions between IS backsourcing and backshoring could be examined to a similar extent as in ISO research. Switching the point of view may lead to additional insights. Integrating various stakeholder perspectives might enhance the robustness of IS backsourcing research results. Furthermore, research on hiring and re-hiring strategies should be conducted, both in IS backsourcing and ISO. Having this in mind, more research should be conducted on comparing the phenomena of backsourcing and outsourcing.

C. Research Approach

Most of the reviewed publications make use of empirical research methods (13 papers), which are dominated by interpretive (nine papers) and followed by positivist research (three papers). Interpretive research is conducted across both stages whereas positivist research only considers the "why"-stage. Descriptive research is used only once. Among the empirical research methods, case studies are by far the most popular. Non-empirical research was conducted in seven articles, in each case in a conceptual manner. The allocation of the empirical papers corresponds to the findings of [4] and [23], except that the share of the conceptual papers is higher.

Considering the current predominance from an interpretive epistemological view, a more balanced application of interpretive and positivist methods seems appropriate. As the research field is emergent, descriptive studies should be conducted as well. The obvious dominance of case study research should be complemented by a wider use of other methods (e.g., field study research and action research) and the design of research approaches.

D. Future Research

Apart from the small number of search results for IS backsourcing, future research should primarily consider all perspectives along the multi-perspective framework, following [2], [4]. Thus, one goal might be a higher pervasion of IS backsourcing research to be able to subdivide the two main stages that are specified in this paper into sub-stages according to the five-stage model. To complete the analytical framework of [4], a third perspective should be considered in future, namely, *reference theory*. Matching various approaches and their conclusions with existing theories might lead to additional insights and research questions and could function as an extension of the review at hand. Future research should be aimed at building a fundamental understanding of the phenomenon of backsourcing by varying the points of view, investigating various cases and scenarios and applying various research approaches to verify and extend previous findings.

Abstract—**The article presents a prototype of an intelligent Early Warning System based on real option approach to prospective financial assessment of Small and Medium-Sized Enterprises (SME). The described approach constitutes a continuation of development of the intelligent cockpit for managers (InKoM project), the main objective of which was to facilitate financial analysis and evaluation of economic status of a company. The current project is related to the design of smart evaluation of critical financial situations of SME using real options, domain ontology, and AI methods. The content of the knowledge is focused on essential financial concepts and relationships connected with risk assessment, taking into consideration internal and external economic and financial information. A case study based on the real option has been carried out on financial data extracted from financial information system.**

I. Introduction

TODAY, innovative methods combined with advanced financial analysis tools are required to correctly assess critical economic standings of Small and Medium-Sized Enterprises. The main stumbling block and difficulty is that managers of SMEs often do not possess solid background knowledge in financial analysis and new available IT solutions, in particular Decision Support Systems. The problem is often caused by lack of the knowledge required to correctly interpret economic indicators. This knowledge may be improved using real option approach to investment appraisal in SME.

In general, an enterprise works better on the competitive space if it tries to identify development opportunities and threats of disruption a company's leading activity. This requires implementation of prospective financial assessment in SME. Most of SME managers are not skilled enough to understand and respond to threats coming from the business environment. Real options have been applied in practice to solve such issues as just described. In addition, they are treated as the risk management instruments used to assess financial risk of high-risk development projects as well as to influence the company's ability to continue as a going concern in the future [1-2].

Taking into consideration all managerial requests and the complexity of business problems, solutions are needed to integrate managerial knowledge and computational methods so as to support intelligent analysis and decision making [3].

The aim of the paper is to present the of a prototype based on the real option approach that integrates financial knowledge, predictive models, and business reasoning to support financial assessment in Early Warning Systems. The term "real option" can be defined using the analogy to the financial option. Real option therefore means the right of its holder to buy or sell some underlying assets (basic instrument, which is usually an investment project) in specified sizes, at a fixed price and at a given time [4, p. 172]. Generally, it can be said that the real option is the right to modify an investment project in an enterprise [5, p. 269].

Thus, we demonstrate how to employ real option approach in Early Warning Systems to support financial assessment in SME with the aim of avoiding bankruptcy. In our project, it is assumed that financial knowledge is formally defined by the domain ontology. The essential part of the work is to develop a smart solution facilitating automated analysis of information available in financial databases and external data.

The paper has been structured as follows. The first part in a critical way introduces the application of Early Warning Systems in the context of financial assessment. In the succeeding section, the concept of application of real option for the purposes of investment appraisal is discussed. In section three, knowledge conceptualization and reasoning are elaborated, with proposal of an appropriate ontology. Next we present a case study explaining the prototype that refers to prospective financial assessment based on real option approach. Finally, in the last section, some conclusions are drawn and the future directions of the project discussed.

II. Critical analysis of Early Warning Systems in the context of financial analysis

Early warning is a process which allows an organization to consistently anticipate and address competitive threats. As far back as early seventies, managers of firms had started thinking about methods that would allow for early identification of opportunities and threats present in their business environment. It led to the emergence of Early Warning Systems, which were to as early as possible forewarn of approaching threats and opportunities and explore their weak signals. Many methods have been developed to analyze SME performance aimed at creating the Early Warning

System [6]. Unfortunately, they are more often based on past data, and this at present is simply not enough. The essential requirement for SME to survive in a competitive market is development of mechanisms allowing for generation of revenues from core operations in the future. In planning future activities, company's managers emphasize the need to maintain existing customers. If this is not possible, attempts are made to search for new customers. It is also necessary to analyze competitive actions, which in the near future could lead to a significant decrease in market share.

One of the main weaknesses of existing Early Warning Systems is the lack of a formal representation of the knowledge and analytical models that take into consideration both internal and external information. Managers using simple Early Warning Systems receive various alerts, but they don't know which problems should be addressed first. Moreover, these systems do not indicate for managers which suggestions are to be implemented, hence managers have to rely solely on their managerial intuition. It is therefore necessary to extend the EWS functionality.

The proposed prototype is focused on prospective information as well as value embedded in real options. Financial forecasts serve as the basis for the remedial actions that take into account contingent factors. Such activities are focused on searching for value hidden in real options, so as to take advantage of opportunities that may emerge in the future. This is not possible without extending the EWS with regard to external information. This kind of external information is not formalized, thus this extension is another challenge. Moreover, external information may be supplemented with data processing algorithms based on management accounting and finance learning tools.

III. Real options in assessing investments

Standard approach to investment appraisal is based on discounted cash flow methodology, in particular NPV (Net Present Value) analysis. This approach is currently insufficient mainly due to the high volatility of external factors affecting a company [7-8]. The commonly used net present value criterion is currently considered as static mainly because it is calculated at a given moment and does not anticipate changes that may occur in the future. As a result, the NPV criterion does not take into account the opportunity to react to new circumstances, such as [9]:

- an unexpected collapse of the market, which leads to a reduction in the business size,
- significant changes in prices, which may have a significant impact on the profitability of the project,
- an exceptionally favorable situation that allows for expanding the scope of activities.

Taking into account of the limitations of NPV criterion, address suggest to apply the concept of real options[1]. Techniques based on the net present value are still necessary and valuable, hence they should not be underestimated in any case. However, real options allow for a deeper analysis of the investment appraisal issue and somehow expand the traditional methods due to the identification of various investment possibilities embedded in the investment projects. Jahanshahi et al. [12] argues the role that real options can play in SME to increase market orientation and organizational learning, consequently providing a firm with the ability to both attain and sustain competitive advantage, particularly in a volatile environment.

The value of this flexibility is reflected in the option price (option premium); it increases if the probability of receiving new information increases and ability to risk bearing increases. The value of this flexibility is the difference between the value of the investment project with the right of managers to modify the project embedded and the value of the project in the absence of managerial discretionary to modify project. This relationship can be described as follows [see: 13]:

$$S\text{-}NPV = NPV + OV \tag{1}$$

where *S-NPV* – a strategic net present value,
NPV – a standard (static, passive, direct) net present value
OV – an option value.

The lack of flexibility is especially the main factor preventing managers from taking risk. Power and Reid [14] test empirically whether real options logic applies to small firms implementing significant changes (e.g. in technology). Their research findings imply that strategic flexibility in investment decisions is necessary for good long-run performance of small companies.

The valuation of real options is a difficult task and very often impossible to be carried out by manager of SME. It should be noted that value of real options is closely linked with high risk. A manager without advanced financial knowledge can increase the level of risk associated with running a business. Thus, it is necessary to build a prototype that will guide the manager through all the risks associated with the investment project taking into account contingency factors. The prototype also indicates additional opportunities which result from the company's environment. It is also required to create a smart analytical tool that processes signals coming from the environment and integrates them with the real option pricing module.

IV. knowledge Conceptualization and reasoning

Implementation of any development project should be preceded by a multi-faceted analysis confirming its profitability. The objective of analytical activities, mainly based on external sources, is focused on confirmation of the necessity of unconditional implementation of changes in the enterprise. After obtaining external information, it is necessary to integrate them with data describing an entity's potential to implement new projects and solutions.

The prototype includes extended analytical methods. This method is aimed at integrating data from internal reporting with external information. In the prototype, it is assumed that business knowledge is formally described using

1 The term „real option" was initially used in 1977 by S.C. Myers from *Massachusetts Institute of Technology* [10]. This concept was further developed by A.K. Dixit and R.S. Pindyck [11].

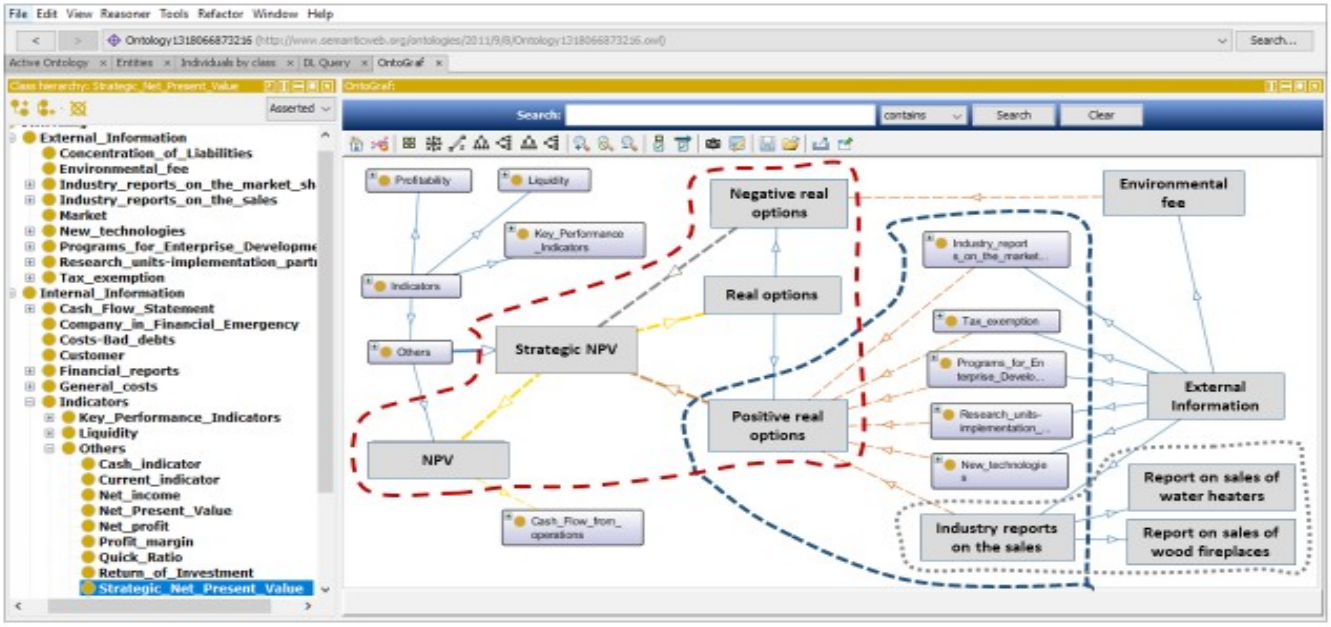

Fig. 1. An example of visualization of a semantic network of *Strategic NPV*

ontology[2], which is one of commonly used method of representing knowledge in the information systems. The ontology includes internal information and external information essential for the functioning of the company. A manager can browse hierarchy of concepts, relationships, and annotations. In addition, post conditions such as positive and negative effects of decision process execution can be defined.

The ontology has been encoded using the Protégé platform (http://protege.stanford.edu/). It is important to note that the given ontology describes only static structures, namely the financial concepts and their relationships and external information having influence on the functioning of an enterprise (especially for SME). The ontology presented in Fig. 1 shows a few concepts related to the analysis of the strategic NPV.

Figure 1 illustrates a sample visualization of external and internal information focused on the issue of the strategic NPV. There are two panels on the screenshot. The panel to the left shows taxonomic relations, while the one to the right allows for visualization of taxonomic and semantic relations between defined topics (semantic network visualization). There are two types of lines between topics: (1) the solid line represents a relation subclass-of and (2) the dashed line represents the experts' defined relationships (for example: depends on) on the figure.

Figure 1 presents topics important topics in rectangles for the analysis of the strategic NPV. The presented part of the ontology shows that *Strategic NPV* depends on standard *NPV* and *Real options*, which contain *Positive real options* and *Negative real options*. Positive real options *increase* strategic NPV, while negative real options *decrease* Strategic NPV. Instances of positive and negative real options are *External information* (for example: *Industry reports on the sales*, *Environmental fee*). This part of ontology shows to the manager, that if he wants to calculate *Strategic NPV*, he should estimate *Real options*. The manager can see that he should analyze *External information* affecting the calculation of the positive and negative values of real options. The manager can add, modify as well as retrieve topics related to the problem at hand.

Our proposal to extend the functionality of the system is based on introduction of financial ontology, containing internal and external variables related to real options, as described in Fig. 2. The system processes selected information from financial reports and business environment, subsequently forecasting a company's economic and financial situation. In a situation of a negative forecast, in addition to warning messages, it indicates the possibility of using the real options that would allow a manager to exit a critical situation. The financial ontology not only helps identify the concepts and relationships between them, but it also helps in the interpretation of the current and future situations of the company.

In order to explain the operation of the system, let's describe the vector of the input information as follows:

$$[(f_1, \ldots, f_k), (e_1, \ldots, e_l), (r_1, \ldots r_m), (\delta_1, \ldots \delta_n)] \qquad (2)$$

where $f_1, \ldots, f_k$ denote information from financial reports,
$e_1, \ldots, e_l$ information from the business environment,
$r_1, \ldots r_m$ information about real options,
$\delta_1, \ldots \delta_n$ are estimates of future changes of variable values.

2 Ontology "is an explicit specification of a conceptualization" [15, p. 907].

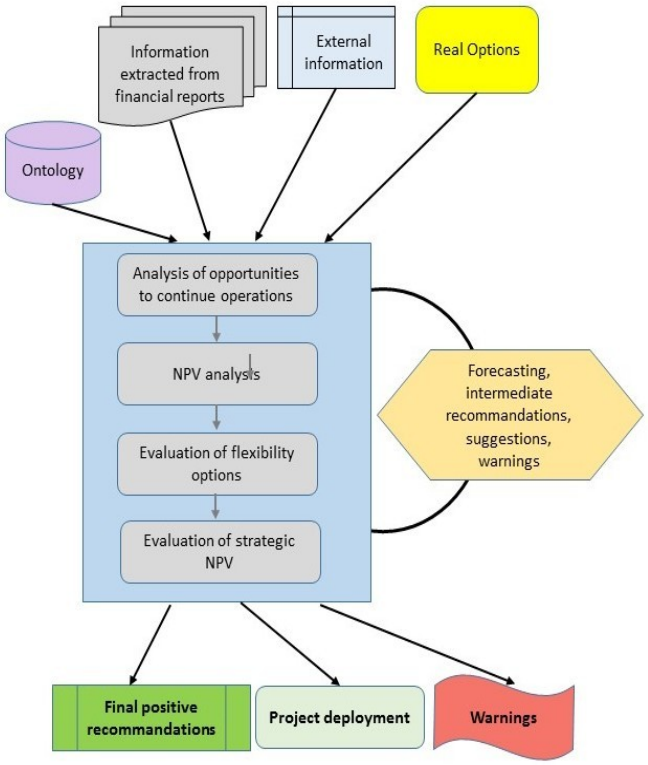

Fig. 2. Functional schema of smart EWS

This information is interpreted by the decision rules described in the ontology, for example:

if f_i ® *threshold f*
then message f-warning else message f-positive

where ® denotes a specific relationship between values of f_i and the threshold.

Depending on the values and number of thresholds, the messages can be more or less varied. If we left the output messages in this form, then the logic of our system would not be different from the classic EWS.

We have introduced several new solutions in the project. The first is the transformation of information qualification into the values of multivalued logic. An example of a transformation with regard to NPV is shown in Fig. 3.

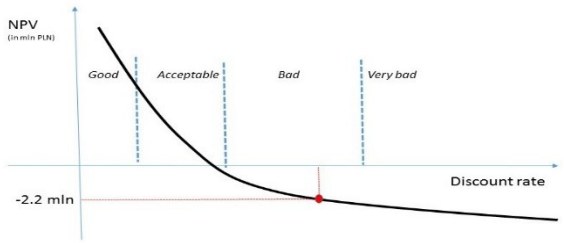

Fig. 3. Example of values transformation

In order to assess the overall situation of the company, these values (Very bad, Bad, Acceptable, and Good) can be transformed into numeric values, for example (*2,3,4,5*), and use in computational models. Additionally, a manager can give weights to variables in the range prototype *[0,1]*, where *0* is a negligible variable, and *1* is a very important variable. In the prototype, the weights of variables may be taken by default or defined by a manager.

With these assumptions, assessment of the company *S* situation can be computed in two ways: as an arithmetic average or as a geometric mean:

$$S = \Sigma (f_i * w_i + e_j, * w_j + \{r_k * w_k + \delta_l * w_l\})/m \quad (3)$$

or

$$S = \sqrt{} f_i * w_i * e_i, * w_j * \{r_k * w_k * \delta_l * w_l\}/m. \quad (4)$$

Note that the evaluation is performed twice, first without taking into account variables related to real options and estimating the increase in values resulting from accepting real options (expression $\{r_k * w_k + \delta_l * w_{lj}\}$, and the second time after accepting the real options. Interpretation of the assessment and its justification are prepared using financial ontology and data from an enterprise's information system.

The design of an inference process illustrating this concept will be discussed in the next section.

V. Case Study

To illustrate the need for real option valuation, we present the case of a project that would be rejected on the basis of traditional analytical methods. Based on valuation of flexible option to expand, we have shown that to avoid going bankrupt, the management should choose_to implement the project.

Assumptions of the case study:

- managers of a manufacturing company producing water heaters and wood fireplaces, while preparing sales forecasts, identify a significant problem with the company's ability to continue its operations,
- managers, based on their expertise and experience, foresee that if they decide to abandon development projects, the company will lose the ability to continue its operations within 5-7 years,
- when planning innovations in the enterprise, a new design of a fully ecological cogeneration fireplace meeting the most stringent ecological standards has been developed,
- the forecasted product cost suggests high selling price that does not allow for launching the project,
- it is necessary to implement changes in production technology, that would make it possible to reduce costs and offer a lower price of the new product, however, NPV analysis indicates that the project would still be unprofitable.

Due to the limited size of the article, it is not possible to indicate a detailed valuation of the real option, and thus strategic value of NPV. Such activities require a large number of calculations, calibration of input parameters, and adoption of discretionary assumptions for the valuation of future benefits. The prepared EWS prototype allows the manager to assign any rank to each source of information.

However, less experienced managers can use the hint embedded in the prototype, which suggests default solutions.

The prototype of the system presented in Fig. 2 contains next analytical steps. The ontology built into the prototype (Fig. 1) explains to the manager the basic concepts and problems associated with the sales profitability. The ontology also presents the knowledge that combines the profitability issue with the investment project appraisal. The manager receives information from the system that it is not possible to conduct development activities. The knowledge contained in ontology explains to the manager the essence of valuation of the flexibility option. The system presents a set of fundamental information needed to evaluate the flexibility option, but the information should be verified by the manager. The manager may or may not expand this information base based on his own expertise. In the analyzed company, the situation allows for initiating preparatory activities to launch the project.

Improvement of the financial situation should be the dominant objective of any manager. It is very difficult for the manager to determine the right moment to implement an investment. Contextual analysis of the impact of real options on a given project is very often beyond the scope of most SME managers. The SME manager is not in a position to take into consideration all the aspects of the development project on his own. It is often necessary to hire a consultant, which is an additional cost. Therefore, creation of a prototype that makes it possible to handle prospective analysis seems indispensable.

VI. Conclusion and Future Works

The main objective of the paper was to present foundations of a prototype based on real option approach that incorporates financial knowledge, predictive models, and business reasoning to support financial assessment in Early Warning Systems. The implemented prototype contains unique methods of prospective analysis used to assess profitability of an investment project. The novelty of the approach consists in applying real options embedded in the Early Warning System. The example is based on real data extracted from a small company. Risk of bankruptcy could be avoided by making decisions based on intelligent in-depth analysis of external information combined with the analysis of financial situation that allows for implementation of corrective solutions.

From a financial perspective, the presented case study supports the conclusion that the decision to undertake any investment cannot be based solely on estimation of standard NPV. It also requires analysis of various external factors determining decision making process. Managers of SMEs may take advantage of the proposed system that integrates financial knowledge and predictive models. Therefore, the system provides knowledge not only on the required internal information from various reports, but also from external information (which are weak signals). The proposed ontology seems to be a promising extension to Early Warning Systems. It not only improves the quality of analysis, but also enhances managerial ability to better understand relations between financial data (internal information) and various factors affecting development of the SMEs (external information).

Further work should be focused on a global process-oriented approach to financial assessment. This will not be possible without large databases of real case studies and use of knowledge possessed by experienced managers and financial analysts. For a company, the multidisciplinary approach to develop the prospective analysis in the Early Warning System could contribute to attainment of a competitive advantage and to increase its financial stability.

e-Assessment Management System for Comprehensive Assessment of Medical Students Knowledge

Jaroslav Majerník
Pavol Jozef Šafárik University in Košice, Faculty of Medicine, Trieda SNP 1, Košice, Slovakia
Email: jaroslav.majernik@upjs.sk

***Abstract*—The evaluation of students' knowledge, skills and performance is one of inseparable parts in education process. Except of various teaching approaches, the history brought also various, more or less effective assessment methods. Nowadays, thanks to the learning management systems, the e-assessment methods become more available and widespread across education institutions. The heterogeneity in usage of various assessment methods at our faculty, as well as involvement of natural subjective factors, forced us to search for the solution that can be applicable and acceptable in all study programs, courses and examinations. Furthermore, the system should be secure, intuitive and available for all teachers and their students. In this paper, we describe main principles and methodology of e-Assessment management system we implemented into the medical education for automatic assessment of students' knowledge and competences at the Faculty of Medicine in Košice, Slovakia.**

I. Introduction

PAPER based tests and oral examinations have been used as the main forms to evaluate students' knowledge for many years. Traditionally, teachers used the tests in exams to evaluate learners' knowledge obtained during educational process. Some forms of tests were also involved in course requirements to measure concept assimilation presented in lectures or classes [1]. Various clinical performance assessment tools are also used in practice education [2, 3]. However, there is still no general framework of competency assessment in medicine [4].

Advances in information and communication technologies (ICT) reduced the needs of papers and the time the teachers spent by evaluation of individual tests too. Many educational institutions already discovered advantages of modern innovative digital technologies and adopted some type of smart tools to facilitate assessment. Simulations and work-based assessments methods for specific purposes and clinical performance, including medical history taking, physical examination skills, procedural skills, clinical judgment etc. have also been used and involved in systems of medical education [5, 6]. The common electronic assessment tools are integrated either in Learning Management Systems (LMS) that offer complex modules for teaching, learning and assessment within education institution [7], or they are designed as individual or separate systems to fully manage all assessment needs, and are generally known as Assessment Management Systems (AMS). In both cases, assessment practices serve teachers and students as a part of continual teaching and learning.

In general, the e-Assessment management systems can be classified as systems based either on client-server architecture or as web-based services [8]. Nowadays, the majority of administrators prefer to adopt online available AMS, where everything can be organized through networks and without the needs to use any papers. Except of these environmental factors, there is also no need to install any clients on students' devices. Thus, the tests can be accessed anytime and anywhere, no matter which platform is used to manage assessment procedures.

The higher education benefits from the e-assessment as it assists learning and determines the effectiveness of the education system. e-Assessment systems have a great potential to improve or replace traditional paper-based assessment processes. It is because they allow users development and managing of various types of questions and tests; assigning of students to the tests/exams; setting of dates, times and places/rooms for the tests/exams; summarizing of tests results; analysing of questions' quality etc. In addition, a well implemented e-Assessment system and understood by the teachers can save the time needed to organize and evaluate exams. In this point of view, their performance is also positively affected as the marking load is reduced and the results are available immediately after the exam is completed [9]. However, the assessment should have clear purpose and has to match the educational programmes and learning outcomes. Thus, any assessment method must be reproducible to show similar results on different occasions and valid to reflect appropriate

This work was not supported by any organization

representation of educational content. Finally, the e-Assessment systems are considered comfortable in all assessment related tasks, including measurement and documentation of knowledge, skills, and attitudes of individual learner and/or learning community [10, 11, 12].

The e-Assessment technology principles should be based on methodology that, except of others, allow examiners to create a bank of questions, to generate different types of tests, to mix questions and/or answers in the tests, to specify exact dates and times when the learners must take the exams and to automatically score and share test results to learners. The capabilities of the e-Assessment systems should be also focused on the ways how the users interact with the systems and how it is adopted to their needs.

Aiming to solve the assessment issues in a complex and comprehensive way, we had to consider various factors and questions. Is there any system that will meet the requirements of our teachers and that can be integrated at institutional level? Do the systems allow specifying assessment plans in relation to the learning outcomes? How to grant the permissions of different groups of users to access the system? These and many other similar questions were solved and discussed during our initiative and resulted in a satisfying solution that was accepted very well by both the teachers as well as by the learners.

II. Materials and Methods

To find and/or design the AMS that will be well accepted by all of our teachers, we conducted a survey in which we wanted to discover what kind of assessment methods are currently used, what are the preferred forms to evaluate students' knowledge during diagnostic, formative and summative exams, and what are/should be the most preferred features of assessment system.

The survey was realized online using Google forms, and 65 teachers of our faculty participated on it. The findings illustrated wide usage of ICT in everyday praxis, however, the engagement with e-Assessment was only 12,3%, i.e. only 8 of 65 respondents actively utilize some electronic form to evaluate students' knowledge. The responses resulted in the list of features our teachers require from AMS. These features included: possibilities to test large number of students at the same time; place/room independence; protected access and high security of all exams related data; repository of questions and tests; multimedia support in tests; limited access to registered students only; easy to use interface in national language; reporting per examination; and not surprisingly for academic environment, low or no financial expenses.

Except of the above mentioned features, the technicians had to consider numerous technical and administrative related aspects too. Thus, the fully functional e−Assessment system required to solve the tasks related to the safe and reliable server(s), network infrastructure, computer classrooms, and professional administrative staff support.

Comparing the features, technical requirements and supporting documentation of various commercial (AEFIS, beSocratic, Blackboard Learn, Digication AMS, eLumen, LiveText, rGrade, Taskstream) and open-source (openIGOR, Rogō, Unicon, TAO) assessment systems, we decided to test the Rogō system. The Rogō AMS was developed at the University of Nottingham together with partner institutions, now involved in development community. The results of the tests and the functionalities offered in Rogō convinced us to integrate the system into the ICT infrastructure of the faculty including Slovak language pack developed during testing phase. Our decision was supported also by abilities of the system to integrate third party systems, including LDAP authentication and functionalities, which allow a VLE or other LMS to launch and single sign into Rogō.

III. Results

The integration of AMS was fully adopted to the faculty infrastructure and requirements. The hierarchic structure reflects the faculty units, study fields, courses with learning objectives, different assessment methods and the users with different roles in the system as it is shown on Figure 1.

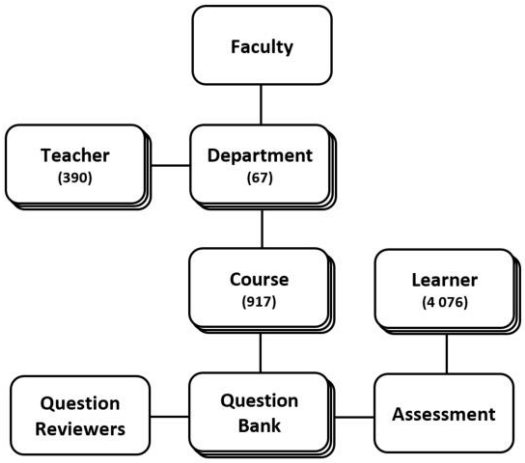

Fig. 1 The structure of e-assessment management system integrated at the Faculty of Medicine in Košice.

All authorised users of the system (teachers, question reviewers and learners) were connected to the accounts of faculty's LMS. Thus, 390 teachers and 4,076 learners were able to use the system without any registration procedures. Similarly, the full list of all courses (917) was imported to the system. Information related to the course registration lists ensured the teachers create questions and examination papers only within their courses and the learners do the exams only in courses they are enrolled in.

Depending on the course management, the Question Banks of particular courses were created by guarantors or by the team of teachers associated with courses. Naturally, the questions can be imported and/or added manually if there is no previously created electronic list of questions. Almost any type of questions is supported that makes the assessment easily adjustable to various types of courses as well as their

learning objectives. Except of commonly used Multiple Choice Questions (MCQ) the teachers can create questions like Area, Calculation, Dichotomous, Extended Matching, Fill-in-the-Blank, Image Hotspot, Labelling, Likert Scale, Matrix, Multiple Response, Random Question Block, Ranking, Script Concordance Test (SCT), Textbox or True-False as it is defined in the Table 1. The users can combine all these question types in Random Question Blocks if there is a requirement to organize exams with randomly generated questions. Once the questions are stored in the Question Bank then it is possible to export them to external QTI or Rogō files and use them in other systems or in other Rogō instances.

Considering various purposes for which the students are assessed and relations to in-course or end of course teaching activities, there was a need to organise different types of assessment. The most frequent types included summative, formative and diagnostic exams. In summative assessment, the learner performance against the standard knowledge is awarded by grades. Then, the grade can either be a part of in-course assessment, or assessment at the end of a course. Formative assessment is organized during the course, and provides feedback to learners. While the summative assessment is used for certification, the formative assessment helps students improve their learning as the failure rate can be reduced and the performance can be increased. Diagnostic assessment is used to evaluate the level of learning that has been achieved by learners. In general, it can be used at the beginning of the course to determine the level of knowledge, or at the end of lessons to know how the learners understood the topics. However, diagnostic assessment does not provide tools of feedback as it is in formative assessment. Individual types of supported assessment methods are show and described in Figure 2.

