DEAR Reader, it is our pleasure to present to you Proceedings of the 2016 Federated Conference on Computer Science and Information Systems (FedCSIS), which took place in Gdańsk, Poland, on September 11–14, 2016.

FedCSIS 2016 was Chaired by prof. Krzysztof Goczyła, while Zenon Filipiak acted as the Chair of the Organizing Committee. This year, FedCSIS was organized by the Polish Information Processing Society (Mazovia Chapter), Systems Research Institute Polish Academy of Sciences, Warsaw Univesity of Technology, Wrocław University of Economics, and Gdańsk University of Technology. It was organized in technical cooperation with: IEEE Region 8, IEEE SMC Technical Committee on Computational Collective Intelligence, IEEE Computer Society Technical Committee on Intelligent Informatics, IEEE Poland Section, Computer Society Chapter Poland, Gdańsk Computer Society Chapter Poland, Polish Chapter of the IEEE Computational Intelligence Society, ACM Special Interest Group on Applied Computing, Łódź ACM Chapter, European Alliance for Innovation (EAI), Committee of Computer Science of the Polish Academy of Sciences, Polish Operational and Systems Research Society, Mazovia Cluster ICT Poland and Eastern Cluster ICT Poland. Furthermore, the 11th International Symposium Advances in Artificial Intelligence and Applications (AAIA'16) was organized in technical cooperation with: International Fuzzy Systems Association, European Society for Fuzzy Logic and Technology, International Rough Set Society and Polish Neural Networks Society.

FedCSIS 2016 consisted of the following events (conferences, symposia, workshops, special sessions). These events were grouped into FedCSIS conference areas**,** of various degree of integration. Specifically, those listed in italics and without indication of the year 2016 signify "abstract areas" with no direct paper submissions (i.e. paper submissions only within enclosed events).

- **AAIA'16 – 11th International Symposium Advances in Artificial Intelligence and Applications**
  - AIMaVIG'16 – 2nd International Workshop on Artificial Intelligence in Machine Vision and Graphics
  - AIMA'16 – 6th International Workshop on Artificial Intelligence in Medical Applications
  - AIRIM'16 – 1st International Workshop on AI aspects of Reasoning, Information, and Memory
  - ASIR'16 – 6th International Workshop on Advances in Semantic Information Retrieval
  - DSTUI'16 – 6th International Workshop on Dealing with Spatial and Temporal Uncertainty and Imprecision
  - LTA'16 – 1st International Workshop on Language Technologies and Applications
  - WCO'16 – 9th International Workshop on Computational Optimization
- ***CSS - Computer Science & Systems***
  - AIPC'16 – 1st International Workshop on Advances in Image Processing and Colorization
  - CANA'16 – 9th Computer Aspects of Numerical Algorithms
  - CPORA'16 – 1st Workshop on Constraint Programming and Operation Research Applications
  - IWCPS'16 – 3rd International Workshop on Cyber-Physical Systems
  - MMAP'16 – 9th International Symposium on Multimedia Applications and Processing
  - WSC'16 – 8th Workshop on Scalable Computing
- **ECRM – Education, Curricula & Research Methods**
  - IEES'16 – 1st International E-education Symposium - Education of the Future
  - DS-RAIT'16 – 3rd Doctoral Symposium on Recent Advances in Information Technology
- **iNetSApp'16 – 4th International Conference on Innovative Network Systems and Applications**
  - EAIS'16 – 3rd Workshop on Emerging Aspects in Information Security
  - SoFAST-WS'16 – 5th International Symposium on Frontiers in Network Applications, Network Systems and Web Services
  - WSN'16 – 5th International Conference on Wireless Sensor Networks
- ***IT4MBS – Information Technology for Management, Business & Society***
  - ABICT'16 – 7th International Workshop on Advances in Business ICT
  - AITM'16 – 14th Conference on Advanced Information Technologies for Management
  - ISM'16 – 11th Conference on Information Systems Management
  - KAM'16 – 22nd Conference on Knowledge Acquisition and Management
  - UHH'16 – 2nd International Workshop on Ubiquitous Home Healthcare
- ***JAWS – Joint Agent-oriented Workshops in Synergy***
  - MAS&S'16 – 10th International Workshop on Multi-Agent Systems and Simulations
  - SEN-MAS'16 – 4th International Workshop on Smart Energy Networks & Multi-Agent Systems
- **SSD&A – Software Systems Development & Applications**
  - BTMSPA'16 – 1st Symposium on Balancing Traditional and Modern Software Process Approaches
  - MDASD'16 – 4th Workshop on Model Driven Approaches in System Development
  - MIDI'16 – 4th Conference on Multimedia, Interaction, Design and Innovation
  - SEW-36 – The 36th IEEE Software Engineering Workshop

This year (2016) is the year of the 90th anniversary of the birth and the 10th anniversary of the death of Professor Zdzisław Pawlak. Therefore, a special plenary panel devoted to the “Legacy of Professor Zdzisław Pawlak” has been or-

ganized. During the panel, friends, students and collaborators of Prof. Pawlak shared their memories and reflections.

Furthermore, an AAIA'16 Data Mining Competition, focused on "Predicting Dangerous Seismic Events in Active Coal Mines" has been organized. Its results constitute a separate section in these proceedings. Awards for the winners of the contest were sponsored by: Research and Development Center EMAG and the Mazovia Chapter of the Polish Information Processing Society.

Each paper, found in this volume, was refereed by at least two referees and the acceptance rate of full (regular) papers was 25.39% (130 papers out of 512 submissions). Here, let us note that this year the number of submissions has been the largest in the history of the FedCSIS conference series.

Each event constituting FedCSIS had its own Organizing and Program Committee. We would like to express our warmest gratitude to the members of all of them for their hard work attracting and later refereeing 512 submissions.

FedCSIS 2016 was organized under the auspices of dr Jarosław Gowin, Minister of Science and Higher Education, Anna Streżyńska, Minister of Digital Affairs, Paweł Adamowicz, Mayor of the City of Gdańsk, Wojciech Szczurek Mayor of the City of Gdynia, and prof. Henryk Krawczyk, Rector of the Gdańsk University of Technology.

Finally, FedCSIS 2016 was sponsored by the Ministry of Science and Higher Eduction and Intel.

Maria Ganzha, *Co-Chair of the FedCSIS Conference Series, Systems Research Institute Polish Academy of Sciences, Warsaw, Poland, and Warsaw University of Technology, Poland*
Leszek Maciaszek, *Co-Chair of the FedCSIS Conference Series, Wrocław University of Economics, Wrocław, Poland and Macquarie University, Sydney, Australia*
Marcin Paprzycki, *Co-Chair of the FedCSIS Conference Series, Systems Research Institute Polish Academy of Sciences, Warsaw and Management Academy, Warsaw, Poland*

Proceedings of the 2016 Federated Conference on Computer Science and Information Systems (FedCSIS)

September 11–14, 2016. Gdańsk, Poland

TABLE OF CONTENTS

Plenary Panel on the Legacy of Professor Zdzisław Pawlak

Data Mining Challenge: Predicting Dangerous Seismic Events in Active Coal Mines

2ND International Workshop on Artificial Intelligence in Machine Vision and Graphics

6TH International Workshop on Artificial Intelligence in Medical Applications

1ST International Workshop on AI aspects of Reasoning, Information, and Memory

6TH International Workshop on Advances in Semantic Information Retrieval

6TH International Workshop on Dealing with Spatial and Temporal Uncertainty and Imprecision

1ST International Workshop on Language Technologies and Applications

9TH International Workshop on Computational Optimization

8TH Workshop on Scalable Computing

Education, Curricula & Research Methods

1ST International E-education Symposium–Education of the Future

3RD Doctoral Symposium on Recent Advances in Information Technology

4TH International Conference on Innovative Network Systems and Applications

3RD Workshop on Emerging Aspects in Information Security

5TH International Symposium on Frontiers in Network Applications, Network Systems and Web Services

5TH International Conference on Wireless Sensor Networks

Information Technology for Management, Business & Society

7TH International Workshop on Advances in Business ICT

14TH Conference on Advanced Information Technologies for Management

11TH Conference on Information Systems Management

22ND Conference on Knowledge Acquisition and Management

4TH Conference on Multimedia, Interaction, Design and Innovation

The 36TH IEEE Software Engineering Workshop

Big Data Meets Big Water: Analytics of the AIS Ship Tracking Data

Stan Matwin
Institute for Big Data Analytics
Dalhousie University
Halifax, NS, Canada B3H 1W5 Canada
Email: stan@cs.dal.ca

IN THIS presentation we will argue that Big Data technologies can contribute in an important way to an unprecedented breakthrough in the understanding of oceans as a factor in climate change, in transportation, and in supplying humanity with its important food component.

Oceans cover almost 70% of the surface of the earth, and supply at least 15% of animal protein intake for 4.5 billion people. At the same time, ocean are an area of human interest that undergoes currently a massive infusion of information technology. As a result, ocean data and its challenges will become a fertile ground for data science.

After briefly introducing Big Data, we will argue that many of the emerging data sources focused on oceans are Big Data. We will use the global Automatic Identification System as an example. We will introduce the AIS system and characterize it quantitatively. We will then illustrate some of the Big Data projects under way in the Institute for Big Data Analytics, Dalhousie University. In particular, we will focus on the analysis of fishing ship trajectories available through AIS data, and will show how this analysis can lead in the future to unprecedented quality of estimates of the fish intake by global fisheries.

We will discuss AIS data management, data preprocessing techniques, data segmentation, data representation, and data modeling (point-wise and geometrically). We will demo a specific implementation of our data management solution. We will present our early experiences with some of the basic classification tasks (ship kind classification, fishing gear classification, fishing-non fishing classification) using Markovian approaches, standard data exploration approaches, and classifier induction approaches. We will also show how alternative methods from Natural Language Processing can assist in the same task. We will also discuss early results and challenges with the use of Deep Learning methods (e.g. Long Short Term Memory) on the AIS data.

Finally we will discuss the ongoing efforts in data integration, particularly in standardization of ocean data metadata under way as an IODE and Ocean Data Integration Project. International Oceanographic Data and Information Exchange.

How Digital Transformation Shapes Corporate IT: Ten Theses about the IT Organization of the Future

Frederik Ahlemann
University of Duisburg-Essen Essen, Germany
Email: frederik.ahlemann@uni-due.de

DIGITAL transformation is a major challenge for many organizations. IT managers in particular not only wonder what the next digital trends in their industry will be, they also need to understand how today's IT organizations will change in light of digital transformation. I will first discuss some foundations of digital transformation and will then present 10 theses on how digital transformation will influence corporate IT.

Thesis 1: *There will be no business without IT: IT is the indispensable driver and enabler of value creation*

IT is already the backbone of many enterprises and a key resource. At the same time, many executives still do not view it as a crucial competitive factor. Digital transformation will change this. IT will not only be used to automate internal and external business processes. It will also be used to realize new digital products, services, and business models. Beyond this, IT will fundamentally change the ways enterprises will be organized and managed. Even many demanding management tasks can be performed by AI systems fueled by machine learning. This will revolutionize how enterprises operate—in terms of speed, reliability, efficiency, and quality. At the same time, business will increase its dependency on IT. System crashes that cannot be fixed immediately will lead to insolvency faster than ever before owing to interrupted business operations.

Thesis 2: *Development and operations will lose weight: Tomorrow's IT functions will follow the paradigm of* Innovate-design-transform

Innovate-design-transform Classic corporate IT follows the *Plan-build-run* paradigm, which serves as a blueprint for the structure of an IT organization and places significant emphasis on long-term planning and subsequent implementation in a more or less stable environment. The focus is on efficiency. However, digital transformation requires enterprises to become more flexible so as to realize innovative business models. Thus, future IT functions will follow the *Innovate-design-transform* paradigm that stress the importance of innovation, subsequent design of IS with high acceptance and adoption rates, and a transformation of the organization to serve the new business model.

Thesis 3: Shadow *IT becomes normal: IT innovations are developed through joint interdisciplinary teams in the business departments*

Today, in most enterprises, IT projects are initiated by the business and then realized in the IT organization. However, this process neglects some key characteristics of innovation in the digital age: (1) innovations must be developed quickly, (2) innovations are the result of a (very) close collaboration of business and IT (and external parties), (3) requirements change rapidly, (4) communication is intense and frequent. Thus, in the future, IT professionals will be part of the business department to continuously work on digital innovations, whether these be process, product, or business model innovations. At the same time, the business can decide, with some constraints, on the IT/IS they need.

Thesis 4: *Innovations through networks: Strategic vendors become innovation partners Most of today's IT organizations struggle to implement*

Most of today's IT organizations struggle to implement disruptive IT innovations because they lack the required capabilities. For instance, many businesses have ideas regarding the use of big data and machine learning. However, they lack the data scientists necessary to implement these concepts. Thus, digital partnerships and digital innovation networks will become more important. These partnerships and networks will often be very different from classic vendor relationships. They are long-term, eye-level, strategic, and will also often involve benefits-sharing.

Thesis 5: *From applications to user: Development processes are agile, user-centric, and closely linked to IT operations*

Even today, software development is often based on the waterfall model. The timespan between an initial idea and handover to IT operations is fairly long. In times of digital innovation, this can significantly hinder the gaining of market shares quickly and the building of positive brand images. Future IT will be lightweight, characterized by agile development processes, and free from too many architectural and organizational constraints. It will allow developers to focus on user needs and user feedback. High acceptance rates and intense usage are primary goals of development. Developers will iteratively improve applications to satisfy users, and mostly in very short cycles. A close integration of development and IT operations is key for this approach (DevOps).

Thesis 6: *Infrastructure as a commodity: IT infrastructure services will be traded on free markets*

Despite the trend towards outsourcing, many companies still operate their own IT infrastructure in data centers. The decision to have an own IT infrastructure is based on a few assumptions. For instance, organizations believe that an own IT infrastructure allows for better controlling, higher security levels, better compliance, and a better cost structure. These assumptions will soon be invalid, if they are not already invalid. In the future, data centers will no longer be necessary, and corporate IT will completely be based on public cloud offerings, with very few exceptions. These public cloud offerings will largely be standardized, allowing for trading at new types of exchanges for IT services.

Thesis 7: *Digital transformation as a major risk: Security and business continuity will be primary cross- departmental functions The growing use of IT—even as parts of products and services*

The growing use of IT—even as parts of products and services—will increase dependency and vulnerability. Attacks against central IT will directly jeopardize a company's continued existence. Thus, security and business continuity management (SBCM) will gain importance. It will pervade all areas of an enterprise and will no longer be a field of only IT experts. Businesses will realize that SBCM is an indispensable tool for long-term business success, because attacks and threats from the outside as well as from the inside will become 'normal'.

Thesis 8: *Transformable IT landscapes: IT architectures will be standardized, modular, flexible, ubiquitous, elastic, cost-efficient, and secure*

Today's complex IT landscapes will undergo tremendous transformation. Via practices such as enterprise architecture management (EAM), increased standardization both at the industry and company levels, technological advances and the trends towards cloud computing, the IT architectures of the future will leave many current challenges behind. We expect them to be more standardized (through cloud computing and industry starndardization), more modular (through technological and architectural advances), more flexible (through technological advances), ubiquitous (through mobile computing, new device categories, more flexible architectures), elastic (through cloud computing), more cost- efficient (through cloud computing), and more secure (through technological advances and cloud providers' expertise). This will allow for more dynamic, fast, and easy implementation of new products, services, and business models.

Thesis 9: *The end of the IT department: IT experts will be part of business departments*

Given that the aforementioned trends come on-stream, the largest share of IT specialists will likely work on the specification, development, configuration/customization, and maintenance of applications. However, because close collaboration with business is key for the success of these activities, we expect them to become part of the business departments, where they can sit next to users and business managers and can develop new products, services, and processes necessary to make IT innovations happen. The IT department will shrink significantly, because fewer infrastructure experts are required (owing to the use of cloud services) and the move of IS specialists to the business. The remaining unit will focus on more strategic tasks such as EAM, SBCM, procurement, partner management, innovation management, and portfolio management. Since these functions are crucial for a corporate success, we expect them to be located alongside the board.

Thesis 10: *Demographics, digital natives, and individual entrepreneurship: Employees become a strategic competitive factor*

A key factor for the success of digital initiatives today and in the future will be access to skilled human resources. Digital transformation requires specific qualifications and skills that are currently fairly rare. Even in the future, with new study programs at universities (e.g. for data science), it is likely that the professionals required will be scarce. The demographic changes in many western societies, the changes in young professionals' value systems, and the growing desire for individualism and self-determination will make a dedicated and innovative IT human resource management necessary.

Location always matters: how to improve performance of dynamic networks?

Michael Segal
Department of Communication Systems Engineering
Ben-Gurion University of the Negev, Israel
Email:segal@bgu.ac.il

IN OUR talk we will focus on networks with no predefined infrastructure (ad-hoc networks, sensor networks, vehicular networks). There are many optimization problems derived from the context of such networks including power assignment mechanisms, scheduling, data gathering, etc. We will discuss various techniques tacking these problems emphasizing the importance of mobile nodes locations and its influence on the tightness of the solutions.

In particular, we consider the following scenarios.

- Wireless Sensor Network. A wireless sensor network (WSN) consists of n wireless sensor nodes, $S = \{s_1, \ldots, s_n\}$, distributed in some area A. These nodes perform monitoring tasks and periodically report to a base station r which is located somewhere within the area A (we consider different locations throughout the paper). During the report phase, the sensor nodes propagate a message to the base station through a *data collection tree*, $T_S = (S \cup \{r\}, E_S)$, rooted at r. We consider *data collection with aggregation*, where every node $s \in S$ forwards a single unit size *report message* to its parent. The message holds an accumulated information collected from a subtree of T_S rooted at s. An example of this scenario can be found in temperature monitoring systems for fire prevention, intrusion detection, seismic readings, etc. **Minimizing the energy requirement** is one of the primary optimization objectives when deploying a WSN due to the very low battery reserves at the sensor nodes and the high costs that are associated with replacing these batteries (if at all possible). The second measure that we are interested in is **transport capacity**, $D(T_S)$, of the data collection tree T_S. Another critical aspect in the design of a WSN is the **hop-diameter** of T_S. We consider different approaches of T_S construction including: short-cutting Minimum Spanning Tree (MST) [1], identification of balance nodes [1], centroid-based constructions [2], (r, d)-index constructions [2].
- Wireless Ad-hoc Network. A wireless ad-hoc network consists of transceivers (nodes) that are located in the plane and communicate by radio. In contrast to wired networks, wireless ad-hoc networks have no fixed communication backbone. The temporary physical topology of the network is determined by the relative disposition of the wireless nodes and the transmission range assignment of each of the nodes. The combination of these two factors produces a directed communication graph where the nodes correspond to the transceivers and the edges correspond to the communication links. The topology of the induced communication graph has a strong effect on the routing algorithms' efficiency. In this talk we will discuss one of the key properties of the induced communication graph – energy stretch factor [3], [4]. Let $\gamma_{u,v}$ be the minimum energy required to send a message from u to v (using other nodes if necessary). The energy spanner is aimed at minimizing the energy stretch factor t_E of the induced communication graph, that is, for any u, v, the energy required to propagate a message from u to v is at most $t_E \cdot \gamma_{u,v}$.
- Vehicular Ad-Hoc Network. Vehicular ad-hoc network (VANET) is a promising branch of traditional MANET. VANET is designed to provide wireless communication between vehicles and between vehicles and nearby road-side equipment. This communication intends to improve both safety and comfort on the road. VANET has a number of difficulties regarding the traditional MANET. Due to the dynamic nature of VANET environments, configuration is always changing, where links may appear and disappear very quickly and vehicle density is constantly changing. In this talk, we also will discuss self-organizing hierarchical topology to serve as the infrastructure for beacon dissemination process in VANET by carefully partitioning the network into geographically optimized clusters with chosen clusterheads [5].

11th International Symposium Advances in Artificial Intelligence and Applications

THE AAIA'16 will bring scientists, developers, practitioners, and users to present their latest research, results, and ideas in all areas of Artificial Intelligence. We hope that theory and successful applications presented at the AAIA'16 will be of interest to researchers who want to know about both theoretical advances and latest applied developments in AI.

TOPICS

Papers related to theories, methodologies, and applications in science and technology in this theme are especially solicited. Topics covering industrial issues/applications and academic research are included, but not limited to:

- Decision Support
- Machine Learning
- Fuzzy Sets and Soft Computing
- Rough Sets and Approximate Reasoning (see also FedCSIS'16 Plenary Panel commemorating Prof. Zdzisław Pawlak)
- Data Mining and Knowledge Discovery
- Data Modeling and Feature Engineering
- Data Integration and Information Fusion
- Hybrid and Hierarchical Intelligent Systems
- Neural Networks and Deep Learning
- Bayesian Networks and Bayesian Reasoning
- Case-based Reasoning and Similarity
- Web Mining and Social Networks
- AI in Business Intelligence and Online Analytics
- AI in Robotics and Cyber-Physical Systems
- AI-centered Systems and Large-Scale Applications

We also encourage researchers interested in the following topics to submit papers directly to the corresponding workshops, which are integral parts of AAIA'16:

- AI in Computational Optimization (see WCO'16 workshop)
- AI in Language Technologies (see LTA'16 workshop)
- AI in Machine Vision and Graphics (see AIMaViG'16 workshop)
- AI in Medical Applications (see AIMA'16 workshop)
- AI in Reasoning and Computational Foundations (see AIRIM'16 workshop)
- AI in Semantic Information Retrieval (see ASIR'16 workshop)
- AI in Spatial and Temporal Analytics (see DSTUI'16 workshop)

All papers accepted to the main track of AAIA'16 and to the above workshops will be treated equally in the conference programme and will be equally considered for the awards listed below.

PROFESSOR ZDZISLAW PAWLAK BEST PAPER AWARDS

We are proud to announce that we will continue the tradition started during the AAIA'06 Symposium and award two "Professor Zdzislaw Pawlak Best Paper Awards" for contributions which are outstanding in their scientific quality. The two award categories are:

- Best Student Paper—for graduate or PhD students. Papers qualifying for this award must be marked as "Student full paper" to be eligible for consideration.
- Best Paper Award for the authors of the best paper appearing at the Symposium.

In addition to a certificate, each award carries a prize of 300 EUR provided by the Mazowsze Chapter of the Polish Information Processing Society.

IFSA AWARD FOR YOUNG SCIENTIST

We are proud to announce that, as in the recent years, the International Fuzzy Systems Association (IFSA) Best Paper Award for Young Scientist, will be presented.

Candidates for all the above awards can come from the AAIA'16 and all workshops organized within its framework.

EVENT CHAIRS

- **Janusz, Andrzej,** University of Warsaw, Poland
- **Ślęzak, Dominik,** University of Warsaw & Infobright Inc., Poland

ADVISORY BOARD

- **Kacprzyk, Janusz,** Systems Research Institute, Warsaw, Poland
- **Kwaśnicka, Halina,** Wroclaw University of Technology, Poland
- **Markowska-Kaczmar, Urszula,** Wroclaw University of Technology, Poland
- **Skowron, Andrzej,** University of Warsaw, Poland

PROGRAM COMMITTEE

- **Artiemjew, Piotr,** University of Warmia and Mazury, Poland
- **Bartkowiak, Anna,** Wrocław University, Poland
- **Bazan, Jan,** University of Rzeszów, Poland
- **Bordogna, Gloria,** CNR IREA, Italy
- **Borkowski, Janusz,** Polish-Japanese Academy of Information Technology & Infobright Inc.
- **Błaszczyński, Jerzy,** Poznań University of Technology, Poland

- **Cetnarowicz, Krzysztof,** AGH University of Science and Technology, Poland
- **Chakraverty, Shampa,** Netaji Subhas Institute of Technology, India
- **Chen, Phoebe,** La Trobe University, Australia
- **Cheung, William,** Hong Kong Baptist University, Hong Kong S.A.R., China
- **Cyganek, Bogusław,** AGH University of Science and Technology, Poland
- **Czarnowski, Ireneusz,** Gdynia Maritime University, Poland
- **Czerniak, Jacek M.,** Casimir the Great University in Bydgoszcz, Poland
- **Czyżewski, Andrzej,** Gdańsk University of Technology, Poland

***Abstract*—We consider concept of *approximate query* in RDBMS i.e. query that returns results which may differ from common (exact) query results in a way but its evaluation requires less resources. In the work we focus mostly on time and storage space aspects. We follow one of the state-of-the-art trends using synopses of data as the input of approximate query evaluation. We propose some measures of approximate query results quality. Basing on them we present steps of adaptive elaboration of synopses quality measure that should be mutually corresponding.**

***Index Terms*—Approximate Query, Quality Measures, Histograms.**

I. Introduction

APPROXIMATE query concept emerged as a tool of coping with continuous growth of data volume gathered in databases. Disposing limited budget of resources like time, storage space, computing power etc. database user wanted to gain information from the data quickly but accepting fact that achieved results may not be crisp. Two main classes of solutions are present in the literature: data sampling techniques [1], [2] and data synopses calculation [3], [4]. The former one utilizes statistical apparatus for choosing representative sample of the data, considerably smaller than whole data set, and using it to estimate results of query for whole data. The latter is based on concepts of data synopses which are data descriptions built once during load, stored and exclusively used during query evaluation. Some compact comparison between both approaches is contained in e.g. [5].

In the world of RDBMSs synopses are considered as the descriptions of e.g. columns value data sets. We may consider both one or multicolumns descriptions. The most common and well-examined types of data synopses described in the literature are histograms. In standard approaches, histograms are built per whole column (or more columns) and inference based on histograms is done for whole relation.

Our approach differs from this while we utilized some elements of *granular computing*[1] in the query evaluation process. Despite our approach may be treated as an example of the synopses calculus trend, we create synopses and inference on their basis not on whole relation level but on their parts. This may require some additional operations during query evaluation like compound partial results of evaluated query from each data packs. On the other hand it enables reflecting potential changes or differences in columns value sets in time and avoiding complex operations on synopses when e.g. consecutive loads into relations are considered.

Other consequence of this fact is that the size (in bytes) of generated synopses must be of orders of magnitude smaller than compressed data themselves and synopses build in standard approaches for whole column. For effectiveness sake and in order to easily control storage we assume also existing size budget for single synopsis. That means in particular that for most cases we cannot afford storing e.g. exact histogram of value set from part of the table (i.e. histogram in which all intervals are single-valued). The idea of utilizing granularity concepts may go further in building hierarchical structures of synopses e.g. for subsets of row/data packs.

The presented analysis concerns measures of histogram quality. We will say that the histogram is of good quality when applying used methodology led to achieve good approximation of query results. That raises immediately question of quality of the latter one. In the article we introduce measures of quantifying approximate query results and their selected aspects. The main purpose of the work remains though developing and analyzing measures of histogram quality that will directly translate to proposed quality measures of the query results.

Section II describes basics of the Infobright RDBMS engine that we had chosen for experiments, explains terminology we use in the work and presents methodology used in experiments framework. We discuss problem of measuring approximate query results in Section III and propose some formulas for it. In Section IV we describe standard methods of 1dim histogram generation and classic quality measures for them. As the experiments result presented in latter section run for standard approaches were not satisfactory, we propose in Section V some modifications of them.

[1]https://en.wikipedia.org/wiki/Granular_computing

II. Basic Definitions and Methodology

A. Definitions

We consider *1–dimensional histograms* as a collection of *bars* (*buckets*), each of which then consists of: interval (determined by 2 numbers - interval's begin and end) and *frequency* which in our work is cardinal (but finite) number. If single histogram bars' intervals are disjoint, frequencies should be interpreted as number of elements which occur in the interval. Exemplary 1dim histograms are in Figures 3 – 5 . We may easily extend this definition to *multidimensional histograms* changing intervals to *cubes* however we do not consider multidimensional case in the article so we omit it here. Histograms might be generated using many algorithms. Some of them are presented in Section IV. In the work we may refer to information contained in synopses as to *rough data* or *granuled data*.

B. Infobright Basics

In the considered RDBMS engine [6], [7], during the data load process, the sets of relation tuples are split into chunks of equal and fixed cardinality (apart from the last chunk perhaps) which form *row packs*. Sequence of values from row pack for single column forms *data pack* for this column. As *data pack range* we mark interval from minimal to maximal values of data pack. In actual implementation of the database engine chunk size is equal to 2^{16}. Data packs are then compressed separately and stored. For each of formed data pack there is additionally built and stored compact information (data synopsis) of values from data pack. Such synopsis may be considered as the information granule of the data pack. Prepared data synopses are loaded into memory during query evaluation and used in several ways e.g. to filter out irrelevant data (e.g. to avoid costly I/O operations for corresponding data packs).

As pointed out, in the described engine, both compressed data packs and synopses are stored. In some of our previous works, we investigated how to further decrease the amounts of accessed data packs and focus more on synopses-based computations in order to accelerate computations, on the cost of possible inexactness of query results [8], [9]. However, in the case of the new Infobright's engine dedicated to approximate queries only synopses are stored, while exact data are accessible only during their load (when synopses are being generated) and then forgotten.[2] This is also the assumption that we follow in this paper. Another aspect that distinguishes our approach from most of standard methods is the fact that our data synopses are built for each data pack – not for each column only.

C. Experiments Framework

As there is no room for describing methods of using synopses in internal operations of the query engine and, on the other hand, this is not the main purpose of this article, we decide to emulate behaviour of the engine designed for approximate queries. Generally speaking, histogram reflects probability distribution and therefore might be the input of random value generator. To make histogram the distribution we assume that (1) inside each interval all values are uniformly distributed and (2) frequencies of each value in domain should be normalized (their sum should be equal to 1).

During query evaluation histograms were read from storage and data pack is constructed of randomly chosen 2^{16} column values according to distribution described by histogram.

For the purpose of this work we assume, that each approximate query evaluation consists of 2 stages: (1) generating data according to calculated 1dim histograms and (2) evaluate the query using such prepared (approximate) table with exact engine. We created set of benchmark queries which were evaluated on data sets generated according to specific histograms. The overall rating of specific histogram depended on query results quality gained from experiments on these data sets (we will call it *approximate data*).

D. Storage Budget Discussion

As we had chosen histograms as types of data synopsis used in our framework, we should indicate how one can control existing storage budget in histogram construction. Remind that we consider budget per 1 data pack. Few question may be raised here. The most natural way to control budget in the case of histograms is to adjust number of stored buckets. This parameter affects not only storage factor but has also influence on calculation complexity (number of performed operations). The other factor may be also method of storing histogram. In general, as presented in definition, each bucket of histogram is described by left and right boundary. However with additional assumption (made also in this work) that set of histogram intervals covers whole data pack domain, apart from storing data pack minimum and maximum, to identify the bar in histogram suffice to store only its e.g. right boundary (left can be induced from prior interval). So each bucket can be stored as 2 numbers - its maximum and its frequency. Deeper optimizations of storage may depend on type of synopsis or on implementation method. In the work we focus on number of buckets as the main control parameter.

III. How to Compare Query Results?

In order to compare query results evaluated on exact (real) data and on rough data one needs to elaborate quality measures of query results. Below we describe measures used in the article. One can easily notice that they are to some extent inspired by the notions of fuzzy similarity and multi-label classification, now adopted for new purposes.

The result of every SELECT has a tabular form. We will denote it as $R = (U, C)$, where U and C are sets of its tuples and columns. U can refer to original rows or groups, possibly with limit.

In C, we distinguish columns A that are results of aggregate functions and columns G used in group by clause. Alternatively, G can gather columns that are primary key and A - all

[2]https://infobright.com/introducing-iaq/

other columns. Some columns in A can be used in ORDER BY clause. In such case the new rank function is added to C.

Let us consider two results of the same query, real result $R_r = (U_r, C)$ and an approximate result $R_a = (U_a, C)$. The idea is to check to what extent tuples in U_r and U_a match with each other with regard to columns in G and, for those tuples which can be matched, how similar are their values over A. Similarity of R_r and R_a should be within [0,1], and equal to 1 only if R_r and R_a are identical.

Consider a pair of tuples $t_r \in U_r$ and $t_a \in U_a$, such that there is $g(t_r) = g(t_a)$ for every g in G.

A score of similarity of t_r and t_a is as follows:

$$s(t_r, t_a) = \prod_{c \in A} s_c(c(t_r), c(t_a))$$

where $\prod$ denotes multiplication and:

$$s_c(c(t_r), c(t_a)) = 1 - \frac{|c(t_r) - c(t_a)|}{|c(t_r)| + |c(t_a)| + 1}$$

If rank is added, it can take a form of:

$$r(t_r, t_a) = 1 - \frac{|rank(t_r) - rank(t_a)|}{|rank(t_r)| + |rank(t_a)|}$$

While rows (and groups) from results achieved from exact query and approximate query may differ we distinguish two types of mismatched rows (groups):

- False Positives (FP) - rows (groups) which shouldn't occur but did

$$FP = card(U_a \backslash U_r) = card(U_a) - card(U_r \cap U_a)$$

- True Negatives (TN) - rows (groups) which should occur but didn't

$$TN = card(U_r \backslash U_a) = card(U_r) - card(U_r \cap U_a)$$

We define ***Aggregation Similarity*** as follows:

$$AggSim(R_r, R_a) = \frac{\sum_{t_r \in U_r, t_a \in U_a : G(t_r) = G(t_a)} s(t_r, t_a)}{card(U_r)}$$

We define ***Ranking Similarity*** as follows:

$$RankSim(R_r, R_a) = \frac{\sum_{t_r \in U_r, t_a \in U_a : G(t_r) = G(t_a)} r(t_r, t_a)}{card(U_r)}$$

And finally, we define ***Total Similarity*** as follows:

$$TotSim(R_r, R_a) = \\ = \frac{\sum_{t_r \in U_r, t_a \in U_a : G(t_r) = G(t_a)} s(t_r, t_a) \cdot r(t_r, t_a)}{card(U_r) + card(U_a \backslash U_r)}$$

In Fig. 1 there is a simple example of calculation of presented measures.

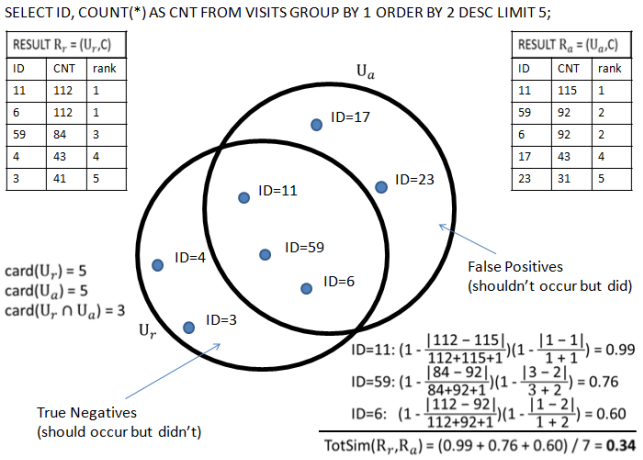

Fig. 1. Example of comparison between results of exact and approximate queries

IV. Standard Approach

A. Generation of 1-Dimensional Histogram

We had started experiments with three standard approaches to histogram generation.

As mentioned earlier we built separate histogram for each data pack (value set of 1 column from 2^{16} consecutive rows) i.e. exact data were the input to create each 1-dim histogram. After being build each histogram was stored.

Looking for the best correspondence between histogram quality measures and approximate query results quality we tested many different methods of histogram generation. Here we present results of experiments on 3 most commonly used in databases types of histograms: EquiWidth histogram (classic), EquiDepth histogram (quant) and MaxDiff histogram (diff).

Each type of histogram splits data pack range into k buckets.

- EquiDepth histogram divides the set of values into k ranges such that each range has the same number of values [10].
- EquiWidth histogram divides the set of values into k buckets of equal width [11].
- In MaxDiff histogram boundaries of intervals are chosen after analyzing differences between frequencies of adjacent bars from exact histogram (adjacency is induced by natural order of values). $k - 1$ largest differences determine split points of histograms intervals [12].

As inside each histogram's interval we assume uniform distribution for contained values, and intervals from each considered 1-dim histograms cover whole range of data pack, we may achieve in natural way from random generation values which did not occur in original data pack (False Positives). As turned out they constituted the biggest challenge.

Each type of histogram splits data pack range into k buckets, where k is established parameter corresponding to storing budget. In our experiments we took $k = 64$.

All experiments were run on the table containing 33 columns and $10 \cdot 2^{16}$ rows.

B. Standard Quality Measures for Histogram

In order to use approximate query in most efficient way not only results comparison aspect should be examined but also methods of prediction to what extent type or scale of used synopsis could affect query results quality. Such knowledge would let one to choose optimal type/size of histogram and also to control by the user threshold between storage footprint of created synopses (or on the other hand: volume of data processed during query evaluation) and query results quality. We assume that the database user is aware of the existence of such threshold.

That brings us to subproblem of defining measure of histogram quality which is correspondent to approximate query results.

We acknowledged as fundamental here the ability of generated histogram to reflect original distribution of the data pack's values. As mentioned earlier due to existing budget, in most cases, we are not able to store exact histogram of value set (such case we recognize as optimal), so such possibility is crucial to make more sophisticated inference of approximations successfully.