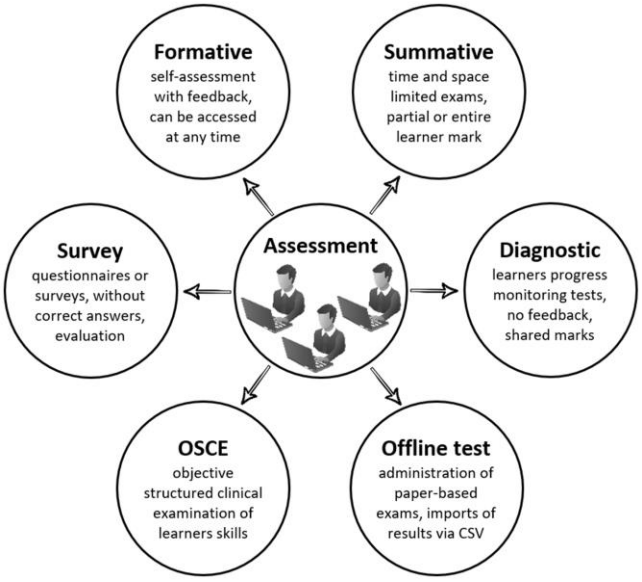

Fig. 2 Assessment methods integrated in e-assessment management system.

The questions for various assessments can be chosen from the same Question Bank of the course or group of courses.

TABLE I.
TYPES OF SUPPORTED QUESTIONS IN E-ASSESSMENT SYSTEM.

Question type	Purpose and description
Area	To draw a shape around a specified part of an image. The most commonly used formats including JPG, GIF and PNG are supported.
Calculation	To use one or more variables (random values) specified in the task by the teacher and to define formula for verification of calculated value given by the learner in the answer field.
Dichotomous	To present a lead-in question together with a number of stems displayed below. The learner must select either True or False for each stem.
Extended Matching	To present multiple scenarios based around a common theme. Each question has the same list of options from which the learner is asked to choose the answer.
Fill-in-the-Blank	An alternative to open ended question. Used to allow learners fill-in the blank textboxes or to select answer from dropdown lists.
Image Hotspot	To identify parts of the graphic, e.g. anatomical structures, body regions etc. One question may cover up to 10 different items to be identified by the learner.
Labelling	To place labels (one label can only be used once), using drag and drop method, to the spaces shown over the graphic.
Likert Scale	To list the answers with the support of both Likert Scales and Semantic Differential questions.
Matrix	To reduce test space via better visual appearance. The questions are presented in rows with possible answers as columns. Radio buttons are used as only one answer per row can be selected.
Multiple Choice	To choose correct answer from up to 20 options. Radio buttons are used in the interface so that only one option can be selected.
Multiple Response	To identify various number of correct options. Each option can be selected or unselected.
Ranking	To see if the learner can put various options in the correct order.
Script Concordance Test	To assess reasoning skills in clinical situations, specifically those with uncertain scenarios.
Textbox	To collect written answers, e.g. open-ended textual questions used for surveys.
TrueFalse	To confirm statement that is displayed with an option that is either True or False.

The system holds large amount of highly important data which must be kept safe at all times. Therefore, the users' data, question banks, exam tests, results as well as all the information stored in AMS are secured using several protection levels. From the security point of view, it is very important that the summative exams are not available anytime and anywhere. The students should not find the tests before the exam dates and the results must be delivered to them securely. On the other hand, the security issues are not necessary to be so strict in formative assessments.

Summative assessments can only be taken by learners assigned to the course during the time allocated to the exam in specific allocated room or place. Thus, the summative tests are not accessible to the students anywhere and at any other time. To increase security, the tests and all questions are locked and cannot be amended to ensure that the questions in the bank accurately match the results of the exam. The protection levels used in summative exams are shown in Figure 3.

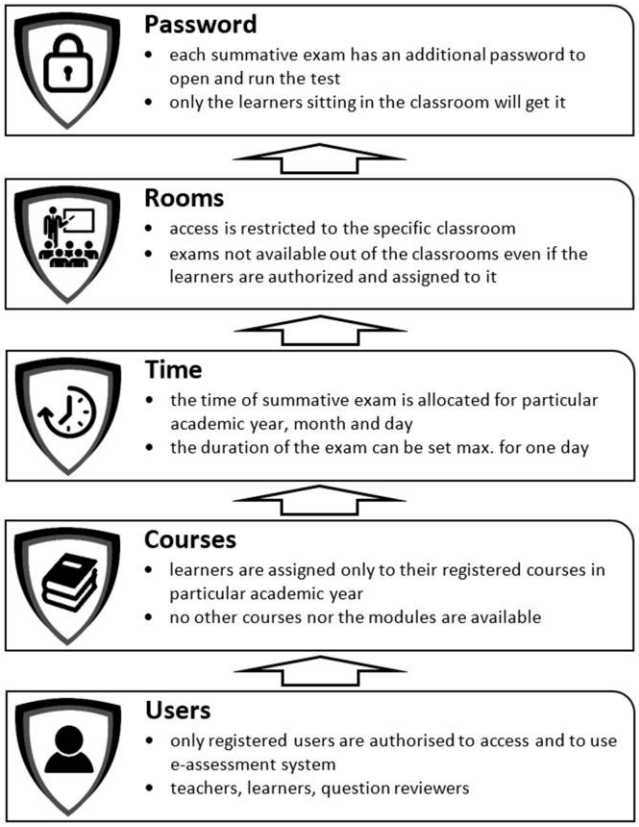

Fig. 3 Security levels applied in summative assessment.

Despite of combination of various security levels there were still some doubts of teachers related to the personal authentication of learners to be sure that the learner completing the assessment is learner that confirmed its identity. Regarding the importance of particular type of assessment, the summative types have to be delivered under invigilated conditions using secure systems. Other assessment forms, where no grading of the results is required, need not to be additionally secured. Thus, for example the formative assessments can be opened to be completed anytime, anywhere and even using learners own devices connected either to the faculty or commercial network. On the other hand, all summative exams at the faculty are organized using advanced mechanisms for personal as well as for equipment identification. Figure 4 shows main concept of additional summative assessment security mechanism we implemented to ensure the summative exams are performed personally by the learners.

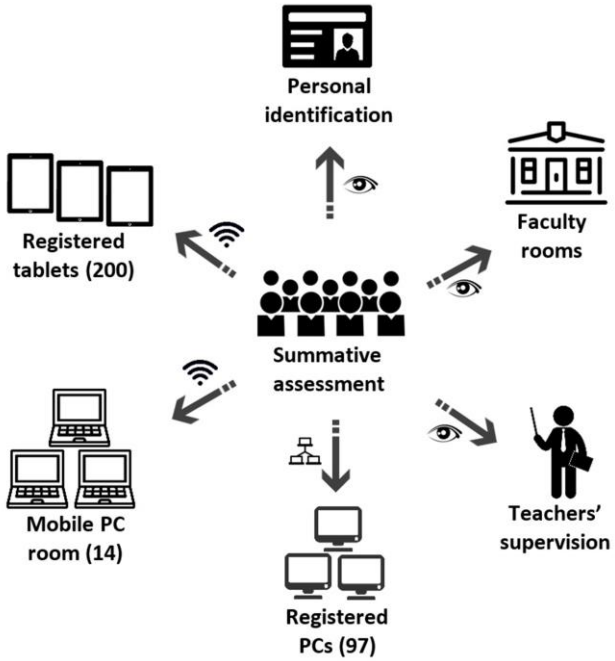

Fig. 4 Additional security mechanisms incorporated into the summative assessments.

All summative exams are organized only in designated faculty computer classrooms and/or lecture halls depending on the size of tested group. The learners are identified by the teacher(s) before they will enter the examination room. Learners' personal identification cards can be used in all lecture halls to register attendance. One or more teachers supervise the summative examination and offer the support to the learners if they have some technical problems during exam. Six computer classrooms with 97 PCs all together are used to test smaller groups of learners. All computers are protected and the internet connection is blocked. The e-Assessment is the only available service during the exams. If the test is restricted to the particular room, then it is not possible to see and open it in another room even if the learner is authorized to perform it. Small groups of learners can be also tested everywhere at the faculty using mobile computer classroom where the connection to the e-Assessment system is realized through protected and hidden WiFi network that is a part of that mobile classroom. However, the biggest challenge was to assess the mass of all learners in particular study field. Therefore, we built a network of secured wireless hotspots across main lecture halls (12 all together). This network has also restricted

access limited to the e-assessment system. In these lecture halls, the learners are doing the summative exams using tablets (200 learners can do the exam in one lecture hall). The tablets are set to access the exams only and everything is preloaded. So the learners are only asked to login to the system, to enter the exam's password that is announced by the teacher once the exam will start and to do the exam.

The AMS is also prepared to solve some problems in the case of unexpected events. The most frequently mentioned doubts of the teachers during their first exams related to the network failures or problems with computer hardware. The system registers each activity of the learners during exam. Therefore, if there is a network failure or computer related problem and AMS cannot be reached, then the assignment can be extended until the problem is solved. Then, the learner can be logged into the system again and continues to solve the exam with all previously marked answers. However, during almost two years' experience we noticed only one problem related to WiFi failure and no problems with PCs. So, the likelihood of such failures is very low.

The system was successfully implemented into the faculty infrastructure and the number of involved teachers is continuously growing. During the period of almost two academic years, the teachers generated almost 1,200 summative exams with more than 8,500 tests and more than 46,000 questions in their question banks.

IV. Conclusion

Implementation of AMS into the education at our faculty minimized the subjective assessment factors and saved the time of our teachers. Of course, many of them disagreed when they started to use it. Initially, they were loaded by the same tasks and problems as it was in paper-based forms. It was because they had to spend time by preparing questions and organizing of all assessment issues. Teachers mind was changed once they understood this is a long-term investment, in which the lifecycle of e-assessment material will save considerable development and supporting workload. Integration and adaptation of AMS brought also many other advantages, as reported by the teachers. These include possibilities to generate both the summative and formative exams with various types of questions; to follow progress in individual learners through stored results; to obtain course feedback or to identify problematic parts in taught topics via analysis of collected answers.

In the next stage of our work we plan to increase the awareness of formative assessment benefits among our teachers to be utilized more frequently in their curricula. The great potential of formative assessment is in instant feedback and continuous monitoring of learners' progress through which they can identify areas of their weakness and are motivated to study for better understanding of particular topics before final summative exams will take place.

The teachers have variety of reasons to use assessment tools, including to pass or fail students, to grade students, to select best ones for future courses, to prove what students have learnt, to reveal strengths and weaknesses of both students and courses, and many others. When implementing an AMS, it is necessary to clarify requirements and needs of particular educational institutions and staff working at these institutions. Only the well fitted system can be accepted across whole institution, can satisfy the need of users and may have positive effect on overall performance.

Acknowledgment

Results presented in this work were obtained with the support of the national agency's grant KEGA 017UPJS-4/2016 "Visualization of education in human anatomy using video records of dissections and multimedia teaching materials".

***Abstract*—The article discusses the importance of the recommendation systems based on data mining mechanisms targeting the e-commerce industry. The article focuses on the use of clustering algorithms to conduct customer segmentation. Results of the operation of many clustering algorithms in segmentation inspired by the RFM method are presented, and the method of collective clustering using the positive effects of each algorithm is separately presented.**

I. Introduction

THE first seminars and conferences of the 90s on advisory systems [1],[2],[3] were a significant stimulus for the rapid interest in the methods and techniques of automation of recommendations not only in practice, but also by research. In recent years, under the influence of IT development, social networks, and artificial intelligence methods, the concept of the recommendation system and the scope of its main functionalities has significantly expanded. Today, the recommendation system constitutes a complex interactive system that allows one to determine the rank of a product or preferences that the customer should assign to a given product or group of products [4]. In the literature, this system is considered in three main perspectives. From the managerial perspective, the recommendation system is a decision support system that uses large, heterogeneous data and mechanisms generating recommendations related to the sales strategy and promotion of the products offered. From the client's perspective, it is an advisory system facilitating selection of products in accordance with one's interests, needs, and preferences. From an IT perspective, the recommendation system is an interactive computing platform containing a number of data analysis and exploration models, integrated with transactional systems of the online store and the environment. This platform must guarantee not only access to various information resources, but also scalability of applications operating on a large number of information collections.

The specific economic benefits of a personalized recommendation achieved by e-commerce tycoons (Amazon, Alibaba, eBay, Booking, etc.) have proven the increasing effectiveness of recommendations systems. It has resulted not only in increased sales and marketing effectiveness, but also in significant analytical and decision support for marketing managers. Modern recommendation systems are not limited to giving the recommendation *"You bought this product, but others who bought it, bought / watched X, Y, Z products"*. Many of them have based their recommendations on the customer profile, product characteristics, behavioral, and psychological analysis of customers.

Currently, the systems are distinguished by four categories of advisory mechanisms: recommendation by collaborative filtering of information, content-based recommendation, knowledge-based recommendation, and hybrid recommendation [5],[6],[7],[8],[9],[10]. Recommendation by collaborative filtering is the most common method based on recommending products highly rated by clients with similar profile and preferences [11],[12],[13]. The key issues here are: designation of the similarity between clients and choosing the customer segmentation method. These issues will be discussed in more detail later in the article. The content-based recommendation is founded on the analysis and data mining of products purchased by the customer [1],[14]. In contrast to the previous method, the key issue here is to analyze a customer's purchase history and determine the similarity of the products. The third group of methods builds recommendations based on analysis of product features with reference to its usefulness for the client [15]. In order to take advantage and reduce the negative features of the aforementioned methods, hybrid recommendation systems are increasingly being designed [16],[17].

For several years, we have also been observing a growing interest in recommendation systems by owners and managers of online internet shops in Poland. In 2010, every third online shop used a recommendation based on a simple analysis of CBR and Business Intelligence systems [18]. In recent years in Poland, artificial intelligence, personalized recommendation, and digital marketing have dominated the orientation of developers of e-commerce systems which until recently had focused on the efficiency of shopping services [19]. Currently, almost all big online stores use recommendation systems. However, these systems are to a large extent based on a simple business analytics, limited computational intelligence and reduced possibility of dynamic customer profiling.

The aim of the article is to present methods of analysis and profiling of clients available in the Upsaily[1] recommendation system targeting online internet stores. It is a hybrid system combining recommendation techniques through collaborative filtering and through contextual analysis. In the development of recommendations, in addition to transactional data, the system also uses geo-location and social network data. The data is a source of information for many clustering algorithms in the system. These algorithms can work autonomously or collectively, cooperating with each other in order to achieve semantically rich segmentation that is interesting in business interpretations. This second approach is the subject of the article. Although the source data set is the same, the innovativeness of the solution manifests itself in the selection of algorithms; each of them was selected from a different computing class and applies different similarity criteria. Among the algorithms, in addition to the commonly used k-means that uses Euclidean distance measure, we chose for the Gaussian Mixture Model based on probability distributions the DBSCAN algorithm taking into account the density of observation and the RMF involving the manager engagement. The unification of clustering results in our application is specific to the e-commerce applications – not all the clusters are used, but only one or several clusters. The cluster selection criteria include both statistical metrics as well as external, mainly economic, criteria.

The structure of the article is as follows. The next section describes the main functionalities of the Upsaily recommendation system and sketches its functional architecture. The third section defines the problem of individual and collective clustering together with descriptions of the applied algorithms. The concepts of similarity and criteria for unification of clustering results have also been outlined. The last section of the article describes the experiments carried out and further shows the advantages of collective clustering on real marketing data.

II. Functional Architecture and Functionalities of Upsaily System

The Upsaily system, based on the B2C model, is oriented towards current customers of the online internet shops. In the system database, not only all customer transactions are stored, but also basic data about their demographic and behavioral profile. The system is able to record customer reactions to offers directed at them through various contact channels. Functionally, the system can be classified as a Customer Intelligence solution, i.e. the one whose primary interest is current customers, and the aim is to increase customer satisfaction that translate into increasing turnover through the Based on literature [21],[22],[23],[24] and drawing conclusions from the research carried out as part of the RTOM project [25], the schema of advanced data analysis in marketing has been proposed (fig. 2). The schema is helpful in organizing marketing activities. Depending on the specific purpose, a group of clients to be covered by the campaign should be selected. In general, for the defined clients, the subject of the campaign is selected, e.g. product groups that

customers making follow-up purchases, increasing the value of individual orders by cross-selling or more valuable products (up-selling). The immediate goal of the system is not to help in acquiring new customers. The Customer Intelligence approach is related to conducting analytical activities leading to creation of a clear image of the customer so that one can find the most valuable clients and send them a personalized marketing message [20].

The results of research conducted as part of the RTOM project on Polish online stores operating in various industries that showed that in each of them over 75% of all customers are one-off customers, meaning they never returned to the store after making a purchase form the basis of such orientation of the system. Analysis of the average value of the order for a one-off customer shows that it is lower than for customers who make subsequent purchase. Interestingly, it can be noticed that the general trend of an increase in the average value of the order with the increase in customer loyalty expressed in the number of purchases made by them. This observation is presented in Figure 1. The average value of orders have been hidden due to the company's confidentiality. From this observation, it was concluded that it is worth sacrificing the resources of the online store to build customer loyalty, for the simple fact that a loyal customer is ultimately more valuable than a one-off customer.

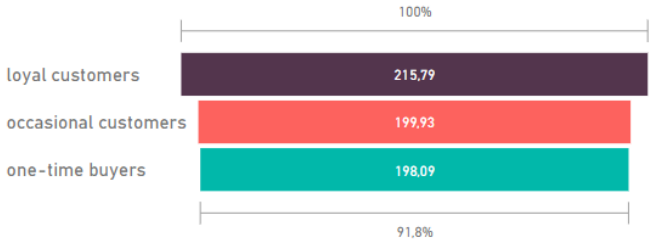

Fig. 1 Graph of the dependence of the average order value on the total number of orders placed by customers.

It should also be pointed out that acquisition of a new customer is always related to the extra cost to be incurred to reach the customer with the marketing message in a selected medium. Usually by acquiring a client then sending them a general message. Without knowing the customer's previous transactions, we are unable to propose an effective offer tailored to client's preferences, therefore in many cases the presentation of a marketing message will not cause projected customer reaction. In case of communication with current clients whose contact details are available and for whom all necessary marketing consents are established - at least at the assumptions level, it can be stated that reaching the customer should cost significantly less and the effectiveness of messages should be definitely higher.

[1]Upsaily system was developed by the Unity S.A., Wrocław, in the framework of the Real-Time Omnichannel Marketing (RTOM) project, RPO WD 2014-2020.

they will potentially be interested in. The final stage is defining the conditions under which customers will be offered participation in the campaign. As the schema shows, cluster algorithms have a wide application in this approach, and this will be shown later in the article.

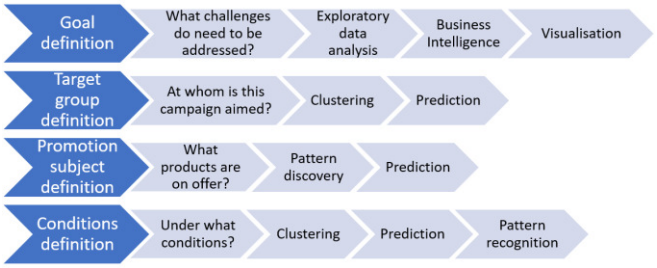

Fig. 2 Stages of building a marketing message with the proposal of using methods and tools for data analysis.

The functional architecture of the recommendation system Upsaily is presented in Figure 3. The Upsaily system collects data from many sources, but the basis of its analysis is transactional data. Data from other sources such as marketing automation systems, social media, systems analyzing activity on the store's website enrich the customer profile and, thus, expand the set of input data for analytical modules that, thanks to them, are able to provide better analyzes and better predictive models. The research platform on which the experiments are carried out has a significant place in the architecture of the system.

These experiments are evaluated in terms of business suitability and when their effects are positive, then they are transformed into regular modules operating in a production manner.

The system information outputs are integrated with:

- Marketing panel or application presenting the results of conducted analyzes, visualizing identified trends, found patterns, and segmentation effects. The recipient of this application are primarily managers and marketing analysts who, in using it, expand their own knowledge on the clients and their behaviors,
- A real-time recommender, an application whose aim is to offer an online store an offer that is as congruent as possible with its needs.
- Module "*campaign for today*", which is based on discovered trends and customer behavior patterns, at the moment of launching it is able to automatically indicate groups of customers, and the product that they may be interested in at that moment.

The results of the Upsaily system will be detailed in the next sections of the article.

III. COLLECTIVE CLUSTERING ASSESSMENT METHODS

There are many algorithms that can be used in collective clustering approach [26], [22], [23]. In the project the composition idea was based on maximum variability and differentiation of clustering paradigms. Therefore the following algorithms were chosen:

- k-means based on the Euclidean distance between observations,
- Bisecting k-means acting on a similar basis to k-means, however, starting with all the observations in one cluster and then dividing the cluster into 2 sub-clusters, using the k-means algorithm,
- Gaussian Mixture Model (GMM), which is a probabilistic model based on the assumption that a particular feature has a finite number of normal distributions,
- DBSCAN identifying clusters by measuring density as the number of observations in the designated area. If the density is greater than the density of observations belonging to other clusters, then the defined area is identified as a cluster.

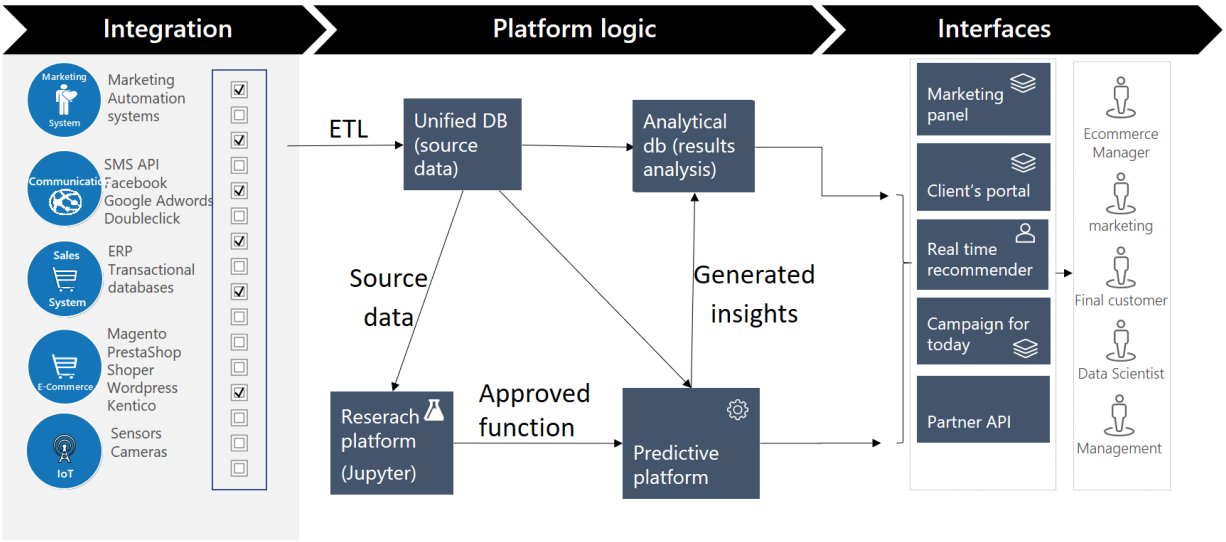

Fig. 3 Functional architecture of the Upsaily system.

Usually the results of clustering algorithms are evaluated according to internal and external criteria. The internal criteria relate to the hierarchy of clusters, taking into account the similarity of observations within clusters and the similarity

between clusters. The Davies-Bouldin[2] and Dunn[3] metrics are usually applied for assessment measures. In addition to the mentioned measures, other functions of assessment are used, such as the silhouette index, measures of cluster cohesion, cluster separation measure, and intra-class scattering matrix [26],[27].

According to external criteria, the results of clustering are evaluated using external data, not considered in the clustering process. Such data are observations which membership in the cluster is assigned earlier by experts. Then the assessment of clustering results from comparing of the content of clusters marked by experts with clusters created by the algorithm. Among the measures used, one should mention the clusters homogeneity index[4] , Jaccard index[5], Rand index[6] . In addition to the specified measures of the assessment, other indicators are also used, such as Kappa, F-score, Fowkes-Mallows index, etc. [26],[27].

In the case of using many clustering algorithms, the obtained results usually differ from each other not only by the number and hierarchy of clusters, but also by the allocation of observations to clusters. In the article, we treat the set of algorithms as a collective of experts whose task is to make the grouping of the set of observations from the business point of view as best as possible. Discrepancies in grouping that appear in the results of the algorithms must be minimized. The solution to this problem is determined by the unification process.

In order to assess the results of clustering, it is often helpful to assign a category to collected observations. In the case of very large data sets, it is not possible to assign all observations by experts. Therefore, it has been proposed to enable the assignment of observation to the clusters through decision rules that define clusters selected by the expert, in the form:

$$X_i \in C_j \mid if\ [(w_{11} \cap w_{12} \cap \ldots \cap w_{1k}) \cup (w_{21} \cap w_{22} \cap \ldots \cap w_{2m})\ \ldots]$$

Where Xi is a given observation, C_j is a cluster in the conditional expression. Attributes used in conditional clauses indicate their importance and usefulness in the characteristics of clusters.

The decision rules are determined by the algorithm of inductive decision tree algorithm C4.5 [28]. These rules make in possible, on the one hand, to interpret the obtained clusters and, on the other hand, to symbolically determine the observations belonging to individual clusters. This solution enable finding of similar semantic clusters generated by different algorithms. The symbolic interpretation of clusters is complemented graphically, which facilitates a quick identification of similar clusters. It should be noted that these works generally require significant involvement of marketing analysts.

In general, in the recommendation systems, the manager is only interested in a few clusters describing similar clients, similar products, or similar transactions. Therefore, for the analyst the first task involves identifying clusters that are still subject to unification. Although the task can be performed algorithmically, our experience has shown that much better results are obtained through selection of clusters by the analyst. If the visual selection is difficult, finding for a cluster C_i, a counterpart among clusters $C_j \in C_k$ obtained from another algorithm, then the formula of similarity between clusters $S(C_i,C_j)$ can be applied:

$$S(C_i,C_j) = max\ (|C_i \cap C_j| / |C_i|).$$

In cases where the cluster's observations C_i are distributed into several clusters from C_k, the assignment should take into account the distribution of S values and the weights of related cluster similarities.

After selecting the clusters obtained from different algorithms, one can start unifying the results. There are many methods of unification [29]. The most commonly used methods are the following:

- Consensus methods [30],[31],[32],[33], which are used more in the first phase of unification to create initial clusterization than to unify the results
- Multi-criterial grouping methods [30],[31] are mainly used to harmonize the criteria of different algorithms,
- Clustering methods supported by domain knowledge [35],[36],.

The last group of unification methods was used in the Upsaily system. The domain knowledge of marketing has been used to direct the unification process of selected clusters. In the system, the earlier created decision rules were used to govern the process of unification, in particular, the conditional expressions of which are treated as grouping constraints. The idea of the proposed method consists in determining semantic relationships-constraints indicating observations that must be included in the cluster (called must-link), and those that

[2] The Davies-Bouldin index is computed according to the formula: $DB = 0.5n\Sigma\ max\ ((si + sj) / d(ci,cj)$ where n is the number of clusters, the cluster centroids, si and sj mean d distances between the elements of a given cluster and the centroid The algorithm that generates the smallest value of the DB indicator is considered the best according to the criterion of internal evaluation.

[3] The Dunn index is calculated according to the formula: $D = min\ (d(i,j) / max\ d'(k)$ where $d(i,j)$ means the distance between clusters i i j and $d'(k)$ the measure of distances within the cluster k. The Dunn index focuses on cluster density and distances between cluster. Preferred algorithms according to the Dunn index are those that achieve high index values.

[4] Cluster homogeneity index is computed according to the formula: $CH = 1/N\ \Sigma max\ |\ m \cup d\ |$ where M is the number of clusters created by the algorithm, D is the number of expert classes.

[5] The Jaccard index measures the similarity between two sets of observations according to the following formula: $WJ = TP / (TP + FP + FN)$, where TP means True Positive error, FP False Positive, FN False Negative. In the case of two identical sets of $WJ = 1$.

[6] The Rand measure is calculated according to the formula: $WR = (TP + TN) / (TP + FP + TN + FN)$. The Rand index, as well as the previous ones, is based on a comparison with the benchmark given by an expert. It informs about the similarity of the assessment of correct decisions between the results of the clustering algorithm and the benchmark.

should not be included in it (called cannot-link). In order to improve the quality of clusters, fuzzy logic is proposed in some works [37],[38],[39] or characteristics of clusters such as values of inter-cluster distances, density [40], [41].

Let us now follow the entire unification process step by step aiming to achieve consensus on the content of the final clusters without a significant loss of quality of the partitions. Let us assume that they were pre-designated as similar two clusters C_j i C_l, each generated by a different algorithm. As indicated, the interpretation of each cluster is given in the form of decision rules, namely:

C_j | *if* $[(w'_{11} \cap w'_{12} \cap ... \cap w'_{1k}) \cup (w'_{21} \cap w'_{22} \cap ... \cap w'_{2m})$ ...]

C_l | *if* $[(w''_{11} \cap w''_{12} \cap ... \cap w''_{1k}) \cup (w''_{21} \cap w''_{22} \cap ... \cap w''_{2m})$ ...]

The final cluster can be created by merging of conditions containing variables (attributes) indicated by the analyst based on domain knowledge. This operation can be called a subsumption according to which the more detailed condition are covered with a less detailed one. However, the resulting cluster may contain too many observations that are too far away from the class sought (as shown in Fig.4). In narrowing the cluster's space, the observations given earlier by the expert might help, defined as a must-link or cannot-link marked in Fig. 4 in green and red respectively.

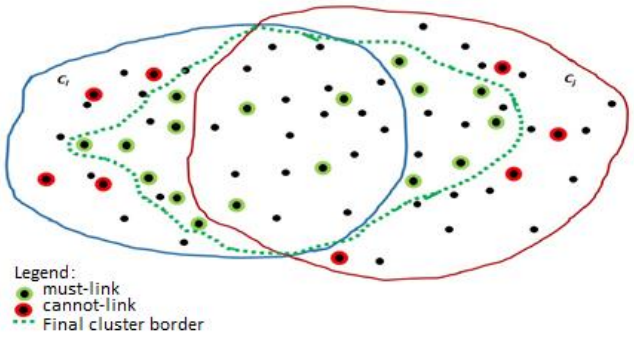

Fig. 4 Example of space of merged clusters.

The boundary of the final cluster (green dotted line) is determined between the sum of observations belonging to two clusters minus the surroundings of ε observations belonging to the *can not-link* relationship and the intersection of the observation plus the surroundings ε observations belonging to the *must-link* relationship. It can therefore be noted that the unified cluster includes observations lying in the space $|C_i \cup C_j|$ - ε *Xi/cannot-link* and $|C_i \cap C_j|$ + ε *Xi/must-link*. The radius of the surroundings ε can be determined based on ½ distance between the closest observations belonging to the *can not-link* and *must-link* relationships.

After the first unification of clusters, the process should be repeated for all similar clusters obtained from all algorithms. It should be noted that the order in which the clusters are selected influences the calculation time. We suggest choosing the most numerous clusters of interest in the first place. The next chapter will show examples of unification of the results of collective clustering.

Due to the thematic orientation of the conference and the restricted volume of the article in the next chapter, we will concentrate only on the business assessment of the results of clustering (domain knowledge). The RFM analysis will be used which is a traditional approach to analyze the customer behavior in the retail industry. Its acronym comes from the words "recency" (period from the last purchase), "frequency", and "monetary value". In this type of analysis, customers are divided into groups, based on information on time which has elapsed from last purchases, how often they make purchases, and how much money they spent (see [42]).

The following observations explain why RFM is interesting for retail companies:

- Customers who have recently made purchases are more likely to make a new purchase soon
- Customers who frequently make purchases are more likely to do more shopping
- Customers who spend a lot of money are more likely to spend more money

Each of these observations corresponds to one of the dimensions of RFM.

In the next section, the usefulness of this approach for assessing clustering algorithms is shown on the real marketing data.

IV. The Results of Experimental Research

In order to show the usefulness of the collective clustering method in specific business conditions, this chapter presents an experiment aimed at finding customer segments with similar behavior on the market. The clustering method should support a process of customer assignment to particular segment, assessment of proposed segments and interpretation of characteristics of these segments. The segmentation example was inspired by the RFM method. The customer is described by the following characteristics: frequency of their purchase (frequency dimension), the number of days which has passed since the last order (recency dimension) and the average order value (monetary value). We extended the customer description by information about the number of orders. Such dimension is essential in the case of an online store in order to determine the loyalty customer. The customers were divided into 6 segments. For each segment, we calculated its value (the sum of all customers' orders from a given segment). The number 6 was chosen arbitrarily. Marketing employees were able to prepare 6 different marketing communication policies addressed to individual customers. With more segments, it would be very difficult for the marketing analyst to interpret segments and subsequently develop a tailored communication policy for selected customers. A larger number of segments will be justified only if the automatic recommendation mechanism uses this segmentation.

The experiment was carried out using three clustering algorithms: bisecting k-means, Gaussian Mixture Model and

DBSCAN[7]. After each experiment, an expert evaluated the results of the segmentation. The analysis covered 56 237 customers who made at least 2 purchases in the online store.

When assessing segmentation, it is very helpful to visualize the data. Having 4 dimensions and ability to present it on surface (with only two dimensions). We used two methods for projecting the multidimensional space into a smaller number of dimensions. In order to prepare the visualization in the experiment, the four dimensions were reduced to two (X and Y), while the color means the segment number to which the given customer was assigned. One of those methods is The Principal Component Analysis[8] (PCA). PCA is a popular technique for reducing multidimensional space [43].

An example of RFM segmentation using the k-means algorithm and visualization using the PCA method is presented in Figure 5. One dot represents one real customer on the visualization (on left hand side of picture). After hovering over the selected dot, one can read the values describing the selected customer. This solution will help the marketing analyst to understand the prepared segments.

In the right part of the report there are funnel charts, presenting the average value of the given dimension attribute in individual segments; for example, average customer from segment 1 purchases with frequency of 14.22 days.

The column chart located in the bottom right corner of the report shows the sum of customers' orders in a given segments. It can therefore be observed that the highest revenue was generated by customers from segment no. 6, while the smallest in segment no. 5.

Another method of reducing dimensions that is useful for visualization is the Uniform Manifold Approximation and Projection (UMAP) [44]. It is a novel manifold learning technique for dimension reduction. UMAP seeks to provide results similar to t-SNE, which is the current state-of-the-art for dimension reduction for visualization, with superior run time performance. A theoretical framework of UMAP is based on Riemannian (a non-Euclidian) geometry and algebraic topology. In overview, UMAP uses local manifold approximations and patches together their local fuzzy simplicial set representations.

It is based on the approximation of the local manifold (local manifold approximations) and fuzzy simplicial sets. In contrast to a simple method such as PCA, where the projection is mainly based on two dimensions, the UMAP method takes all dimensions into account equally. An example of a visualization made using the UMAP method is presented in Figure 6.

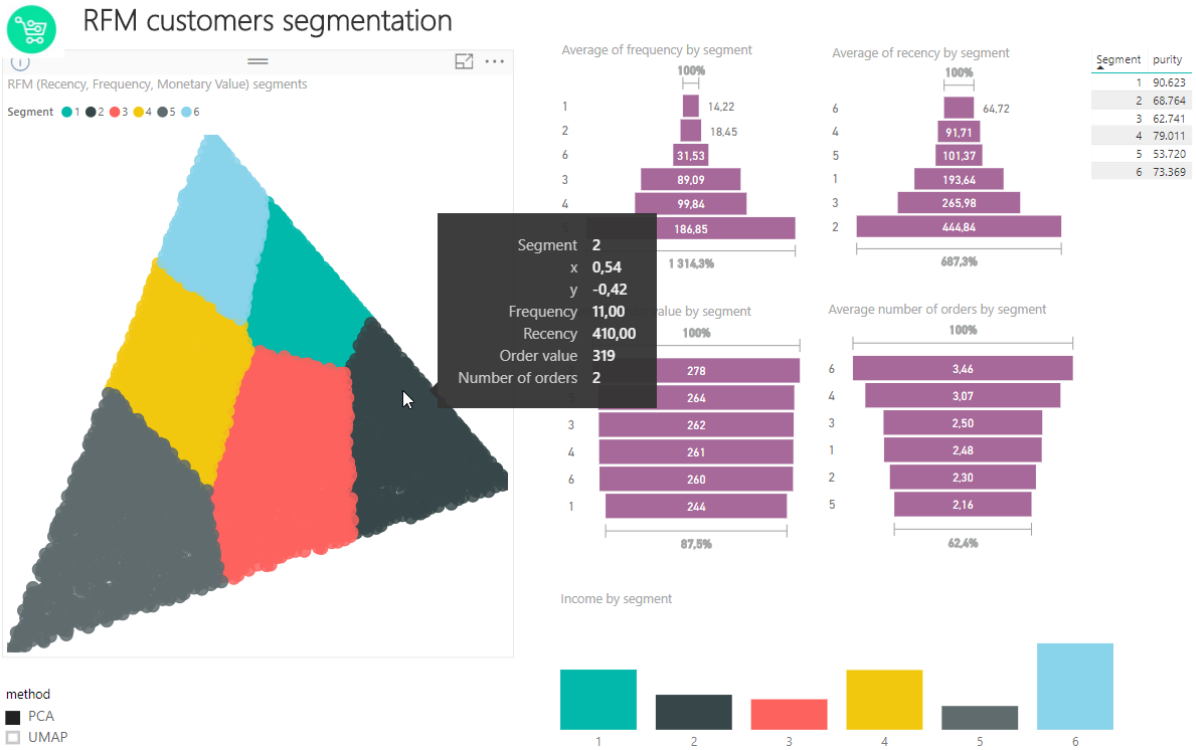

Fig. 5 Segmentation using the k-means algorithm and PCA visualization.

[7] The HDBSCAN algorithm was used, which is an extension of the DBSCAN algorithm. A library available on the GitHub platform was used for this purpose: https://hdbscan.readthedocs.io/en/latest/index.html

[8] The purpose of the PCA method, in brief, is to find a linear subspace (in our case 2-dimensional) in which the variance after projection remains the largest. The PCA method, however, is not to easily reject the dimensions with the lowest variance. It builds a new coordinates system in which the remaining values are the most diverse.

Visualization using two methods as well as presentation of the values of individual dimensions in clusters allow the analyst to better understand the individual customer segments and make an expert assessment of clustering.

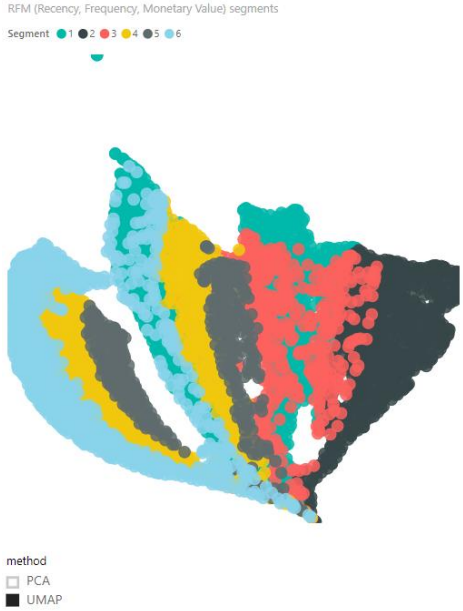

Fig. 6 Visualization of segmentation using the UMAP method.

Clustering using the k-Means algorithm based on the Euclidean distance between observations has many drawbacks. These include the fact that, when assigning customers to segments, the most varied dimensional values have the greatest impact (in our case, recency and frequency). The other dimensions impact less, and this can be observed in the low differentiation in the dimensions of average orders' values. In addition, it should be noticed that the boundaries between individual segments are not sharp. For example, segment 6, with the lowest average value, recency dimensions, includes both customers with a value of 0 and customers with a value of 147, these customers from the perspective of the RFM method, made their purchases relatively long time ago. The main advantage of this algorithm is the fact that the segments are relatively well balanced (their size is relatively similar). It makes those segments worth creating a dedicated marketing policy.

The next algorithm of clustering used in the experiment was the bisecting k-means. In the case of this algorithm, greater diversity was observed in individual dimensions than in the case of k-means. The clusters were again relatively balanced, however, the problem of the slight diversification of the 1 dimension remained, and in some segments there were clients located far away from the average value on a given scale.

Subsequent clustering was performed using the Gaussian Mixture Model algorithm. That method resulted with significant differences in the value of individual dimensions, due to which we can observe interesting cases of outliers (e.g., segment 1 includes customers with a very large number of orders and very high value of orders). Unfortunately, the size of such segments is relatively small (in this case 34 customers), which makes the legitimacy of building a special communication policy targeted to the customers from such a segment questionable. The same experiment was repeated for the DBSCAN algorithm. In case of this algorithm, the number of clusters was defined. Algorithm takes as parameter only the minimum size of the cluster. The disadvantage of this approach is the fact that a large part of the observations were not assigned to any cluster, and also that the majority of clusters are very small. The advantage is that the average values of the dimensions in the indicated segments are very diverse. The use of this algorithm to build communication policies is therefore debatable, but its advantage is the fact that clusters of relatively few but very similar observations are found, which can be used in the automatic recommendation mechanism.

For the marketing analyst, in order to perform the clustering using all the mentioned algorithms, they should observe the boundaries identified by algorithms on individual dimensions, and then those borders to build their own clusters, which will be referred to as according to their interpretation, e.g.

If average order value> 1000 zł
and number of orders > 10 and recency < 300
and frequency < 60
then segment=„active frequent valuable buyers"

If average order value< 200 zł
and number of orders < 3 and recency > 250
and frequency > 200
then segment=„occasional past cheap buyers"

In the platform, client filtering for clustering assignments can be done "manually" using the provided "sliders" presented in the upper right corner in Figure 7.

In the last phase of the experiment, a collective segmentation was proposed, taking into account the results of the three selected clustering algorithms. Because of similar results of the k-means and bisecting k-means algorithms, the k-means was not finally used in the experiment. We created collective segments basing on the results of 3 algorithms. The label of new clusters is constructed with the 3 numbers of clusters generated by the algorithms: bisecting k-means, GMM, and DBSCAN. For example, cluster 326 means that the customer has been assigned originally to clusters with numbers: 3 - bisecting k-means; 2 - GMM; 6 – DBSCAN.

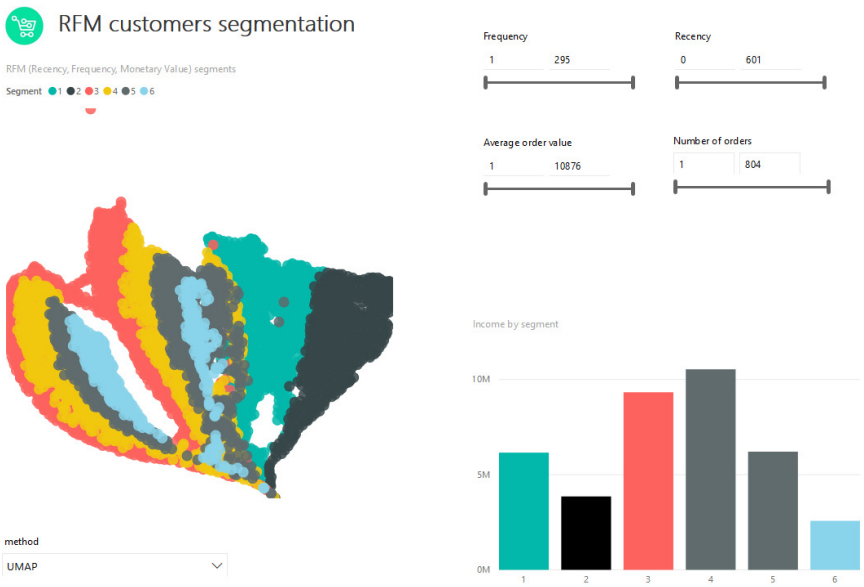

Figure 7 Manual segmentation. Source: Own elaboration in the Upsaily.

As a result, 52 segments were created (on 216 possible combinations), which is presented in Figure 8.

Such a large number of segments, of course, do not allow for an in-depth analysis of each of them and for "manual" preparation of marketing policies. However, these segments can be successfully used in the automated recommendation mechanism.

If the marketing analyst needs to analyze and interpret individual segments, in order to limit the number of clusters, similar segments may be merged. After the analyst decides on the maximum number of clusters or the minimum cluster size, then segments below the thresholds are included in the larger segment meeting the criterion of cardinality. Clusters' merge can be made with the lowest distance between them. The distance of clusters is not determined by the Euclidian measure, as for each of the aforementioned methods, cluster number is just an identifier without any meaning. Such identifiers do not determine similarity of clusters (e.g., cluster 1 doesn't have to be close to cluster 2). Taking the fact into account, distance in this case should be understood as the number of algorithms indicating a different cluster number, e.g., between clusters 525 and 520 the distance is 1 - which means that the clusters differ by the result of 1 method.

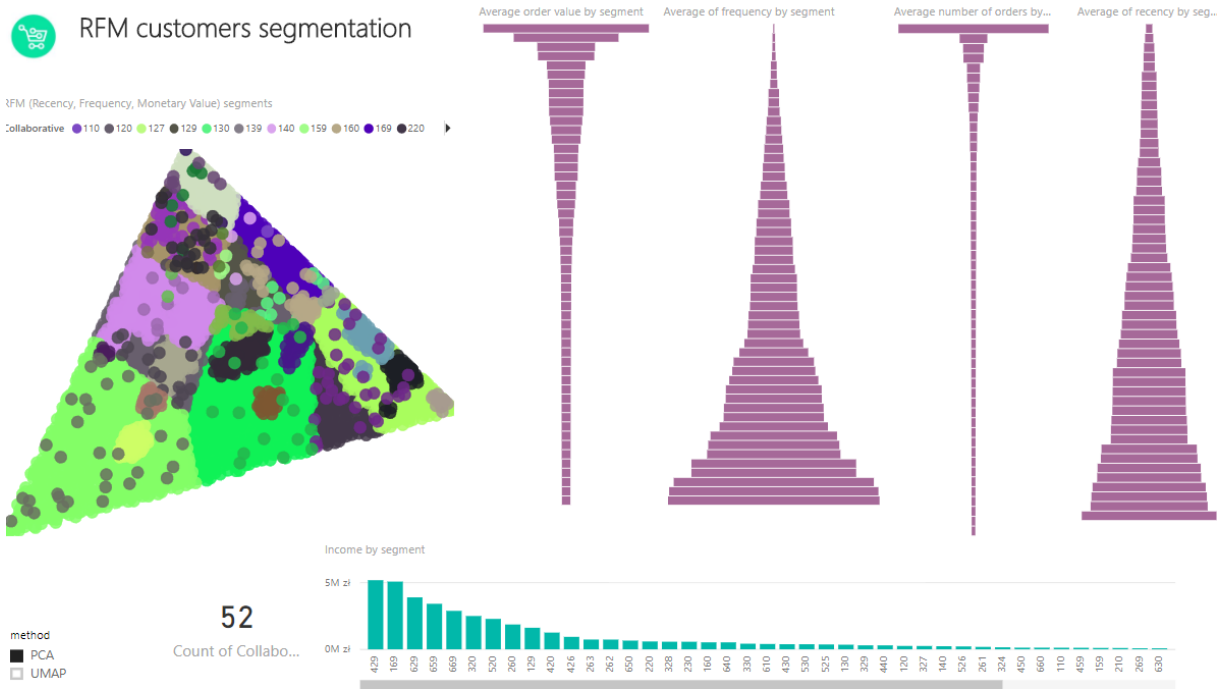

Figure 8 Visualization of 52 segments prepared using a collective approach.

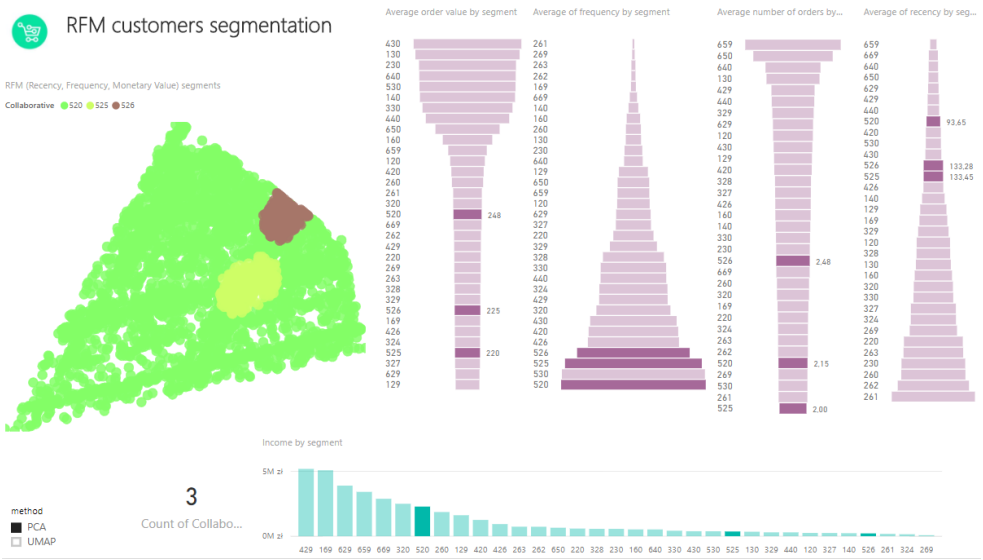

Figure 9 Visualization of the merge of 3 similar clusters prepared using a collective approach.

Between the clusters 320 and 525, the distance is 2. If clusters that should be merged are identified, a number of conflicts is encountered - clusters of the same distance. In this experiment, we will solve the conflict by selecting the highest cardinality cluster to which we attach a cluster that does not meet the criterion of cardinality.

Figure 9 illustrates an example of how to merge clusters 525 and 526 to cluster 520 (as the most numerous).

The k-means, bisecting k-means or GMM algorithms require a pre-determined number of clusters beforehand that we want to receive. The DBSCAN algorithm autonomously selects the number of clusters basing on other parameters, but in its case a large part of the observations are not included in any resultant cluster. We can state that DBSCAN cannot be used in case we would like to define marketing policies covering all clients, but is well suited for identifying smaller groups of observations that are very similar to each other.

Segmentation using a few selected algorithms gives more interesting results from the perspective of the marketing analyst than the segmentation using only one algorithm. First of all, the clusters obtained as a result of collective clustering have better and more useful marketing semantics. In addition, the analyst can decide on their own whether in using the described approach they focus on selecting the optimal number of large clusters, or analyze smaller clusters to identify hidden patterns of customer behavior.

V. Conclusions

The Upsaily system uses clustering as one of the methods for analyzing customer behavior in order to support generation of purchase recommendations. The RFM analysis answers the question when and what value products should be recommended to the customer. Other methods, such as association rules and sequential rules, additionally answer the question of what product / product category to offer to the customer. The Upsaily system also uses classification algorithms to refine the recommendations addressed to the customers.

Segmentation using one algorithm from the marketing analyst's point of view always has disadvantages such as small diversity of segments on particular dimensions or existence of segments with very low cardinality. In order to get rid of these indicated drawbacks and emphasize the advantages of each algorithm, we proposed a collective approach consisting in building a cluster by unification of the segmentation performed by the insights generated by all algorithms. Such segmentation gave us a result of more consistent segments with easier interpretation, however the final number of segments is definitely higher than when using each algorithm individually. Small segments can be useful in situations where we build an automatic mechanism of generating recommendations based on the client's assignment to the segment, where the large number of segments do constitute a problem. Segments consisting of a small number of customers are also useful in the task of identifying atypical clients as outliers.

If we want to provide a marketing analyst with a limited number of segments for the purposes of preparing a tailored marketing policy to each segment separately, then we suggest aggregating segments so that they meet the criterion of cardinality.

In future works, the authors will deal with the subject of collaborative clustering, automatic identification of the optimal number of segments and client clustering based on subsequent dimensions that also take their transactions and purchased products into account.

Utilizing online collaborative games to facilitate Agile Software Development

Adam Przybyłek, Wojciech Kowalski

***Abstract*— Effective collaboration and interaction among the development team and between the team and the customer as well as proactive attitude in initiating and implementing improvements play vital roles in the success of agile projects. The challenge is how to address these social aspects since neither the Agile Manifesto nor the Scrum Guide specify techniques that aid the human side of software development. To fill this gap, we developed a web portal which provides 8 collaborative games to be used in agile software development. The feedback received from a Scrum team, who leveraged the games in an industrial project conducted in OKE Poland, indicates that our approach improves participants' communication, motivation, commitment, and creativity.**

Introduction

THE emergence of agile methods has triggered a growing awareness that social aspects play a key role in the success of software projects [1, 15, 27, 28]. Indeed, the Agile Manifesto [11] promotes principles and values such as "face-to-face conversation", close collaboration between developers and stakeholders, "motivated individuals", and regular retrospectives. In addition, in agile software development both developers and stakeholders are expected to be engaged – proactive and creative in identifying problems, envisioning future business practice and shaping solutions that exceed company's expectations [2, 3-5, 9, 14, 16, 18, 19, 23]. Unfortunately, neither the Agile Manifesto nor the Scrum Guide specify techniques to address the human side of software development. Responding to this challenge, in our previous studies [21, 23], we proposed to equip Scrum teams with a set of collaborative games.

Collaborative games refer to several structured techniques inspired by game play, but designed for the purpose of solving practical problems [23]. They involve strong visual or tactile elements that help the participants leverage multiple dimensions of communication, resulting in richer, deeper, and more meaningful exchanges of information [12, 23]. At the same time, they make use of the concepts of teamwork and collaboration, which lead to a variety of measurable societal outcomes.

Our previous studies [21, 23] revealed that playing collaborative games during Scrum meetings improves participants' communication, commitment, and creativity. In this study, we go one step further and make it easier for agile teams to adopt collaborative games. We developed a web portal (http://153.19.52.168) which provides online versions of 8 collaborative games. In these games, a team or a group of stakeholders participates in a collocated session and plays a game to discover requirements, prioritize requirements, or provide feedback related to the development process or the software system being implemented.

Related work

Although there have been hundreds of papers related to the application of serious games for teaching software engineering and software project management [10, 17, 24, 25], the interest in using collaborative serious games has not received so much attention yet. An important cornerstone for this research area were innovation games introduced by Hohmann [12] as market and product research techniques and later adopted by Ghanbari et al. [7] and Przybyłek & Zakrzewski [23] to support distributed requirements engineering and agile requirements engineering respectively. Likewise, Gelperin [6] defined six collaborative games that support requirements understanding. In turn, Trujillo et al. [26] proposed a game-based workshop as an alternative for the software project's Inception phase. Being inspired by their work, Przybyłek & Olszewski [22] proposed an extension to Open Kanban, which contains 12 collaborative games that help inexperienced teams better understand the principles of Kanban. Recreantly, Przybyłek & Kotecka [21] and Mesquida et al. [16] adopted collaborative games to support Agile Retrospectives.

Selection of collaborative games

The first decision to be made was the selection of collaborative games to be implemented. Our main objective when developing the portal was to offer at least one game for each Scrum meeting except the Daily Scrum, which is too short and too well-structured to take advantage of collaborative games. Since there are several games that may be utilized during each Scrum meeting, we chose those that had received the most positive feedback in our previous studies and were easy to implement. Ultimately, our portal provides 8 collaborative games. The assignment of the

games to the Scrum meeting in which the game is applicable is as follows:

- **Product Planning**: Whole Product, AVAX Storming, SWOT Analysis;
- **Sprint Planning**: Buy-a-Feature, How-Now-Wow Matrix;
- **Sprint Review**: Speedboat;
- **Sprint Retrospective**: Mood++, 4Ls.

A. Whole Product

The game helps the team discover new features that can make the product distinct and prioritize the product backlog [12]. The game board comprises four stairs levels that represent four kinds of features:

- Generic – the fundamental features that define the software system;
- Expected – the features that the customer considers absolutely essential;
- Augmented – the features that the customer wishes to have implemented;
- Potential – the features that go beyond the customer expectations.

B. AVAX Storming

The game aims at identifying "needed" and "desired" features of the system to be developed. The final result should be a mind map demonstrating the size of the project [25]. Unfortunately, due to implementation difficulties our version of this game only allows for categorizing features without the possibility of creating a mind map.

C. SWOT Analysis

The game is a strategic planning technique used to help an organization identify the Strengths, Weaknesses, Opportunities, and Threats related to a project. Strengths and weaknesses are internal to the business, while opportunities and threats arise externally. This game can be also employed to discover requirements for a software system [13].

D. Buy-a-Feature

The game is a way of choosing the right set of features to be developed in the next Sprint. In this game, customer representatives collaborate to purchase their most desired features using game money (Fig. 1). Strictly speaking, they jointly prioritize their desires as a group [12]. Each features has a price related to its development cost. Some features may be priced so high that no single player can buy them individually. This motivates negotiations among players because they have to pool their money to buy the feature.

E. How-Now-Wow Matrix

The game helps stakeholders identify features that make the software system unique and distinguish it from its competitors. It should be played in later sprints after the core features are implemented. The game board is a 2×2 matrix with "originality" on the x-axis and "feasibility" on the y-axis as shown in Fig. 2 [23].

Figure 1. Buy-a-Feature

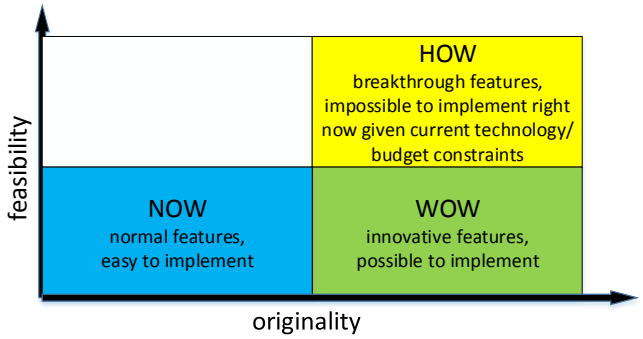

Figure 2. How-Now-Wow Matrix [23]

F. Speedboat

The game explicitly asks customer representatives to say what they do not like about the product. Nonetheless, it lets the facilitator stay in control of how the complaints are stated. The game starts by drawing a speedboat. The speedboat represents the software system. Everyone wants the speedboat to move fast. Unfortunately, the speedboat has a few anchors holding it back [8]. Customer representatives write what they do not like on sticky notes and place them under the speedboat as anchors. The lower an anchor is placed, the more significant the issue is. Customer representatives may also add engines to the speedboat. The engines represent features that can "overpower" the anchors and enable the speedboat to move faster [12].

G. Mood++

The game helps release a heavy emotional steam and gather data about feelings during the Sprint. The game board comprises five areas [21]:

- Mad – frustrations, issues that annoyed the team and/or wasted a lot of time;
- Sad – disappointments, issues that did not work out as well as was hoped;
- Glad – pleasures, issues that made the team happy;
- Flowers – appreciation to colleagues who did something magnificent for the team or a particular team member;

- Ideas – suggestions how to improve the teamwork or the process.

H. 4Ls

The game handles both the positive and negative aspects of the Sprint, but also brings forth the continuous improvement [21]. The game board contains four columns:

- Liked – what did the team really appreciate about the Sprint?
- Learned – what new things did the team learn during the Sprint?
- Lacked – what things could the team have done better in the Sprint?
- Longed For – what things did the team wish for but were not present during the Sprint?

IV. EVALUATION

The evaluation was performed during the second half of 2017 and the first half of 2018 in OKE Poland (oke.pl). OKE Poland is a software development company that provides innovative IT solutions for its partners in Europe and the United States. 6 out of 8 games hosted by our platform were utilized by a Scrum team when they were developing software for a Dutch company. Since the customer was located in a different country, its availability throughout the project was limited. Accordingly, we were not able to evaluate Buy-a-Feature and AVAX Storming, which require the participation of numerous customer representatives. The team consisted of 6 developers, who had experience in all evaluated games due to their participation in our previous research. The second author of the paper facilitated all game sessions. After each session, a questionnaire was issued to collect feedback on game-playing experiences (Fig. 3-10). The responses were on a Likert scale of 5 points. Overall, all games were evaluated positively. The detail results are presented in the succeeding subsection. As the next step, the results were discussed in a focus group. The details about the meeting and its findings are given in Section IV.B.

A. Questionnaire

Figures 3-10 aggregate the number of responses for each Likert level and game for a given question. Although some games required participation of the customer representatives, who varied slightly between the sessions, each game was evaluated by the development team only to ensure the comparability of the results between the games.

The great majority of participants state that each evaluated game produces better results than the standard approach (Fig. 3) and is easy to understand and play (Fig. 4). However, as for Whole Product, Mood++, and 4L's the opinions on whether these games should be permanently adopted by the team, are divided almost equally between supporters, opponents and undecided (Fig. 5). The opponents complain that playing a retrospective game is much more time-consuming than running a traditional retrospective. In turn, the final result of Whole Product was unreadable, because most of the identified features fell into the first category.

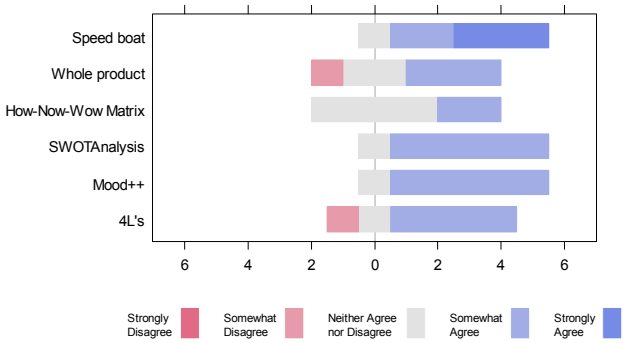

Figure 3. The game produces better results than the standard approach

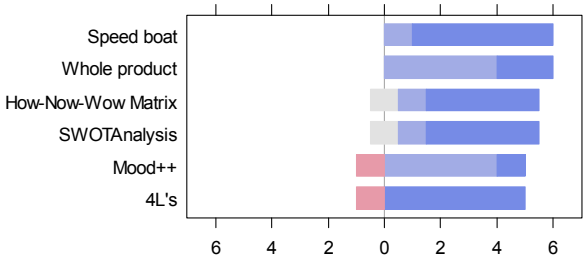

Figure 4. The game is easy to understand and play

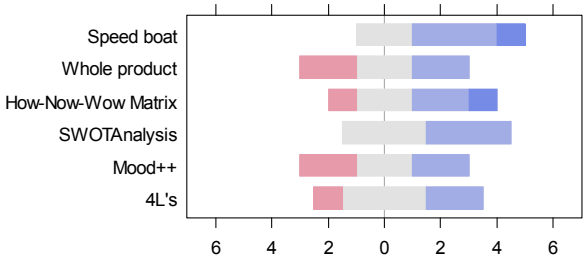

Figure 5. The game should be permanently adopted by the team

The great majority also consider that the games foster participants' creativity (Fig. 6) and improve communication among participants (Fig. 7). Especially, communication between the team and its customer has been improved.