At the first stage we applied standard measures of similarity between distributions based on deviations from mean, which work fine for the cases without generated false positives [13], [14].

Here is the first examined measure:

$$Q1(c,p) = \sum_{v \in Dom(c)} min\{\frac{freq(p_v)}{ALL_{p_v}}, freq(v)\},$$

where c is a column, p - data pack range split (set of intervals), p_v - interval (from split) containing v, $freq(p_v)$ - frequency of p_v, $freq(v)$ - number of occurences of v and $ALL_{p_v} = end(p_v) - start(p_v) + 1$. Intuitions of measure $Q1$ are presented at Fig. 2

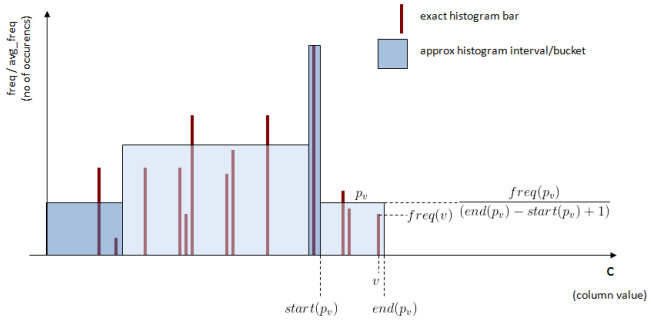

Fig. 2. Measure $Q1$ components.

The second analyzed measure was the sum of squares of deviations of exact value frequencies from corresponding bar frequency, with additional assumption that all values from intervals range is included in the sum (those which did not exists in original data have frequency equal to 0)

$$Q2(c,p) = \sum_{v \in ALL_{Dom(c)}} (freq(v) - \frac{freq(p_v)}{ALL_{p_v}})^2,$$

where c is a column, p - data pack range split (set of intervals), p_v - split interval for v, $freq(p_v)$ - frequency of interval containing v, $freq(v)$ - number of occurrences of v in data pack (non existing values have freq = 0), $ALL_{p_v} = end(p_v) - start(p_v) + 1$ and $ALL_{Dom(c)} = end(Dom(c)) - start(Dom(c)) + 1$.

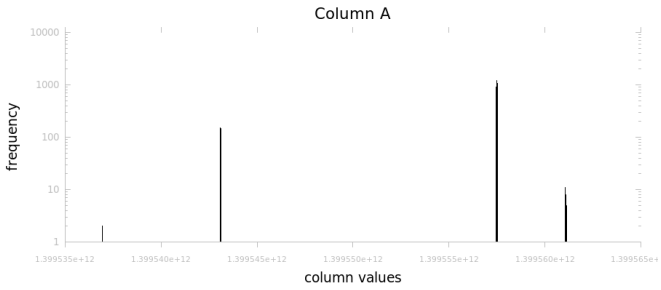

Fig. 3. Exact histogram (distribution) on 1 data pack of real-life column (Column A; logarithmic scale of frequencies)

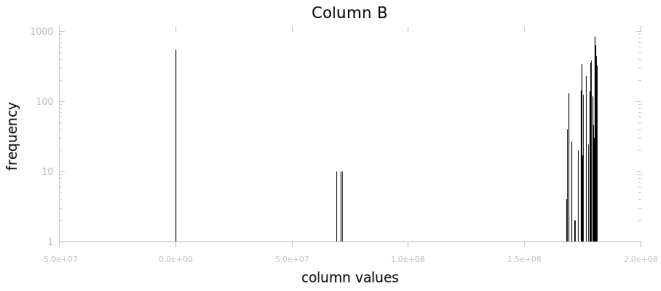

Fig. 4. Exact histogram (distribution) on 1 data pack of real-life column (Column B; logarithmic scale of frequencies)

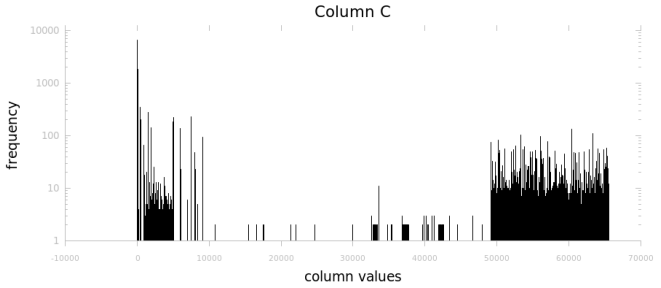

Fig. 5. Exact histogram (distribution) on 1 data pack of real-life column (Column C; logarithmic scale of frequencies)

At the first stage of experiments we calculated $Q1$ for every considered type of histograms. Next we evaluated set of prepared queries on exact data and on data generated from every histogram. We found achieved results encouraging, however we identified many hard cases for presented approach.

Lack of satisfactory correspondence between $Q1$ and query results quality for each histogram was visible both on simplest single-column queries and more complex queries. Fig. 6–9 illustrate results of testing query that simulate calculation of exact distribution of column values:

```
SELECT col, count(*) FROM t GROUP BY col
```

We chose exemplary columns from real data set and mark them as A, B, C. Their real distributions are presented on Fig. 3–5.

Calculated value of $Q1$ was additionally divided by number of rows in table t. The higher the value of $Q1$ the better quality of the histogram.

Column	Metric	Diff	Classic	Quant
A	Q1 Measure	0.8620	0.0601	0.8460
	TotSim	0.0281	0.0014	0.0351
B	Q1 Measure	0.1086	0.0004	0.0925
	TotSim	0.0036	0.0002	0.0075
C	Q1 Measure	0.4812	0.3612	0.3674
	TotSim	0.4562	0.5192	0.4520

Fig. 6. Illustration of lack of satisfactory correspondence between $Q1$ and quality of approximate queries results. Diff, Classic and Quant stand for MaxDiff, EquiWidth and EquiDepth histograms respectively. Values of $Q1$ are averages from 10 data packs.

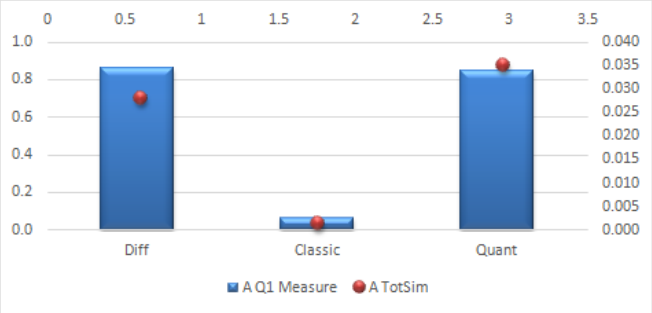

Fig. 7. Lack of satisfactory correspondence between $Q1$ and quality of approximate query on column A

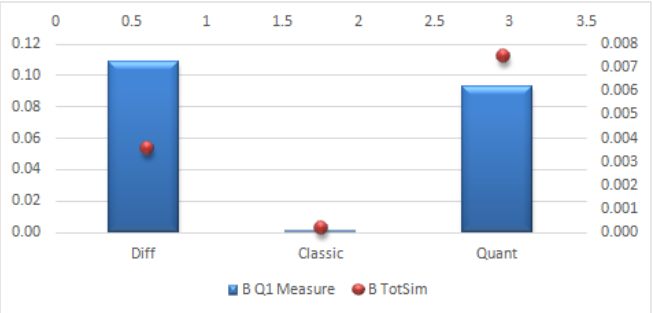

Fig. 8. Lack of satisfactory correspondence between $Q1$ and quality of approximate query on column B

Similar tests were run for $Q2$. Here also observed correspondence between histogram quality and quality of approximate query results was disappointing. Results are presented

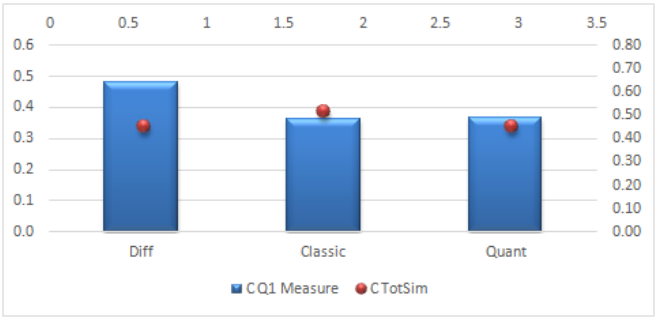

Fig. 9. Lack of satisfactory correspondence between $Q1$ and quality of approximate query on column C

on figures 10–13. Analogously value of $Q2$ was divided by number of rows in the table. In contrast to the measure $Q1$, the higher the value of $Q2$, the worse the quality of the histogram.

Column	Metric	Diff	Classic	Quant
A	Q2 Measure	330.669	981.971	351.434
	TotSim	0.028	0.001	0.035
B	Q2 Measure	2 785.017	2 837.871	2 821.522
	TotSim	0.004	0.0002	0.007
C	Q2 Measure	4 446.830	5 694.313	5 587.474
	TotSim	0.456	0.519	0.452

Fig. 10. Table illustrating lack of satisfactory correspondence between $Q2$ and quality of approximate queries (on data generated according to specified histogram)

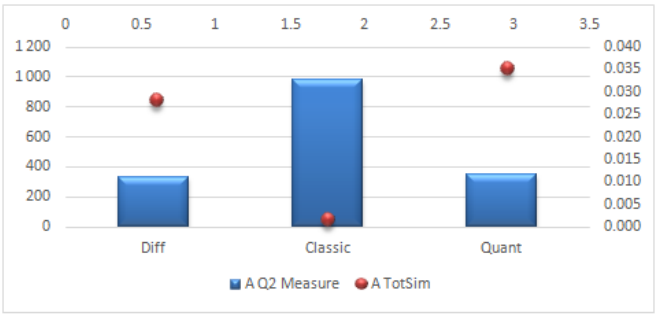

Fig. 11. Lack of satisfactory correspondence between $Q2$ and quality of approximate query on column A

V. Specific Histogram Quality Measures

Because of discrepancies between both $Q1$, $Q2$ and approximate query results quality, some new histogram quality measures had to be developed. Discrepancies analysis revealed that the main reason of inadequacy of applied measures was assumption of uniform distribution of values frequencies inside each interval. In particular no information of gaps in data packs domain was involved. By *gap* (if exists) we take interval between two consecutive values that exists in original data set. More formally:

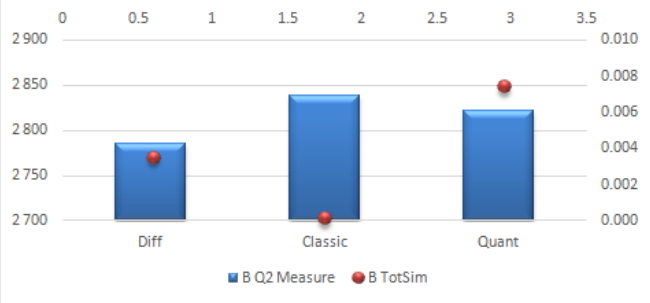

Fig. 12. Lack of satisfactory correspondence between $Q2$ and quality of approximate query on column B

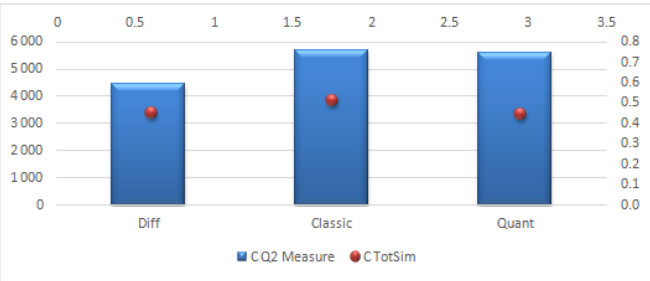

Fig. 13. Lack of satisfactory correspondence between $Q2$ and quality of approximate query on column C

Definition. Let $v, w \in Dom(c)$ be two consecutive (in the sense of linear order on values of column c) values that exist in considered value set. Then by *gap* we take set $\{x \in ALL_{Dom(c)} : x > v \wedge x < w\}$

As pointed out earlier because of method of data generation from considered types of histograms, one is exposed to generating false-positive cases. Gaps (especially wide ones), present in original data set would cause deterioration of quality of approximate query results in two ways. First – due to numerous false-positive cases and in the consequence also true-negative cases – it will reduce Total Similarity value. On the other hand too voluminous domain of interval makes average frequency lower and as a result may decrease Aggregation Similarity.

After testing some preliminar candidates, we introduced measure of the histogram which indicates difficulty of gaining proper correspondence between histogram quality and approximate query quality:

$$Q_{HG}(c,p) = \sum_{i=1}^{p_{cnt}} freq(p_i) \cdot FALSE(p_i)$$

, where c stands for column, p - split (set of intervals), p_{cnt} - number of intervals, $freq(p_i)$ - frequency of ith interval, and $FALSE(p_i)$ - number of false-positives generated in ith interval (which does not exist in original data set).

Q_{HG} was divided by number of rows in table t. The higher the value of Q_{HG}, the worse the quality of the histogram. Figures 14–16 show that Q_{HG} does not correspond to approximate query quality in direct way, however we may notice some regularities. First, calculated value of Q_{HG} explains poor quality of query results for columns A and B. For column C considered query returned better approximations and corresponding value of Q_{HG} was significantly lower than for A and B.

Column	Metric	Diff	Classic	Quant
A	Q_{HG} Measure	66 441 005.00	13 120 751.37	71 920 778.98
	TotSim	0.028	0.001	0.035
B	Q_{HG} Measure	71 474 878.37	36 296 002.79	60 186 447.39
	TotSim	0.004	0.0002	0.007
C	Q_{HG} Measure	1 087.03	588.48	859.77
	TotSim	0.456	0.519	0.452

Fig. 14. Illustration of the rule: high value of Q_{HG} corresponds to poor approximate query results quality

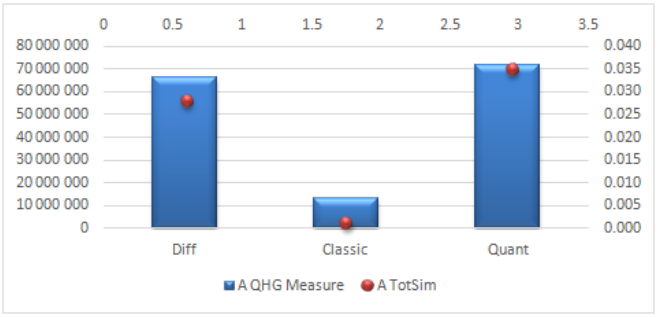

Fig. 15. Illustration of the rule: high value of Q_{HG} corresponds to poor approximate query results quality - for column A

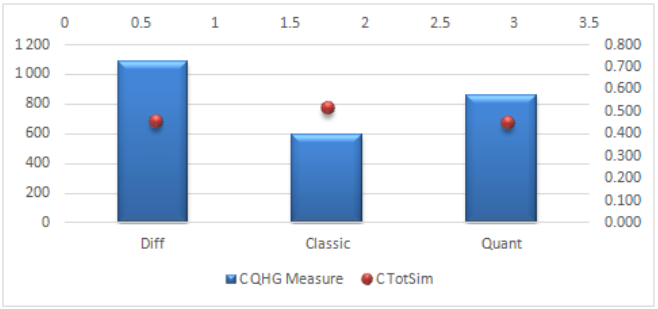

Fig. 16. Illustration of the rule: low value of Q_{HG} corresponds to well-approximated query results quality - for column C

To confirm hypothesis of correspondence between high value Q_{HG} and poor query results, we perform more experiments. We defined importance ranking formula for gaps and added to synopsis information of 100 most important gaps per data pack.

Definition. Gap importance ranking for each data pack (of column c) with given split p is defined as follow:

$$RANK\_GAP_{c,p}(gap) = freq(i(gap)) \cdot FALSE(gap),$$

where $freq$ stands for interval frequency, $i(gap)$ stands for index of interval containing gap , and $FALSE(gap)$ stands for number of false-positives covered by gap.

We consider also the case where data packs differ between themselves w.r.t. contained gaps. We observed such situation in real life data. In such case we may consider aggregated budget for gaps for several e.g. consecutive data packs (not per single data pack like in assumptions made at the beginning). Such modification enable to assign parts of the budget to data packs in more flexible way (bigger part to data packs with a lot of gaps, smaller - to the data packs with a few). In next series of experiments instead of 100 most important gaps per data pack we add information of 1000 most important gaps but for 10 data packs (whole column value set). Importance we calculate using formula:

Definition. Holistic gap importance ranking for column c and given split p is defined as follow:

$$BIGRANK\_GAP_{c,p}(gap) = \\ = \sum_{j=1}^{10} freq_j(i(gap)_j) \cdot FALSE_j(gap),$$

where $freq_j$ stands for frequency of interval in jth data pack, $i(gap)_j$ stands for index of interval in jth data pack containing gap, and $FALSE_j(gap)$ stands for number of false-positives covered by gap in jth data pack.

At Fig. 17 we presented dependency between order of magnitude of Q_{HG} and approximate query results quality. For clarity sake dependency was shown only for MaxDiff histogram (for other types dependency is the same). We can observe that if value of Q_{HG} is not low there is no chance to achieve good results of approximate query. However relatively small values of Q_{HG} would not guarantee good quality of approximate query results, and strength of correspondence is depended on chosen column. Therefore, we conclude there are some other factors that affect approximate query results quality.

Column	Metric	Diff	RANK Diff	BIGRANK Diff
A	Q_{HG} Measure	66 441 005.00	14.02	19.95
	TotSim	0.028	0.489	0.713
B	Q_{HG} Measure	71 474 878.37	206 719.29	844.31
	TotSim	0.004	0.011	0.171
C	Q_{HG} Measure	1 087.03	553.17	561.79
	TotSim	0.49	0.59	0.69

Fig. 17. Correspondence between order of magnitude of value Q_{HG} and approximate query results quality.

VI. Conclusions and Future Work

In the article we present preliminary method for calculation of quality of histogram representing original column values in data set. Such measure should in the assumption correspond to quality of approximate query run over data generated from the histogram. Development of such measure would allow at the loading stage to construct histogram reflecting the input data in the best way with limited storage budget maintained.

Performed experiments confirm that many features of input histograms may have influence on quality of approximate query results. Some of them are not identified yet. We suspect such characteristics might be related to intervals width or - like in case of gaps - to distributions of exact values frequencies inside each interval. Probably most of these factors may be expressible in terms of statistical measures of dispersion, symmetry or skewness. We can adapt them to histogram quality formulas however proper choice and the way of applying chosen measure requires much more experimental work.