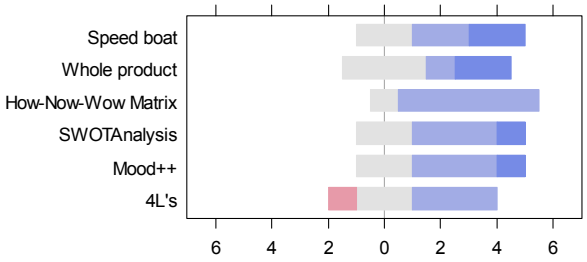

Figure 6. The game fosters participants' creativity

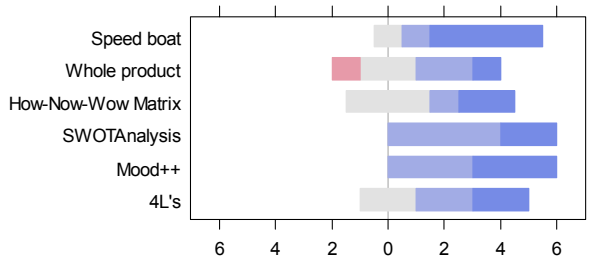

Figure 7. The game improves communication among participants

All games except 4L's are claimed to foster participants' motivation and involvement with only single opposite voices (Fig. 8). As for 4L's, the opinions are divided equally between supporters, opponents and undecided.

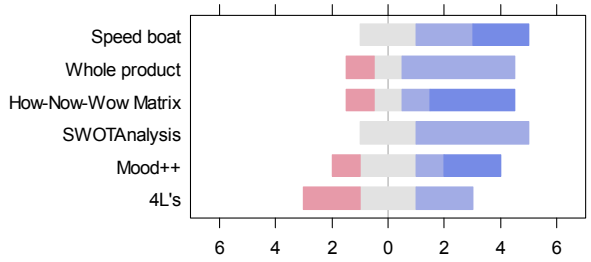

Figure 8. The game fosters participants' motivation and involvement

When it comes to the impact of the games on the willingness to attend the meeting, the responses are dominated by those who purport that it is difficult to unequivocally determine the impact (Fig. 9). Although these respondents see the value in the games, they are afraid that playing a game at each Sprint may be tiring.

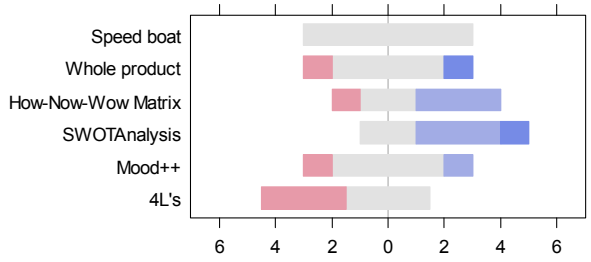

Figure 9. The game makes participants more willing to attend the meeting

The key question for this study is whether the online versions outperform the non-digital ones (Fig. 10). Although the online versions do not perform worse, only the online version of Speedboat, Whole Product, and Mood++ perform significantly better than their non-digital counterparts. As for Whole Product, its digital game board is considered more apparent than the original one (we changed the original game board [12] due to implementation difficulties).

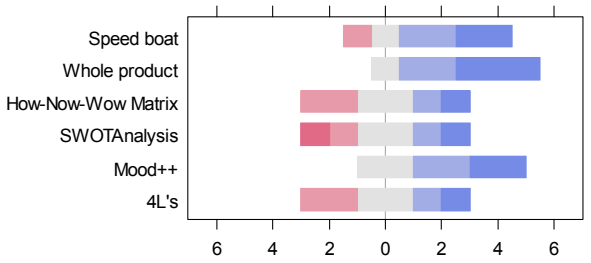

Figure 10. The online version of the game outperforms the non-digital version

B. *Focus group*

We conducted a focus group with the team to analyze and discuss the results presented in the previous subsection. The discussion was structured around four questions:

- What are your comments on the results?
- What are advantages and disadvantages of the online collaborative games over their non-digital counterparts?
- Why did some games perform better than the others?
- Is there something that can be improved in the provided games?

At the end of the day, the findings were as follow. The non-digital versions impose overhead to draw the initial template that participants have to fill in. Accordingly, the more complex the game board, the greater the gain from an online version. One debater noted that our portal cannot be used by distributed participants and suggested that it could be improved by adding a chat facility.

Making corrections (e.g. moving cards/notes between different areas or updating the content) is easier and more flexible in the online versions. Thereby, outcomes generated from the online versions are more readable. Moreover, the non-digital versions require physical game accessories to play a game. Even though most of the games use only simple accessories such as posters, colorful sticky notes and coloring markers, the team encountered situations where there were not enough colors of sticky notes. As for the online versions, there are no problems with missing artifacts.

Joining an existing game session is cumbersome. It would be better if there is a drop-down list of all available game sessions that users can join. Furthermore, the rules of a game should be accessible when the game is running.

V. Conclusions

In this study, we developed a web portal which provides 8 collaborative games to be used in agile software development. The received feedback not only confirms our previous findings that playing collaborative games during Scrum meetings improves participants' communication, commitment, and creativity, but it also suggests that our online collaborative games can substitute their non-digital counterparts. Nevertheless, the intention of this work is not to convince anyone to switch from the non-digital versions into the online versions, but to simplify the adoption of collaborative

games into daily practice by those who have never used them. Our portal lets agile teams try collaborative games without any investments in physical game artifacts. However, we still believe that playing collaborative games in their non-digital form creates a type of glue that bonds participants together and made them more comfortable to participate in the discussion. We hope that our research will inspire practitioners to utilize collaborative games to address the social aspects of software development.

As future work, the provided games need to be evaluated in other settings and contexts. We also hope that new games will be added in our portal in the future, since its source code is publicly available and we invite the community to contribute. Moreover, we want to study the effect of collaborative games on social aspects of software development in a controlled experiment with settings similar to [20].

ACKNOWLEDGMENTS

The authors would like to thank other programmers who developed the web portal, i.e.: Alicja Białous, Monika Czwartosz, Bartosz Stefański, Bartosz Zaborowski, Tomasz Piwowarski, Mateusz Górski.

***Abstract*—Data creation for Human Activity Recognition (HAR) requires an immense human effort and contextual knowledge for manual annotation. This paper proposes a framework for semi-automated annotation of sequential data in the order picking process using a motion capturing system. Additionally, it introduces proper annotation labels by defining process steps, human activities and simple human movements in order picking scenarios. An attribute representation based on simple human movements meets the challenges set by the versatility of activities in warehousing.**

I. Introduction

ORDER picking is the process of pulling items from a warehouse to satisfy specific customer orders. This basic warehousing process makes up more than half of the total operating expenses [1, p.1-30]. Sub-processes may be partially automatized in high-wage countries. Nevertheless, manual order picking systems remain dominant in practice [2]. To evaluate order picking systems, manual processes need to be quantitatively determinable [3]. Manual assessment of the order picking efficiency is unfeasible as trained specialists would be required to manually gather the necessary information in a highly versatile environment. Due to advancements in sensor technology and data processing, IT-supported approaches of Human Activity Recognition (HAR) gain significance.

HAR is a classification task where time-series segments are assigned to a specific activity class [4], [5], [6]. The authors in [5] provided the first approach of HAR in the order picking process. They recorded multichannel time-series from Inertial Measurement Units (IMUs). IMUs were attached to both arms and the torso of three workers in two warehouses. IMUs provide measurements of three different sensors: accelerometers, gyroscopes and magnetometers for three axes (x, y, z). The authors followed a standard pipeline in pattern recognition; that is, segmenting sequences, extracting handcrafted features, and training a classifier. They used a sliding window approach for segmenting time-series segments. For each of these segments, statistical features were computed and processed by three classifiers. Recently, deep convolutional neural networks (CNN) and recurrent neural networks (RNNs) were successfully used for recognizing human activities [6], [7], [8], [9]. A combination of convolutional layers and recurrent units is proposed in [7] for recognizing activities of daily life. In [8], different deep architectures were deployed to recognize human locomotion activities. In particular, they used a CNN, a long-short term memory (LSTM) network, and a bi-directional LSTM network. The authors in [6] proposed a CNN for solving HAR in the order picking process. In contrast to previous architectures, this CNN contains parallel branches. Each of these branches is composed of two or three convolutional layers and max-pooling operations processing segments per IMU. This architecture, called IMU-CNN, showed the state-of-the-art performance in HAR.

The success of deep architectures in different tasks heavily depends on the amount of data. Nowadays, large collections of data are available for tasks such as image classification, image segmentation and face recognition. However, this is not the case for HAR, which datasets are rather small and scarce. Providing data collections involves recording high quality raw data along with their respective class annotations. Data should be large, variate and correctly labeled. This process in HAR is more challenging in comparison with other tasks. For image classification datasets, label annotations can be carried out using a combination of unsupervised clustering and manual work [10]. However, HAR is diverse involving different type of data sources, e.g. from videos, or multichannel time-series from on-body sensors. HAR faces challenges with regards to environment settings, number of participants and number of sensors [4]. Furthermore, due to the large intra- and inter-class variability of the human movements, a large number of experiments must be carried out, which draw motion repetitions from the same or different persons [7]. These circumstances increase the data collection and annotation efforts. Obtaining and annotating data from videos is computational expensive, and, in the case of multichannel time-series signals, signals are visually hard to interpret. In both cases, annotations are carried out manually, involving the synchronization of the time-series with videos, observing the actions and labeling the sequences. This procedure takes enormous time. For example, annotations of time-series in the order picking dataset in [11] demanded $26min$ in average per minute of annotated data. In addition, annotations are inconsistent among different

The work on this publication has been supported by Deutsche Forschungsgemeinschaft (DFG) in the context of the research project "Adaptive, ortsabhängige Aktivitätserkennung und Bewegungsklassifikation zur Analyse des manuellen Kommissionierprozesses"

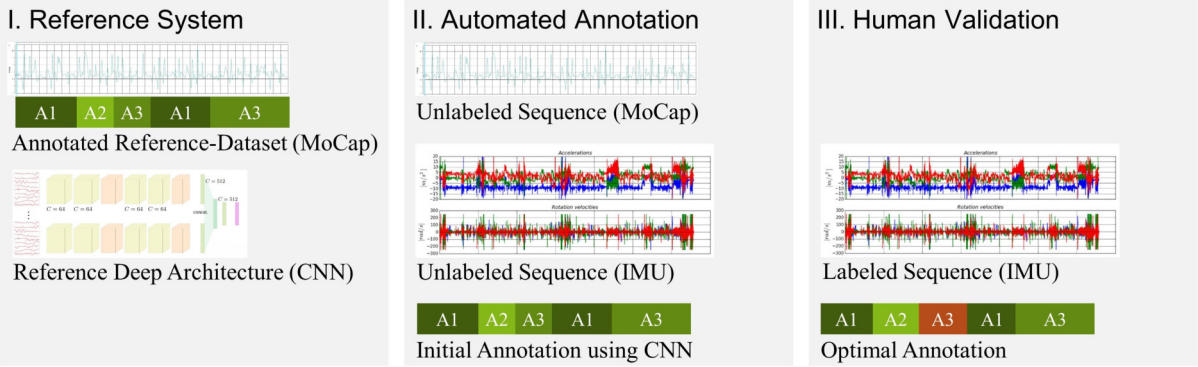

Fig. 1: Framework for semi-automated Annotation

annotators. Repetitions in the annotation process enhance the data quality [11], but escalate the data collection effort.

Apart from the annotation effort, the definition of activities is of high interest. In order picking scenarios, coarse activities like walking, picking and searching are often used [6], [11]. However, these scenarios are highly versatile involving a variety of activities. A possible way out is the definition of more finely subdivided activities. This implies more effort for creation and annotation of datasets. Following [9], activities could be represented by a set of attributes. Attributes are high level semantic descriptions of activities [12], [13]. These attributes are shared among all of the activities. For example, attributes like moving or not moving a foot and the velocity could define walking, running, and standing. Using an attribute based representation, problems like imbalanced data and overfitting are reduced. Sequential data from the most frequent activities could be used for learning attributes that are shared with less frequent activities, as simple human movements are shared among activities. In general, attribute annotations in the context of multichannel time-series HAR are not available. The annotations are related with specific coarse activities, for example standing or walking. However, there are no annotations of attributes describing those coarse activities. In [9], attribute representations for HAR are learned using an evolutionary algorithm, starting from a random combination of attributes. The learned attribute representations are suitable for solving HAR as classification task. However, their semantic interpretation is missing and therefore not understandable by humans.

II. Method

Datasets consisting of multichannel time-series from on-body sensors are of special interest in order picking. Usually, multiple sensors, e.g. IMUs, are worn by a worker gathering recordings in a simple and non-invasive manner. Besides, these sensors are impersonal, i.e. recordings do not portray the identity of the person. In comparison with HAR using videos, they do not suffer from occlusion, as the person's visibility changes along videos. In addition, IMUs are rather economic. Nevertheless, datasets from these devices are hard to annotate manually. As they are difficult to interpret by a human, additional video material is necessary to visualize the respective activity. This paper presents a framework, see Figure 1, to annotate multichannel time-series from on-body sensors using a deep learning model that is trained on highly accurate data. This framework is divided in three parts. First, sequential high quality data are created and annotated from a controlled environment as a reference dataset. Humans are recorded following activities that are commonly seen in order picking scenarios. Proper annotation labels are defined and, in addition, an attribute representation for human activities is introduced. This attribute representation is based on basic human activities and warehousing components. A deep model for solving HAR is learned on the reference dataset. Second, using this model, sequential data from an uncontrolled environment are initially labeled. This initial label includes the computation of uncertainty for the initial predictions. Third, uncertain predictions are revised by human work for final labeling.

A. Controlled Environment

On the one hand, naturalistic, real-life data are desired. On the other hand, data is prune to be disturbed in uncontrolled environments [14]. The primary reason to use a controlled environment set-up is the high accuracy of the available sensors. Interfering signals can be averted, and recording sessions can be conducted and repeated with different settings. The Motion Capturing (MoCap) that has been used for this paper is based on photogrammetry methods for measuring object positions on $2D$ and $3D$ spaces using a string of cameras. As an installation of the motion capturing system in a real warehouse is not practicable, it is located at the "InnovationLab Hybrid Services in Logistics" of the chair of materials handling and warehousing at the TU Dortmund University. The MoCap system consists of 38 cameras that cover a space of approximately $22m \times 10m \times 6m$. It uses passive markers to track rigid and flexible objects, such as drones, robots or humans in real time [15]. The passive markers reflect incoming infrared signals to the cameras, and their $3D$ positions are determined via triangulation.

The purpose of the MoCap system is to construct and record skeleton data from workers performing activities in an

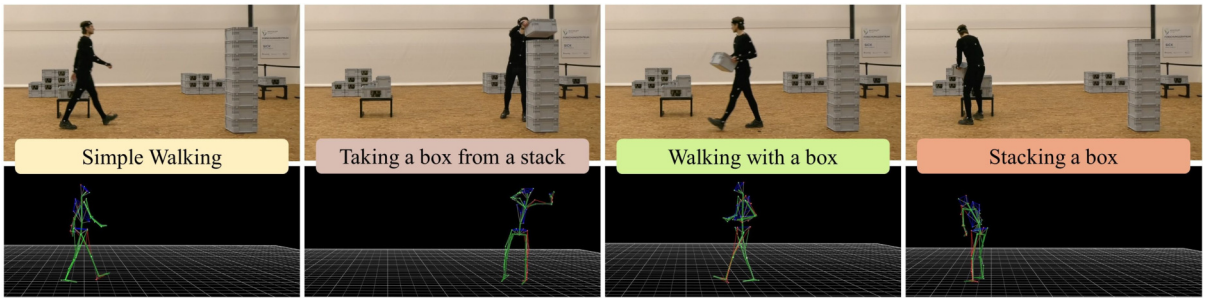

Fig. 2: Exemplary Activities and Motion Capture Data Skeleton

order picking scenario, as shown in Figure 2. Workers wear a specific suit with a set of passive markers. The MoCap computes the global $3D$ positions and it constructs a human skeleton. The MoCap System provides global poses from different parts of the human body, e.g. head, torso, arms and feet. A pose is a combination of position and angular values in $[X, Y, Z]$ of a certain reference system.

B. Annotation of Order Picking Activities

From a macro-level perspective, the human activity in order picking systems can be segregated into basic activities such as locomotion, retrieving and confirming [1, p.1-30]. An obvious approach of HAR would be to interpret each activity as a class. However, this approach is incapable to deal with the versatility of actions in real-world systems. Members of the same class differ significantly in terms of motions and tasks that are executed by the pickers [3]. For example, a warehouse employee can simply walk or walk while carrying a box. A single class cannot account for such distinctions. There is a wide variety of components that influence the human activity, ranging from the type of storage and collecting unit to the information technology [1, p.1-30], [16], [17]. These components and their combinations define coarse order picking process steps, e.g. *putting a box from a shelf onto a cart*. However, process steps can be composed of fine human activities such as *taking a box from a shelf* and *putting a box onto a cart*. Thus, each relevant process step needs to be defined with regards to human activities. This approach offers a high degree of flexibility. On the one hand, the definition of each human activity is fixed so that patterns in the sensor can be recognized and the obtained data is reusable. This is feasible as the definition of human activity is supposed to hold global validity irrespective of a specific context and environment. On the other hand, the definition of process steps is not fixed. Depending on the user's requirements, process steps can be defined very specifically or in more general terms. In addition, following [9], human activities are represented by a set of attributes that describe them semantically. These attributes are simple human movements, for example moving an arm or a foot. As shown in [9], attribute representations boost HAR tasks using deep architectures.

The proposal is to annotate time-series with a respective activity and a set of attributes, see Figure 3. The definition of both the activities and the attributes must be created a priori by a warehousing specialist to ensure that they are semantically understandable. The attributes are the output of the CNN that operates on the sensor data. The combination of attributes implies a specific activity. The activity sequence is then comprehended as a process step of order picking.

C. Creation of Reference Dataset

A reference dataset for order picking scenarios using the MoCap system, see subsection II-A, is created. The closeness to reality within the controlled laboratory environment was ensured by using the same kind of equipment, such as boxes or racks, that are used in real warehouses.

For this reference dataset, eight activities have been recorded: *Standing (none)*, *Walking (none)*, *Standing (box)*, *Walking (box)*, *Reaching forward (none)*, *Lifting (box)*, *Putting down (box)*, *Straighten up (none)*. Here, the words *box* and *none* express whether a worker walks with or without a box. Thus, the sequence of *reaching forward (none)* and *lifting (box)* implies the process step *picking up a box*. The box was a standard small load carrier with the dimensions L 600 mm x W 400 mm x H 220 mm and a gross weight of 4 kg.

The sample recording for this paper was conducted with eight participants of which four have been female and four male. Their height ranged from 161 to 192 cm and the average age was 25. Five participants have been right-handed and three participants have been left-handed. Previous research suggests that the handedness and gender have an impact on the motion [18]. The amount eight participants is equivalent to state-of-the-art approaches [19].

The activities were not recorded in a sequence and subsequently segregated into activities. Rather, they were recorded successively as modular units to ensure the creation of a balanced dataset; that means, all activities have a similar number of recordings regardless of their occurrence in a given scenario. All standing and walking activities have been recorded for five minutes per participant in 5 individual recordings of 60sec each. Both the activities *Reaching forward (none)* and *lifting (box)* were recorded in a single run to reduce the recording effort. The box was picked 10 times from 9 different heights, from the ground level up to a stock of 8 boxes. The participants approached the stack from different starting positions to ensure a natural motion. The boxes had to be lifted with both hands.

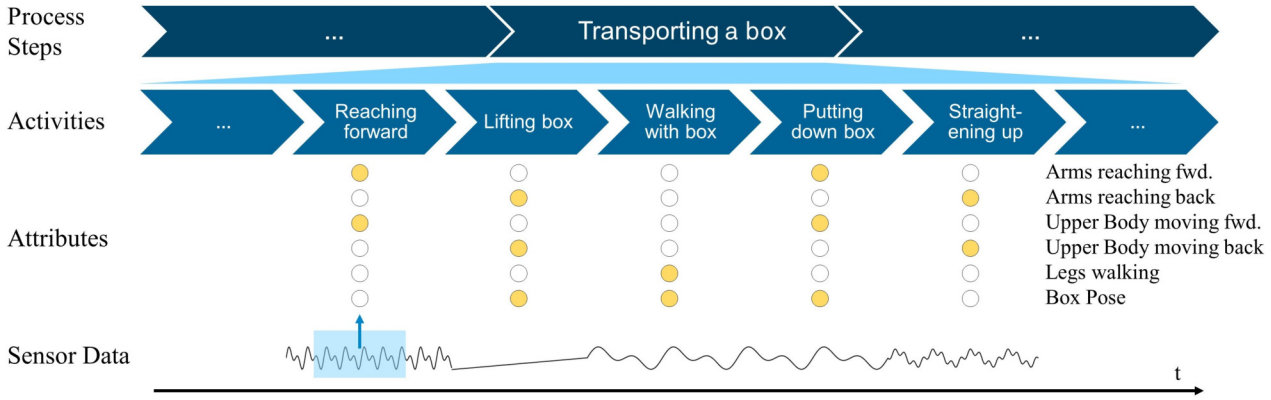

Fig. 3: Attribute based representation of a process step composed of activities that are semantically described

Apart from that, no instructions were given. The total amount of 90 recordings was likewise recorded for the activities *put down (box)* and *straighten up (none)*. A testing data set of 60 sec were recorded for each participant. In the testing data set, the participant conducts a sequence of the previously classified and annotated activities in an arbitrary order and duration. This data set is manually annotated. 202 recordings were conducted with eight participants each, resulting in a total of 1616 recordings. As the data set is based on skeleton poses, one can visualize them easily for annotation purposes. The annotation of walking and standing data sets is simple, as there is no alteration of neither the attributes nor the activity over time. The activities that included the stacked boxes contained not only the two activities *Reaching forward (none)* and *lifting (box)*, as well as *put down (box)* and *straighten up (none)*. The stack was approached and departed by the participants by feet. Therefore, the two *walking* activities and the two *standing* activities were annotated as well. Having this modular recording from activities, the annotation took approximately $2.5min$ per recorded minute.

D. Convolutional Neural Networks for HAR based on Skeleton Datasets

This paper uses the deep architectures, proposed in [6], [9]. These architectures are suitable for multichannel time-series. They are composed of temporal-convolutions and pooling layers, which perform convolution and downsampling operations along the time axis. These architectures extract hierarchical-temporal relations of human movements creating abstract representations of an input sequence. Fully-connected layers connect these representations creating a global one of the input data. The network will compute an attribute representation of an input sequence. This representation is a vector $a \in \mathbb{B}$ containing $1s$ and $0s$ in which 1 for having or not an attribute, the sigmoid activation function is applied to each element of the output layer. Its output corresponds to pseudo-probabilities for each attribute a_i being present in the representation.

The architecture was designed for handling sequences from multichannel time-series, which are measured from m individual portable-devices. These devices are located on different parts of the human body. Convolutional and pooling layers are configured in parallel branches for processing these sequences. Specifically, a single branch processes sequences from a single device increasing the descriptiveness. This architecture is called CNN-IMU. Besides, this configuration allows for more robustness against different and asynchronous devices. This architecture contains m convolutional branches, one per device. Each branch is composed of four temporal-convolution, two max-pooling layers and a fully-connected layer.

Different from [6], [9], the input sequences are not measurements from any portable sensor located on human body parts. Sequences are provided from the MoCap System, see subsection II-A, which provide global poses of human segments. Then, for each of these segments, one has six different measurements. There are in total 22 human segments, e.g. the head, torso, feet, knees and arms. In total, 134 channels have been taken into account. The global pose sequences are normalized with respect to the lower back human-segment. This is necessary to avoid a dependency of the human activity recognition to a global position of warehousing equipment in the laboratory. Each of this measurements is taken as a channel, similar to sequences from portable devices. One considers in total 132 channels and $m = 22$ branches. In the CNN-IMU, convolutions are computed along the time axis, and their filters are shared among the channels.

For training, the following configurations are employed. Sequences from persons $1 - 6$, person 7 and person 8 are used as training, validation and testing sets respectively. The parameters of the networks are updated by minimizing the binary-cross entropy loss using the stochastic gradient descent with the RMSProp update rule as in [7], [9]. Sequence segments, extracted using a sliding window approach, are fed to the networks. These segments are assigned the most frequent ground truth. In general, learning rates are decreased by $\gamma = 0.1$ at a certain epoch or iteration during training. Additionally, we use dropout with probability of 50% on the inputs of the first and second fully-connected layer, and orthogonal initialization [7]. As suggested in [6], [7], input sequences were normalized per channel to a range $[0, 1]$. Moreover, a Gaussian noise of $\mu = 0$ and $\sigma = 0.01$ is

added, simulating inaccuracies on the MoCap System. For a given attribute representation A describing the aforementioned activities in the reference dataset, a nearest neighbour approach is used for predicting a specific activity by measuring the cosine distance from the CNN's output for a certain input sequence $\tilde{a}$ to the set $a \in A$. Different sets A of attribute representations, provided by experts, will be evaluated.

E. Human Validation

Following a sliding window approach with a window size of T and step of s, an unlabeled sequence from the reference dataset and an unlabeled sequence from IMU's measurements are segmented. A set of D sequences of size T are then obtained. These sequences are fed to the CNN-IMU computing their attribute representations. By means of a nearest neighbor, these sequences are assigned to the activity where the distance between their representations is minimal. Following [20], an uncertainty measure can be computed for each of the predictions. This measure give a value of how certain a CNN is with respect to a prediction. Uncertain predictions are then revised by experts for generating the final annotation of the sequence.

III. Discussion and Conclusion

This contribution proposed a framework to reduce the annotation effort for multichannel time-series. An attribute based representation creates a high-level semantic description of activities. This is beneficial to make full use of imbalanced data, avoid overfitting and to recognize unseen activities. The logical connection of activities and process steps has been explained and an exemplary attribute representation has been provided. Motion Capture datasets of eight activities including a training and validation data set have been recorded with eight participants each, resulting in a total 1616 recordings. The recordings have been annotated, normalized and used to train a state-of-the-art CNN. Recording further participants and the manual annotation of the MoCap data requires few manual effort. The attributes used by the CNN can be understood by a human and thus transferred to new activities.

Based on the proposed framework, a large multichannel time series can be annotated with respect to semantics in a semi-automated manner. It is not restricted to IMU data but can be used for other sources, such as video data, as well.

Faculty of Management and
Economics of Services
ul. Cukrowa 4, 71-004 Szczecin Poland
Email:agnieszka.tomaszewicz@wzieu.pl

***Abstract*—ICT which constitutes basis for e-administration development, is used more and more often in office-citizen kind of communication. Thus, terms regarding the state and directions of local e-administration development are quite often discussed in polish literature. However, they are seldom held on the local level i.e. local authorities. The issues regarding improvement of service among local communities resulting from applying e-administration solutions are particularly researched. Hence, the article presents the results of enhanced scientific research in the area of impact of local e-administration solutions on service efficiency among citizens which result in proposal of the model of local e-administration development. Its' application shall enable proper usage of local e-administration potential as well as improving service for local communities.**

I. Introduction

IN TODAY'S economy, the Internet plays an important role as a mean of communication and distribution and as such it shall be used intensively by local units in order to improve the service for their communities. The Internet shall be used by offices to improve the whole process of providing services so that it would result in implementation of full offer of e-services available on the offices' web pages. Providing dynamic development of e-administration and wide usage of provided services via electronic channels shall result in better, more efficient and effective functioning of local offices. It will foster both, more efficient customers service and implementing new computerised solutions enabling growing customers' needs and even stay ahead of them. Thus, it may be assumed that e-administration is public administration in which the use of information and communication technologies (ICT) contributes to better administrational service for citizens thereby improving the quality of their life. On the basis of the needs and improvements identified in the research, which result from the implementation of e-administration in municipalities of West Pomeranian Voivodeship, it was concluded that self-governmental administration has the potential which may contribute to improvement of services for local communities. The development of public e-services, particularly at the initial stage of development, depends on the access and the quality of public e-services which specify the advance level of their development. Therefore, in order to increase the access to public e-services in municipalities, the growth of their maturity and improvement of customer service, resulting in better quality of life regarding citizens and better quality of realized business processes regarding entrepreneurs, the model of local e-administration development was created on basis of research held in municipalities of West Pomeranian Voivodeship. The municipalities do not vary from the whole population regarding the researched qualities.

II. Literature review

The innovative approach towards improvement of governmental effectiveness, according to M.A. Abramson, J.D, Breul, J. M. Kamensky, is driven by the technological development which lead to vital changes in functioning of organizations both, in public and private sector contributing to improvement of administration efficiency. They claim that technology shall be seen not only as a basic activity of public administration but as a driving force for its activity [1]. The biggest advantage of that kind of innovation is to create grounds to change the nature of business and interpersonal communication and to establish new relationships between people and organizations [2]. According to H. Izdebski [3], progress connected with the technical development of IT facilitates contact with offices by obtaining desired information or settling the matter via electronic way. Thanks to the development and better access to the technologies, the meaning of electronic administration shall be systematically growing [4]. The influence of the administration on the economy, particularly by using ICT in recent years is seen as a factor which boosts economy and leads to public sector transformation, drastically changing the way of functioning of public institutions [5]. Within the research conducted for the needs of eGovernment Readiness Index, five e-administration models were found [6]:

1. centralized- where the information and public services system is organized around the main national portal and presented information are highly unified;
2. decentralized- based on the individual sites, created separately for particular institutions, initiatives and programs in which collective public platforms play only referential function and presented information are not standardized;
3. network- in which systemic character is obtained by the number and kind of links between particular websites;
4. e-participation oriented- in which the base constitute the tools enabling citizens' engagement in creating the administrational processes and making decisions;
5. e-services oriented- in which computerization of the processes like *back-office* and *front-office* are treated as the most important factor in creating e-administration systems.

The approach to local administration keeps on evolving all the time. Currently, it is expected that it shall implement citizens' participation in the process of creating public services. Additionally, in places where it has not been implemented yet, administration shall pass from top-down hierarchical effectiveness to bottom-up, meaning democratic one. This effectiveness is measured on the basis of the results and in the given context. As far as changes in new administration paradigm are considered, in e-administration focus on the client shall prevail.

III. Research methodology

A. Population of the study

The subject and the main area of the research were local authorities in West Pomeranian Voivodeship (urban, including city with powiat rights, urban-rural and rural) and local communities which are serviced by these authorities. The research includes the subjects: (1) Local authorities in West Pomeranian Voivodeship in which research was conducted on three stages: (Stage I) - online survey regarding the state of local e-administration; (Stage II) - the analysis of the websites of municipalities chosen from stage I of the research; (Stage III) - direct interview with the representatives of the local authorities; (2) Local communities of the West Pomeranian Voivodeship which were included in the survey.

B. Data collection

The model was elaborated on the basis of the used secondary and primary information sources by using the following research methods: CAWI technique *(Computer Assisted Web Interviews)*, survey technique, was used among local communities which was drawn on the basis of random sample; direct interview, applied in order to identify problems connected with the development of local administration; critical analysis method- including observation of the websites' content method and applying e-administration solutions in municipalities in West Pomeranian Voivodeship; analysis method of the service provided for the local communities by local authorities in order to identify needs and expectancies within the scope of e-administration; *Case Study Method*- presenting particular solutions connected with local e-administration.

The data collected from the primary and secondary sourced was used to create the model of improving local e-administration.

C. Reliability and validity

The questionnaire that was used in the present study was rigorously tested for its content and construction validity. A draft of the final questionnaire was shown to two officials and three academics, in order to test whether it met all theoretical and practical requirements.

The research conducted at the second stage regarded mainly functioning of the websites on the task level. The subject of the research were local e-services. The content of the offices' websites was not analyzed multidimensionally but it focused merely on the basic terms within the scope of adjusting the websites to providing services for local communities.

IV. Conceptual framework

The basic approach in the proposed model is process approach. Implementing the model which enables meeting the requirements of the local communities, requires its' constant adjustment to changing citizens' and environment's needs. The model was graphically presented in the Figure 1.

A. Modules of local e-administration

In the structure of the model aiming at creating coherent work of local e-administration, it was necessary to identify particular stages designed to improve the service for local communities by local authorities units. The model includes five basic modules which constitute the core of local e-administration (e-A). They include: (1) inventory of the customers service processes in the local offices, (2) recognizing the needs of local customers (citizens, entrepreneurs, other public institutions), (3) the standardization and improvement of processes and public services (in the traditional and electronic meaning), (4) interoperability of the processes and implemented/developed e-services by development and closer cooperation of the units engaged in the process of providing e-services, (5) digitalization of the public services/ the increase in maturity of the available public e-services. In order to specify the level of citizens' satisfaction, offices may use monitoring. Due to changeable character of local communities' needs, the process of monitoring must be in compliance with the rule of continuous improvement by Deming [7]: constant checking whether implemented solutions still respond to citizens' preferences. This activity will not require financial or material outlays. Specifying the needs and preferences of the final customer of local e-administration influences the increase in adaptability of the proposed model.

Bearing in mind, that the customers' needs are tightly connected with the realization of public services, it is legitimate that the accepted model is targeted at creating new

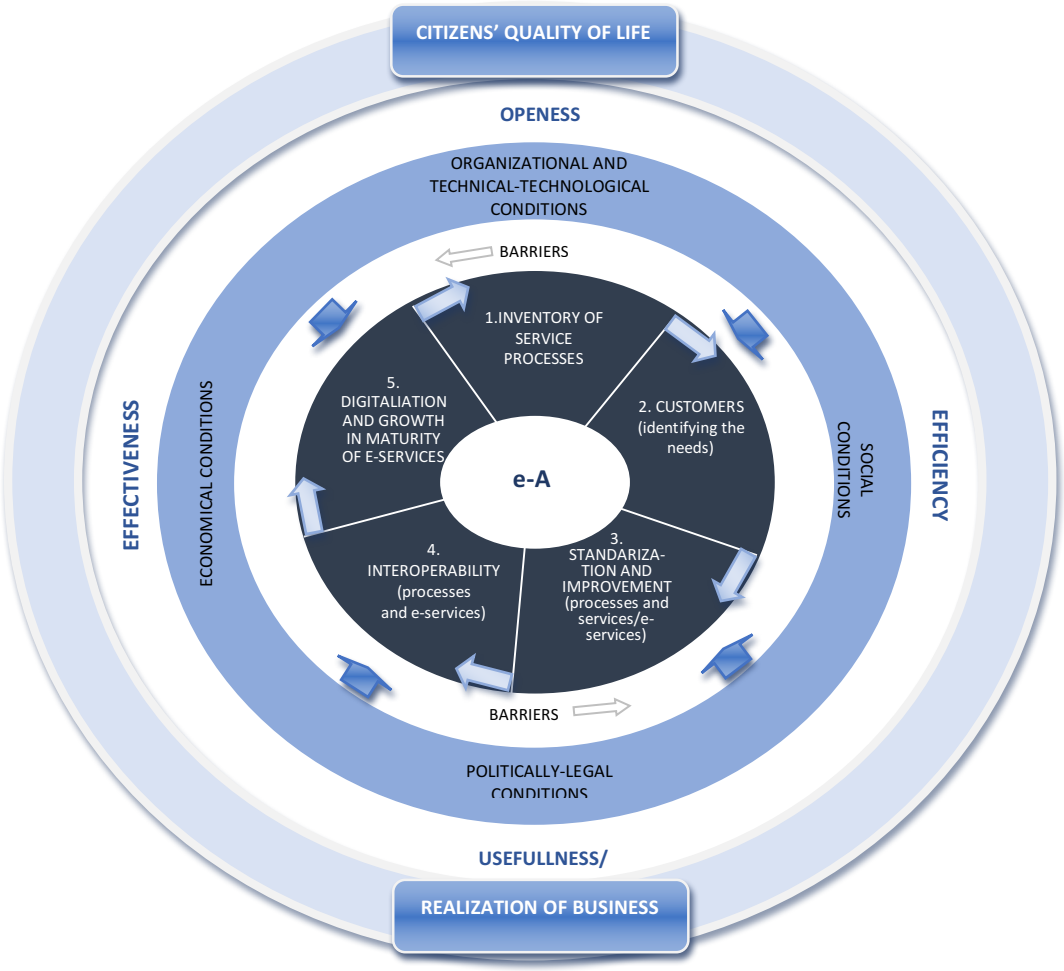

Fig.1 The model of improving local e-administration (e-A)
Source: own elaboration

services and expanding maturity of the existing e-services which main objective is to be adjusted to the local communities' needs. Digitalization constitutes the basic tool in creating social models, including local administration units which shall broadly use its potential, particularly in stimulating social development.

B. Barriers in e-administration development

Implementing the model ay encounter numerous obstacles which may include; organizational barriers, legal, economic, political, technological or social. They may occur on different staged and levels and ay influence slowing the whole process down. One of the most prominent limits are lack of interoperability, lack of unified standards on municipalities' websites, customers' low knowledge on ICT use, necessity of autonomous search of information while handling the matters on the Internet or too complicated service implementation process via the Internet. The access to ICT technology or the willingness to handle the official matters online are believed to be the most crucial obstacles. The obstacle in implementing e-administration in municipalities may be unclear or the websites be not functional. In order to remove this barrier, it is particularly necessary for offices to share services via one website especially designed for it. Currently, councils use even 4 websites (council's own website, BIP, eBOI and ePUAP) having discretion in posting e-services on them. The key barrier which often is finally associated with responsibility for success in e-administration implementation is the cost barrier. EU funds are particularly helpful in this area. From the implementation of the model point of view, particularly important stage is identification and fast elimination of the existing barriers or their removal. These activities shall be consequences of continuous improvement of the e-administration process in communal authority units.

C. Conditions for e-administration development

The success of realizing the model for e-administration development depends on the understanding and knowing the external conditions which may influence it. These conditions may enable it to reach the highest stage of public e-services development, thus, constituting administrational offer for the users. Conditions which are particularly emphasized, include

technically-technological, economic, politically-legal, social and organizational conditions. Besides presenting determinants specified in the model of e-administration development one shall also refer to the theory of critical success factors. In Poland the most important critical success factors (CSFs) of e-administration, as well noticed by E. Ziemba and T. Papaj, are these which are connected with finances, integration and interoperability of public e-services with various systems of public administration institutions, employees' IT skills and top-level management engagement, information safety or implementing innovative teleinformatic infrastructure in public institution, availability of free software [8],[9],[10].

V. Empirical Results

The results of the conducted research enable formulating the following detailed conclusions: 1. E-administration improves communication between citizens and councils. Along with the development of the Internet, this form of communication will be more popularized and intensified. 2. Municipalities of West Pomeranian Voivodeship are characterized with low level of local e-administration development. 3. Low level of local e-services maturity influences rather poor citizens' interest in handling matters with the use of the Internet. In West Pomeranian Voivodeship amounts to 47% (including only 69% of citizens who only download the electronic forms from the websites). However, the vast majority of the participants, up to 74%, feel the need to fully manage at least one out of 12 basic official issues. 4. The increase in advance level of public e-services development and functionality of the websites shall contribute to better service provided for local communities. 5. Higher percentage of citizens who used the Internet while dealing with official matters, claim that it had a positive effect on the quality of the services provided than these people who claimed that there was no improvement. 6. The level of adjusting the websites and their functionality are varied and it is hard to evaluate them clearly. However, mostly customers due to council's use of few internet portals, encounter obstacles in finding the matter they are interested in because it may be provided on different websites. 7. A meaningful problem remains; the lack of coherence and standardization of documents. Local authorities shall establish cooperation with other units, particularly on local level. 8.The factor conditioning wider scope, form and intensity of public e-services use is obtaining proper digital skills both, by employees and customers. IT courses may seem helpful in this area.

VI. Conclusions

The local e-administration has potential to enable, in a considerable manner, contributing to improved service provided for local communities. In conclusion, essential factors which condition the success of implementing the model of local e-administration are as following: 1. Noticing the need for changes by local authorities and their engagement in the process of implementing solutions within the scope of local e-administration on every stage. 2. Accepting efficiency, effectiveness, openness and usability as basic results' measures of implementing the model of e-administration development. 3. Implementing standardization and interoperability as basic factors responsible of work efficiency. 4. Reliable valuation of the project costs and guarantee in financing it. 5. Obtaining proper IT skills by employees and social communities. 6. Using the teleinformatic technology. 7. Participation of local communities and their approval for new tools implemented in municipal administration. 8. Coordination, cooperation, monitoring and evaluation. 9. Constant adjustment to changing needs of the environment.

The benefits of implementing the model of local e-administration are connected with improved skill of satisfying the needs of local communities as a result of the maturity growth (improving the quality of services) or sharing new public e-services.

24th Conference on Knowledge Acquisition and Management

KNOWLEDGE management is a large multidisciplinary field having its roots in Management and Artificial Intelligence. Activity of an extended organization should be supported by an organized and optimized flow of knowledge to effectively help all participants in their work.

We have the pleasure to invite you to contribute to and to participate in the conference “Knowledge Acquisition and Management". The predecessor of the KAM conference has been organized for the first time in 1992, as a venue for scientists and practitioners to address different aspects of usage of advanced information technologies in management, with focus on intelligent techniques and knowledge management. In 2003 the conference changed somewhat its focus and was organized for the first under its current name. Furthermore, the KAM conference became an international event, with participants from around the world. In 2012 we’ve joined to Federated Conference on Computer Science and Systems becoming one of the oldest event.

The aim of this event is to create possibility of presenting and discussing approaches, techniques and tools in the knowledge acquisition and other knowledge management areas with focus on contribution of artificial intelligence for improvement of human-machine intelligence and face the challenges of this century. We expect that the conference&workshop will enable exchange of information and experiences, and delve into current trends of methodological, technological and implementation aspects of knowledge management processes.

TOPICS

- Knowledge discovery from databases and data warehouses
- Methods and tools for knowledge acquisition
- New emerging technologies for management
- Organizing the knowledge centers and knowledge distribution
- Knowledge creation and validation
- Knowledge dynamics and machine learning
- Distance learning and knowledge sharing
- Knowledge representation models
- Management of enterprise knowledge versus personal knowledge
- Knowledge managers and workers
- Knowledge coaching and diffusion
- Knowledge engineering and software engineering
- Managerial knowledge evolution with focus on managing of best practice and cooperative activities
- Knowledge grid and social networks
- Knowledge management for design, innovation and eco-innovation process
- Business Intelligence environment for supporting knowledge management
- Knowledge management in virtual advisors and training
- Management of the innovation and eco-innovation process
- Human-machine interfaces and knowledge visualization

RC-ASEF: An open-source tool-supported requirements elicitation framework for context-aware systems development

Unai Alegre-Ibarra, Juan Carlos Augusto, Carl Evans
Middlesex University, London NW4 4BT, U.K.
Email: {U.Alegre, J.Augusto, C.Evans}@mdx.ac.uk

***Abstract*—In terms of software engineering, context-aware systems (C-AS) have notably different development needs than those of traditional computing. Yet, there are no established methodologies that uniformly support the development life-cycle of these systems. A key goal of this research is to improve the current state-of-the-art with respect to engineering techniques for the life-cycle of a C-AS. Within the scope of this higher order goal, this paper addresses the lower level order goal of a holistic framework for gathering requirements which is specialised to the creation of C-AS. The framework follows an end-user, stakeholder-centred vision, which guides the analysis of stakeholders towards the discovery of specific stakeholder profiles and their particular needs, preferences, and limitations. It allows the operationalisation of the high level objectives of the system into requirements, which are more tangible and related to the implementation of the system. An evaluation procedure is supported, based on heuristics and rules from the NFR framework and REUBI. All the diagrams introduced for this framework have been developed as part of an open-source tool based on Modelio, which is intended to be developed in the future as part of a framework that covers all the stages of the development process. The proposal is illustrated through the analysis of an application for a European funded project.**

I. Introduction

The creation of context-aware systems (C-AS) can entail a great amount of challenge and complexity [1]. In comparison to the development of traditional systems, C-AS are more expensive, diverse, and prone to change. During its creation, developers might find difficult, or even impossible to identify the situations in which to display services, as well as what services should be exhibited in those situations [2]. Also, developers might find it challenging to describe the information to identify these situations, and make the system aware of them by using a heterogeneous array of sensors, which are likely to provide inaccurate, overlapping, contradictory or missing data. Additionally, advanced reasoning techniques need to be implemented in order to make the system infer that situations are happening, based on sensor information. This intricacy emphasises that there is a substantial difference between developing conventional systems and those that are context-aware. As part of previous research, an extensive analysis has studied the different approaches to the development of C-AS [1]. Although there is lot of research related to the development of these kinds of systems, this is focused on solving particular issues and it is usually scattered and not connected with other development stages. The evidence presented in [1] supports the need of a more holistic and unified approach for the development of C-AS.

A key goal of this research is to improve the current state-of-the-art with regard to techniques and methods to help establish the foundations of a uniform engineering process that covers the entire life-cycle of a C-AS. As part of a lower-order goal of the bigger picture, this paper focuses on the creation of the foundations for the *Requirements for Context-Aware Systems Framework* (RC-ASEF), a holistic framework for the requirements elicitation stage, which takes into account the specific demands of C-AS development. The support provided for the requirements elicitation stage in RC-ASEF is divided into two main foci. During early stages of the requirements elicitation process, the methodology is focused on the generic or non-contextual aspects of the system (F_1), to then iteratively advance towards the requirements which are more related to the identification of situations (context), the way in which they are planned to be detected by the system, and their associated context-aware features (F_2). Previous research towards the high order goal of this work has focused on F_2, creating a deeper analysis into the conceptualisation of context and context-awareness [2], which takes into account the philosophical limitations of C-AS in order to create a perspective for developing more usable C-AS. The aim of the work presented in this paper is focused on a generic methodology for gathering the non-contextual aspects of a C-AS, corresponding to F_1, reusing existing methods and tools to provide a coherent requirements elicitation methodology that can cover the demands of C-AS development. Particularly it has been developed with reference to previous work [3] [4] [5], including the mentioned conceptualisation of context and context-awareness [2]. In particular, the framework is based on a collection of models, presented as a combination of dynamic and static diagrams which collectively define this new requirements elicitation framework, for which in addition, new, open-source tools have been developed. These constructs have been strategically chosen to be based on UML profiles, as this facilitates its use along with other existing standards such as UML [6], SysML [7], and U2TP [8], or other UML-based requirements profiles such as UML-AT [9]. These diagrams have been developed as an extension of the open-source tool

framework RC-ASE, Modelio[1], which is further introduced in [2], and which can be found in [10]. The reminder of the paper is as follows. Section II analyses previous work in relation to the framework. Section III introduces the requirements elicitation framework. Section IV is related to the establishment of a project scope. Section V corresponds to the stakeholder analysis of the methodology. Section VI is related to the objective establishment activity. Section VII corresponds to the identification of functional requirements. Section VIII corresponds to the evaluation activities of the methodology. Finally, Section X concludes the paper.

II. Related work

Previous work related to requirements which are specialised for C-AS can be divided into three main groups: scenario-based, goal-oriented and hybrid approaches. Related work has been reviewed [1] in order to find an approach that can be suitable for creating a more holistic approach, which reuses the most positive aspects of existing methodologies and tools. This paper focuses on an analysis of methodologies for a number of aspects that are considered relevant for the higher order goal of creating a more holistic framework for C-AS development, as shown in Table I. Columns 4, 5 and 6 focus on the coverage of the methodologies for the most common elicitation activities for C-AS development. These activities are covered by most of the analysed methodologies. Columns 8 and 10 represent whether or not the methodology is based on goals, scenarios or a hybrid approach. Column 9 describes if the methodology has support for the partial satisfaction of goals rather than just being binary. Column 11 indicates whether or not the methods provide specific and systematic treatment of non-functional requirements. The most complete approach is that of REUBI [3], which has the potential to cover all these approaches. Column 12 indicates whether or not the methodology takes into account the needs, preferences and limitations of the end-users, or in its absence, they support personalisation to a certain degree. Only three methodologies support this feature, from which PC-RE [4] and R4IE [5] are highlighted. Column 13 shows whether or not the methodologies take into account the influence of contextual aspects. Many methodologies support this, but each has its own particular way to manage this. Column 14 indicates if the methodology has specific support guiding developers into: (a) enumerating the set of contextual states that may exist, (b) knowing what information could accurately determine a contextual state within that set, and (c) stating what appropriate action should be taken from a particular state [2]. Oyama et al. [11] present a series of templates for this purpose which could be reused for other methodologies. Columns 15 and 16 show whether or not the approaches have tool support and if such tool is freely and easily available for other researchers to be extended.

From the point of view of the analysis of those aspects, REUBI [3] is the most complete methodology, as it can be observed in Table I. Nevertheless, there are three main aspects that this method does not completely cover. Namely, the explicit lack of a user-centred perspective, and a lack of a tool which is publicly available. Also, it does not provide guidance for developers to discover context, according to the three main principles to get the context right [12] [2]. From the point of view of guiding the developers towards the discovery of situations and context [2], the data-information-knowledge-wisdom model of Oyama et al. [11] could also be employed for this purpose. Nevertheless, Oyama's model lacks mechanisms for elaborating and modelling requirements. Compared to REUBI [3], it also lacks mechanisms for handling soft goals and non-functional requirements. Additionally, there is no tool support for this approach. For the purpose of this research, the REUBI methodology [3] is the most relevant reference point. Therefore, it is concluded that REUBI will be used as the foundation from which the requirements framework for engineering C-AS will be built. Although REUBI has partial support for scenario based techniques, which can be used to understand and gather the context of the system, scenario-based techniques are not a necessary requirement for this work, and they can be further complemented with other techniques. A necessary aspect that needs to be covered for this work, is that of the user-centred perspective. This gap can be addressed by combining other existing methodologies. The R4IE [5] and PC-RE [4] approaches have some synergies that can be used to complement this characteristic. Additional techniques for analysing stakeholders and their needs can also be useful for this purpose. In order to address the shortcomings related to guiding developers into context discovery, a set of guidelines which are based on the perspectives of [2] will be included as part of the methodology. Finally, and significantly, whilst the REUBI approach has no explicit open-source tool support, the work described here has a specific goal of developing an open-source tool to support the proposed software development framework, which includes specific support for requirements engineering.

III. RC-ASEF: Requirements for Context-Aware Systems Engineering Framework

Figure 1 presents the six main activities of a coherent methodology out of the most relevant approaches identified for the purpose of creating a framework for supporting the non-contextual aspects of the requirements elicitation, influenced by R4IE [5]. The main enhancement is that the identification of system performance qualities, used for gathering non-functional requirements, is now part of the objective establishment. A new activity group, corresponding to the evaluation of the objectives and requirements, which is partially based on the harmonisation activity from R4IE, is introduced. The activities in Figure 1 are divided into different sub-activities, as shown in Figure 1, which are mainly influenced by the works presented in [3] [5]. The method gives great importance to the exhaustive analysis of the stakeholders of the systems, as part of the identification of their needs and preferences in further stages. The sub-activities constitute an enhancement

TABLE I
COMPARISON OF CURRENT METHODOLOGIES FOR REQUIREMENTS ENGINEERING IN TRADITIONAL AND CONTEXT-AWARE SYSTEMS.

of the R4IE methodology, where the first sub-activity of the stakeholder analysis is inspired by [17], and the second sub-activity is impacted by the profiling of users [4] [5], the ethical analysis recommendation in [17], and the e-FRIEND ethical framework [18]. It is also influenced by the conceptualisation presented in [2]. The last activity in the stakeholder analysis, and the sub-activities related to the establishment of objectives, have been adopted from [3]. Finally, those sub-activities corresponding to the identification of functional requirements and the application of the evaluation procedure are inspired by those activities in [3], and influenced by the heuristics and rules from the NFR Framework [19] as well as the SySML [7] standard.

IV. ESTABLISH SCOPE

The central activity of the methodology during F_1, is to establish the scope of the system in terms of the system boundaries (*i.e.*, what is inside the system and what is immediately external to it) . As it can be observed in [5], this activity is influenced by the remaining core activities in F_1, which help to determine the objectives, resources, budget and schedule to be included within the scope statement.

V. STAKEHOLDERS ANALYSIS

The initial step consists of a stakeholder analysis, which allows documenting and modelling the outcome from the array of techniques proposed in [17], using a UML profile for the creation of Stakeholder Diagrams. The stakeholders are identified, and their different relevant relationships to the project are analysed. The outcome of this activity is used as part of the scope statement and part of the models. Finally, the aim is to identify different user profiles, in order to pave the way for discovering useful Situations of Interest in F_2. Using the information gathered during the stakeholder analysis, it focuses on the identification of activities.

A. Identify stakeholders

This activity is initiated by a small group, and later reviewed with a larger group of stakeholders. After the review with a larger group of stakeholders, the participants should think about those stakeholders who are still not included. If there are more interested parties, a bigger group should be assembled to review the stakeholders [17]. This process iterates until a consensus has been arrived at such that it is considered that all relevant stakeholders have been accounted for. A set of techniques are recommended to guide this process [17]. Each of which can build on the previous technique, and it includes the listing of stakeholders, its basic analysis, the power versus interest grids as well as the stakeholder influence diagrams. The stakeholder identification task can also be complemented with a stakeholder analysis, as further explained in [17].

B. Determine stakeholder profiles

The aim of this activity is to identify stakeholder profiles, by establishing personal goals and setting different levels of achievement. The user profiling is attained by setting certain achievement levels and monitoring progress towards those personal goals [4]. In order to set the achievement levels, three main dimensions are analysed during F_1, which include the cultural aspects of the stakeholders, their quotidian activity, and their relevant ethical aspects. Finally, the information obtained from this analysis is used to customise the requirements, as well as the system set-up and training. In activities related to stakeholder profiling corresponding to F_2, other dimensions are analysed, namely, the interaction modalities, and the mechanisms for monitoring the achievement of personal user goals. The user profiling activity is mainly based on the activity with the same name in R4IE [5], but it also includes the cultural analysis and profiling guidelines from PC-RE [4] and the ethical analysis mechanisms from [17] and [18]. The main enhancement is that the *task subset* and *context-interaction requirements* sub-activities of R4IE [5], and the *monitoring mechanism specification* related activities of PC-RE [4] have been moved to the context-aware specialised stage, F_2. Also, a new sub-activity has been proposed, to analyse the activity of stakeholders in order to prepare the situation of interest identification in F_2.

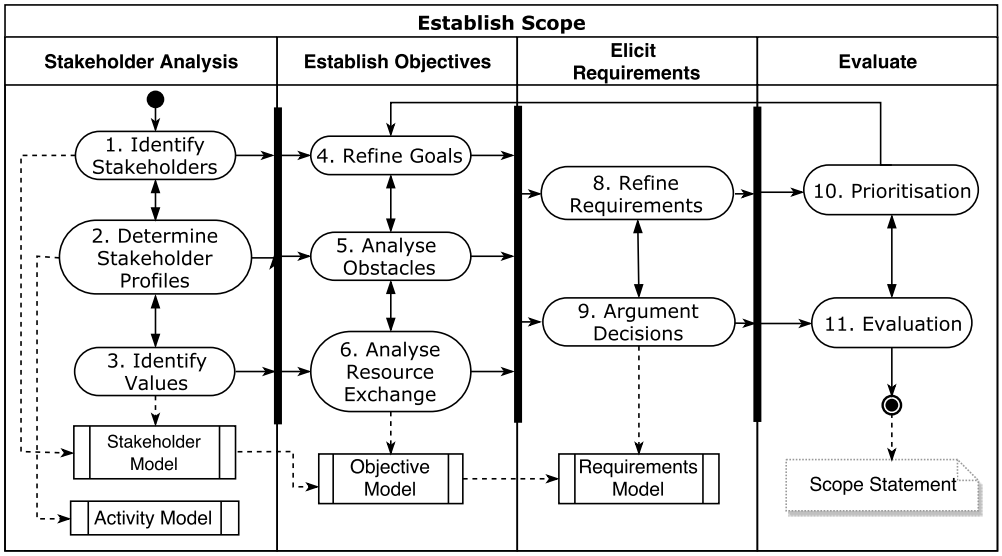

Fig. 1. Activity model representing the core activities and corresponding sub-activities in the early requirements elicitation stage, corresponding to F1.

1) Cultural analysis: The first sub-activity of stakeholder profiling deals with the system from an international point of view, where the different effects of culture are analysed in order to influence the definition of requirements for localising systems and specifying how it will be tailored for its different cultural profiles. During this activity, scenarios are sourced from users who belong to the cultures, nationalities and linguistic groups inside the intended market. The four[2] main steps of the guide proposed in [4] can be applied for this purpose.

2) Ethical analysis: An ethical analysis can contribute to ensure the ethical appropriateness of actions are ultimately taken in a project. For this purpose the use of Ethical Analysis Grids is recommended [17]. This grid can aid the satisfaction of both deontological (duty-based) and teleological (results-oriented) obligations. It consists of classifying some characteristics of each stakeholder into: High, Medium, Low and None. The characteristics are the vulnerability and gravity of the stakeholder, her/his dependency on the government, likelihood remedy, risk to fundamental value and policy impact. Although the ethical analysis proposed in [17] is useful for general purpose systems, it is not focused on C-AS. Context-awareness is the essence of different areas[3] that typically raise some ethical concerns which are different to those of traditional systems. For this reason, this sub-activity also adopts the eFRIEND ethical framework [18]. In order to apply it, it is recommended to carefully evaluate and discuss with the end-user stakeholders the different ethical concerns that might arise, until there is an agreement between all parties (*e.g.,* increasing user safety at the expense of giving up some privacy). The discussions can be complemented by questionnaires or interviews. The outcome of those discussions at a conceptual level can be used to modify or create different objectives and requirements.

3) Activity analysis: This stage consists of analysing the activity of end-user stakeholders, and is especially focused on that activity of end-user stakeholders. The purpose is to facilitate (for the benefit of developers) the identification of the meaning behind the behaviour of the end-user stakeholders. Particularly, by analysing how they usually behave in their quotidian tasks, and by thinking about how the stakeholders could use the proposed system to improve the way in which they achieve these tasks. This gives more opportunities to identify services that can be provided to them according to their particular needs, preferences, and limitations. Techniques such as observation, prototyping, scenarios or *wizard of oz* [20] can be used. Other approaches such as ethnomethodology can be adopted to understand the meaning of the actions of the end-user stakeholders. On the other hand, data analysis techniques such as classification or pattern-recognition could also help in revealing unexpected relations in the behaviour of the stakeholders.

4) Determine customisation, set-up, and training: The method proposed in Figure 1 is iterative. Once developers have defined some requirements, it is time to use the information gathered during this activity to customise existing requirements. The main dilemma is to specify C-AS that suit the requirements of individual users, while delivering a general system that can be used by many (individually different) users [4]. Not only this, but requirements can also evolve for the same user. For instance, as users become more experienced using the system, they require less help and supportive dialogues, and can access more sophisticated features. Also, the requirements engineering process should take into account aspects of maintenance and bespoke tailoring (to different stakeholders) after the system is deployed [5]. In

[2]Note that the fifth step has been moved to the user profiling activity in F_2.

[3]Particularly referring, in this case, to Ubiquitous & Pervasive Computing, Intelligent Environments, Ambient Intelligence and Ambient Assisted Living.

order to help the identification of different stakeholder profiles, there is a need to think about how the system will be set-up by/for the different stakeholders, trying to distinguish the different common needs of stakeholders that can be classified into profiles. As well as how the different stakeholders will want to customise the system, what type of training will they receive, and how will they receive it. In order to enable the customisation of the system, an individual user profile is defined first. The requirements are frequently set by another expert stakeholder (*e.g.,* a teacher sets certain requirements for a student's learning abilities). Individuals directly elicit (and own) personal goals. For both personal goals and user profiles, attainment targets can be set which become benchmarks for monitoring processes. A trade-off analysis might help to identify any conflicting user profile goals set by the expert stakeholders with the personal ambitions of the end-user stakeholder.

C. Identify values

During this sub-activity the aim is to identify the different values to be produced by the system and consumed by the stakeholders. This model has been adopted from the value model introduced in REUBI [3]. It takes existing stakeholders, humans or agents, and identifies the different values that are expected to be exchanged. Particularly, stakeholders which produce, consume a value, or are interested in a value or in its acquisition quality. Also, developers analyse what values are interchanged by the system and other stakeholders. Then developers reflect on how these values can be enhanced. Aspects such as how to improve the value, what is the expected quality of the value, what time restrictions exist in the provision of the value are taken into account. Other enhancement aspects apply, such as the flexibility in the value acquisition, precision or reliability restrictions, as well as cost or security restrictions applicable to the value.

D. Stakeholder diagram

Inspired by the techniques of the sub-activities explained in this section, the Stakeholder Diagram is introduced, which can model relevant stakeholder related information, as it is shown in the meta-model of Figure 2. In addition to the meta-models of this diagrams, each stakeholder can be associated to a *userProfile* stereotyped element. This user profile is composed of *profileFeature* stereotyped elements that can have *profileFeatureInstances*. This is better illustrated in the example from Section IX-A.