***Abstract*—This article is a continuation of previous work, in which a new method of decision tree construction was presented. That method is based on the use of so-called verifying cuts, which can provide knowledge obtained from the attributes frequently eliminated when greedy methods of the choice of singleton best cuts are applied. Till now only one strategy of choosing verifying cuts was examined. It exploits a measure based on a number of pairs of objects discerned by a chosen cut. In this paper, we examine two additional measures used for determining the best verifying cuts. They are based on Gini's Index and Entropy. The paper includes the results of experiments that have been performed on data obtained from biomedical database and machine learning repositories.**

I. Introduction

DECISION tree with verifying cuts [1] (denoted by v-tree) is a method of decision tree construction formed in response to the problem of classification data with a large number of attributes. Such data can contain a lot of attributes that bear similarity with respect to the quality of potential cuts but significantly different with respect to domain knowledge represented. In contrast to the method of classifier construction based on the decision tree with local discretization techniques known from literature (see, e.g., [2], [4], [8]), for which always singleton best cuts are used and therefore there are serious doubts as to the validity of such approach, v-tree uses the so-called verifying cuts. They are additional cuts, which enable to evaluate the quality of cuts in tree nodes during classification of objects. Our experiments conducted on real data and described in [1] have shown that data with numerous set of attributes constitutes a class of data where v-tree outperforms the conventional approach. However, only one technique of choosing verifying cuts was tested, namely the one based on the maximization of the number of discerned object pairs with different decision class membership. Accordingly, the following hypothesis arose. Perhaps, using another measures of determining the quality of verifying cuts v-tree can enhance its effectiveness. Another question is whether new techniques of choosing verifying cuts may be helpful in the case of input data with non-numerous set of attributes. In this paper two another techniques of verifying cuts construction based on the Entropy and the Gini's Index are tested. Furthermore, we conducted comparative experiments using these two approaches and the one described in [1].

II. Classical discretization tree

Decision tree of the local discretization [2] is a technique of a binary tree construction based on supervised discretization which introduces iterative binary partitioning of data set into groups with respect to the value of certain attribute. This algorithm is well known from literature (see, e.g., [4], [8]), therefore we will refer to it as the *classical method*.

The greedy method of choosing a pair - an attribute and its value (for numeric attributes often called the cut), which are used in the process of data partitioning - is a key element of the discussed local discretization tree construction method and is taking into consideration decision attribute values of training objects. In construction of local discretization tree we decided to use two various measures of best cut, i.e., Information Gain and Gini's Index.

1) Information Gain measure: First method for calculating quality of cuts that was chosen for our research is Information Gain - approach used in C4.5 algorithm [9]. The method uses concept of Entropy which was described by Claude Shannon in his work on information theory [10]. In relation to construction of decision trees of the local discretization, this measure represents diversity of objects set that corresponds to particular node in tree. Thus, let X be the set of objects which comprises of two decision classes - C_0 and C_1. Furthermore, $p_0 = \frac{|C_0|}{|X|}$ and $p_1 = \frac{|C_1|}{|X|}$ are the distribution of C_0 and C_1 in the set X. Therefore the entropy is calculated by the following expression: $Entropy(X) = -\sum_{i=0}^{1} p_i * \log_2 p_i$
The quality of a binary partition, which is defined according to the cut value c in the set X of objects, is computed by Information Gain measure as follows.

$$Gain(c, X) = Entropy(X) - \sum_{i=0}^{1} \frac{|X_i|}{|X|} * Entropy(X_i) \quad (1)$$

where X_i for $i = 0, 1$ are subsets of X, that corresponds to split which is defined by cut value c.
The value of information gain is determined for all possible cuts and next a cut is greedily chosen which maximizes that measure. Surely, this method can be generalized to greater number of decision classes than 2.

978-83-60810-90-3/$25.00

2) Gini's Index measure: An alternative example of measuring the quality of cuts, that was used in our work, is the method used in CART algorithm [5] - Gini's Index. For indications such as in the previous paragraph, if X contains examples from classes C_0 and C_1, the measure of diversity of X set is defined as $Gini(X) = 1 - \sum_{i=0}^{1} p_i^2$
where p_i is the class distribution in X. Moreover, the quality of cut can be calculated as fallows.

$$G(c, X) = Gini(X) - \sum_{i=0}^{1} \frac{|X_i|}{|X|} * Gini(X_i) \qquad (2)$$

As previously, the best cut is chosen greedily from all possible cuts. Furthermore, this approach can also be generalized to more than two decision classes.

Binary tree classifiers for which Information Gain or Gini's Index were used in the procedure of best cut finding we call in this paper the Entropy-C classifier and the Gini-C classifier, respectively.

III. Decision tree with verifying cuts

As in the previous article [1], the motivation for our work concerns the validity of classical approach used to data sets with large number of attributes. We recall that the method chooses only one split (for a single attribute) with the best quality based on the selected measure, at the given step of searching for optimal binary partitions. In such case, the method would greedily eliminate the information contained in attributes, which are similar in terms of quality of potential cuts, but are different with respect to domain knowledge, which they represent. The main idea presented in [1] is based on the fact that at a given stage of searching for partitions of a set of attributes, the family of k-binary verifying partitions is determined after construction of the optimal binary partition of a set of objects. Obviously, it refers to family of partitions which are similar to the optimal partition and concerns other attributes than the attributes used in the optimal partition. Moreover, the concept of similarity depends on measure which is used to determine the best split. Thus, in the case called *MaxDiscPair*, the similarity means to distinguish between set of pairs of objects of different decision classes as similar as possible to the optimal partition. Whereas in the case of measures based on Gini's Index and Information Gain, verifying partitions should separate objects in possible the same manner as the main split. The differences in selecting verifying cuts between all three measures are such that in case of discernibility-based measure we determine objects that are separated by both cuts simultaneously, while in case of Gini's Index and Information Gain based measures, the candidate for additional cut divides the set of object independently of the main cut.

The algorithm for construction of a decision tree with verifying cuts [1], has been enhanced to use all three measures. Assume that a decision table $\mathbf{A} = (U, A, d)$, a parameter k (in our experiments the value of k was empirically chosen) belonging to natural numbers, template T_p defined by the optimal cut and template T_{p_i} (for $i = 1, \ldots, k$) defined by the verifying cuts are given. Depending on a chosen measure the following criteria are optimized during the v-tree construction:

MaxDiscPair (see [1]) – criterion is maximized.
Entropy based measure – criterion is minimized:

$$EM(p_i) = \begin{cases} 0 & \text{for } \frac{|W|}{|\mathbf{A}|} \geq t_w \\ \big|ES\big(\mathbf{A}(T_p), \mathbf{A}(\neg T_p)\big) - \\ \quad ES\big(\mathbf{A}(T_{p_i}), \mathbf{A}(\neg T_{p_i})\big)\big| & \text{otherwise,} \end{cases}$$

where:

- W is a set of objects that at the same time are not matching patterns T_p and T_{p_i} as also patterns $\neg T_p$ and $\neg T_{p_i}$ (for $i = 1, \ldots, k$),
- t_w is a fixed threshold (t_w was equal 0.1 and 0.05 in our experiments for "microarray" and "normal" data, respectively),
- $ES\big(\mathbf{A}(T_q), \mathbf{A}(\neg T_q)\big) = \frac{\big|\mathbf{A}(T_q)\big|}{\big|\mathbf{A}\big|} * Entropy\big(\mathbf{A}(T_q)\big) + \frac{\big|\mathbf{A}(\neg T_q)\big|}{\big|\mathbf{A}\big|} * Entropy\big(\mathbf{A}(\neg T_q)\big)$ ($q \in \{p, p_1, \ldots, p_k\}$) is the weighted sum of entropies of partitions p and p_i, respectively ($q \in \{p, p_1, \ldots, p_k\}$).

Gini's Index based measure – criterion is minimized:

$$GM(p_i) = \begin{cases} 0 & \text{for } \frac{|W|}{|\mathbf{A}|} \geq t_w \\ \big|GS\big(\mathbf{A}(T_p), \mathbf{A}(\neg T_p)\big) - \\ \quad GS\big(\mathbf{A}(T_{p_i}), \mathbf{A}(\neg T_{p_i})\big)\big| & \text{otherwise} \end{cases},$$

where:

- W is a set of objects that at the same time are not matching patterns T_p and T_{p_i} as also patterns $\neg T_p$ and $\neg T_{p_i}$ (for $i = 1, \ldots, k$),
- t_w is a fixed threshold (t_w was equal 0.1 and 0.05 in our experiments for "microarray" and "normal" data respectively),
- $GS\big(\mathbf{A}(T_q), \mathbf{A}(\neg T_q)\big) = \frac{\big|\mathbf{A}(T_q)\big|}{\big|\mathbf{A}\big|} * Gini\big(\mathbf{A}(T_q)\big) + \frac{\big|\mathbf{A}(\neg T_q)\big|}{\big|\mathbf{A}\big|} * Gini\big(\mathbf{A}(\neg T_q)\big)$
is the weighted sum of ginis of partitions p and p_i, respectively ($q \in \{p, p_1, \ldots, p_k\}$).

The stop condition mentioned in algorithm of v-tree construction is separation of all possible pairs of objects from different decision classes. It is worth pointing out, that the only part of the above algorithm, which would increase the time complexity compared to the classical algorithm from Section II is step 3. This step can be performed in time $O(n \cdot log\ n \cdot m)$, where n is the number of objects and m is the number of attributes.

The determination of the best verification split for the symbolic attributes can be done in time $O(n \cdot l)$, where l is the number of values of symbolic attribute.

Below we present the algorithm for selection of verifying partition for the constructed earlier binary partition p. We assume that the verifying split is determined by a numerical attribute. For ease of discussion, we consider a situation that

there are only two decision classes C_0 and C_1 in the data. This method can be easily generalized to the case of more than two decision classes. The output of this algorithm is the computed collection of cuts that verify partition p.

Algorithm *Selection of verifying cut*
Step 1 Sort the values of the numerical attribute a.
Step 2 Browsing the a attribute values from the smallest to the largest, determine for each appearing cut c the following numbers and store them into a memory (about cuts) M:
$V_L(a, c, C_0), V_L(a, c, C_1)$ - number of objects from decision class C_0 or C_1 with values of attribute a smaller then c,
$L(a, c, C_0, T_p), L(a, c, C_1, T_p)$ - number of objects from decision class C_0 or C_1 with values of attribute a smaller than c and at the same time matching the pattern T_p.
Step 3 Browsing the a attribute values from the highest to the lowest, determine for each appearing cut c the following numbers and place them in a memory (about cuts) M:
$V_H(a, c, C_0), V_H(a, c, C_1)$ - number of objects from decision class C_0 or C_1 with values of a greater then or equal c,
$H(a, c, C_0, \neg T_p), H(a, c, C_1, \neg T_p)$ - number of objects from decision class C_0 or C_1 with values of attribute a greater than or equal to c and at the same time matching the pattern $\neg T_p$.
Step 4 Using information from the memory M, determine the quality of cuts on a in the manner that depends on measure selected for determining the quality of cuts:
MaxDiscPair (see [1])
Entropy:
1. determine the size of set W:
$|W| = |\mathbf{A}| - \big(L(a, c, C_0, T_p) + L(a, c, C_1, T_p) + H(a, c, C_0, \neg T_p) + H(a, c, C_1, \neg T_p)\big)$,
2. discard cuts for which $\frac{|W|}{|\mathbf{A}|} > t_w$,
3. determine the sizes of tables designated by cut c:
$|\mathbf{A}(T_c)| = V_L(a, c, C_0) + V_L(a, c, C_1)$,
$|\mathbf{A}(\neg T_c)| = V_H(a, c, C_0) + V_H(a, c, C_1)$,
4. compute the weighted sum of entropies for partition designated by cut c from $ES\big(\mathbf{A}(T_c), \mathbf{A}(\neg T_c)\big)$,
5. determine the optimum cutting such that the value of $\big|ES\big(\mathbf{A}(T_p), \mathbf{A}(\neg T_p)\big) - ES\big(\mathbf{A}(T_c), \mathbf{A}(\neg T_c)\big)\big|$ is the smallest.
Gini:
1. determine the size of set W:
$|W| = |\mathbf{A}| - \big(L(a, c, C_0, T_p) + L(a, c, C_1, T_p) + H(a, c, C_0, \neg T_p) + H(a, c, C_1, \neg T_p)\big)$,
2. discard cuts for which $\frac{|W|}{|\mathbf{A}|} > t_w$,
3. determine the sizes of tables designated by cut c:
$|\mathbf{A}(T_c)| = V_L(a, c, C_0) + V_L(a, c, C_1)$,
$|\mathbf{A}(\neg T_c)| = V_H(a, c, C_0) + V_H(a, c, C_1)$,
4. compute the weighted sum of Ginis for partition designated by cut c: $GS\big(\mathbf{A}(T_c), \mathbf{A}(\neg T_c)\big)$,
5. determine the optimum cutting such that the value of $\big|GS\big(\mathbf{A}(T_p), \mathbf{A}(\neg T_p)\big) - GS\big(\mathbf{A}(T_c), \mathbf{A}(\neg T_c)\big)\big|$ is smallest.

Assuming that the memory about cuts M is accessible in constant time, the above algorithms runs in time $O(n \cdot log\ n)$, where n is the number of objects (due to the sorting of objects on the basis of the a attribute).

The algorithm for an object classification, using a v-tree with verifying partitions was introduced in [1].

The classifiers constructed with the use of v-decision tree will be called here the *MaxDiscPair-V* classifier, *Entropy-V* classifier or *Gini-V* classifier – depending on used measure during construction, respectively. Note that the algorithm [1] to classify the object in the node utilizes a single tree only when all verifying cuts classify the object just as the main partition p. In other cases, the classification is done by both subtrees. Then the following two cases are considered. The first case refers to the situation when the two subtrees returned the same decision value. Then the value of the node is returned as the decision. The second case refers to a situation where one of the subtrees returned one decision value, and the second subtree the other one. Then that node returns a decision coming from the subtree, which is associated with a greater number of such verifying patterns that classify a test object for this tree. If the numbers of verifying cuts are equal, then the decision comes from subtree selected nondeterministically.

IV. Experiments and results

To verify the effectiveness of classifiers based on our approach, we have implemented classifiers based on the verifying cuts in the programming library CommoDM (Common Data Minnig), which is a continuation of the RSES-lib library (forming the kernel of the RSES system [3]). The experiments have been performed on the data sets obtained from Kent Ridge Biomedical Dataset [7], UCI ML repository (see [11]) and website of The Elements of Statistical Learning book (Statweb)(see [6]). 6 data collections from the first source relates to microarray experiments and they are characterized by a large number of attributes. Our experiments were conducted on the merged original training and testing data sets. The objective of conducted experiments was to test the quality of the classification algorithms discussed in this paper. Table I presents the experimental results received for given data sets and two discretization methods (Entropy and Gini Index based ones) applied to classical tree and v-tree. The counterparts received for discretization method based on maximum number of discernible pairs is presented in [1].

For determining quality of classifiers we applied 10 fold cross-validation technique, which was repeated 10 times for every data set (i.e., 100 cycles of a train-and-test scheme was conducted). The final result of the algorithm is the average of 100 cycles. Popular parameters accuracy (ACC) and coverage (COV) were used to measure the classification success. It is easy to observe that in most cases better results were obtained when the v-tree classifier was applied, both for entropy and Gini's Index based discretization method. That observation is confirmed by the Wilcoxon mached pairs test with 0,05 level of significance in the following cases: (1) [ACC, Entropy-V classifier, num] > [ACC, Entropy-C classifier, num], i.e., the classification quality expressed by ACC coefficient and entropy based discretization method for v-tree is better than for c-tree when applied for data with numerous sets of

attributes; (2) [ACC, Gini-V classifier, num] > [ACC, Gini-C classifier, num]; (3) [ACC*COV, Entropy-V classifier, num] > [ACC*COV, Entropy-C classifier, num]; (4) [ACC*COV, Gini-V classifier, num] > [ACC*COV, Gini-C classifier, num]; (5) [ACC*COV, Gini-V classifier, non-num] > [ACC*COV, Gini-C classifier, non-num];

We have also checked, separately for c-tree and v-tree classifiers, whether one of the three tested discretization methods leads to better classification quality. We used the Friedman test. It showed that none of the three methods has such property. Both Wilcoxon matched pairs test and Friedman test were used in the form implemented in Statistica program ver. 10.

V. CONCLUSION

In the paper, we presented Entropy based measure and Gini's Index based one applied to determining decision tree with verifying cuts classifier. We checked usefulness of those algorithms on - 18 input data sets. Experiments have confirmed (with statistical significance) that v-tree is relevant classifier for data with a large number of attributes. Used 12 input data with non-numerous set of attributes was too little family of data to express analogous observation when input data do not have really many attributes. Moreover, none of three methods of local discretization proved to be better than remaining ones. The novelty of the paper is important because the experimental results showed that the employment of the knowledge contained in the redundant attributes increases the quality of the classifiers not only for the previously used measure. The conducted experiments have proved the correctness of our assumptions that our method will be also effective for the use of new measures. We expect that the methods may be used in various fields.

***Abstract*—The paper presents a new method of building a hierarchical model of the state space. The model is extracted fully automatically from game replays that store executed plan traces. It is used by a novel approach for estimating the distance between states in a state-space graph. The estimate is applied in the A* algorithm as a heuristic function to reduce the search space. The method was validated using the game *Smart Blocks*. It is a testbed environment for studying methods that benefit from game replay analysis. The proposed heuristic is dedicated to difficult classical planning problems, for which problem-specific or automated heuristics are difficult to obtain.**

I. Introduction

FOR A long time, AI experts have been developing new methods of imitating intelligent behaviors that can be observed in games. Their goal is to give the player the impression that a computer-controlled unit is an intelligent being. Planning plays an important role in such a task because it enables us to solve complex problems automatically. In classical planning, state search methods are applied to find a sequence of actions between an initial and a goal state. Depending on a particular application, the solution should be optimal. However, it must be the best one that can be provided fitting in a limited computation time, because planning problems in games are solved during play. In this work, we propose a new and promising approach for solving difficult problems in the field of classical planning, which is aimed at application in games. The method introduces a novel technique of extracting and storing information from game replays to increase the performance of planning by providing a new heuristic of estimating the distance to the goal.

Supporting the planning process by information extracted from game replays is a promising direction. This is because, for the majority of games, accumulating the recordings is relatively easy. The data is often used for collecting statistical information that models a player. Among many other benefits, this enables us to analyse players' behaviors and predict their actions.

This work focuses on a particular aspect of the game replay analysis that is a reduction of the search space of a state-space search algorithm. It is assumed that the input data contains traces of plans executed by players. The proposed method processes observed plans to build a general model of the state space. Then, the model is employed in the heuristic of the A* algorithm [1]. It is used for estimating the distance to the goal in a state-space graph. The phase of replay processing is separate. It can be done earlier, so the planning process is not slowed down.

In contrast to the popular planners, our method does not require a STRIPS-like representation of a game state [2]. Instead, it operates on an abstract state-space graph, which is representation-independent. This simplification is significant because providing a symbolic model is time-consuming and difficult in many cases. In comparison with other methods that use plan traces, our approach does not require manual annotations [3]. The proposed method is characterized by a high level of automation. It uses a minimum amount of knowledge about a game and its rules.

The approach is original, and its evaluation requires an adequate testbed environment. The environment should have a nontrivial planning problem. There are relatively few research environments accumulating game replays. Usually, stored replays enable us to reproduce a match visually. However, they do not allow us to access full information about the game state. Adding proper replay storing mechanisms to a complex game is a rather large undertaking. Many of the obstacles can be avoided by developing a new game environment that focuses on the research aspects. Thus, we introduce the *Smart Blocks* game [4]. This light-weight environment enables us to store replays in a simple format, investigate a game state easily, and conduct experiments quickly. It was designed for a range of studies related to planning.

To summarize, the goal of the research was to build a method of accelerating the planning process using information retrieved from the plan traces provided by human players. The original contribution of this paper is:

- the novel method of building a hierarchical model of the state space from game replays,
- the heuristic estimate that relies on the hierarchical space model,
- the new testbed environment designed for analysing actions of players solving difficult planning tasks.

The document is divided into eight sections. At the beginning, references to the related works are provided. Next, the *Smart Blocks* environment is characterized. Subsequently, statistics of the collected replays are presented. In the follow-

978-83-60810-90-3/$25.00

ing section, the algorithm of building a hierarchical model of the state space is introduced. Then, application of the model as a heuristic in A* is thoroughly discussed. In the experimental study, the proposed method and a traditional approach are compared. Finally, features of the approach are summarized, and future development directions are indicated.

II. Related Work

This section sets the proposed approach in the planning context. The term of planning is used differently depending on the application domain [5]. In control theory and especially robotics, planning methods are usually applied for motion and trajectory planning [6]. In video games, the topic often refers to pathfinding algorithms [7]. In this paper, we refer to planning as problem solving. It is a process of choosing and organizing actions by anticipating their outcomes. The process relies on basic concepts like states and actions. Plans come from a decision maker, and they are executed by agents.

It is assumed that actions have deterministic effects, and states are fully known. Therefore, we use the taxonomy of classical planning [8]. Non-classical planning refers to partially observable or stochastic environments.

Planning is applied in many games to solve complex tasks. A survey of the approaches currently used in games can be found in [9]. According to the author, STRIPS, Hierarchical Task Networks (HTN), utility systems, and behavior trees are applied in most cases. However, apart from STRIPS-like planners, the discussed methods are mainly used for modelling the reactive behavior of AI-controlled players. In these cases, the provided model is a plan, and its execution is defined by designers. Referring to them as planning methods, which search for a path to a defined goal state, is misleading. Goal-Oriented Action Planning is closer to the discussed understanding of planning [10]. In general, planning gives better perception of AI players' intelligence, but it is more complex to apply in practice. Therefore, our research is dedicated to increasing the applicability of planning in games.

A popular hierarchical approach is Hierarchical Pathfinding A* (HPA*) [11]. HPA* searches for a path on terrain. A state-space graph is represented by a mesh of nodes on the terrain surface. The improved method HPA* clusters places that lay in the geographical neighborhood (inside rectangles). The method also considers graphs with different levels of abstractions as we do in our tree. However, the cost between groups of states cannot be easily determined if the Euclidean distance between state variables does not reflect the transition cost, which is the case addressed in this work. HPA* solves problems in the geographical space while our method is applicable for any abstract state space.

Analysis of executed plan traces is a subject that is discussed in many fields, e.g., robotics [12], business [13], and games [14], [15]. With a few exceptions, there is not much attention given for supporting state search in classical planning by observed plans [16], [17]. More often the observations are applied to plan recognition [18], [19] or player action prediction [20], [21]. In the work of Wang [3], whose method is old but close to our idea of solving a planning problem, plans are learned from observation. However, the described method is inefficient because plan traces must be examined and annotated by experts manually. In addition, it suffers from STRIPS negative preconditions that are generated without limitations. Our method avoids these problems.

Another approach that is somehow related to our problem is presented in the work of Hogg [17]. The method learns hierarchical planning knowledge to solve tasks in HTN. It takes as input a set of planning states and a set of semantically-annotated tasks. Our approach is different because the knowledge model does not require information about tasks and goals.

III. Smart Blocks

Smart Blocks is a testbed environment. It was designed to study planning methods that can learn from player actions. The project includes two subsystems. The first one is a video game in which a player solves planning problems. The game sends observed solutions to the server, where they are stored. The second one is a simulation. It enables us to reconstruct saved plans and test planning algorithms.

The game can be classified as a single-player logic game. Its mechanics was inspired by *Sokoban* [22]. It was implemented with *Unity3D* [23]. One of the priorities was to make the game attractive to the players because the more they play, the more data is collected. The game offers a visual interface, simple gameplay, and easy online access[1] [4].

A. Game Rules

The gameplay relies on simple box-pushing mechanics. In the game, a player controls a team of agents, each of which is represented by a block. The blocks are characterized by different sizes and shapes. The main goal of the team is to reach a golden artifact by any of the blocks. The task is complicated by the maze of triggers and gates that block the path. The triggers usually require different blocks working together to open a gate. The paint of a block is also important when matching a trigger pattern. The pattern comprises a shape together with a colour that must be satisfied by the blocks standing on the trigger. The paint is obtained from a colour portal, and it mixes with the current colour of a block.

A player has to take into account an energy reserve, which is limited and consumed in each action step. This constraint prevents infinite game duration. Unlike the time constraint, it does not enforce a player to act hastily. Energy consumption depends on the size of a block, and it can be increased by entering a ground obstacle. The energy level can be refilled by an energy cell – it disappears once it is used. A player's score depends on the energy reserve at the moment of level completion.

An example of a planning problem that involves agent cooperation is illustrated in detail by Fig. 1. The example shows a part of a stage that contains three user-controlled agents: a ring, a box, and a small cylinder. Their objective

[1] *Smart Blocks* game is available at http://unity3ddev.net/smartblocks/. The source code can be obtained by contacting the authors.

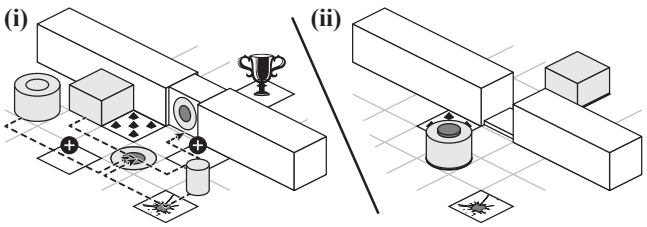

Fig. 1. An example of a planning problem solved in *Smart Blocks*.

is to reach the artifact that is placed behind the wall (the goal is marked with a cup). Initially, the path is blocked by the closed gate **(i)**. It can be opened by using the trigger. First, the box agent approaches the gate avoiding the ground obstacle and collecting one of the energy cells. Next, the small cylinder goes to the trigger through the field where it changes a paint colour to the one that is accepted by the trigger. Then, the big ring collects the last energy cell, and it ends its move in the same place. As soon as the key of the trigger is satisfied, the gate is opened. Now, the box agent is free to reach the goal **(ii)**. If any of the two agents moves from the trigger, the gate will close (unless the third agent is blocking the gate by standing on it).

The presented scheme shows only one of many possible tasks that can be present on a stage. The game levels were designed to be challenging by joining chains of tasks that must be completed before the goal can be reached.

The first version of the game includes ten levels of different difficulty. Subsequent levels can be accessed without solving the previous ones. However, following the order helps to familiarize with the game rules. In the first level, a player learns how to use a simple cooperation to open a gate and reach the artifact. The next level gives an example of multiple blocks interacting with a single trigger. Later, a player is introduced to paint colours and how they mix. In level 4, a player has to use energy cells for the first time. It is a simpler level, but potentially more challenging for a state search algorithm. Level 5 has an alternate route, which is shorter but more challenging to guess. The subsequent level contains many possible routes, and it is difficult to estimate which one will consume the least energy. Level 7 has a long chain of tasks that have to be executed in a certain order. In the next level, misleading trails are present. The last two levels are characterized by a high complexity and a very large state space.

B. Planning Problem

There are several arguments justifying why the planning problem in *Smart Blocks* is nontrivial. The first one is the difficulty of measuring the distance to the goal. For instance, in *Sokoban*, it is possible to count the number of crates on the spots as smaller tasks [22]. It is a good heuristic for estimating the progress of the goal accomplishment. For our problem, the goal progress cannot be measured easily. One of the blocks must reach the location of the artifact. It is unknown which block, what combination of gates and trigger should be used, or how much energy and how many actions it will take. Sometimes it is not necessary to visit locked rooms in order to reach the artifact. However, it may be required to save some energy. The order of blocks in small corridors is also important because the agents can collide with each other. The world can be modified by agents: temporarily by opening a gate or permanently by collecting an energy cell. Each modification applied to the environment builds a subtree in a state search tree (multiplies the search space).

A significant complication is the presence of energy cells. They introduce edges with negative cost to the state-space graph. This type of a state space requires an algorithm that traverses every edge in the graph to ensure optimality (e.g., Bellman-Ford method) [24]. However, the number of states is usually too large to perform a brute-force search. The first three game levels have neither energy cells nor negative cycles in their state spaces.

The problem stated in *Smart Blocks* is the centralized planning of cooperation of agents with limited resources in a mutable environment [25]. It is located in a group of planning problems in which a heuristic estimate is difficult to provide. An abstract version of this problem can be found in a number of real games. Many analogies are present. However, the specificity of the problem in practical application can differ. In some cases, the problem can be solved offline in the phase of game design. Designers can embed a solution schema of a planning problem in a game rigidly. In this research, we are aiming at cases in which the problems can appear dynamically – for instance, problems invented by players during an online game. Therefore, we minimize the amount of predefined knowledge and try to improve planning performance by relying on the observations.

C. Testbed Environment

The simulation is a C# console program. Its function is to parse the recorded plans, execute planning algorithms, and yield the statistics. It contains the model of game rules and a light-weight representation of a game state. Therefore, it enables us to conduct experiments efficiently.

The fundamental motivation for building the environment was a very small number of planning benchmarks that work with observed plan traces. It is a common practice that game replays store only visual effects of player actions. Therefore, they require a lot of reverse engineering to extract actual game states. Our game stores full-information game states in an easy readable format.

Another argument is complexity. In *Smart Blocks*, planning problems are small and flexible. It means that they are easy to understand by players and simple to scale by the level designer. It is easy to follow the execution of a tested method. In environments like *WarCraft (Wargus)* or *StarCraft (BWAPI)* game rules are complicated, and the game state is large [26], [27]. Their state spaces are vast. For most of the tasks, information about optimal plans is unavailable (or practically incomputable). It is difficult to analyse recorded

TABLE I
REPLAY DATABASE STATISTICS

Level No.		*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*	*10*
Replays		230	169	71	56	57	49	30	13	7	7
Steps	min.	23	18	57	24	40	32	69	60	246	429

	max.	231	161	66	11	138	205	187	182	503	141

plans and evaluate planning algorithms. In our environment, plans can always be compared with optimal solutions or even evaluated visually. It should be noted that *Wargus* and *BWAPI* lack simulation modes (iterative and game-time-independent execution). It is crucial for testing algorithms that traverse a state-space graph.

Finally, our project allows researchers to focus purely on the planning procedure. In another popular environment, *RoboCup*, the mechanics rely on continuous state and physics [28]. It is a good benchmark for robotic applications because it reflects the real world. However, planners usually work with a simplified world model. Providing the model is a challenging task. Our environment abstracts from uncertainty and state discretization issues. These are important problems, but they are located in the conceptual phase of preparing an environment for planning. Our study focuses on traversing the state space, which is discrete by definition.

D. Data

A solution of a stage provided by a player is recorded in a replay file, and then it is submitted to the server. Only complete replays are stored – unfinished or partial solution sequences are discarded. Each recorded and stored solution sequence allows game states to be reproduced fully with no uncertainty. A replay consists of a sequence of steps. Each step is an atomic action committed by an agent. Steps are deterministically ordered – simultaneous actions are not allowed. There are no additional complications behind the described process of collecting data. In *Smart Blocks*, recording the game state is almost as simple as in chess. Actions are animated for the purpose of the presentation, but in fact, they are discrete.

Simple statistics of replays stored in the database are given in Table I. They include for each game level:

- the total number of collected replays,
- a number of action steps to solve a stage,
- an amount of energy at the moment of reaching the final goal.

The statistics provide a good reference for the evaluation of planning algorithms.

It can be seen that the largest number of replays has been collected for the initial levels. It is because the difficulty grows rapidly, and many players resign. The data also gives clues how the levels differ from each other and what is the spread of possible outcomes.

IV. HIERARCHICAL SPACE

To have a better understating of what a hierarchical division of the state space is, we can imagine a city, its district, a residential block placed in there, an apartment in the building, and its room. Searching for a specified room is much easier if we know the name and part of the city, the building address, and the apartment number. The model of our hierarchical space can be perceived as a map that is discovered according to visited places. However, it is not necessary to visit every place to outline a region on the map. The same rule applies to game states and state subspaces.

In formal terms, a hierarchical space is a tree structure. It divides the state space into subspaces that contain groups of states. Subspaces on a higher level are nesting the ones on a lower level. Organizing states as graph nodes inside this kind of structure enables us to traverse and search in the graph more efficiently. For instance, we can reduce the search space by simply skipping whole groups of states that are not leading us to the solution. This procedure can be done on different levels of detail – starting from the most general to the most detailed.

Our approach for building the model relies on *state descriptors*, which is a term introduced in this paper. A state descriptor refers to a selected part or some feature of a state. It can be said that a descriptor partially *describes* a game state. Formally, it is a predicate, and it holds a rule or expression that returns a boolean value depending on whether it is satisfied or not. Descriptors are usually related to intermediate objectives and goals in a game. A descriptor enables us to group a set of states based on a defined criterion. In practice, state descriptors can be added to the implementation easily as boolean functions that accept a state as input. They do not impose formal requirements on problem representation.

In *Smart Blocks*, state descriptors are defined by the designer. They are closely related to the game rules and player's objectives. Therefore, they have a simple and intuitive form. A set of descriptors is generated by descriptor classes – their complete list is presented in Table II. They group states taking into account, for example, the colour of an agent, its position in a room, a gate state, or the goal accomplishment. Each game state can be partially depicted by a subset of descriptors that are satisfied at a given moment. For instance, a state can satisfy a group of three descriptors: {⟨`agent 1 is in room 1`⟩, ⟨`agent 1 is on trigger 3`⟩, ⟨`gate 2 is open`⟩}.

In general, the idea that stands behind state descriptors is to provide a degree of flexibility to the approach. A set of descriptors can be optimized for a problem by machine learning methods. It is the aim of the future study. However, here we use rigidly defined descriptors to focus on the heuristic and provide a proof-of-concept.

Each group of descriptors defines a subspace that covers a part of the state space. The more descriptors work together, the smaller part of the space they cover. Less detailed subspaces nest inside more detailed subspaces. The more general a group of descriptors is, the more children it has. However, it is assumed that state subspaces, covered by descriptors, are not

TABLE II
A LIST OF DESCRIPTOR CLASSES IN SMART BLOCKS

Descriptor Class	Description
agent {id} in room {nr}	informs whether a specified agent is placed in a defined area
agent {id} on colour portal {nr}	true if a specified agent stands on a defined colour portal
agent {id} has {R|G|B} component	checks whether a colour of a specified agent contains one of the base colours
agent {id} on trigger {nr}	true if a specified agent stands on a defined trigger
agents {id}, {id} ... {id} stand together	valid while a specified list of agents stays on the same field
trigger {nr} is valid	informs whether a pattern of a specified trigger is satisfied
gate {nr} is open	true if a specified gate is open
gate {nr} is held	checks whether one or more agents is standing on a specified gate
goal ok	true if one of the agents reached the golden artefact; groups the goal states

required to nest each other fully, but they are allowed to intersect. The method of handling the intersections is provided later in the document.

Theoretical foundations and the algorithm of building a hierarchical model of the state space using state descriptors are presented in the following subsections.

A. Formalization

Below are the theoretical assumptions stated. They are required to discuss optimality of the introduced heuristic.

1) State Space: A classical planning problem can be formulated as finding a path between two arbitrarily specified states in an abstract state space. Let us define a state space as a directed graph $G = \langle S, E \rangle$, where S is a set of nodes and E is a set of edges. Each node $s \in S$ is a system state represented by a tuple of state variables v, Eq. 1:

$$s = \langle v_1, v_2, \ldots \rangle. \tag{1}$$

Each edge $e \in E$ has a transition cost $c \in \mathbb{R}_{>0}$ associated with it. It is assumed that the state space is vast and the cost (or distance) estimate function $\delta : S \times S \to \mathbb{R}_{\geq 0}$ between any two noncontiguous states is unknown or complex. Consequently, state search in the defined space is a nontrivial problem.

2) Plan Observations: A set of executed plans is provided by the system users. An observed plan is a sequence $x_i \in X$ of state transitions, Eq. 2:

$$x_i = \langle s_1, s_2, \ldots, s_n \rangle, \tag{2}$$

where $s_1 \in S$ is an initial state, and $s_n \in S$ is some goal state ($s_1 \neq s_n$). Subsequent state nodes in the sequence are connected by edges.

It is assumed that the observed plans are valid but not cost-optimal. A set X of observations does not cover the entire state space, but it allows us to collect information about its structure.

3) State Descriptor: Let $S_i \subseteq S$ denote a subset of the space states, and $d_i : S \to \{0, 1\}$ is a function that determines membership of a state in this subset, Eq. 3:

$$S_i = \{s \in S : d_i(s)\}. \tag{3}$$

Then, the function $d_i \in D$ is called a state descriptor that classifies and groups states by their selected features. Thus, each state $s_j \in S$ is assigned to a set $D_j \subseteq D$ of descriptors that are valid for s_j, Eq. 4:

$$s_j \Rightarrow D_j = \{d \in D : d(s_j)\}. \tag{4}$$

Based on a set $S_X \subset S$ of states appearing in a set X of plan observations, a set D_X of descriptor sets is extracted, Eq. 5:

$$D_X = \{D_j \subseteq D : s_j \in S_X\}. \tag{5}$$

Descriptor sets enable us to discover a hierarchical structure of the state space, and they play an analogous role as transactions in data-mining.