VI. Establish objectives

Taking into account the value analysis, the objectives of the system are declared. Then, from the higher order objectives, a refinement process is applied in order to obtain and decompose them into sub-objectives. This step is followed by an analysis of the adverse conditions that may impede the satisfaction of a goal. Following this, the analysis focuses on the resources required for the satisfaction of goals.

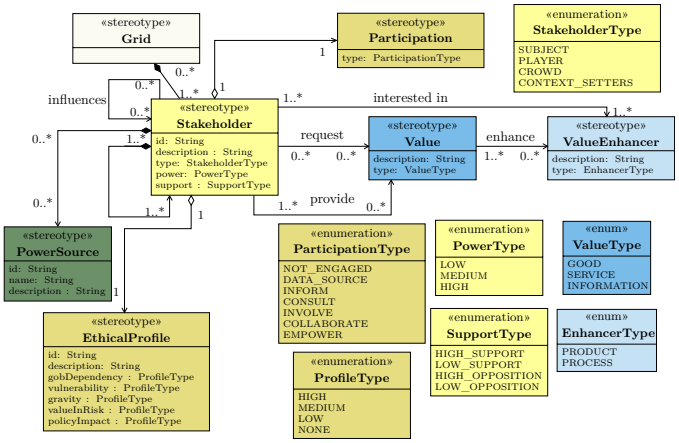

Fig. 2. UML meta-model for the Stakeholder Diagram.

A. Refine goals

Once the system boundaries and the higher-order objectives are identified, in the form of *values* and *value enhancers*, it is necessary to derive more specific objectives, and progressively refine them in order to obtain more knowledge about the system under development. Objectives act as a bridge between the system values and the final requirements of the system, providing specific guidance during the requirements elicitation process. Objectives are divided into *goals* and *soft-goals*, according to the identified *values* and *value enhancers*. Goals have a clear criteria of satisfaction. Soft-goals do not have a clear criteria of satisfaction, which means that they can be used for identifying and modelling non-functional requirements. The objectives can also be progressively decomposed using *inclusive* (AND), *alternative* (OR), or *exclusive* (XOR) relationships between them. Such relationships can help in determining if their corresponding parent objectives are satisfied or not, as further explained in [3].

B. Analyse obstacles

The dynamic nature of C-AS is closely related to the existence of multiple adverse conditions which can make it difficult for system objectives to be met. This sub-activity consists of identifying obstacles which may affect meeting a specific goal, in the same way as described in [3]. The main objective is to determine those situations which are likely to be inconvenient for meeting the objectives, even if obtaining a complete set of adverse conditions can be a difficult achievement.

C. Analyse resource exchange

Sometimes, there exist restrictions on the way in which sub-objectives need to be satisfied in order to satisfy the parent objective; such as not satisfying an objective until other objectives are satisfied, mainly because these require access to certain resources which are generated as a result of satisfying other objectives. The objectives relate to the resources through two different relationships: *provision* and *demand*, as further explained in [3].

D. Objective diagram

With the purpose of facilitating the objective, obstacle and resource exchange analysis explained in this section, the *Objective Diagram* is introduced, which has been adopted from the Interdependency Graph in [3]. The meta-model of this diagram and its corresponding example can be observed in [3].

VII. Elicit requirements

Once the objectives of the system are defined, they need to be operationalised into requirements. Then, an analysis of the contribution that the requirements have to objectives should be performed. This stage is inspired in the *task/function* and *system performance qualities* identification activities of R4IE [5]. Following this, requirements are refined, decomposed into sub-objectives, and related to other model elements. All the decisions taken need to be documented as rationales, in order to facilitate requirements tracing, by modelling the reasons which developers are following to make decisions.

A. Refine requirements

Once the engineers agree upon the representation of values, objectives, their decomposition, obstacles and resources; the next step is to discover alternatives which can satisfy the objectives, finding their possible operationalisations, in the form of requirements. In the previous sub-activity, higher-order requirements are identified, as well as their contribution to the objectives. In this sub-activity, those requirements are refined into more precise requirements, and are related to other elements of the system. In addition to those relationships (RefineObj and Contribute) introduced by the Interdependency Graph in REUBI [3], the Requirements Diagram inherits five different types of relationships from SysML (Derive, Refine, Satisfy, Verify and Copy) [7]. This sub-activity mainly consists of applying these seven relationships between requirements, objectives and other elements of the system. More information on the application of these relations can be found in [3], [7].

B. Argument decisions

Once the requirements are operationalised and refined, the aim is to model the decisions taken during the previous activities. The Requirements Diagram enables this through the use of the Argumentation stereotype, which is related to other elements in the Requirements Diagram. SysML already provides a means to argument relationships via the Rationale stereotype. Nevertheless, the Argumentation stereotype provided in the Interdependency Diagram of REUBI [3], facilitates the specialisation of the rationale into support and rejection arguments.

C. Requirements diagram

For the purpose explained in this section, the Requirements Diagram is introduced, which inherits the stereotypes of the OMG SysML Requirements Diagram [7], and the object and justification meta-models from the REUBI Interdependency Graph [3]. The Operationalisation stereotype from REUBI, has been substituted by the SysML Requirement, which gives several advantages. The requirements traceability relationships help keep track of what happens to a requirement during system modelling and specification by identifying sources, destinations and links between requirements and models. Additionally, the SysML requirements enable a mapping to evaluation constructs such as the test case, providing a way of documenting how the requirements will be tested, which can be used along with other UML-based standards such as the UML 2.0 Testing Profile [8], to facilitate the design and automation of test runs [21]. SysML also offers two requirements visualisation mechanisms to identify, prioritise and improve requirements traceability through requirements tables and requirements traceability matrixes. Although the exclusive use of Use-case diagrams might be limited for the requirements engineering process, the use of SysML requirements to complement them represents an advantage and improves standardisation [22]. SysML requirements can also be related to use-cases with the *refines* relationship. Finally, the approach also inherits some advantages from the use of REUBI objectives, as these are used to facilitate the discovery of requirements and non-functional requirements and act as a bridge between the stakeholder analysis and the requirements. Finally, it is also important to mention that the operationalisation of objectives into requirements can be evaluated using the evaluation procedures from REUBI [3].

VIII. Evaluate

The last activity of the framework consists of an evaluation of the objectives and requirements, which is guided by a set of heuristics, that have been adapted to their application to the framework presented in this paper from [19] [3]. Then, a plan for evaluating the requirements is created, setting the criteria for how each requirement will be evaluated once the system is implemented. For this, the objectives need to be prioritised, in order to enable developers to focus on the development efforts on the most important objectives first. Then, an evaluation helps engineers to determine if the current modelled operationalisation of objectives into Requirements satisfies the objectives. For this the evaluation procedure for the NFR framework is adopted, as presented in [19] and [3].

IX. Case study

The case study introduced in this section is based on the insights gained during the development of the EU funded POSEIDON[4] project [23]. The project name stands for PersOnalised Smart Environments to increase Inclusion of people with DOwn's syNdrome, and is particulary focused on using smart assistive technologies in order to foster the independence of people with this condition. The example presented in this work is constrained to an outdoors navigation application, which is bespoke to this particular disability [25]. More specifically, the case study focuses on a mobile application that uses a real-world representation of maps along with location

[4]http://www.poseidon-project.org/

services to support outdoor journeys that might be walking or by bus. Due to space restrictions, this example is further limited to bus displacements happening in London, United Kingdom. The application uses routes with tailored directions, notifications, reminders, and other services which will be triggered depending on the context. The navigation system described in this case study can be found in [26], and it has been developed using the open-source framework RCASE [10] developed as part of the contribution presented in this paper. All the figures appearing in the remaining of the paper are screenshots of the RCASE tool.

A. Stakeholder analysis

The stakeholder identification activity presents a set of techniques that build on the previous activity. The following list of stakeholders are identified: 1) Primary Users (PU), people with Down's Syndrome; 2) Secondary Users (SU), parents or carers of people with Down's Syndrome; 3) POSEIDON Managers, the management team of the POSEIDON project; 4) POSEIDON Development Partners, POSEIDON project partners which work in creating code or libraries that are to be reused by this application. 5) Developers, the developers of the navigational system; 6) Bus driver, the person(s) that drive(s) the bus in which the PU will get on; 7) Bus company, the company in charge of the bus line; 8) Calls and Internet provider, referring to the company that provides phone calls, SMS and internet to the mobile device; 9) Device Manufacturer, company that manufactures the device; 10) Operating System Developers, group involved in the development of the operating system of the device; 11) Maps Library Developers, group involved in the development of the maps libraries. The list is further refined into the power versus interest grid, which evolves through iterations into the stakeholder influence grid, as it is shown in Figure 3. The stakeholder

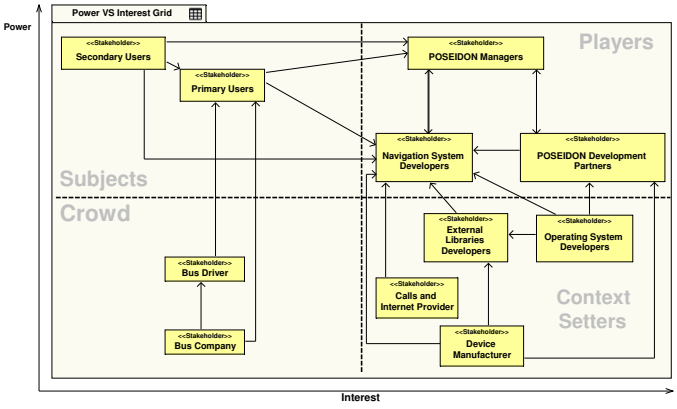

Fig. 3. Power vs Interest Grid representation, created with the Stakeholder Diagram from the RC-ASE Tool.

diagrams introduced give better insights about who are the stakeholders of the system and their relevant aspects to the project. The analysis on the stakeholders and their profiles can provide relevant information of the stakeholders which can be later reused for identifying their needs and preferences in the context related requirements. The stakeholder profiling activity follows. The POSEIDON project, involved a total of three different countries, namely, United Kingdom, Germany and Norway. These three cultures are similar in the sense of avoiding uncertainty, having similar work patterns, and responding similarly to authority, initiative and responsibility, since they all share the same continent. As expecting users with possibly low-skills with technology [27], the use of visual or symbolic representations of context is preferred, as well as the one task at a time approach. Another relevant aspect to take into account is the language difference between these three countries. Additionally, the United Kingdom has a different currency, representation of metrics, and driving direction than Germany and Norway. This might affect the payments of users for public transport, the location of bus stops, as well as the distance representation in the maps. The discovery of personas revealed that some of the particular users have visual or auditive impairments, and the questionnaires revealed that different skill levels using information technologies [27]. There are five different user profile features for the primary user stakeholder: Culture, visual impairment, skills with technology, independence degree, and auditive impairment. Each of the profile features is divided into its corresponding user profile feature instances. For example, the independence degree can be classified into three profile feature instances: *independent*, *moderately dependent*, and *dependent*. Following, the activity of the end-user stakeholders when displacing is analysed. A user will typically walk to the bus station, wait for a bus, take the bus, press the stop button one destination before the stop, get off the bus and walk again if necessary. This information will be used to identify situational interests in F_2, as it is shown in Table 1 from [2].

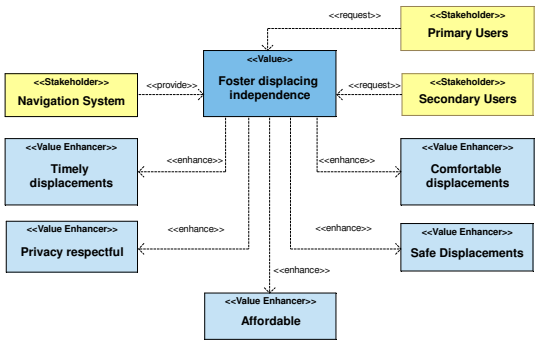

Fig. 4. Value model representation, Stakeholder Diagram, RC-ASE Tool.

The last activity in the stakeholder analysis consists of creating a value model, as shown in Figure 4. The first actor to take place is the navigational system itself, which offers the value of fostering the independence of both primary and secondary users. That value is a service, which is requested by the primary and secondary users. Five main aspects enhance the value provided by the navigation system. These are: that primary and secondary users can afford the system, that the system can preserve the privacy of the users, that the primary users can displace safely when using the system, that the

primary users can reach their destination on time, and that the instructions given by the navigation system are understandable by primary users.

B. Establish objectives

The main goals and soft-goals of the system are derived from the value model shown in Figure 4. In this way, the goal *Guide displacements*, is related to the *Foster displacing independence* value, as shown in Figure 5. Since this value is still too generic, it needs to be refined. The goal can be decomposed into two sub-goals: *Walking displacement guidance* and *Bus displacement guidance*. Note that for satisfying the high level objective, both lower level objectives must be satisfied. It equally happens with the value enhancers. *Walking displacement guidance* is refined into the objective "*Time-based guidance*", which proposes that the guidance received by the stakeholders will take into consideration time constraints. This goal is divided into another two lower level goals, which are to *provide guidance about when to start the displacement*, and to *provide guidance according to the waking speed*. The value enhancer *Affordable*, is distilled into the *Low-cost* soft-goal, which at the same time is divided into *Low-cost hardware* and *Low-cost software* soft-goals. The value enhancer *Privacy respectful* is also refined into the soft-goal *User privacy*, that is divided into the two soft-goals *Anonymity/pseudonimity* and *User intimacy*. The value enhancer *Safe displacement* is refined into the soft-goals *Displace through safe environments*, and *Support lost users*. Finally, the value enhancer *Comfortable displacement*, is distilled into the goal *Guide on required objects*, that supports the user with a list of objects that can make more comfortable the displacement or the activity to do where the user is displacing. Also, this value enhancer is refined into the soft-goal *Provide understandable guidance*.

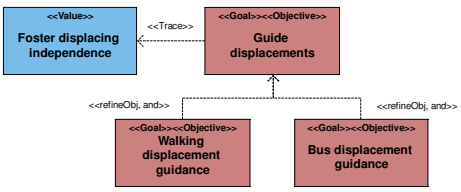

Fig. 5. Goal Decomposition I, Objective Diagram, RC-ASE Tool.

Following, an obstacle analysis over the objectives proceeds. The main obstacle found is due to the interruption of the service, caused by a lack of power. The battery may run off, and the user is left without instructions to follow. In order to mitigate, the soft-goal *Availability* is added. Next, is the Resource analysis. Here, the goal of guiding displacements refines from the *Start instructions* resource, generated from the time-based guidance goal. Additionally, the goal for guiding displacements also requires from the *Personal object list* resource, generated from the *Guidance on object list* goal.

C. Elicit requirements

At this stage of the method, the different goals of the system are refined into requirements, that represent a condition or capability that the system needs, and which contribute to the satisfaction of objectives. These design decisions, as well as the positive or negative contributions of the decisions are studied. For this, the lowest-level goals are considered (*i.e.,* those goals which do not have any sub-goal). In the previously introduced goal models, there are 5 low-level goals, which are used to define the functional requirements of the system, and 7 low-level soft-goals, which are used to define the non-functional requirements. For simplicity, the Requirements Diagrams of this example have been divided into three parts: requirements related to navigation, as shown in Figure 6; requirements related to reminders of the system; and non-functional requirements. Navigational requirements are based on a main requirement, *Navigation Map*, that specifies that the user will be able to observe a map that represents the real-world surroundings. Note that this requirement is a positive contribution towards two low-level goals: *Walking displacement guide* and *Bus displacement guide*. However, since just

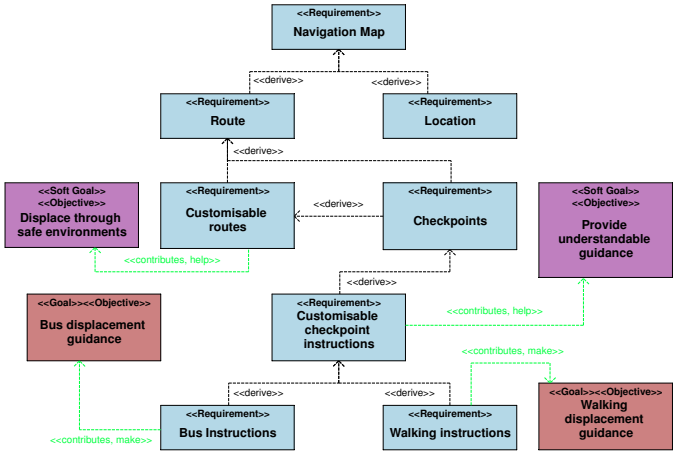

Fig. 6. Requirements model I, Requirements Diagram, RC-ASE Tool.

showing a map can not be considered as providing enough guidance, the contribution relationship can not be considered as a *Make* contribution. To keep the diagram simple, the *help* relationships between requirements and these two goals have been omitted in Figure 6. Since the *Navigation Map* requirement is not enough proof for satisfying the two previously mentioned goals, this main requirement is divided into another two additional requirements which are to show specific instructions on the next movements that users need to do in order to ultimately arrive at their destination. The navigation map will have a *route*, indicating the path that the user has to follow in order to arrive at her/his destination. Additionally, the navigation map will display the *location* of the user in the map in real-time. Although these two new requirements also provide a positive contribution towards the satisfaction of the two main guidance goals of this diagram, they are still not enough proof for providing adequate guidance to the users when walking and displacing by bus. Taking into account the low level objective of *Displacing through safe environments*, the requirement *Customisable routes* is included, where it is

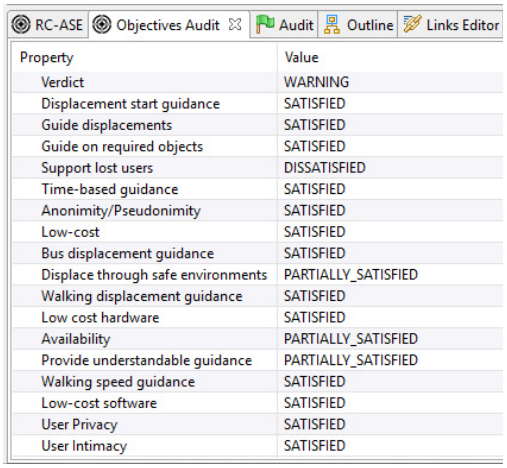
specified that the secondary users will be able to create their own routes for the primary users. The difference between the application under development and other navigation applications, is that this option increases the security of the primary users, as parents are expected to send them through safer and easier routes, instead of the most complicated ones. This requirement also satisfies the needs of users with different skill levels. As it can be observed in Figure 6, this new requirement is considered as a positive contribution towards the soft-goal for safe environments. Routes, will also have *checkpoints* that divide the route into more manageable smaller parts. Although this requirement by itself does not provide any contribution to the objectives, it is necessary to understand the next requirement that derives from it: *Customisable checkpoint instructions*. The checkpoints of the routes, will not only be located by the secondary users, but they will include a set of personalised instructions about the next movement. For example, it could be " *When you see the blue house with a white door, turn left, using the crosswalk*". An additional picture of the blue house can be included for making the instruction more clear. This requirement positively contributes to the soft-goal of *Provide understandable guidance*. These customisable checkpoint instructions can map to *walking* or for *bus displacements*. These last two instruction types *make* the main guidance goals. Therefore, the requirements engineers can consider this diagram as finished, and continue with the following diagram. Due to space reasons, reminder-related requirements and non-functional requirements have been omitted from this example. The operationalisation into requirements from objectives will occur similarly to that of navigational requirements.

After completing the operationalisation of objectives into requirements, the next step is to personalise or create new requirements according to the different user profiles. As it can be observed in the first figure, the cultural profile affects the existing communication with the users. Therefore, this figure illustrates the different requirements that are created to satisfy the demands of a British profile. The project supports English, German and Norwegian languages, British pounds (BGP) and Euros (EUR), as well as the Imperial and Metric systems. On the other hand, the second figure enables a different communication with the users. For those users with visual impairments, audio based communications will be present, and for those with auditive impairments visual communications will be enabled. The sub-activity for personalisation introduced in Section V-B4 it also includes a specification of the set-up and training. The users of the navigation application, will have to their disposition a training tool for letting them acquire navigation skills in a virtual environment, without exposing themselves to unnecessary risks. For space reasons, the further explanation on the training framework is out of the scope of this example, but the Reader is referred to [28] for more information about how users can train using this system.

Finally, an ethical analysis of the stakeholders is done. For example, an ethical analysis of the primary user stakeholder can be conducted against the *Login*, *Mobile platform*, *Reminders*, *Navigation map*, and *Communication with the users* requirements. For this profile, there is no *dependency* of the stakeholder on the government regarding the mentioned requirements. Also, there is a medium level of *vulnerability* from the users, in case they can get lost by misinterpreting indications. Nevertheless, the *gravity* of this stake is low. There is a high *likelihood* that there will be a remedy for this which will be addressed when creating the context-awareness specialisation of the requirements methodology. There is a medium *risk* to the integrity of the stakeholders, and the *policy impact* is high.

D. Evaluate

First of all, if it has not been done already, all the objectives defined in IX-B need to be prioritised. Then, the R-CASE module will automatically give a verdict on the satisfaction of the objectives of the system, according to the algorithm and rules explained in Section VIII. For this example, the result of this evaluation can be observed in Figure 7. The current verdict of the example is *WARNING*, as the *Support lost users* objective is *DISSATISFIED*, and the *Availability* objective is *PARTIALLY_SATISFIED*. This means that in order to improve the verdict to *PASS*, special attention should be payed to the completion of these objectives when eliciting requirements related to the context-awareness of the system.



Property	Value
Verdict	WARNING
Displacement start guidance	SATISFIED
Guide displacements	SATISFIED
Guide on required objects	SATISFIED
Support lost users	DISSATISFIED
Time-based guidance	SATISFIED
Anonimity/Pseudonimity	SATISFIED
Low-cost	SATISFIED
Bus displacement guidance	SATISFIED
Displace through safe environments	PARTIALLY_SATISFIED
Walking displacement guidance	SATISFIED
Low cost hardware	SATISFIED
Availability	PARTIALLY_SATISFIED
Provide understandable guidance	PARTIALLY_SATISFIED
Walking speed guidance	SATISFIED
Low-cost software	SATISFIED
User Privacy	SATISFIED
User Intimacy	SATISFIED

Fig. 7. Screenshot of the evaluation of objectives using the RC-ASE module in Modelio.

X. Conclusions and Future Work

This paper proposes a framework for facilitating the systematic treatment of requirements, and which is specialised for the non-contextual aspects of C-AS. The framework proposes a guide for developers that spans from the identification of stakeholders, to the identification of objectives and its operationalisation of goals, and introducing a UML/SysML profile for supporting the documentation and modelling of the process. The process is based on the strong points of different methodologies which are gathered as a coherent framework, helping to cover the gaps in the development of C-AS that current requirements elicitation methodologies have (Table I).

Additionally, the framework has been implemented as part of an open-source tool which supports the Diagrams introduced in this paper, as well as other SysML features to increase the traceability of elements throughout the models. A novel module for Modelio has been developed, namely Requirements for Context-Aware Systems Engineering (RC-ASE) [10], which implements not only the Diagrams introduced during this section, but also the missing SysML features that the free version has, including *traceability matrixes* and *requirements tables*, as well as other relevant functionality such as partial documentation generation. The approach has been applied to a navigation system of the POSEIDON project. Currently, there is undergoing work to create a more specialised UML/SysML profile that is more focused on the contextual aspects, related to F_2, as introduced in [2]. More work is being dedicated to the creation of another framework that facilitates the design and automatic code generation, aimed for the management of context information for context-aware rule-based reasoning support in both mobile [29] and stationary [30] platforms. The aim is not only to create services that can create C-AS that are more related to the preferences and needs of the users, but to create more reliable services by automating the verification of reasoning rules.

ACKNOWLEDGMENT

The research leading to these results has been partly supported by the POSEIDON project funded by the European Union (FP7/2007-2013) under grant agreement no. 610840.

e-mail: {jerzy.korczak, marcin.hernes}ue.wroc.pl

***Abstract*—The article presents the problem related to evaluation of Forex trading strategies in multi-agent systems. The ratios based on financial measures cannot be assumed to be only evaluation criteria because other aspects determining effectiveness of the strategies, such as, for instance, investment risk, statistics on winning, and lost transactions, transaction costs, should also be taken into consideration. The aim of this paper is to review the general financial investments performance measures in relation to the performance analysis of trading strategies. The characteristics of the commonly used performance measures are outlined. The discussion will be illustrated by solutions developed in the trading support system, called A-Trader system. The performance analysis in A-Trader is detailed on real FOREX quotations.**

I. Introduction

TODAY the multi-agents systems are increasingly being used as trading support on Forex market [1, 2]. Agents operating in such systems provide strategies for open/close long/short positions with the use of various investments methods and techniques. There arises the need of constant evaluation of the agent performance to guarantee satisfactory benefits to the trader. Many of the performance evaluation methods [e.g. 2, 3, 4] and practical solutions (e.g. MetaTrader [5], Plus500 [6], MetaStock [7] or NinjaTrader [8]) are based on ratios of return (e.g. rate of return, gross profit, and the number of unprofitable transactions).

Investment decisions are made under conditions of risk and uncertainty. In the case of a trading decision, it is difficult to talk about the optimal decision as the decision bringing the highest possible rate of return for the investor, rather should be said about the decision bringing a satisfactory rate of return for the trader under a given level of other factors (e.g. risk). Many authors [e.g. 9, 10] have drawn attention to the fact that making an optimal decision is in practice very difficult in a situation of risk and uncertainty. If, on the other hand, we adopt the principle of satisfactory benefits, referred to in the literature as the principle of subjective expected utility [11], decision-making process becomes less complicated. According to this principle, for each alternative, its expected usefulness can be determined, and then the alternative that has the most usability is to be selected. The idea is to "set the bar" at such a level that it would not be too low, because then the result would be unsatisfactory, and not too high, because it might be unattainable for a trader. Note that in this case, the trader can set the "bar" higher and higher in sequence, which will bring him closer to the optimal value. Therefore, the ratios based measures cannot be assumed as the only evaluation criterion because other aspects having influence on the effectiveness of the strategies, such as, for instance, investment risk [12], statistics on winning and lost transactions as well as transaction costs should also be taken into consideration.

The aim of this paper is to review the general financial investments performance measures in relation to the performance analysis of trading strategies. The discussion will be illustrated by solutions developed and provided by the A-Trader system [13]. A-Trader system is composed of the agents capable of generating independent trading decisions on FOREX market. It allows for High Frequency Trading (HFT). It is realized in near real time (the notion of "near real time" can be understood as a very short delay between the last quote and the time of generated trading decision; usually 10-250 ms) and characterized by high speed, short-term positions, it concentrates attention on price formation process using sophisticated algorithms based on efficient and robust indicators and modern IT [14]. High frequency traders take decisions on the basis of real-time quotes changes in order to achieve satisfactory rate of return.

In the first part of this paper, the characteristics of performance measures are outlined. Next, the methods of performance analysis in the trading support system, called A-Trader, are detailed. In the final part of the article, conclusions and future works are presented.

II. Performance measures for financial investment

There are many performance measures in related works. These measures was developed in economics, management, and finance, both by researchers and practitioners. The related works [15, 16] divide performance measures for financial investments into three main groups:

- measures based on ratios of excess returns (ratios-based),
- measures based on systematic risk measured by factor models (risk-based),
- measures based on endogenous benchmarks derived from portfolio theory (benchmarks-based).

The major differences between these groups, but also between specific measures refer to the definition of risk. The next part of the section presents characteristics of particular groups.

A. *Measures based on ratios of excess returns*

Ratio-based performance measures specify the return per unit of risk. Ratio-based performance measures are usually easy to compute and have only low data requirements. These measures are of high relevance in practical applications and are frequently used in publications [12, 15, 17,18].

All ratios of return-based measures follow a similar schema: a measure of the return of asset in excess of the return on the benchmark is divided by a measure of the investment risk of asset. The most popular are the following::

- arithmetic rate of return,
- logarithmic rate of return,
- the number of transaction,
- gross profit,
- gross loss,
- total profit,
- the number of profitable transactions,
- the number of profitable transactions in a row,
- the number of unprofitable transactions in a row.

All of them are available in A-Trader.

B. *Measures based on systematic risk measured by factor models*

Risk-based performance measures adjust for risk by computing the spread between actual returns and a hypothetical benchmark return which is determined [17].

These measures indicate whether the trader was able to beat the benchmark, strictly speaking, they do not allow for comparison of different investment products because risk-based performance measures are subject to manipulation by leverage. For identification of relevant and meaningful risk factors and computation of "fair" or expected returns, risk-based performance measures draw heavily from the asset pricing literature. This group contains measures, such as [17, 19]:

- *Sharpe Ratio*

$$S = \frac{E(r)-E(f)}{|O(r)|} \cdot 100\% \quad (1)$$

where:
$E(r)$ – arithmetic average of the rate of return,
$E(f)$ – arithmetic average of the risk-free rate of return,
$O(r)$ – standard deviation of rates of return.

- *Treynor Ratio*

$$T = \frac{E(r)-E(f)}{\beta(r)} \quad (2)$$

where:
$E(r)$ – arithmetic average of the rate of return,
$E(f)$ – arithmetic average of the risk-free rate of return,
$\beta\,(r)$ – beta coefficient of rates of return.

- *The Kappa ratio*

$$T = \frac{E(r)-E(f)}{\sqrt[n]{LPM(r)}} \quad (3)$$

where:
$E(r)$ – arithmetic average of the rate of return,
$E(f)$ – arithmetic average of the risk-free rate of return,
$LPM(r)$ – lower partial moments of rates of return.

- *Omega ratio*

$$\Omega = \frac{\sqrt[n]{HPM(r)}}{\sqrt[n]{LPM(r)}} \quad (4)$$

where:
$HPM(r)$ – higher partial moments of rates of return.
$LPM(r)$ – lower partial moments of rates of return.

- *Average coefficient of variation*

$$V = \frac{s}{|E(r)|} * 100\% \quad (5)$$

where:
V – average coefficient of variation,
s – average deviation of the rates of return,
$E(\mathrm{r})$ – arithmetic average of the rates of return.

- *Jensen Model*

$$JM = E(r) - (E(f) + \beta\,(r) \cdot \big(E(m) - E(f)\big)). \quad (6)$$

where:
$E(r)$ – arithmetic average of the rate of return,
$E(f)$ – arithmetic average of the risk-free rate of return,
$E(m)$ – arithmetic average of the realized return of the appropriate market index,
$E(f)$ – arithmetic average of the risk-free rate of return,
$\beta\,(r)$ – beta coefficient of rates of return.

- *Value at Risk*

  The measure known as a value exposed to the risk - that is the maximum possible loss of the market value that a financial instrument can bear in a specific timeframe and at a given confidence level.

$$VAR = P * O * k \tag{7}$$

where:
P – the initial capital,
O – volatility - standard deviation of rates of return during the period ,
k – the inverse of the standard normal cumulative distribution (assumed confidence level 95%, the value of k is 1,65).

Some of these measures are available in A-Trader (Sharpe ratio, average coefficient of variation and Value et Risk).

C. *Measures based on endogenous benchmarks derived from portfolio information*

This group of measures usually compares the return of each security in the portfolio to the return of a "benchmark" security in order to determine abnormal performance. The comparable securities are selected based on characteristics, or they are derived from portfolio in another time period. Consequently, data requirements are higher for these models, while the statistical concepts are relatively simple [15, 16].

- *Characteristic-Based Models*

  Characteristic-Based Models are interpreted as portfolio-weighted sum of the differences in returns between the stocks and the benchmark portfolios, and can be calculated, for example by following equation:

$$CM_t = \sum_{j=1}^{m} w_{jt} \left(r_{jt} - r_{jt-1}^{b}\right) \tag{8}$$

where:
w_{jt}– weight of asset j at time t,
r_{jt} – corresponding excess return of asset j,
r_{jt-1}^{b} – the return on a benchmark portfolio that is matched to asset j measured in $t-1$.

- *Holdings-Based Models*

  These models define managerial skill as a co-variation between portfolio weights and returns of single stocks taking into consideration an omega ratio.

$$HM = \sum_{j=1}^{m} Cov\left(w_{jt,} r_{jt} | \Omega_t\right) \tag{9}$$

where:
w_{jt}– weight of asset j at time t,
r_{jt} – corresponding excess return of asset j at time t,
Ω_t – omega ratio at time t.

- *Trade-Based Models*

  These models define managerial skill as a co-variation between portfolio weights and returns of single stocks.

$$TM = \sum_{j=1}^{m} Cov\left(w_{jt,} r_{jt}\right) \tag{10}$$

where:
w_{jt}– weight of asset j at time t,
r_{jt} – corresponding excess return of asset j at time t,

Performance measures presented in this section allow for a wide range of evaluation of investment strategies on Forex. There are many other measures in the related works, however we have tried to select such as are more often used in practice and which can be implemented in High-Frequency trading systems due to low computational complexity.

In A-Trader, a characteristic based models are available (based on buy and hold and random walk benchmarks).

Next part of paper presents method for performance evaluation in A-Trader multi-agent system.

III. PERFORMANCE EVALUATION METHOD IN A-TRADER

In general, A-Trader system is composed of the agents capable of generating independent trading decisions on FOREX market. It should be noted that decisions can be consistent or contradictory, e.g. two independent agents may generate buy and sell decision at the same time [20, 21]. The trading opportunities are provided by consensual advice, generated by multiple software agents that use technical and fundamental analysis as well as behavioral sentiments [22]. Trading agents in the A-Trader form the investment strategies, which advise recommended open and closed positions for online FOREX traders. There are many strategies implemented as Supervisor Agents, such as:

- Basic Strategy,
- Consensus,
- Candle genetic algorithm,
- Kohonen network,
- Growing neural gas,
- Fundamental back propagation network,
- Evolutionary algorithm.
- Deep Learning

Supervisor Agent is the most important agent in A-Trader. Its goal is to generate profitable trading advice, on the basis of three groups of The Supervisor Agent coordinates functioning of the other agents (which form a given strategy) presented, and to provide the final advice to the trader. Its other task include resolving conflicts between agents [23]. The strategies are permanently evaluated by Supervisor Agents, and those with the highest evaluation value can be taken by default or chosen by the trader.

The performance analysis in A-Trader is carried out with the consideration of the following measures (ratios):

- rate of return (ratio x_1),
- number of transactions,
- gross profit (ratio x_2),
- gross loss (ratio x_3),

- total profit (ratio x_4),
- number of profitable transactions (ratio x_5),
- number of profitable consecutive transactions (ratio x_6),
- number of unprofitable consecutive transactions (ratio x_7),
- Sharpe ratio (ratio x_8)
- average coefficient of variation (ratio x_9)
- Value at Risk (ratio x_{10})
- the average rate of return per transaction (ratio x_{11}).

There are many ways of defining the performance evaluation function. For the purpose of comparison of the agents' performance, the following simple evaluation function has been proposed:

$$y = \left(a_1x_1 + a_2x_2 + a_{3(1-}x_3\right) + a_4x_4 + a_5x_5 + a_6x_6 + a_7(1 - x_7) + a_8x_8 + a_9(1 - x_9) + a_{10}(1 - x_{10}) + a_{11}x_{11} \quad (11)$$

where x_i denote the normalized values of particular performance measures from x_1 to x_{11}. It was adopted in the test that coefficients a_1 to a_{11}=1/11.

It should be mentioned that these coefficients may be modified with the use of, for instance, an evolution-based method, or they could be determined by the trader in accordance with their preferences (for instance the trader may determine whether they are interested in higher rate of return with accompanying higher risk level or lower risk level but accepting a lower rate of return).

The output of the function is a value in the range [0..1], and the agent's efficiency is directly proportional to the function value.

Figure 1 presents performance evaluation panel in A-Trader. The upper part of window presents information related to open/close positions generated by strategy in a given period. The profitable ones are marked on green and unprofitable ones are marked on red. The bottom part of window presents performance evaluation values related to selected positions (it is possible to mark all positions, or only selected positions).

Referring to the evaluation analysis related to particular measures performed in other systems (mentioned in section 1), as previously underlined, these systems only offer the functions calculating the rates of return based ratios. It should be noted that evaluation, in most cases, is performed "manually" by the trader. This work has many inconveniences. Due to its time consumption, the trader can use only selected measures of performance, and choice of these measures may be narrow. Also the trader acting under time pressure may select inadequate measures, and, in consequence, important financial losses may be generated. In addition, it is very difficult to have valid current knowledge on online trading (the trader's knowledge, in very turbulent market conditions, may be outdated or/and incomplete). These issues imply that systems operating in real time are very limited.

As has been mentioned, the evaluation function used in A-Trader enables the evaluation of performance of specific strategies. These operations are made automatically, in time close to real time, by the Supervisor Agent which may then

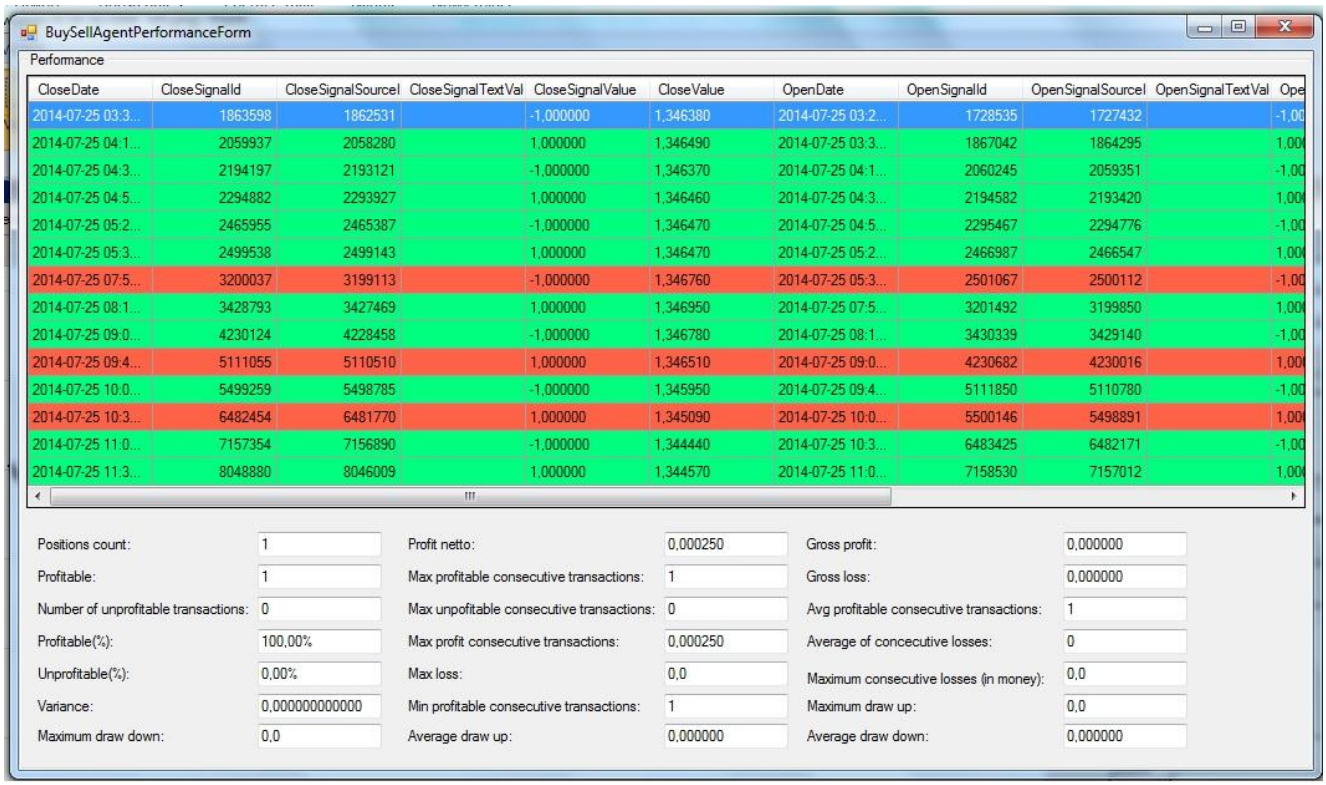

Fig. 1. Performance evaluation panel in A-Trader.
Source: Own work.

suggest to the investor taking final decisions on the basis of strategy with the highest level of performance. In addition, enabling the user to change coefficients a_i and ratios x_i parameters of the evaluation function allows for considering their preference concerning the criterion of importance of particular evaluation ratios. The performance evaluation function also considers the transaction costs with the assumption that this reflects the relationship between the number of transactions and the average rate of return from the transaction. However, this simple principle cannot be adopted because a large number of transactions has impact on the reduction of the strategy's efficiency level, especially for the transactions with a high rate of return.

A-Trader uses only selected measures because using largest number of ratios require higher computing resources than are now available (in HFT this measures must be calculated near real time). In future, we plan to use the cloud computing resources, then we will be in a position to implement a larger number of measures. It should be noted that the number of performance measures in A-Trader is not limited and they can be added to evaluation function in an easy way.

IV. Conclusion

The strategies in the A-Trader system open/close independent long/short position use multiple criteria of trading performance, which belong to three groups of performance measures: ratios-based, risk based, and benchmark-based. As a consequence, this enables the trader to compose an evaluation function according to their preferences and to apply to the strategies of the best Supervisor Agents. The results presented in our previous research [13, 14, 21, 22, 24, 25] allow us to come to the conclusions that there is no universally accepted evaluation function nor universal measures. The choice of measures and the composition of the evaluation function is highly dependent on trader preferences and trading market. We have already demonstrated that the level of performance of particular strategies changes depending on prevailing FOREX market situation. Based on the obtained results, there is no one strategy which definitely dominates over the others.

The use of this performance evaluation function allows for automatic setting of the best strategy in time close to real time, which has, in turn, a positive influence on investment effectiveness.

Future works should concern, among others, implementation of other performance evaluation measures (presented in section 2), development of an evolution method for determining ai coefficients into the A-Trader system, and implementation of cognitive agents performing analysis experts' opinions in the scope of forecasts referring to quotations on the FOREX market..

Mining e-mail message sequences from log data

Paweł Weichbroth
Faculty of Management, WSB University in Gdansk,
Grunwaldzka 238A, 80-266 Gdansk, Poland
pawel.weichbroth@hotmail.com

***Abstract*—Communication by electronic mail (e-mail), once extravagant, is now the usual way to exchange data and information. Widely accepted by Internet users, business and governments, it is claimed to be the key part of the e-revolution. E-mail systems have been successfully implemented in almost all computer-aided domains of human interest, providing efficient, effective and permanent mechanisms of transmission. However, to date, the capability to exhibit an ordered list (sequence) of e-mail message senders and recipients, with the respective duration time between receiving and answering is still lacking. To fill this gap, in this paper we introduce the SOMF algorithm for mining such sequences from server log data. We specified a three-stage approach to comprehensively target the problem. The first stage concerns a data preparation task in order to assemble the input for the algorithm. The second, known as data mining, is the automatic analysis of data input performed in an unsupervised model by the SOMF algorithm. The third embraces output (knowledge) visualization, interpretation and evaluation. The given case study is based on the log data from an operational STMP server. By design, this simplified example brings about a better understanding of the solution, indicating one of its potential applications to identify and eliminate deadlocks in the realization of business processes. We also tested the efficiency of the implementation of the algorithm in five independent experiments on seven datasets, ranging in size. The results show that mining even 1 million rows is performed in approximately less than 6 minutes.**

I. Introduction

IN THE last decade, we have observed that the approach to information system design is evidently shifting from data to processes. Effective identification, construction, evaluation and deployment of mission-critical processes can give a competitive and strategic advantage to an organization [1]. Some argue that knowledge is still the most important asset to influence overall performance and the ability to innovate [2], [3], [4].

Knowledge workers utilize information technologies and their productivity depends on particular computer applications. The McKinsey Global Institute (MGI), through interviews with 4200 managers from companies in different businesses, in July 2012, reported that 28 percent of total work includes time reading, writing or responding to e-mails [5]. In 2015, the number of business e-mails sent and received per business user per day totalled 122 e-mails, and by the end of 2019 is expected to average 126 messages [6]. Today, there is rising concern that for some workers the volume of e-mail has grown to the size which in turn has negative effects on well-being and performance [7]. The perception of an individual being unable to find, organize or process his/her e-mails effectively is defined as the feeling of e-mail overload [8].

Knowledge management has long been a valuable part of business process architectures and models of various complex and collaborative domains [9]. A business process can be defined as a sequence of activities located and bounded in the frame of a particular organization [10], describing steps and corresponding tasks assigned and performed by particular participants (humans or other physical beings), the objective of which is to achieve a desired result [11]. Speaking from the margins, Adam Smith's theory of labour division is still up-to-date.

Business process design presents assumptions and beliefs in compliance with specified goals [12]. However, in real-life scenarios, an empirical business process can suffer from the following burdens: (1) some participants may not respect assumptions, their roles or tasks, and in consequence, act in a different way; on the other hand, even if they do, (2) some of them may delay performing assigned tasks, intentionally or not (for instance due to e-mail overload). Thus, one can ask for an objective method that provides data-driven evidence that shows how the process is empirically achieved.

In this paper, we investigate one particular activity which concerns e-mail correspondence between participants, and the primary focus is to introduce an algorithm, namely SOMF, for discovering e-mail message sequences from server log data. In this narrow extent, the obtained knowledge can be used for conformance checking, which aims to detect inconsistencies between the model of processes and their corresponding execution. In particular, it can be a way to detect communicated burdens on the one hand, and act as a starting point to discuss possible improvements on the other.

We devote our contribution in the field of data mining algorithms, to extracting sequences from data. From a broader perspective, the elaborated approach can be seen as an autonomous component of competitive intelligence [13], which, being a strategic tool producing actionable intelligence, in turn supports organizations in the decision-making process [14], improves their performance [15], and eventually fosters a competitive advantage [16].

The rest of the paper is organized as follows. The next section provides the problem statement for mining sequences from data. In Section III, the knowledge discovery process is outlined and specified in the frame of the research agenda, and divided into three subsections. In the next section, the process is exemplified by the case study. The last section closes the paper by presenting and discussing the obtained results from testing the efficiency of the algorithm.

II. The Problem Statement

As stated in the previous section, this research study introduces the concept of mining e-mail message sequences from server log data. The problem can be epitomised by three main aspects: (1) data preparation, (2) data mining, and (3) knowledge visualization, interpretation and evaluation.

This study mainly focuses on solving the first and second, by explicitly formulating algorithms devoted to each one. To achieve this goal, firstly, we formulate and provide all the relevant definitions.

Definition 1. A dataset $D = \{t_1, t_2, \ldots, t_n\}$ is a set of transactions, where each transaction is described by four attributes: message-id, time, sender and recipient.

Definition 2. A message m_i is an abstract term that may represent a document or e-mail uniquely identified by the message-id.

Definition 3. The time of the transaction tt_i is the recorded execution time of the performed action by the sender.

Definition 4. A set $P = \{p_1, p_2, \ldots, p_m\}$ is the finite collection of participants, which can be both message senders or recipients.

Definition 5. An event e is a pair $(x \rightarrow y)$ of the sender x and the participant y, where $x \neq y$.

Definition 6. A weight w_i is the difference between execution times tt_i and tt_{i-1} of two subsequent transactions, where $w_1 = 0$, and for $i = 1, 2, \ldots, n$.

Definition 7. A sequence $s \leq (e_1) : w_1, (e_2) : w_2, \ldots, (e_k) : w_k)$ of events is an ordered list of nonempty events; for each integer $k = 1, 2, \ldots, n$; a sequence of the length k is called a k-sequence.

Definition 8. A directed, weighted and labelled graph G is a tuple (V, E, w) consisting of a finite set V, together with a subset $E \subseteq VxVxR$. The elements of V are the vertices of the graph, and the elements of E are the arrows of the graph. An arrow of a graph is an ordered pair $[x, y]$, where x and y are the vertices of the graph, and w is the associated real number of the pair, called its weight, where $x \neq y$. The labels for vertices are a subset L of P.

To visualize knowledge, a user can use any application capable of processing data, which as a result, displays the adequate drawing. The remaining two tasks are usually associated with the specific context of the problem domain, and therefore should not be generalized.

III. The Knowledge Discovery Process

In our approach, the process of knowledge discovery is divided into three stages, followed one by one and independently performed ($1 \rightarrow 2 \rightarrow 3$), in a similar way to well-recognized and accepted models, such as KDD or CRISP-DM.

A. Data preparation

The data preparation stage concerns sorting objects. In the first step, a new message list is initiated. Next, a data set D is scanned, and the total number of rows n is determined. In the body of the loop $(4-6)$, where n is the termination condition, four attributes are selected from each row and form a new object, inserted into the message list. Next, a message list is grouped by the message-id, and sorted in ascending order by a time stamp. The corresponding pseudocode is given below.

Input: D

```
1 Initiate New List(Message-List);
2 Read(D);
3 for i := 1 to n
4  select MessageId, Time, Sender, Recipient from D;
5  create Object(Object-Message);
6  insert to List(Message-List);
7 end;
8 group List(Message-List) by MessageId and
9 sort ASC List(Message-List) by Time;
```

Output: a Message-List.

B. Data mining

The message list is now the input with no parameters for the SOMF algorithm. The pseudocode below shows the main idea lying behind its construction.

Input: List(Message-List)

```
1  while i < Count List(Message-List) do
2   CheckMessage:= read Object.MessageId[i];
3   MessageTime:= read Object.Time[i];
4   for each unique object from List(Message-List)
5    MessageTime:= read Object.Time[i];
6     add vertex(sender) to Sender List(Adjacency-List[0]);
7     add vertex(sender) to Sender List(Adjacency-List[1]);
8     weight:= (MessageTime[i] – MessageTime[1]);
9     add vertex(recipient) & weight to Recipient List(Adjacency-List[0]);
10  end;
11  for each object from List(Message-List)
12   if vertex(sender) exists in List(Adjacency-List[i]) then
13    weight:= (MessageTime[i] – MessageTime[1])
14    add vertex(recipient) & weight to Recipient-List(Adjacency-List[i+1]);
15   if vertex(sender) does not exist in List(Adjacency-List[i] then
16    add vertex(sender) to Sender-List(Adjacency-List[i+1]) and
17    weight:= (MessageTime[i] – MessageTime[1])
18    add vertex(recipient) & weight to Recipient List(Adjacency-List[i+1]);
19   if vertex(recipient) does not exist in List(Adjacency-List[i]) then
20    add vertex(recipient) to Sender-List(Adjacency-List[i+1]);
21   end;
22  if Object.MessageId[i] ≠ Object.MessageId[i+1] then
23     create Graph(MessageId);
24  i++
25 end.
```

Output: A set of graphs.

In the body of the first loop (2–9), for each unique object from the message list, the time of the first sent message is determined; next, a new vertex, representing the message sender, is created and added to the adjacency list on the left side; a new vertex, representing a message recipient, is created and added to the adjacency list on the left side; the weight between the top vertex and the vertices one level down equals zero.

In the body of the second loop (12–22), if the vertex of the sender exists in the adjacency list, then the weight is calculated, and a new vertex, representing a recipient, is created and added along with the weight to the adjacency list on the right side; if the vertex representing the sender does not exist, then a new vertex is created and added to the adjacency list on the left side; the weight is calculated and a new vertex for each recipient is created and added along with the weight to the adjacency list on the right side; if the vertex representing a recipient does not exist, then a new vertex for each recipient is added to the adjacency list on the left side. Finally, if the identifier of the next object is different, then a graph representing a unique e-mail message sequence is created.

We used an adjacency list as the graph representation. This was the most suitable form for us to use. Our goal is neither to prove its appropriateness or efficiency nor to investigate different representations. Having said that, however, if we take into account the results obtained from implementation feasibility and performance testing of the algorithm, the correctness of choice should not be a subject for long discussion.

C. Knowledge visualization, interpretation and evaluation

Knowledge visualization aims to use visual representation to facilitate the understanding of discovered complex data structures [17]. Knowledge interpretation is an arbitrary construct of the information perceived by an individual who aims to specify its meaning by incorporating context, logic and experience [18]. Knowledge evaluation is a subjective judgment on its applicability and validity to solve a particular problem [19]. These three tasks are wider discussed in the next section, having the input, i.e. visualized knowledge, already generated.

IV. Case Study

Let us consider a dataset $D = \{t_1, t_2, t_3, t_4, t_5\}$ of five transactions and a dataset $U = \{a, b, c, d, e\}$ of five users that are both senders and recipients, whose e-mail account names equal their names in the *gdansk.com* domain. Let $M = \{m_1\}$ be a set of one message m_1, represented by the unique identifier $m.1$. Each transaction is described by four attributes, i.e. *message-id, time stamp, sender* and *recipient*. The first transaction t_1 of the input for the data preparation stage is shown below.

```
Message-ID: <m.1@gdansk.com> Date: Fri, 19 Aug 2016
11:30:00 From: =?ISO-8859-2?Q?a?=<a@gdansk.com> To:
=?ISO-8859-2?Q?b?= <b@gdansk.com>
```

To simplify the log data, on the same day, in the one message domain, for the first user, it takes 5 minutes to pass over the message, and for each subsequent user, five minutes more. The message list is depicted in Table 1. Each transaction can be interpreted analogously to the first one: “at 11:30 a.m. the user a (sender) sends the e-mail to the user b (recipient)”.

In the second stage, the algorithm scans the message list, and for the first transaction t_1 determines the execution time of the message sent; next, the sender vertex a and recipient vertex b are added respectively to the first and second position on the left side of the adjacency list; only for t_1 the weight is not calculated and equals zero; the sender vertex b is added to the first position on the right side of the adjacency list and the weight (0) is assigned. The sender vertex b exists on the list; the weight is calculated and the vertex recipient c is added with the weight (5) assigned. The sender vertex c is added to the third position on the left side of the adjacency list; the weight is calculated, and vertices d and e are added on the right side with the weight (10) assigned. The sender vertex e is added to the fourth position on the left side; the weight is calculated and the recipient vertex a is added on the right side with the weight (15) assigned. The sender vertex a exists, the weight is calculated and the recipient vertex e is added as the second on the right side with the weight (20) assigned.

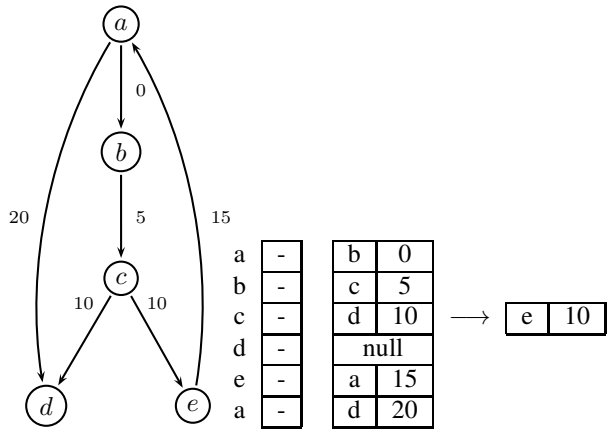

Figure 1. The graph G and the adjacency list

The discovered graph G can be interpreted literally as the following sequence of events:

- (e_1): at a given time, a message was sent from participant a to b;
- (e_2): five minutes later, a message was sent from participant b to c;
- (e_3): ten minutes later, a message was sent from participant c to d and e;
- (e_4): fifteen minutes later, a message was sent from participant e to a;
- (e_5): twenty minutes later, a message was sent from participant a to d;

TABLE I. THE MESSAGE LIST

transaction (t_i)	**time stamp** (hh:mm)	**sender** (name)	**recipient** (name)
t_1	11:30	a	b
t_2	11:35	b	c
t_3	11:45	c	d, e
t_4	12:00	e	a
t_5	12:20	a	d

TABLE II. THE ALGORITHM EFFICIENCY ACCORDING TO DATASET SIZE

D no. of rows	**file size** (KB)	**test1** (mm:ss.ms)	**test2** (mm:ss.ms)	**test3** (mm:ss.ms)	**test4** (mm:ss.ms)	**test5** (mm:ss.ms)

V. EFFICIENCY EVALUATION

The SOMF algorithm has been implemented in C#. Firstly, to verify its correctness, we prepared and used a dataset in such a manner that allowed us in advance to determine the output. Secondly, we implemented and executed a stand-alone script which randomly generated seven datasets, ranging in size from 10 to 1 million records. Finally, we separately performed five tests on each dataset, using a mobile computer equipped with an Intel Core I5 (3230M @ 2,6 GHz) processor, 4 GB (DDR3) RAM, and Microsoft Windows 8.1 (x64). The obtained results are summarized in Table 2.

If we take into account only the first four datasets, then the mining duration does not exceed 2 seconds and is comparably the same. Differences can be noticed in the last two datasets; however, the standard deviation is again relatively low, respectively 2,87 and 8,95 seconds. Now, if we consider the largest dataset, such a total number of rows cannot represent one hypothetical message sequence because it is simply too complex to be realized in any real-life scenario. Yet, conversely, in our opinion, the duration of less than 6 minutes is relatively low, if compared to other typical domains of the application of data mining algorithms. To sum up, the algorithm efficiency is at an acceptable level.

Software Systems Development & Applications

SSD&A is a FedCSIS conference area aiming at integrating and creating synergy between FedCSIS events that thematically subscribe to the discipline of software engineering. The SSD&A area emphasizes the issues relevant to developing and maintaining software systems that behave reliably, efficiently and effectively. This area investigates both established traditional approaches and modern emerging approaches to large software production and evolution. Events that constitute SSD&A are:

- MDASD'18—5th Workshop on Model Driven Approaches in System Development
- MIDI'18- 6th Conference on Multimedia, Interaction, Design and Innovation
- LASD'18—2nd International Conference on Lean and Agile Software Development
- SEW-38 & IWCPS-5—Joint 38th IEEE Software Engineering Workshop (SEW-38) and 5th International Workshop on Cyber-Physical Systems (IWCPS-5)

AREA SUPERVISORY COMMITTEE

- Hinchey, Mike, SEW-38-IWCPS-5
- Kornecki, Andrew J., MMAP'18
- Luković, Ivan, MDASD'18
- Marasek, Krzysztof, MIDI'18

5th Workshop on Model Driven Approaches in System Development

FOR many years, various approaches in system design and implementation differentiate between the specification of the system and its implementation on a particular platform. People in software industry have been using models for a precise description of systems at the appropriate abstraction level without unnecessary details. Model-Driven (MD) approaches to the system development increase the importance and power of models by shifting the focus from programming to modeling activities. Models may be used as primary artifacts in constructing software, which means that software components are generated from models. Software development tools need to automate as many as possible tasks of model construction and transformation requiring the smallest amount of human interaction.

A goal of the proposed workshop is to bring together people working on MD languages, techniques and tools, as well as Domain Specific Languages (DSL) and applying them in the requirements engineering, information system and application development, databases, and related areas, so that they can exchange their experience, create new ideas, evaluate and improve MD approaches and spread its use. The intention is to target an interdisciplinary nature of MD approaches in software engineering, as well as research topics expressed by but not limited to acronyms such as Model Driven Software Engineering (MDSE), Model Driven Software Development (MDSD), Domain Specific Modeling (DSM), and OMG's Model Driven Architecture (MDA).

1st Workshop on MDASD was organized in the scope of ADBIS 2010 Conference, held in Novi Sad, Serbia. From 2012, MDASD becomes a regular bi-annual FedCSIS event.

TOPICS

- MD Approaches in System Design and Implementation – Problems and Issues
- MD Approaches in Software Process Models

***Abstract*—Elasticsearch is a distributed RESTful search engine, capable of solving growing number of use cases and can handle petabytes of data in seconds. However, Elasticsearch comes with a complex query language which causes a steep learning curve for the developers and, therefore, creation of queries can be difficult and time-consuming in many cases. Hence, in this paper, we introduce a Domain-specific Modeling Language (DSML), called Dimension Query Language (DQL), to support the model-driven development of Elasticsearch queries. Elasticsearch queries can be automatically generated from DQL models and DQL's IDE is capable of executing these auto-generated Elasticsearch queries on remote repositories. An evaluation of using DQL has been performed at the industrial level with the participation of a group of developers. The conducted evaluation showed that the use of the language significantly decreases the development time required for creating Elasticsearch queries. Finally, qualitative assessment, based on the developers' feedback, exposed how DQL facilitates the development of Elasticsearch queries.**

I. Introduction

ELASTICSEARCH is a distributed RESTful search engine, which is based on Lucene information retrieval software library [1] and is capable of solving growing number of use cases. Many types of searches (e.g. structured, unstructured, geo, metric) can be prepared and combined. It works in clusters, and according to some tests performed by its developers (namely, Elastic Team), it is reported that Elasticsearch can handle petabytes of data in seconds [2].

Elasticsearch differs from classical relational database management systems (RDBMS) in many ways: Elasticsearch's primary database model is a search engine and it stores documents instead of key-values. Each document in Elasticsearch is a JavaScript Object Notation (JSON) object, and hence it does not use Scripted Query Language (SQL). Queries are provided with its own language based on JSON. A given search can be performed not only in a form of a query; filters can also be used for document search which is faster than the queries. Finally, it is schema-free, i.e. two documents of the same type can have different sets of fields [3]

However, such kind of powerful engine comes with a very complex query language which causes a steep learning curve for the query developers. Moreover, there are numerous types of queries and scripts combinable with each other whose creation and use can be difficult and time consuming in many cases.

There exists a tool for visualizing Elasticsearch data, called Kibana, which is also developed by the Elastic Team [4]. It works on top of the content indexed on an Elasticsearch cluster and it can directly connect to an Elasticsearch server to be used for generating visualizations and reports; but again, the users must have prior knowledge about how Elasticsearch works and need to be experienced in dealing with its complex query language.

The paradigm shift introduced by model-driven development (MDD) [5, 6] in which the focus changes from code to models, leverages the abstraction level and promotes the software development for various application domains (e.g. [7-13]). Moreover, domain-specific languages (DSLs) / domain-specific modeling languages (DSMLs) [14-18] which have notations and constructs tailored toward a particular application domain, assist to the developers during execution of MDD processes by providing first a user-friendly syntax for modeling systems (mostly in a visual manner) and then a translational semantics for generating application software and any other artifacts automatically [19].