4) Subspace Tree: State groups separated by descriptor sets are used to build a tree of state subspaces. A state subspace $h_k \in H$ is a pair $h_k = \langle D_k, p_k \rangle$ comprising a set $D_k \subseteq D$ of state descriptors together with an index p_k of a parent subspace. The set D_k determines a set S_k of states that belong to the subspace h_k. The set S_k is the intersection of states grouped by each $d_j \in D_k$, Eq. 6:

$$h_k = \langle D_k, p_k \rangle \Rightarrow S_k = \{s \in S : \left(\forall_{d_j \in D_k} d_j(s)\right) \vee D_k = \emptyset\}. \tag{6}$$

If a subspace h_i is a parent of a subspace h_k, then the set of states covered by the child is a subset of the parent's set, Eq. 7:

$$(p_k = i) \Rightarrow S_k \subset S_i, \tag{7}$$

which is equivalent to Eq. 8:

$$(p_k = i) \Rightarrow D_k \supset D_i. \tag{8}$$

Considering the parent-child relation, it is worth noticing that the implication operator does not have to be applicable in the opposite direction. In other words, a set of states representing a part of the space can be associated with more than one subspace, and thus it has more than one possible parent. For instance, the intersection $S_k = S_i \cap S_j$ of descriptor sets D_i and D_j can be nested by h_i as well as h_j. The selection of a parent subspace is disambiguated algorithmically.

B. Algorithm

The algorithm starts from collecting a set D_X of all possible descriptor groups, which can be found in a set S_X of observed game states. Additionally, the common parts of the groups that intersect are added to D_X. The nesting relations are then stored. Next, a tree structure is assembled by disambiguating the parent-child relations. The result is a tree expressed by a set $H = \{h_1, h_2, \dots\}$ of subspaces, which models a hierarchical structure of the state space.

The basic steps of the algorithm are expressed in pseudocode in Alg. 1. The algorithm accepts a set of game states observed in a replay database as input. A state contains complete information about a temporary situation in a game. Global variables are declared in the context of all methods. In the beginning, unique groups of descriptors are collected (line 2). In the same process, relations between the groups are determined. Next, based on these groups, a hierarchical model of the state space is built (line 8). The sorting in line 7 will be explained later.

Alg. 1: BuildHierarchy ($states$)

```
Data: set of observed states
Result: hierarchical model of state space
1  global descriptorSets ← ∅
2  CollectDescriptorSets ( states )
3  var root ← ⟨ϵ, ϵ⟩
4  global subspaces ← {root}
5  global usedDescSets ← ∅
6  global usedStates ← ∅
7  var descriptorSetsSorted ← Sort ( descriptorSets )
8  foreach descSet ∈ descriptorSetsSorted do
9      BuildSubspaces ( descSet, root )
10 return root
```

At the beginning of the routine, unique groups of descriptors are collected by iterating over every input state (Alg. 2). A descriptor group consists of all the descriptors that are satisfied by a state (line 2). Observed descriptor groups usually overlap (as well as state subspaces). Thus, additional groups are created by intersecting new groups with the already observed ones (line 7), and then stored (line 9). An intersection of two descriptor groups separates a subspace that can be nested by the subspaces of both operands.

Alg. 2: CollectDescriptorSets ($states$)

```
Data: set of observed states
Result: list of descriptor sets
1  foreach s ∈ states do
2      var newDescSet ← DescriptorSetFromState ( s )
3      if InsertDescriptorSet ( newDescSet ) then
4          var intersections ← ∅
5          foreach descSet ∈ descriptorSets do
6              if descSet ≠ newDescSet then
7                  intersections ←
                       intersections ∪ {descSet ∩ newDescSet}
8          foreach descSet ∈ intersections do
9              InsertDescriptorSet ( descSet )
```

It can be concluded that different game states represented by exactly the same groups of descriptors are redundant, and they do not contribute to the model. Therefore, only one state is sufficient for discovering a subspace. The more unique descriptor groups are observed, the richer the structure of the model is.

While the new descriptor groups are added to the list (Alg. 3, line 3), parent-child relations are assigned (line 4). A group of descriptors is a parent of another one if the first one is a subset of the second one. In other words, all descriptors from a parent group can be found in its child. In this relation, a parent will always cover an equal or bigger number of states than its child. The information about subspace nesting will be used in the next step.

Alg. 3: InsertDescriptorSet ($newDescSet$)

```
Data: new descriptor set
Result: stores new descriptor set and assigns parent-child links
1  if newDescSet ∈ descriptorSets then
2      return 0
3  descriptorSets ← descriptorSets ∪ {newDescSet}
4  foreach descSet ∈ descriptorSets do
5      if descSet ⊂ newDescSet then
6          descSet.children ← descSet.children ∪ {newDescSet}
7      else if newDescSet ⊂ descSet then
8          newDescSet.children ←
               newDescSet.children ∪ {descSet}
9  return 1
```

Having prepared such a set of descriptor groups, we can proceed with assembling a data structure that expresses a hierarchy of state subspaces – Alg. 4. Each state subspace is created based on a corresponding descriptor group. State subspaces maintain the same parent-child relation as descriptor groups. At this point, the relation links are copied and disambiguated. A descriptor group may have many possible parents if the group is a product of the intersection operation. However, a subspace in a tree can have only one parent, and it can appear in the structure only once.

In the process of disambiguation, each subspace receives one parent. The process must be performed in a certain order. For instance, if a small subspace is attached to a big one too early, we may lose an opportunity to add an intermediate layer. Therefore, the procedure begins from bigger subspaces that nest the largest number of smaller subspaces. To do so, each time a list of descriptors is sorted descending by the number of unassigned descendants (children, grandchildren, etc.) – line 7 in Alg. 1, and line 6 in Alg. 4.

The recursive procedure in Alg. 4 begins from the root, and it expands the children down to the tree leafs. A subspace can be added to the structure only if it nests (directly or through a descendant) at least one observed state that was not used previously (line 15). Otherwise, the subspace is discarded (line 32). Near the end of the procedure, if there is a subspace that holds a child subspace, and it contains any states at the same time, an additional subspace is created inside the scope of the current subspace to take over these states (line 21).

Alg. 4: BuildSubspaces ($descSet$, $parent$)

```
Data: descriptor set and its parent subspace
Result: subspace tree
1  if descSet ∈ usedDescSets then
2      return 0
3  usedDescSets ← usedDescSets ∪ {descSet}
4  var subspace ← ⟨descSet, parent⟩
5  var anyStateInChild ← 0
6  var descriptorSetsSorted ← Sort ( descSet.children )
7  foreach childDescSet ∈ descriptorSetsSorted do
8      if BuildSubspaces ( childDescSet, subspace ) then
9          anyStateInChild ← 1
10 var anyStateHere ← 0
11 foreach s ∈ descSet.states do
12     if s ∉ usedStates then
13         anyStateHere ← 1
14         break
15 if anyStateInChild ∨ anyStateHere then
16     subspaces ← subspaces ∪ {subspace}
17     parent.children ← parent.children ∪ {subspace}
18     if anyStateHere then
19         var leaf ← subspace
20         if anyStateInChild then
21             leaf ← ⟨descSet, subspace⟩
22             subspaces ← subspaces ∪ {leaf}
23             subspace.children ← subspace.children ∪ {leaf}
24         foreach s ∈ descSet.states do
25             if s ∉ usedStates then
26                 usedStates ← usedStates ∪ {s}
27                 leaf.states ← leaf.states ∪ {s}
28                 s.subspace ← leaf
29                 if IsGoal ( s ) then
30                     leaf.hasGoal ← 1
31     return 1
32 else
33     delete subspace
34     return 0
```

This action ensures that the states are placed only in leaf subspaces. Observed states are assigned to leaf subspaces in line 27. Finally, subspaces that contain goal states are marked (line 29).

The next section explains how the resulting structure can be utilized in planning.

V. Hierarchical Space Based Estimate

In a planning task, the least expensive (shortest) path between an initial state and any state that satisfies the goal is being searched. In our case, the result is a sequence of actions that solves a stage consuming the least amount of energy.

In the considered problem, the best performance can be achieved by applying the A* algorithm [29]. However, it requires a heuristic estimate function to approximate the distance to the goal. Providing such an estimate is not an easy task. In *Smart Blocks*, it is difficult because the progress of solving a stage is hard to measure. The problem structure makes relaxation heuristics futile, which was explained in Section III.B. The goal progress could be calculated using the designer's knowledge about all possible solutions of a level. In this benchmark environment, a solution pattern can be generated, but in real problems, it is an unrealistic assumption.

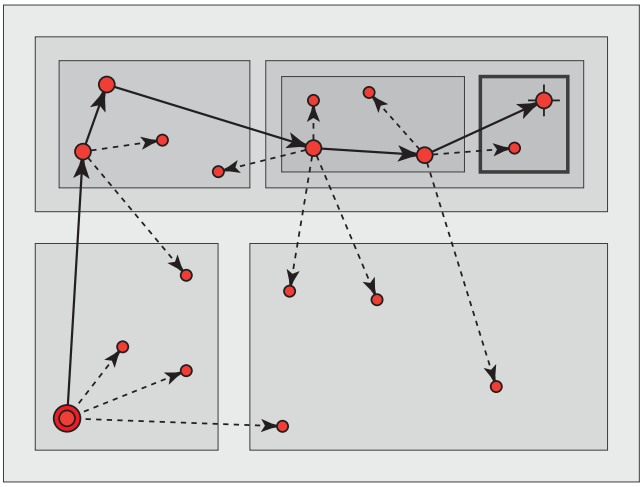

Fig. 2. A visualization of state search supported by the hierarchical model of the state space.

Our idea is to use a hierarchical state-space model to roughly estimate how close a state is to the goal. The distance is calculated based on the number of parent subspaces that a state shares with the nearest goal subspace. The more mutual nodes in a tree they have, the closer to the goal the state is. It is an abstract measure. It supports state search by leading it to more promising regions of the state space.

Fig. 2 provides a visual example of state search that uses information stored in the hierarchical model of the state space. In the picture, the state search begins in the bottom left corner of the figure, and it ends in the top right one. The initial state shares only one parent (the root) with the goal subspace (marked as the bold rectangle). At this point, there are four possible state transitions. One of the subsequent states shares two parents with the goal subspace. This one has a higher priority, and it should be expanded next. The procedure is repeated until the goal subspace is reached.

The formula for calculating the proposed *Hierarchical Space Based Estimate* (HSBE) is defined in Eq. 9:

$$\Delta(s) = 1 - \frac{max_i\Big(\big|parents(s) \cap parents(g_i)\big|\Big)}{d}, \qquad (9)$$

where:

- s is a state,
- g_i is a goal subspace (one of many),
- d is a depth of a hierarchical space tree,
- $parents(\cdot)$ is a function that returns a set of parent subspaces up to the root,
- $max_i(\cdot)$ iterates over all goal subspaces and returns the biggest value.

First, the method finds a parent subspace for a state. It is a leaf subspace with the biggest number of descriptors that match the state. Then, the method collects a set of parent

subspaces of the state (up to the root). The set is intersected with a chain of subspaces from the root to a goal subspace (inclusively). The two sets are intersected to count the number of shared subspaces. The number is divided by the tree depth to normalize the outcome. If there is more than one goal subspace, the most promising one is chosen. The range of $\Delta(\cdot)$ is in $[0, 1)$. The normalized value can be scaled by a minimum transition cost in a state-space graph to ensure that the heuristic never overestimates the cost. Therefore, it is admissible. It should be emphasized that the discussed admissibility is the property of a heuristic that ensures optimality in a state space that does not contain negative cycles, as it was assumed in the formal description.

The main operation of the estimate is tree search, and its computational complexity is logarithmic. A tree structure enables us to quickly collect a chain of nodes between a leaf and the root. In addition, parents of goal subspaces can be stored before the planning phase. Finding a parent subspace for a newly expanded state is linear in the number of leaf subspaces. A significant impact on the computational overhead has the operation of set intersection, which is frequently used. Complexity of this operation depends on the implementation [30]. With some effort, it can be done efficiently.

VI. Experiments

The goal of this study was aimed at checking whether this early concept of a planning method is worth further development. The proposed method is intended for problems in which a heuristic is unavailable, ineffective, or characterized by a high computational complexity [31]. Therefore, Dijkstra's algorithm was chosen as a reference [24]. The algorithm is often used as a benchmark, because it is optimal and represents the worst-case scenario in domain-independent planners [32].

The performance of the methods was measured by:

- the number of iterations in the main loop,
- the number of visited states,
- the maximum size of the state queue (the open set),
- the mean wall-clock execution time.

The results are presented in Table III.

The experiments were conducted on a typical hardware setup: Win 7 x64, Intel i7 @ 3.4 GHz, 8 GB RAM. The wall-clock times were measured for the state search procedure in the main loop. For Dijkstra's algorithm, the measurements were simply averaged from 10 runs. However, HSBE relies on a subspace tree. It can have different sizes, because it can be built from different numbers of plan traces. Thus, the smallest subset of the collected plan traces, which was necessary to obtain full efficiency, was used. Usually, 10% of the set was enough. The subset was chosen randomly, and the procedure was repeated 10 times.

The tests were conducted for the first six game levels. The remaining levels are more complex, their state spaces are larger, and the number of states grows very rapidly. The explosion of states is caused by a bigger number of dynamic objects on the stage. The experiment could not be finished in an acceptable time on the present hardware. However, these levels are somewhat analogous to the preceding ones, and their contribution should not conflict with the initial results.

As expected, the compared methods are equal in the quality of returned solutions. For most of the levels, they provide cost-optimal plans. The exception is level 5 and 6 (compare with the replay statistics in Table I). A slight deviation from the optimal paths is observed. These two levels contain energy cells, which introduce negative-cost transitions to the state-space graph. In this case, solution optimality is not ensured by the algorithms, and the returned solutions may vary depending on the order of states in the queue.

The discussion regarding the performance should begin from comparing the execution times and the number of visited states. In most cases, A*+HSBE is slower than Dijkstra's algorithm. This is caused by the fact that the researched heuristic uses many operations involving complex data structures, while Dijkstra's algorithm is all about adding and removing an item from a queue. On the other hand, the proposed method is characterized by a smaller number of visited states. The execution times include the time of visiting states and the overhead of the method. The more expensive visiting a state is, the lesser part the overhead in the execution time has.

For instance, let us consider level 5. Dijkstra's algorithm is approximately two times faster than A*+HSBE, but it also visits twice as many states. If the cost of visiting a state was tripled, then both algorithms would have almost the same execution time. A*+HSBE is faster if the number of states exceeds this threshold.

The reduction of visited states increases for the larger game levels. The density of the state space division is constant, and it might be too sparse in the simpler ones. If the partition of the state space is low then the heuristic is less informative. On the other hand, if it is too high, then the overhead is considerable.

In the final part of the study, the relation between the number of plan traces, used for building the hierarchical model, and the performance of the proposed method was examined. The experiment was conducted for level 5, and the results are shown in Fig. 3. The subsets of replays in the database were chosen randomly, the process was repeated 10 times, and the measurements were averaged. The quality of the returned solutions remains constant. The reduction of visited states increases as the number of plan traces grows. It appears that a small number of observations is sufficient to discover a large part of the subspace tree. Similar results were observed for the remaining game levels.

Although, the results do not show incontestable superiority of the proposed heuristic over the algorithm used as a benchmark, it should be noted that applying the method in practice may be justified by the reduction of the search space. The profit of employing the introduced approach depends on the computational cost of visiting a state in a particular system. For simple planning problems, the execution time of a complex method can take longer than using a trivial state-search algorithm. *Smart Blocks* as a testbed environment is characterized by a medium-size state space and a very light state so that the experiments could be conducted swiftly.

TABLE III
COMPARISON OF DIJKSTRA AND A*+HSBE (THE LAST TWO COLUMNS CORRESPOND TO BOTH METHODS)

Level No.	Algorithm iterations		Visited states		Max. queue size		Avg. execution time [ms]		Solution length	Solution energy
	Dijkstra	*A**	*Dijkstra*	*A**	*Dijkstra*	*A**	*Dijkstra*	*A**		
1	164	153 **(-6.71%)**	180	163 **(-9.44%)**	13	13 (+0.00%)	0.6	1.3 (+116.67%)	23	231
2	5 271	4 538 **(-13.91%)**	5 800	5 062 **(-12.72%)**	593	593 (+0.00%)	71.3	253.1 (+254.98%)	18	161
3	825 193	747 690 **(-9.39%)**	885 508	806 562 **(-8.92%)**	58 866	58 874 (+0.01%)	12 616.5	13 134.5 (+4.10%)	57	66
4	1 098	440 **(-59.93%)**	1 608	930 **(-42.16%)**	493	493 (+0.00%)	9.3	6.9 **(-25.81%)**	27	11
5	32 609	15 341 **(-52.95%)**	38 025	17 865 **(-53.02%)**	35 45	2 571 **(-27.48%)**	491.7	976.6 (+98.62%)	42	94
6	19 973	12 174 **(-39.05%)**	29 549	19 539 **(-33.88%)**	7 423	7 367 **(-0.75%)**	366.2	993.1 (+171.19%)	53	190

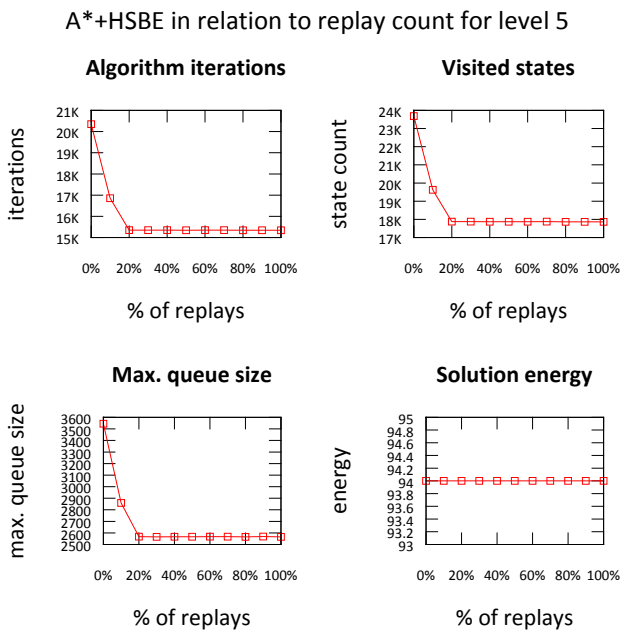

Fig. 3. The set of charts shows the statistics of A*+HSBE for level 5 depending on different numbers of replays used for building a subspace tree.

However, for real planning problems, if the state space is vast and visiting a state is expensive then the method is most certainly worth applying.