Abovementioned features and benefits of applying MDD and using DSMLs in other domains conduce toward producing a MDD framework also for Elasticsearch. Hence, in this paper, we introduce a DSML which can be used inside this MDD framework to facilitate the query writing process required for the Elasticsearch. Although many efforts exist in model-driven database processing and query generation (e.g. [20-23]), they do not consider the specifications of Elasticsearch and do not support generating queries, structured according to Elasticsearch which differs from the traditional databases.

Originating from a metamodel of Elasticsearch, which is also derived in this study, the proposed language provides a graphical concrete syntax for modeling queries within its integrated development environment (IDE). Models of the queries, visually prepared in this IDE, are automatically translated into corresponding Elasticsearch structures which are ready to be executed. If the developer requests execution

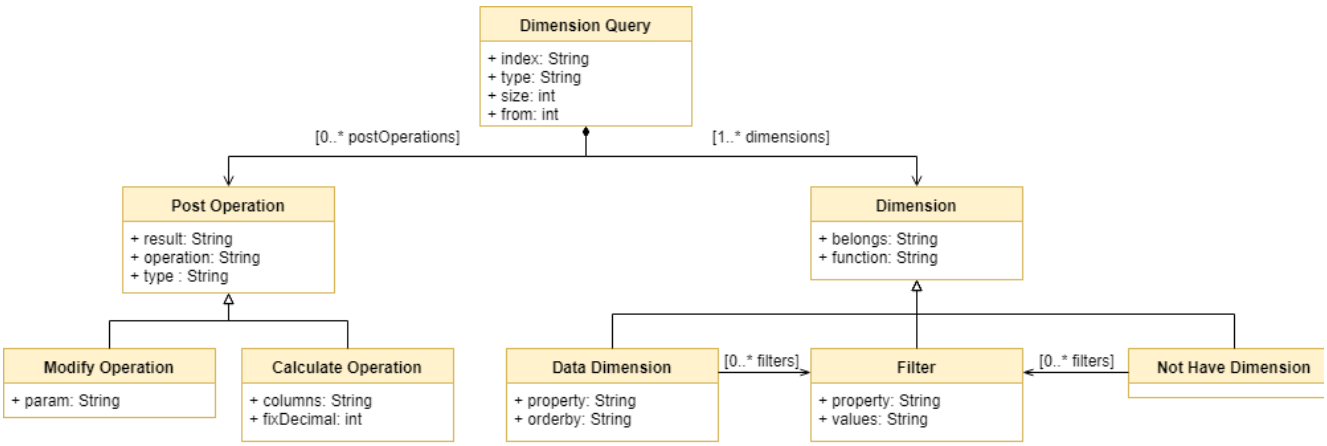

Fig. 1. DQL Metamodel

of these queries, it is also possible to execute those modeled and automatically generated queries on Elasticsearch storages. In this paper, we also discuss the use of this DSML for the industrial applications and give the results of evaluating its use inside a software company specialized for developing commercial Big Data applications.

The rest of the paper is organized as follows: In Section 2, the proposed query language is discussed with including its metamodel, fundamental elements and built-in query transformation process. Section 3 demonstrates the use of the language. Evaluation of the language and results of this evaluation are discussed in Section 4. Related work is given in Section 5. Finally, Section 6 concludes the paper.

II. Dimension Query Language

When we think of the three-dimensional space we are in, every object has coordinates to locate their position and hypothetically, it is possible to list and create reports for each object's or living creature's position on earth. Such report would have three fields for the coordinates linked with the name of the related object or person. To find an entry on the report, we would have needed to know the related entry's name and coordinates.

Mathematics and physics define dimension as the minimum number of points required to know an object's position and velocity on the space they belong. By this definition, we can say that our hypothetical report is a four-dimensional space, containing entries with four dimensions. Originated from this, we named our Elasticsearch query model as Dimension Model (DM) and the proposed Elasticsearch DSML as Dimension Query Language (DQL). In DM, each dimension corresponds to a field of data that must be included within the query.

In the following subsections we first define the fundamental elements and the relations inside DQL which compose the abstract syntax on the DSML for Elasticsearch. Then, we discuss how constraint checks and query validations are performed inside DQL's IDE before automatically transforming prepared query models into Elasticsearch queries. Finally, query transformation process is discussed.

A. *Fundamental DQL Elements*

Our transformation service (that will be discussed later) accepts Dimension Query (DQ) instances and generates Elasticsearch queries. The users can choose to view the transformed queries or directly execute them to view a table report over the underlying Elasticsearch storage. These DQ instances are created by conforming a metamodel which defines fundamental elements and their relations required for Elasticsearch queries. The metamodel, which leads to the generation of DQL syntax, is depicted in Fig. 1. Elements and properties of the metamodel are written in bold in the following text.

Elasticsearch storages, namely indexes, are a collection of documents that have similar characteristics [24]. Documents belonging to the same index may have relations with each other. On Elasticsearch, there are two types of relations. "Parent-child relation" links two documents by marking one as parent while marking the other one as child. "Nested relation" simply writes the whole document into another one.

On query transformation, one of the required properties is the name of the document on the top level, defining the document without a parent document. This needs to be specified as the **type** field in the **Dimension Query**. Another required field is the **index**, which is the name of the index to execute the query on. Finally, on the **dimensions** field, requested dimensions are expected. Along with these, there are some optional fields that a query can uphold, such as expected result size as **size** and offset as **from**.

B. *Dimension Types*

Dimensions vary in three types; **Data Dimension**s, **Filter** and **Not Have Dimension**s. Data dimensions are used to represent the fields to be retrieved upon the execution of the query and filter dimensions, by their name and hence they are used to filter the retrieved data based on some conditions. However, independently from its type, each

dimension must have two main fields; **function** and **belongs**.

The **function** field is used to specify which operation must be performed on the data. With this field; dimensions can be grouped, summed, counted and their average or percentage over their sum may be calculated. **belongs** field represents the name of the Elasticsearch document of the index in which the dimension data are located.

Data and filter dimensions must also have a field called **property**. This field represents the name of the data to be retrieved or filtered. The data dimensions may also have an additional **orderby** field to indicate which dimension must be used on ordering the query results.

If the query designers want to filter data on certain fields, filter dimensions may be used to meet this requirement. These dimensions will filter the data instead of creating another field on the result set. They are different from the data retrieval dimension by having additionally one field called **values**, indicating the values to apply with the filter. Filters can also be applied to specific data retrieval dimensions as well as they can be applied on the query. When used in this way, they affect only the dimension they are getting applied to.

The filtering criterion does not always have to be based on some values. For example, on a customer-invoice database, we may want to list the customers who did not place an order between some dates. To handle this case, there is an additional type of dimension called “Not Have Dimension”. This dimension can be used to filter certain fields, which does not have any relations to the given Elasticsearch document. Considering the customer-invoice example, let us think we have an index with two documents, customer and invoice, and assume that there is a parent-child relation, customer as parent and invoice as child. Creating a “not have dimension” with “belongs” field as `{belongs: 'invoice'}` will allow us to list the customers without an invoice on the whole Elasticsearch index. However, we may want to see the results based on another filter, such as a date interval. On this case, since the “not have dimension”s can also have filters, we can define a filter and add it to our “not have dimension”.

C. Post Operations

Calculations and value formatting is a common thing to do on report generation. When needed, Post Operations may be used to tinker with the retrieved data and they can be elaborated in two types; one for calculating new data, called **calculate operation**, and one for modifying existing data, called **modify operation**.

A post-operation must have the following fields: **result**, **operation** and **type**. They are common for each operation type, where the **result** field is the name of the data field which the post operation will be affecting. For calculation operations, this field will be used as the calculated field’s name. For modify operations, it is the name of the field on which the modification operation works on. **operation** field is the name of the operation to process, such as sum, divide, absolute, floor, ceil. Finally, the **type** field is the indicator of the type of the post-operation itself. It can be whether "*calculateOperation*" or "*modifyOperation*".

Calculate operations have two more additional fields. The first one the "*columns*" which holds the dimensions involved in the calculation operation and the second one is the "*fixDecimal*" which is to specify the number of the digits that should be displayed if the calculated value is a decimal number. Usable calculate operations are essential arithmetic functions; sum, subtract, multiply, divide.

Modify operations have only one additional field called "*param*"; which is the additional required parameter(s) to apply the operation and may not always be necessary. Modify operations, which can be used by the developers, are listed below:

Fix Decimal: To limit the number of the decimals to show of a decimal number. The param field must be the number of the digits.

Floor: To get the floor value of a decimal number.

Ceil: To get the ceiling value of a decimal number.

Abs: To get the absolute value of a number.

Replace: To replace some specific values of a dimension in the result set. A serialized JSON array string, which has objects as elements containing "from" and "to" values, is required as the "param" field.

D. Constraints and Query Validations

Our motivation is to simplify the query generation for the Elasticsearch without needing to know its query formulation details. However, there are also lots of syntactic controls and additional semantic constraints which should also be taken into account while writing Dimension Queries. Based on the metamodel elements and their relations discussed in the previous section, a modeling environment has been developed to use language constructs and features of DQL. Query developers may use our DSML’s graphical syntax and all required constraint checks and hence query validations can be realized automatically according to the Elasticsearch specifications.

Fig. 2 shows a screenshot taken from web-based IDE of the proposed Elasticsearch DQL. On the left side of the screen, the indexes on the system are listed with a combo box. After an index gets chosen, its metadata are shown directly under the index selector. The users then can start to create a DQ by simply dragging and dropping the fields they want to include in the query. The DQ gets automatically updated on the backstage each time the user drops a new field, updates or removes an existing one. The query can be tracked from the query panel at the top side of the screen dynamically.

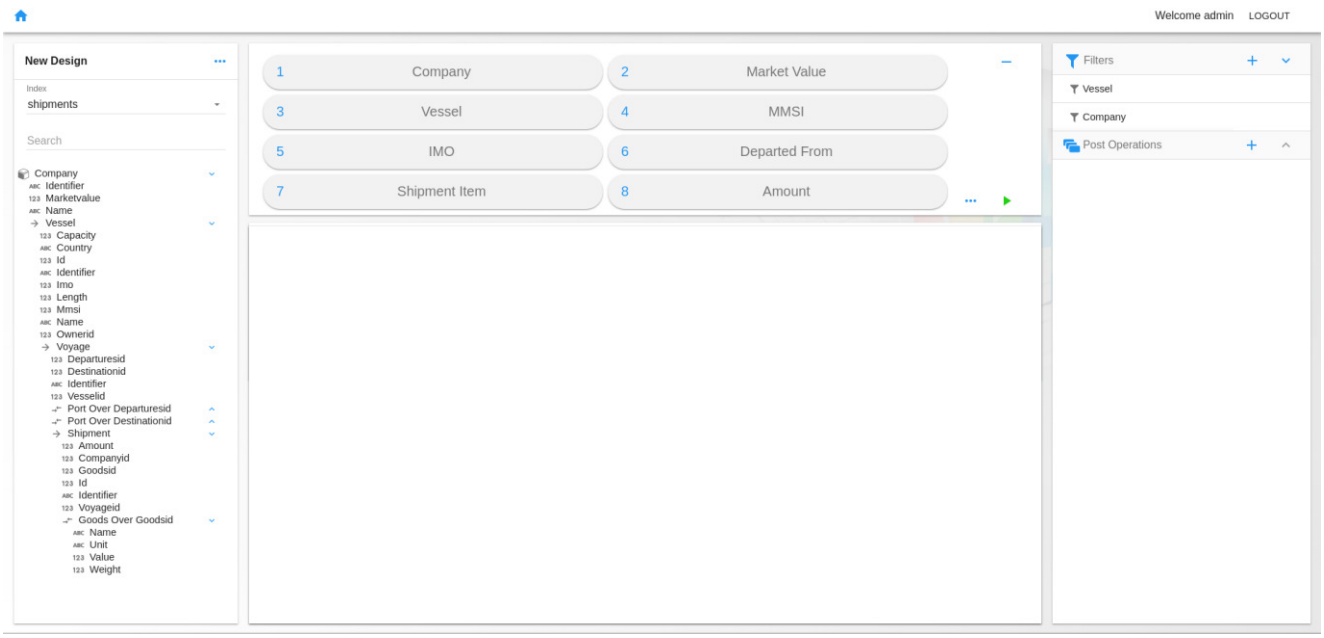

Fig. 2. IDE for the proposed Elasticsearch DSML

Filters and post operations are listed on the panel at the right side of the screen. Users can create new filters and post operations by clicking the add button (+) near them and can include filters to the query by simply dragging and dropping them into either on a data dimension or into the query directly.

After the users finish choosing the fields, the DQ can be sent to the backing server in order to be transformed to the Elasticsearch query. At this point, the users can choose to simply view the transformed query or the results generated with the execution of the transformed DQ.

There are lots of constraints needed to be followed while writing an Elasticsearch query. To be able to generate valid, executable Elasticsearch queries, we have also put some constraints on DQL and hence the IDE warns the user or prints an error message if a constraint gets violated.

Filters are for filtering data; they do not cause a field to be included within the result set. Therefore, filters cannot contain filters. Appending filters to other filters will have no effect on the generated query.

Since they affect the set of all results, the “not have dimension”s can only be used within the query, not within other dimensions.

Fields from different documents with parent-child relation cannot get queried without performing an operation over them. Because, for a member of the parent document, it is possible to have more than one value on the child document and it will not possible to create a result set without making some groupings on the parent document.

Mathematical processes such as number formatting, numerical calculations and digit rounding, can only be performed on numeric dimensions as well as date format operation can only be performed on date dimensions.

Applying group function to a dimension causes an aggregation to get started on Elasticsearch query. On Elasticsearch queries, when an aggregation gets started, all remaining fields must be included into that aggregation in some way. So, when the grouping function is applied over a dimension in the DQ, all remaining dimensions need to have a function value.

Each dimension of the query must be unique. If there is more than one dimension created with the same field of the same document -having also the same function-, one of the dimensions must have a filter different than the other one's filters at least. Semantic definitions on DQL, make all above constraint checks possible inside the IDE.

E. Query Transformation Stage

There are four stages of a query transformation which are all automatized within DQL’s IDE. First one is called the **Reducing** stage where the dimensions in the DQ get inspected and grouped by their respective nested documents on the Elasticsearch index. By doing this, it is possible to make fewer aggregations on the Elasticsearch query, therefore, it increases query execution performance by preventing same nested documents to get aggregated over and over. The requirement for two dimensions to be grouped is that they must be in the same document on Elasticsearch and they must have exactly same filters getting applied to them.

After dimensions are reduced, they get **Sorted** according to their documents and the relations between their documents on the index.

Two rules are applied while sorting the dimensions:

1) For multiple dimensions on the same document, if the document has a nested object, its own dimensions have priority than the nested object's dimensions. For instance,

considering the metadata given in Fig. 3, dimensions of Document A have a higher priority than dimensions of the Nested Object B. Likewise, Document C over Nested Object C1 and Nested Object C1 over Nested Object C1.1 have priorities.

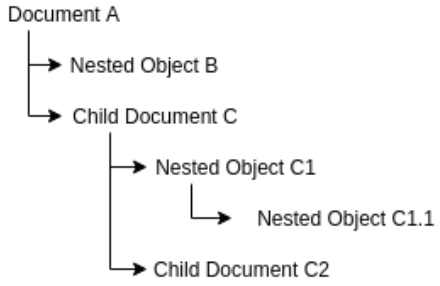

Fig. 3. Sample Index Metadata

2) Finally, calculation dimensions like sum, average, percentage, and count have the lowest priority so they take place at the end of the sorted dimensions list.

Analyzing stage is the one where the Elasticsearch query gets started to be created in pieces. On this stage, each dimension is converted to proper Elasticsearch query fragment and gathered up on a temporary list. This phase is crucial because, during aggregation generation, it is decided whether the aggregations will be linked with a nested relation or parent-child relation. "Not have dimension"s also will be included to the query on this stage.

The final stage of the query transformation is the **Generation** stage. On this stage, the query at hand is already has been reduced (for optimization), sorted and analyzed. The dimensions have been converted to aggregation blocks and relations between these aggregation blocks have been determined.

The list that's holding the aggregation blocks get iterated and linked with respect to their flags set from the previous stage of query transformation. Aggregation link is established with respect to the metadata of the index. That means, aggregation blocks will be linked to the others either as siblings or children according to their dimensions' "belongs" field.

III. Use of DQL During Query Generation

The Dimension Queries may be grouped into four main types corresponding to the types of the result sets they will generate upon the execution of the transformed Elasticsearch queries. This section will briefly explain these types. For a better comprehension, queries are represented in their textual notation during the following discussion, which are achieved automatically by using DQL and its graphical modeling environment.

In the first type, the query aims at getting direct results without making any grouping or filtering. If that's the case, there is only one constraint: As stated on the constraints section, the fields on the query must be on the same Elasticsearch document.

When the created query is in this type (see Fig. 4), dimensions must have three main fields. Function field of the dimensions must have a static value of "*include*" (shown in lines 6, 9, 12). Additionally, **orderby** field (line 5) may be added to one dimension to sort the results.

The corresponding translation (see Fig. 5) may seem simple because the translated query is obviously small and easy to write. However, the real power of the Dimension Queries, comes to stage when groupings and functions get involved with the query.

If the created query aims to fetch fields from different related documents (see "belongs" properties in Fig. 6 on lines 4, 7 and 10), the second type of query comes in. This type of query groups fields so different documents may be included in the result set. Again, on this type of query (Fig. 6), there is only one constraint: If a grouping, namely aggregation, starts with a dimension, all remaining dimensions must have a function applied on them.

```
01  { index:"indexName",
02    type: "doc",
03    dimensions: [
04     {property: "prop_1",
05      belongs: "doc", orderby: "asc",
06      function: "include" },
07     {property: "prop_2",
08      belongs: "doc",
09      function: "include" },
10     {property: "prop_3",
11      belongs: "doc",
12      function: "include"}
13    ],
14    from: 0,
15    size: 50 }
```

Fig. 4. Dimension Query without Groupings

```
01  { from: 0,  size: 50,
02    query: { bool: { disable_coord: false,
03        adjust_pure_negative: true,
04        boost: 1 }
05    },
06    _source: {
07      includes: ["prop_1","prop_2","prop_3"],
08      excludes: [ ]
09    },
10    sort: [{property_1.sort: {order: "asc"}}]
11  }
```

Fig. 5. Transformed Elasticsearch Query without Aggregations

```
01  {index: "indexName",
02    type: "topLevelDocName",
03    dimensions: [ {
04      property: "prop_1", belongs: "doc_1",
05      orderby: "asc", function: "agg"
06    }, {
07      property: "prop_2", belongs: "doc_2",
08      function: "sum"
09    }, {
10      property: "prop_3", belongs: "doc_2",
11      function: "sum"
12    } ],
13    from: 0, size: 50}
```

Fig 6. Dimension Query with Functions

While grouping the results, users may also want to do some calculations to see the summarized result. For example, let us consider a report to list the total invoice price for each customer. To do that, first an aggregation needs to be set up on customers ("function" field on line 5 in Fig. 6) then another summarization can be used on other dimensions. The reason for this aggregation requirement is, Elasticsearch needs to make some groupings to calculate summarized results such as sum and avg. Functions can only be applied when a grouping gets applied to the query.

Dimensions on this type of query must have same fields as the ones within the previous query, except the function field values may be "*agg*", "*count*", "*sum*", "*avg*" and "*percentage*" instead of "*include*" (see lines 5, 8 and 11 in Fig. 6). Fully generated Elasticsearch query for this DQ type can not be shown here due to space limitations. However, aggregations part of the generated query can be seen in Fig. 7.

```
01  ...
02  {aggregations: {
03   prop_1_doc_1_agg: {
04   terms: { field: "prop_1.keyword",
05    missing: "null", size: 2147483647,
06    min_doc_count: 1, shard_min_doc_count:0,
07    show_term_doc_count_error: false,
08    order: { _term: "asc" } },
09    aggregations: {
10     prop_2_doc_2_sum: {
11      children: { type: "documentName_2" },
12       aggregations: {
13        prop_2_doc_2_sum: {
14         sum: { field: "prop_2" } } } },
15        prop_name_3_doc_2_sum: {
16          children: { type: "doc_2" },
17          aggregations: {
18           prop_3_doc_2_sum: {
19             sum: { field: "prop_3" } } }
20  } } } } }
21  ...
```

Fig. 7. An excerpt from transformed Elasticsearch Query with Functions

If the users want to filter their data, they may create filter dimensions. Different usages of different filters are given in Fig 8. Applying a filter directly to the query is the case when the filters will be inserted within the *query* field of the transformed Elasticsearch query; thus affecting the whole result set as mentioned before. The filter (lines between 17 – 20 in Fig. 8) on this sample is for listing the results by the prop_3 field of the doc_2 with a value greater than 1000.

Applying filter to specific dimensions (lines between 13 – 14 in Fig. 8) will cause sub-query blocks to be created and inserted as filters to related aggregations. When this happens, the filters will be applied on only the related aggregation and, if there is any, to its sub aggregations.

Finally, the usage of "not have dimension" is shown between the lines 16 – 19 in Fig 8. In this example, a sample filter has been added to the "not have dimension". Before the "not have" filter gets applied, its inner filter will be applied first to narrow down the results.

An excerpt from the generic filter of the generated Elasticsearch query is given in Fig 9. On the transformed query, **prop_2** on line 4 is the name of the field to which the filter applies. It corresponds to the **property** field's value on the dimension query (see Fig. 8, line 14). The field called **from** (Fig 9, line 5) is the value of the **value** field previously indicated in Fig. 8, line 19. Finally, the **type** field in the line 14 (Fig. 9) is the name of the Elasticsearch document, containing the related fields. It corresponds to the **belongs** field (Fig. 8, line 18) in the Dimension Query filter.

```
01  {index: "indexName",
02    type: "topLevelDocName",
03    dimensions: [ {
04      property: "topLevelDocName",
05      belongs: "prop_1",
06      orderby: "asc", function: "agg" },
07     {property: "doc_1",
08      belongs: "prop_2", function: "avg" },
09     {property: "doc_1",
10      belongs: "prop_3", function: "avg",
11      filters: [ {
12        property: "doc_1", belongs: "prop_4",
13        function: "lt", values: [ 3000 ]}] },
14     {property: "prop_2", belongs: "doc_1",
15      function: "gt", values: [ 1000 ] },
16     {belongs: "doc_2", function: "nothave",
17      filters: [ {
18        property: "prop_4", belongs: "doc_2",
19        function: "gt", values: [ 10000 ]}]
20    } ],
21    from: 0, size: 50}
```

Fig. 8. Dimension Query with Dimension Filters

```
01  ...
02  {"has_child": { "query": { "bool": {
03    "must": [ { "range": {
04     "prop_2": {
05      "from": 1000, "to": null,
06      "include_lower": false,
07      "include_upper": true,
08      "boost": 1.0
09     } }
10    } ],
11    "disable_coord": false,
12    "adjust_pure_negative": true, "boost": 1.0
13   } },
14   "type": "doc_1",
15   "score_mode": "sum", "min_children": 0,
16   "max_children": 2147483647,
17   "ignore_unmapped": false, "boost": 1.0
18  } }
19  ...
```

Fig. 9. An excerpt from transformed Elasticsearch Query's Generic Filter

Depending on the function of the filter in the DQ, Elasticsearch query filter properties have different usages. On Fig 9. line 5, **to** field is used as the upper limit when the DQ function is either *less than or range.* On the given example **include_upper** field is *true* since it is a *greater than* filter and the upper value limit is infinity. **include_lower** field acts like the same when the filter function is *less than*. The same fields get used when the filter is *less than or equal to* and *greater than or equal to*.

```
01  ...
02  {"aggregations": {
03   "prop_1_topLevelDocName_agg": {
04    "terms": {
05     "field": "prop_1.keyword",
06     "missing": "null",
07     "size": 2147483647,
08     "min_doc_count": 1,
09     "shard_min_doc_count": 0,
10     "show_term_doc_count_error": false,
11     "order": { "_term": "asc" }
12    },
13    "aggregations": {
14     "prop_2_doc_1_avg": {
15      "children": { "type": "doc_1" },
16      "aggregations": { "prop_2_doc_1_avg": {
17        "avg": { "field": "prop_2" } },
18   "prop_3_doc_1_avg_filters_prop_4_lt_4000":
19        { "filters" },
20   "prop_3_doc_1_avg_filters_prop_4_lt_4000":
21        { "avg": { "field": "prop_3" } }
22  } } } } } }
23  ...
```

Fig. 10. An excerpt from transformed Elasticsearch Query's Aggregations

Part on the aggregations included in the same transformed query is given in Fig. 10. Aggregation names (bold texts on lines 3, 16 and 20 in Fig. 10) are generated by combining **property**, **belongs** and **function** fields on dimensions. The dimension specific inner filter (Fig. 11) is inserted in place of the bold *filters* text in line 19 of Fig. 10. The transformed "not have dimension" is given in Fig 12. Note that the inner filter is nearly the same as the one in Fig. 10. The *must not* keyword in line 2 determines the purpose of the filter.

```
01  {"filters": { "filters": [ {
02   "bool": { "filter": [ { "range": {
03    "prop_4": {
04     "from": null,
05     "to": 4000,
06     "include_lower": true,
07     "include_upper": false,
08     "boost": 1.0
09     } } } ],
10     "disable_coord": false,
11     "adjust_pure_negative": true,
12     "boost": 1.0
13    }
14   } ],
15   "other_bucket": false,
16   "other_bucket_key": "_other_"
17z } }
```

Fig 11. An excerpt from transformed Elasticsearch Query's Inner Filter

```
01  ...

22   "boost": 1.0 } }
23  ...
```

Fig. 12. An excerpt from transformed Elasticsearch Query's "Not Have" Filter

IV. EVALUATION

An evaluation of using DQL has been performed at the industrial level with the participation of a group of developers from Galaksiya Information Technologies (http://galaksiya.com/). Galaksiya is a software company, located in Izmir, Turkey and its business domain mainly consists of Big Data and its applications. In some of their software solutions, the developers in the company recently started to work on Elasticsearch and related data storage.

At the beginning of the evaluation, we have determined the logistics as the target domain and created a logistics database for our case study. The main reason for choosing that domain is logistics datasets are very large in volume thus making them hard to query. Considering an end-user scenario to create a report over a logistics dataset to view the latest activities around the world, we have created a sample database by using the most active 51 ports on the world, 82 random selected shipping company names, distributed to 19 random countries. Each company on the dataset has random amount of ships with a total of 5000. The dataset has around 4750 auto-generated voyages with randomly selected goods. Total number of goods in the system is 50000, again all randomly generated.

Fig. 2 also shows a DQL instance model prepared for this evaluation. In the query panel residing at the upper middle of the IDE, there exist model items correspond to the required data dimensions in the query, namely Company, Market Value, Vessel, MMSI, IMO, Departure Port, Shipment Item and Amount. On the right panel under the filters, the Vessel and the Company are the defined filters which can be used in the query. Once dropped on a dimension or to the query, they will be transformed into filters within the related dimension or into a filter dimension depending where they are being applied.

As being an instance of DQL, the created query aims at listing the amount of the goods on each shipment with the information of departure ports, vessel details and company information. In addition, the same query model leads to prepare the query results inside a report grouping the data by the companies, vessels and departure ports.

For the qualitative assessment of DQL usage, five software developers became volunteer and agreed on being an evaluator. All of these evaluators has B.Sc. in computer science / software engineering and two of them are M.Sc. students in computer related fields at the time of this evaluation performed. Evaluators possessed the experience of developing software in industrial scale considering Big Data and/or Linked Open Data applications for different business domains (3 years on the average). Although they were skilled with creating database queries and working with data storages, they had no or very little knowledge on the query language required for Elasticsearch. After a brief introduction of DQL and its IDE, the evaluators were requested to create the same report given in Fig. 2. Upon completion their modeling session, a questionnaire including the following open-ended questions was given to the evaluators and their responses were gathered:

1. How does DQL and its IDE make writing Elasticsearch queries easier?
2. Did you encounter any difficulties while modeling queries and creating reports with using DQL? If any, please provide your suggestions to fix them.
3. Do you think DQL is easy to learn and use?

All the evaluators agreed on the biggest advantage of DQL that it eliminates the syntax errors which may be encountered while creating a query since there is no query writing process. They also agreed that the use of the DQL removed hardcoding the Elasticsearch queries hereafter. And most of them indicated that it is possible to create Elasticsearch queries without writing a single line of code. One of the evaluators stated that DQL's graphical syntax is comprehensive enough to cover all Elasticsearch domain and accompanying IDE helped them for determining and visualizing the details of queries from scratch. Some of the evaluators found the model panel residing on the left side of the DQL IDE (see Fig. 2) very helpful by means of dynamically showing the whole data model pertaining to the query under development.

For the second question, some of the evaluators stated that applying a filter to the report directly or using it separately on dimensions is a little bit confusing at the first time but after using the editor for a while, it gets simpler. Based on the feedbacks gained from the evaluators, visual concrete notations required for query modeling and organization of them inside the IDE were also re-arranged since some of the evaluators found the arrangement of these components a bit complicated.

Finally, for the last question, everyone agreed that even end-users with no knowledge on Elasticsearch would be able to use DQL for Elasticsearch query design and implementation after a small training. Most of the evaluators confirmed that there is no need to know any kind of syntax and programming (or querying) language for a person to use DQL and its IDE. They also added that little knowledge about basic query logic is enough for a user before using DQL. However, all of the evaluators also answered the third question by indicating there is still a learning curve to get used to the DQL editor, but with a short training session it becomes easy to learn and design reports.

In order to measure whether the use of DQL speeds up query creation, each evaluator's query design with using DQL has been recorded. The evaluators completed the generation of the Elasticsearch query required for the above logistics case study around 30 mins. on the average. The evaluators were also requested to create the same query again but this time without using DQL. They just used Elasticsearch query syntax and the result was amazing: It took around 6.5 hours to complete writing the same query on the average. Although that measurement was achieved from

only a single case study, we believe that the speedup gain obtained with using DQL in here is promising since the experts in the company confirmed that the query handled in here is complex enough comparing with the exact queries created in their commercial applications for datasets which are almost same size with the logistics dataset used in the case study.

V. Related Work

Like other domains, in order to master the problems of creation, management and evolution of databases and querying on these databases, the researchers investigate the ways of applying MDD principles and/or proposing the use of DSLs / DSMLs. For instance, MDSheet is proposed in [25] for model-driven engineering of spreadsheets. End-users can build sheets within MDSheet framework via its tool. The framework is enriched with a model-driven query language [20] which supports most of the SQL standards. The language is also structured as a DSL and the related MDE framework is integrated with Google Query function in [26]. Similarly, FDL [27] is a description language for spreadsheets, which is empowered with visualization and analysis tool for constructing the separation between the input of formulas and the output of calculation results. Although these studies provide a good MDD framework for spreadsheets, it gets very difficult to extract information on a single potentially large matrix in an effective way inside spreadsheets and this deficiency may cause spreadsheets a weak alternative for databases, especially the ones as being Elasticsearch storages.