VII. CONCLUSIONS

The original contribution of this paper is a new method of building the hierarchical model of the state space from game replays. Information stored in the model represents general knowledge about the structure of the state space. The method accepts executed plan traces as input. The observations are not required to be annotated by experts. The model abstracts from state representation methods. It relies on state descriptors that refer to selected features of a state, and their form is unrestricted. It does not oblige system designers to rewrite a planning problem in PDDL. Instead, they can use the original implementation of a game. It is more convenient and efficient.

The method is used for grouping states hierarchically, and it relies on hyperspace nesting. The proposed heuristic estimates the distance between any two states in the state space to effectively guide the state search towards the goal and reduce the search space. It is intended for difficult cases in which a heuristic estimate of distance in a state-space graph cannot be easily provided and domain-independent heuristics are inefficient.

The proof-of-concept was validated using *Smart Blocks*. It is a testbed environment designed for conducting experiments that involve game replay analysis. The game is modeled as a variant of a multi-agent system. It enables a researcher to focus on classical planning problems. Unlike commercial games, it comes with tools that simplify method testing.

It should be emphasized that the approach is general. Formal assumptions of the method, which include the planning problem definition and the model of the hierarchical state space, are abstract. The same rule applies to the introduced algorithms, because they do not assume any specific properties of the system in which a planning problem is solved. Although the method relies on state descriptors that were implemented according to domain-specific knowledge for this particular study, their formal form is abstract, and it is possible to extract them automatically (see the Future Work section). To summarize, the approach can be applied to any classical planning problem for which input observations are available.

VIII. FUTURE WORK

The presented results mark an important milestone in the development of the approach. There are still many opportunities for improvement, but their examination is a rather large undertaking. This section outlines possible development directions.

In the course of ongoing research, it has been discovered that a concept (Galois) lattice is a more suitable model for expressing relations between state subspaces [33]. In a hierarchical structure described by the lattice, the intersection of state subspaces has many parents, rather than a single one like in the tree structure. Formal foundations of the Formal Concept Analysis (FCA) are consistent with the descriptors introduced in the discussed model of the state space. Thus, a lattice can be built by an algorithm commonly used in FCA [34]. Preliminary study results show a good performance of a heuristic supported by this model. Therefore, a tree will be replaced by a lattice in the subsequent study.

At the current stage of development, issues related to processing a very large replay database have not been taken into account. It is a secondary problem because the process is separated from planning, and its execution time is acceptable. Nonetheless, pruning methods that protect against the overgrowth of the structure should be researched.

Reduction of the search space depends on the quality of the state space division. The algorithm for building a hierarchical space model ensures that the formal assumptions are satisfied. However, the division quality is affected by state grouping, which is handled by state descriptors. Adapting state descriptors automatically can lead to better results. The research is aimed at inventing an adaptive descriptor model that can be tuned by machine learning methods.

***Abstract*—Game theory is a tool that may be used to model a player as an intelligent being – one who seeks to optimize his own performance while taking into account the performance of his opponent. However, it is often challenging to apply the theory in practice. In the naval environment, this approach may be used, for instance, to find the best strategy for an Autonomous Underwater Vehicle (AUV) while considering the intelligence of the submarine opponent. Classic approaches based on Minimax suffer from an explosion of states, and they are difficult to use in real-time. The paper introduces an approach that improves the Minimax algorithm in a complex naval environment. It assumes limited and scalable computational resources. The approach takes advantage of a flexible utility function based on a neural network with parameters tuned by a genetic algorithm.**

I. Introduction

AN AUTONOMOUS Underwater Vehicle (AUV) is a robot that travels underwater (Fig. 1)[1]. Compared to other Unmanned Underwater Vehicles (UUVs) such as Remote Operating Vehicles (ROVs), it is not guided by an operator. AUVs are mostly employed in the field of oceanography and are beginning to be considered for military use [2]. For instance, they can be used for patrolling and monitoring the vicinity of a naval port, or for supporting a surface platform in its search for a submarine. An AUV has an advantage over an ROV because it does not reveal its location by continuous communication with an operator.

A submarine is a very difficult opponent to detect because of its ability to exploit the complicated nature of underwater sound propagation. As a result, it can stay hidden for a long time owing to its superior endurance and speed. By comparison, an AUV has limited mobility, sonar capabilities, computational power, and battery life. More importantly, a submarine is commanded by qualified personnel making it a deliberate and intelligent competitor. Therefore, the robot controller must meet high requirements. AUV's software should provide as much intelligent behavior as possible to mitigate its limited resources.

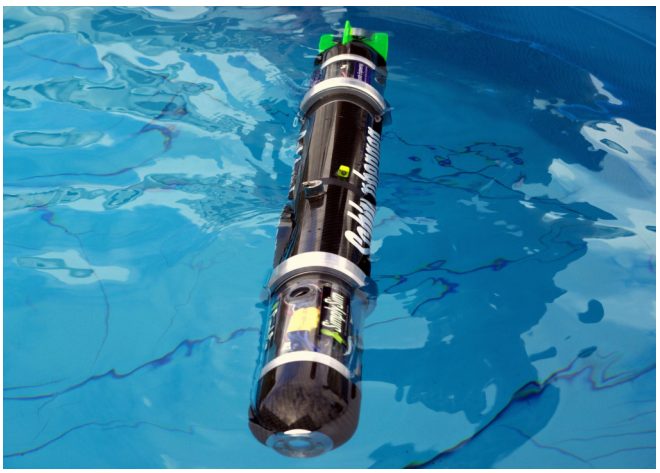

Fig. 1. The picture shows an example of AUV used in military [3]. The Blackghost AUV can attack with no outside control.

In order to maximize the ability of the AUV to detect the submarine, we consider here a bistatic sonar employment. This means that the sonar source and receiver are separated – rather than collocated on a single platform in the more traditional monostatic case. In this study, the sonar source

The project was commissioned and financed by the Visiting Researcher Programme organized by the Centre for Maritime Research and Experimentation (CMRE) located in La Spezia (Italy) – the Centre is an executive body of NATO's Science and Technology Organization (STO) along with the NATO Collaboration Support Office. The research was partially supported by the statutory funds of the Department of Computational Intelligence, Faculty of Computer Science and Management, Wroclaw University of Science and Technology.

is in a fixed location while the receiver is assumed to be a linear array of hydrophones towed by the AUV. Importantly this means that the AUV can receive bistatic sonar contacts – with range and bearing information – without needing to transmit. Sonar transmissions are easily counter detected by a submarine, thereby revealing the location of the asset and allowing the submarine the opportunity to evade.

To achieve an efficient strategy model for an AUV, it must be validated against a challenging foe. Thus, to find the best strategies for both naval units we use game theory [4]. The problem is described as a naval version of a pursuit-evasion game. The players hold different properties; therefore, a skirmish is asymmetrical. It is a multistage non-zero-sum game placed in a complex environment with uncertainty and incomplete information about the game state. The **non**-zero-sum assumption is introduced because the players may have specific and unique objectives. In addition, having a limited access to information about an opponent's state, they might unconsciously cooperate in some cases.

Finding the game equilibrium, which is the problem solution, is a difficult task. In theory, the game should be defined as an extensive-form game. However, adding equivalent state nodes that denote the space of hidden possibilities would greatly increase the problem complexity by extending the game tree, which is already very large. In other words, it is nearly impossible to traverse the entire game tree (extensive or not) in practice. The approach considered here is to employ a pure strategy form of a sequential game with discrete time.

Another complication is that each player receives input that is not readily convertible to a utility value, which expresses how desirable a given state is for a player. There is a significant distance in the state space between actions in the past and their real effect in the future.

In our work, we solve the problem by using a flexible and trained utility function model that is optimized according to specified criteria. A utility function then converts player's input into a utility value of the game state. Both players use the Minimax decision rule to choose the best action. They have their own utility function model that is tuned to gain the best outcome assuming that an opponent is doing the same. In the presented approach, a neural network was chosen as the utility modeling function [5]. Its weights are trained by a genetic algorithm to maximize each player's fitness [6]. The fitness is calculated taking into account the players' objectives.

In the following section, a general overview of the method framework is introduced. Next, a short survey of the existing works related to the stated problem is provided. Subsequently, important properties of the naval environment are described. The following part of the document provides formal foundations and describes the problem as a pursuit-evasion game. Next, naval players are characterized, and their cost functions are defined. A utility function model and its training method are presented in the next part of the document. Finally, results of the experimental study are collated and described.

II. Method Overview

This section provides a general overview on the proposed approach. It briefly summarizes the method framework and its components (Fig. 2).

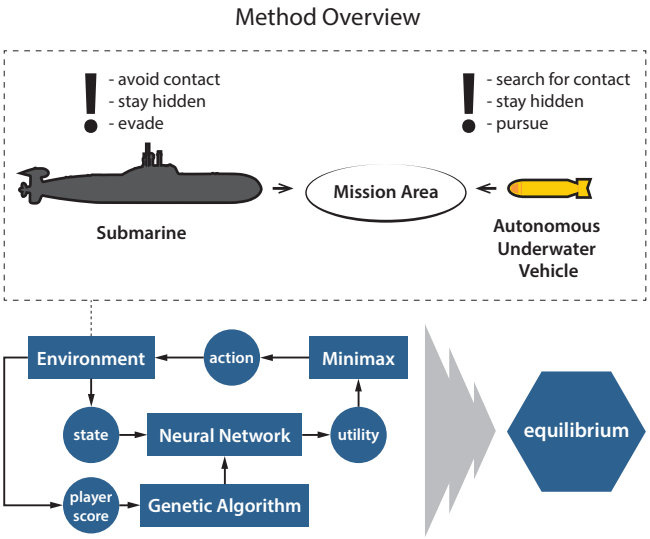

Fig. 2. The picture visualizes the game and the method of solving it.

The proposed method searches for the optimal strategies of players operating in a simulated environment. The problem description uses game-theoretic formalism to model the naval environment as a game. The solution is a saddle-point equilibrium. It is a state in which no player can gain by changing his strategy. In accordance with theoretical foundations, it is assumed that players are rational. The quality of a strategy is represented by its cost value. It is an accumulative cost calculated for a sequence of states from an initial state to a final one.

For the adopted game model, an optimal strategy is expressed by the Minimax decision rule. Application of the algorithm is not straightforward, because a utility value for a given game state is unknown. The utility is a system-wide feedback to the Minimax algorithm. In this approach, a utility value is returned by the output of a multilayer neural network, which is employed as a utility function. Its input is fed with a game state perceived by a player. Each player has a separate neural network, because the players have different capabilities, and they do not share the same view of the environment and its state.

Because the desired (optimal) output of a neural network is unknown, weights inside the network are tuned using an evolutionary approach, rather than the backpropagation learning algorithm. In this method, a genetic algorithm optimizes the cost of the Minimax strategy, which is guided by the output of the neural network. The evaluation procedure requires the game to be simulated over a number of steps. During the optimization process both players improve their strategies until

they reach the equilibrium. It is a theoretical state in which the players have found their optimal strategies.

III. State of the Art

The problem stated in this work is fresh and specific. In the literature, there is a range of works directly addressed to this field but not this particular problem. Most of the papers discuss fundamental issues related to the naval environment [7]. One of the most elementary is modeling of underwater signal propagation and communication [8], [9]. Another is a classic flaming datum problem, in which a fleeing submarine is relocated after momentarily revealing its position [10].

Modern navies are beginning to procure and test multistatic sonar systems at sea. Locations of the sensors are optimized based on a game-theoretic approach, and their efficiency is evaluated in the previous works [11], [12]. Recent technological progress enables us to employ an AUV as a mobile signal receiver instead of using a fixed-position sensor [13]. Despite the fact that an AUV can be considered as a more effective tool against a submarine, the topic is rarely undertaken so far. Related works are focused on the problem of building a probability density map of possible locations of an opponent [14]. Many of the approaches employ simplified behavioral models [15], rather than considering the best strategies for both players and optimizing towards the equilibrium.

Solutions designed for similar problems are often bounded to their domains and cannot be directly applied to this specific case [16]. They are intended for less demanding environments. In the air, aerial vehicles can easily communicate with the command and exchange information. They rely on radar and visual information, which can be processed more efficiently than sonar input. Underwater communication is slow, has a very limited bandwidth, and above all, using it immediately exposes the location of a vehicle to an opponent. Underwater vehicles exploit properties of underwater signal propagation to remain stealthy. They must plan their route very carefully while drones can maneuver more freely, because their environment is mostly uniform. A very limited computational power makes it impossible to run an expensive optimization process on-board while the requirements regarding the method are still high.

The discussed problem is focused on tracking and spying an intelligent enemy unit, rather than patrolling or engaging in combat according to a clearly defined protocol. The task is specific, and it consists of a range of problems that are not addressed by the works related to autonomous vehicles.

The proposed method is based on a known idea of employing an evolutionary algorithm for finding an optimal strategy in game theory [17], [18]. In these works, a population of agents is optimized to achieve the best performance against an opponent who is following a defined strategy. However, that approach cannot be employed in this case, because the behavior of an opponent cannot be easily described by a closed set of rules. Here, both competing sides are optimized simultaneously. To avoid executing an expensive optimization process on-board, the optimization is aimed at tuning a neural network that is used for evaluating the game state and computing utility (reward). The neural network plays the role of a utility function in an on-board decision process. In the light of the above facts, the problem setup and solution are considered as original.

IV. Naval Environment

The underwater environment in which our scenario takes place is both harsh, from a technological standpoint, and complex in terms of the physics that govern the propagation of sound used to detect a submarine [8]. The performance of a sonar system is a complex function of transmission loss, reverberation levels and noise levels, all affected by various oceanographic, surface, and bottom parameters. Not least of which is the sound speed profile within the water column which causes a bending of the sound propagation paths and can result in large regions of water from which sound may be diverted. These shadow zones may then be exploited by an intelligent submarine greatly decreasing its chance of being detected.

The eventual signal-to-noise ratio (SNR), the primary metric used to assess the probability of detecting a submarine by sonar, depends on water temperature and salinity, surface roughness, depth, and shape of the sea bottom. This study considers the use of multistatic sonar whereby performance is a function of the specific geometry between the separated sonar source and receiver (in this case the AUV) together with the submarine location. As a result, detailed (and time consuming) acoustic propagation models are required to accurately predict multistatic sonar performance within range-dependent environments.

Irrespective of the complexities of actually detecting a submarine, the simple operation of an AUV in the ocean also has its challenges. In addition to basic underwater physics, the AUV has limitations imposed on its motion trajectory due to the stability of its receiving array of hydrophones [19]. The complicated propagation effects already discussed also serve to limit the ability of the AUV to send and receive messages through the water. This is in fact a driving force behind the need for better autonomous decision making – since the vehicle cannot rely on regular intervention by operators.

The goal of this study is to provide a proof-of-concept and consequently, some simplifications are introduced to avoid vast computations, which significantly improves the computation time of the experiments. The system is modeled in such a manner that a general characteristic of the underwater environment is captured. Earlier experiments have shown that the acoustic model is a bottleneck for the calculations. It was replaced by a set of rules that cover only the general features.

The operational area is rectangular, and it contains the players' start positions, signal source position, and mission area, which is circular (Fig. 3). It is assumed that the mission area holds an objective that is important to a submarine. The objective is accomplished if the unit closes to within a defined radius of the goal. In the meantime, the AUV's objective is to keep as close as possible to the submarine. While the AUV is

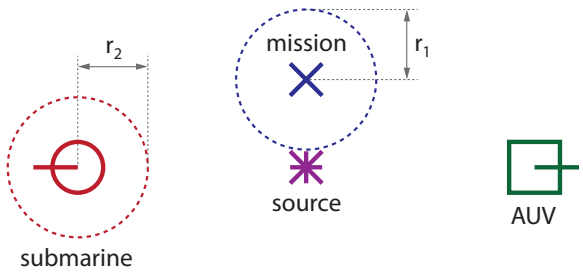

Fig. 3. The image presents an example of game arrangement. The objective of a submarine is to travel to the mission area. The AUV's objective is to be in close surroundings of the opponent. The nearer a unit approaches the signal source, the easier it can be detected.

not intended to prosecute the submarine, thereby preventing it reaching its mission goal, it should nevertheless detect its presence and alert the defenders as soon as possible. Both players benefit from staying undetected. However, the players have different priorities, so the zero-sum property is not valid in this case.

V. Game Theory

The pursuit-evasion game (PEG) is a well-known problem in the class of differential games in game theory [20]. It is often referred to as a simple lion-zebra or cop-robber case.

Let us define a naval version of PEG as a state-feedback discrete-time dynamic game with two non-cooperating players, where P_1 is a pursuer (AUV) and P_2 is an evader (a submarine) executing actions sequentially in each game stage k, Eq. 1:

$$a(k) = \begin{cases} a_k^1 & \text{if } k \text{ is odd} \\ a_k^2 & \text{if } k \text{ is even} \end{cases}, \tag{1}$$

where $a(k)$ is an action at stage k, a_k^1 is P_1's action, and a_k^2 is P_2's action. The game corresponds to dynamics of the form (Eq. 2):

$$s_{k+1} = \Delta_k\Big(s_k, a(k)\Big), \ \forall k \in \{1, 2, \ldots, K\}, \tag{2}$$

where:

- s_k is an entry state node at stage k,
- Δ_k is a transition function modeling dynamics at stage k,
- K is a finite time horizon.

A finite horizon stage additive cost is (Eq. 3):

$$\sum_{k=1}^{K} c_k\Big(s_k, a(k)\Big), \tag{3}$$

that P_1 wants it to minimize, and P_2 wants it to maximize. A state-feedback information structure corresponds to policies of the form (Eq. 4):

$$a_k^1 = \gamma_k(s_k), \quad a_k^2 = \sigma_k(s_k), \tag{4}$$

where γ and σ are state-feedback policies for P_1 and P_2, respectively. The corresponding value of the cost in Eq. 3 for the policies is denoted by $C(\gamma, \sigma)$. A saddle-point pair of equilibrium policies (γ^*, σ^*) satisfies (Eq. 5):

$$C(\gamma^*, \sigma) \leq C(\gamma^*, \sigma^*) \leq C(\gamma, \sigma^*), \ \forall \sigma, \gamma. \tag{5}$$

For games with a finite state space, an optimal policy cost can be found using Minimax Theorem. It is solved algorithmically. However, the players perceive the state differently, and they do not have strictly opposite objectives. Therefore, the game is not considered as zero-sum. For this reason, Alpha-Beta pruning, which would reduce the complexity, cannot be applied [21].

VI. Naval Players

Each player has a set of discrete move actions to choose in his turn. For the sake of simplicity, a move action can be executed with a finite number of speeds and headings (Eq. 6):

$$a(k) \in \{\vec{m}_0, \vec{m}_1, \ldots \vec{m}_n\}, \ \vec{m} = s * \vec{h}, \tag{6}$$

where $\vec{m}$ is a move vector as a product of scalar speed s and unit heading vector $\vec{h}$. In order to avoid inaccuracy and provide more flexibility, player coordinates are expressed by floating point values rather than grid cells. Units cannot currently change depth.

To imitate sonar features, both detection and counter detection ranges were introduced. A naval player does not have access to information about his opponent as long as the distance between them is bigger than the opponent's detection range. The detection range is not constant, and it changes depending on the distance to the signal source. The closer to the source, the more acoustic energy is reflected by a naval unit and so it is easier to detect. The signal source can be received from a far distance and, therefore, its position is always known to all players.

At some point, the algorithm must estimate the opponent's actions to calculate utilities of the future states. Unfortunately, it cannot be easily done if a player does not know the exact position and heading of the opponent. To deal with the problem an approximate map of possible locations of the opposing unit is generated based on its operational range (Fig. 4). The operational range is a circular area placed in the center of the last revealed position with a radius equal to the maximum distance the unit could travel since the last contact time. The map of possible states of an opponent is limited by the complexity of the algorithm.

VII. Cost

A cost value describes how well a player performed during the whole game. AUV is referred to as a pursuer whose behavior is characterized by minimizing the distance to its opponent. The pursuer minimizes cost for staying within a specified range to an evader. The robot is penalized if

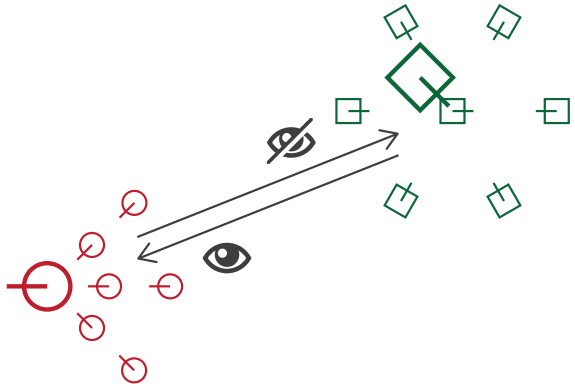

Fig. 4. The picture shows how the algorithm handles limited access to information about the current state of the opponent. The big circle on the left is the actual location of the submarine. The rectangle on the opposite side is the AUV. Small shapes represent their possible positions in the next game step. The state of the player on the left is exposed while the opposite player stays unrevealed, but his last position is known. A map of several possible positions inside the operational range of the hidden player is generated.

its position is revealed. Formally, the cost for the AUV is calculated by the following formula (Eq. 7):

$$C_1(k) = C_1(k-1) + d_o + \\ - \begin{cases} b_1 & \text{if } d_o \leq r_1 \\ 0 & \text{otherwise} \end{cases} + \begin{cases} p_1 & \text{if } v_1 = 1 \\ 0 & \text{otherwise} \end{cases}, \quad (7)$$

where:

- k is a game stage number,
- $C_1(\cdot)$ is the pursuer's (AUV) cost function,
- d_o is a distance to the opponent,
- b_1 is an award given to the pursuer if distance d_o is smaller than threshold r_1,
- p_1 is a penalty if the pursuer reveals his position to the opponent,
- v_1 is the pursuer's state of visibility to the opponent.

By analogy, the submarine is referred to as an evader who maximizes the distance to his opponent and moves towards the mission area. If the unit is sufficiently close to the mission, a positive cost is awarded. Whenever a player is exposed to his opponent, a penalty cost is applied. In order to clarify, the cost for the submarine is calculated by the following formula Eq. 8:

$$C_2(k) = C_2(k-1) + d_o - d_m + \\ + \begin{cases} b_2 & \text{if } d_m \leq r_2 \\ 0 & \text{otherwise} \end{cases} - \begin{cases} p_2 & \text{if } v_2 = 1 \\ 0 & \text{otherwise} \end{cases}, \quad (8)$$

where:

- $C_2(\cdot)$ is the evader's (submarine) cost function,
- d_m is a distance to the mission center,
- b_2 is an award given to the evader if distance d_m is smaller than threshold r_2,
- p_2 is a penalty if the evader reveals his position to the opponent,
- v_2 is the evader's state of visibility to the opponent.

Cost parameters b, r, and p affect the behavior of players by defining objectives and their relative importance. Distance effects included in the cost functions serve to steer the training towards the desired outcome. Ultimately, award and penalty values drive the tactics of a player, and they can be adjusted to observe different behaviors.

VIII. Utility

The utility value of the game state is calculated by a neural network based on information held by a player. Among many benefits of neural networks is an application for non-linearly separable problems and generalization of acquired information [22]. In this study, Multi-layer Perceptrons (MLP) were used as a popular model often applied in a broad class of problems [5]. The neural network has three layers. It gives one hidden layer with eight neurons. The activation function is the hyperbolic tangent.

The model is fed by eight inputs provided by a player:

- angle and distance to the mission area,
- angle and distance to the signal source,
- angle and distance to the opponent,
- heading relative to the opponent's heading,
- opponent contact – informs whether the opponent is revealed to a player or one of his possible states should be considered.

The input contains only relative values to ensure that as much general information as possible is acquired by the neural network. Thus, the training process is more efficient and less constrained to a particular case.

A. Minimax

Each player uses a classic Minimax algorithm with a limited depth of the state tree to choose the best action (Alg. VIII-A).

IX. Evolutionary Training

The utility function model (a neural network) is trained by a classic variant of a genetic algorithm [6]. It is a powerful tool suitable for complex optimization problems characterized by many local extrema. The algorithm optimizes a vector of neural network weights considered as a chromosome without further encoding. To evaluate an individual in a population, it must be decoded to his phenotype level, which means that a neural network is created based on his chromosome.

The optimization process is conducted according to the fitness function that is equal to the cost calculated for each player (Eq. 7 and Eq. 8). Because the players have different goals and fitness functions, the genetic algorithm (Alg. IX) holds two populations – one for each player type. An individual cannot be evaluated without an opponent. Therefore, these two populations periodically pass the copies of their best entities after a defined number of GA iterations. Each population adds a new opponent to a list, and the final fitness is the average cost achieved against a set of foes in the list. This is done to

Algorithm 1 Minimax (node, player, depth)

        end for
    end if
    for pop in populations do
        Evaluate ( pop )
    end for
end while
```

optimize against a variety of enemy strategies rather than a single one.

X. Experiment

The experimental study includes a series of tests carried out to validate the approach. This section describes one of those experiments that was aimed to check the characteristics of a medium-long training process. Thus, it should be emphasized that in the best case scenario obtained results may only represent a near-optimal solution. This study has been preceded by a series of short experiments to select the training parameters. Because of the scale of the problem and the large amount of data, this section includes only selected results regarding the optimization process of the players' strategies.

Taking into account the nature of the research, realistic units of measure have not been preserved. They were adjusted to obtain easily observable behaviors and test the approach. In the experiment, a game arrangement is the same as presented in Fig. 3. However, the picture does not show an additional free space below and above the signal source placed in the center of the stage. A single game was simulated for a limited number of turns that was sufficient for both players to fulfill their objectives. A realistic degree of asymmetry between the players was set by giving to the submarine a better speed and the AUV greater stealth. Another difference is that the submarine is more interested in being undetected than the AUV. More detailed parameters of the experiment setup are provided in Tab. I.

Training results are shown in Fig. 5 and Fig. 6. Surprisingly, training of both populations begins from a relatively high level of fitness. Notwithstanding, an initial population is random, and there is always a chance that one of population entities will accidentally advance to the goal. It is, however, a chaotic behavior, and it changes drastically depending on the input. Thus, any opponent reaction can cause that change.

Further fitness decreases are caused by filling the list of opponents with better enemies. New opponents are added to the list every 20 generations, which is referred to as the pass best phase in the algorithm. Sometimes the period between the transfers of the best entities is too short to invent a better opponent. Nevertheless, it prevents from overtraining to a current set of opponents, which evolve quickly. Forcing an entity to achieve the best average cost against a number of opponents allows it to acquire a more general strategy but may also cause conservative and protective behaviors.

While observing behaviors of both players at the end of the training, it turned out that they acquired interesting strategies. The submarine does not immediately proceed to the mission. First, it glides far below the source, where it has a good cover. Next, it quickly travels toward the mission. It can be said that the submarine takes advantage of its speed and lures the robot. The AUV is not able to catch up with the submarine nor detect the opponent near the mission, because the submarine visits the mission only for a short moment at the end of the game. On the other hand, the AUV tries to follow the trail of the submarine. The robot minimizes its distance to the opponent but never reaches a sufficient distance to receive an award.

During the experimental study, a number of long training runs have been conducted. However, the simulation progress and outcome turned out to be very sensitive to the random nature of the genetic algorithm. Therefore, it was difficult to observe regularity, and averaging results did not lead to clear conclusions. The results from long training runs are placed in Fig. 7 and Fig. 8. For some of the experiments, fitness tend to stabilize in time (Fig. 7) while in other cases, the balance was lost and the fitness of both populations fluctuated (Fig. 8).

TABLE I
THE TABLE SHOWS A DETAILED PARAMETER SETUP OF THE EXPERIMENT.

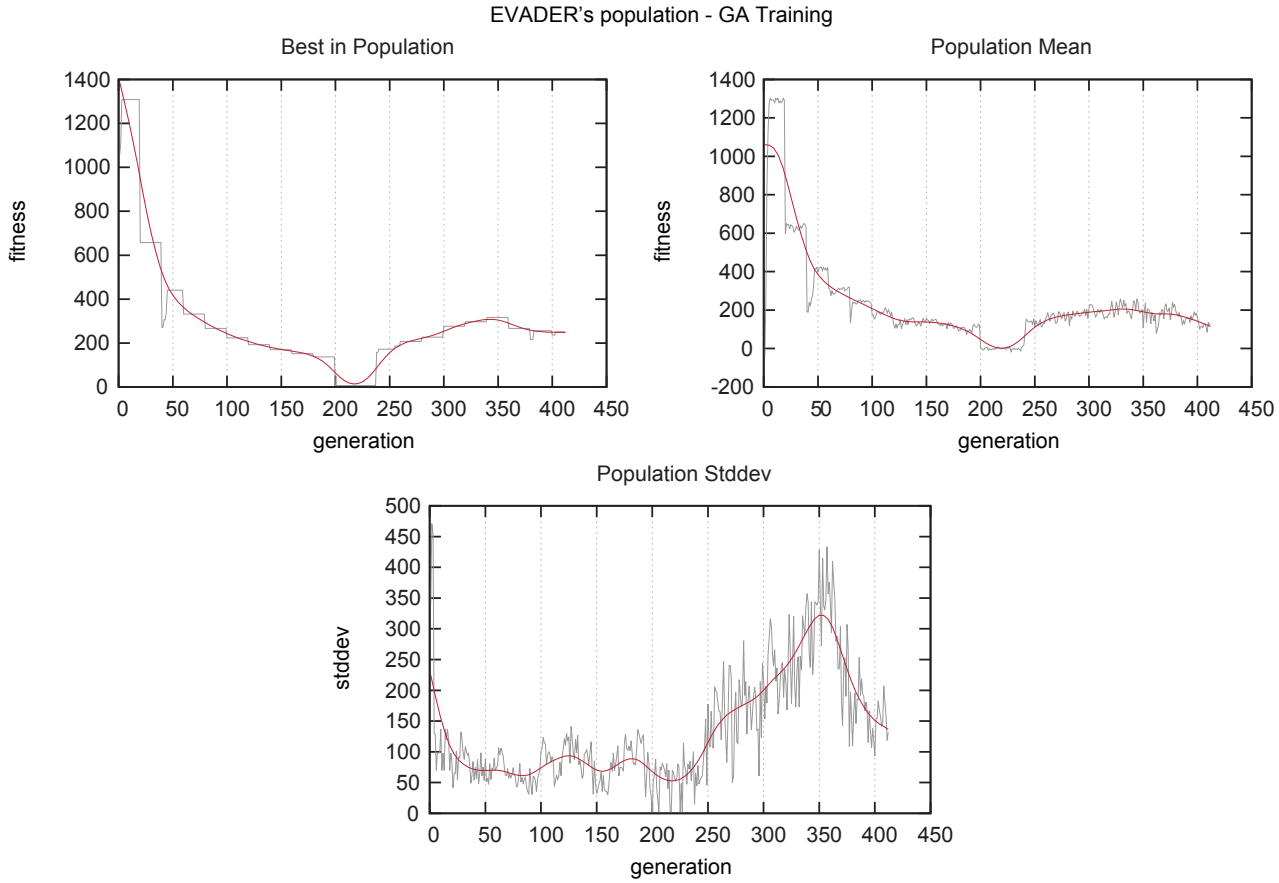

Fig. 5. The plots show the best fitness, average population fitness, and fitness standard deviation over generations of evader's population training.

The solution space is vast, and it has may local extrema. Therefore, it is difficult to clearly state if players could perform any better. Surely, training results may vary depending on the initial parameter setup. However, an important lesson is the training can be adjusted until a satisfactory outcome is achieved.

XI. SUMMARY

Through the training process, the players acquire knowledge that is encoded in the utility model. The knowledge can be used easily, requiring only reduced calculation. However, the information stored in a neural network cannot simply be exported to a human-readable form, unless it is a rule-based model. The study showed that the method can be successfully

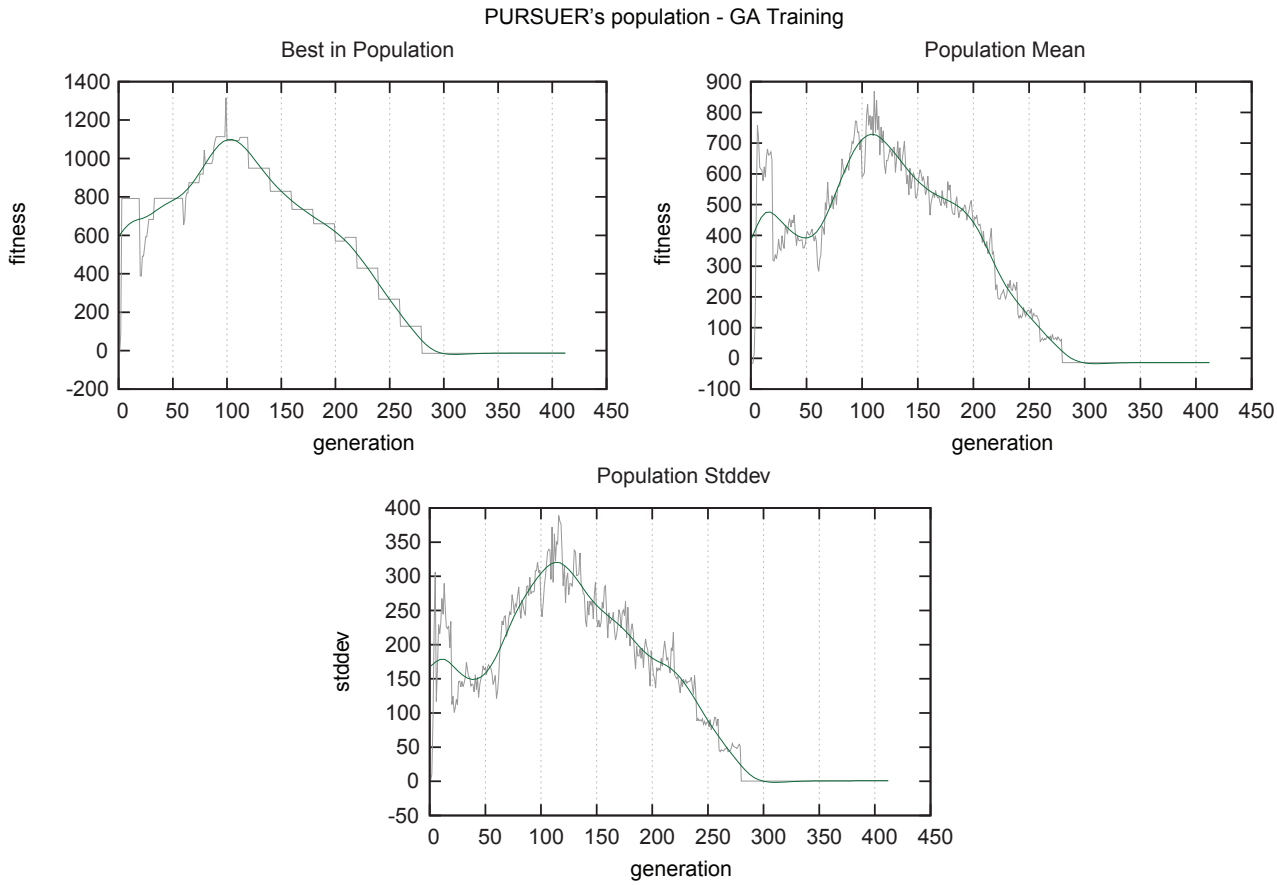

Fig. 6. The plots show the best fitness, average population fitness, and fitness standard deviation over generations of pursuer's population training.

used for observing how the system behaves depending on the game configuration.

Earlier studies have shown that the deeper Minimax algorithm penetrated a game tree, a more intelligent behavior of a player was observed, which is consistent with the theory. Also, it should be noted that the number of possible states of an unrevealed opponent taken into account by the algorithm has a congruent impact.

Another practical observation from the experiment is that the training phase is computationally expensive. Regardless of the fact that the implementation was using C++11 standard and calculations were efficiently distributed over several threads [23], the study was strongly impeded by time-consuming experiments. Accompanying tests proved that the process cannot be easily accelerated by GPU computing [24], [25]. The bottleneck is the Minimax algorithm that involves multiple calculations of the neural network's output. Despite the fact that computations in each network layer can be parallelized by GPU, the gain compared to CPU calculations was hard to observe.

An important achievement in the experimental study is that the players' strategies stabilize at some point. Strategies of competing players often oscillate when a pure-strategy equilibrium cannot be found. Although the stabilization is only one of the conditions that have to be satisfied to obtain a good solution, this should be considered as a significant success.

XII. Future Work

From a theoretical point of view, adopting a pure strategy may not be the most suitable model for this game. Nonetheless, it is one of the simplest approaches, and proved to be sufficient. One of the interesting directions is to check a mixed strategy and stochastic decision rules. Subsequently, player positions and environment parameters should be randomized. Undoubtedly, it will substantially increase the training process since additional evaluation repetitions are required to obtain an acceptable statistical significance level. However, the new model addresses environments with uncertain information, and it should give better results.

Because of the overall problem difficulty, the initial study has employed very basic tools that are commonly used in the field of computational intelligence. In the next step, it would be beneficial to use Minimax hybrids to increase the performance of the tree search [26]. Deep Learning methods could be applied to improve the training process and the generalization capabilities of a neural network [27].

At the current stage of development, the system cannot be used for building a universal model of AUV strategy that could

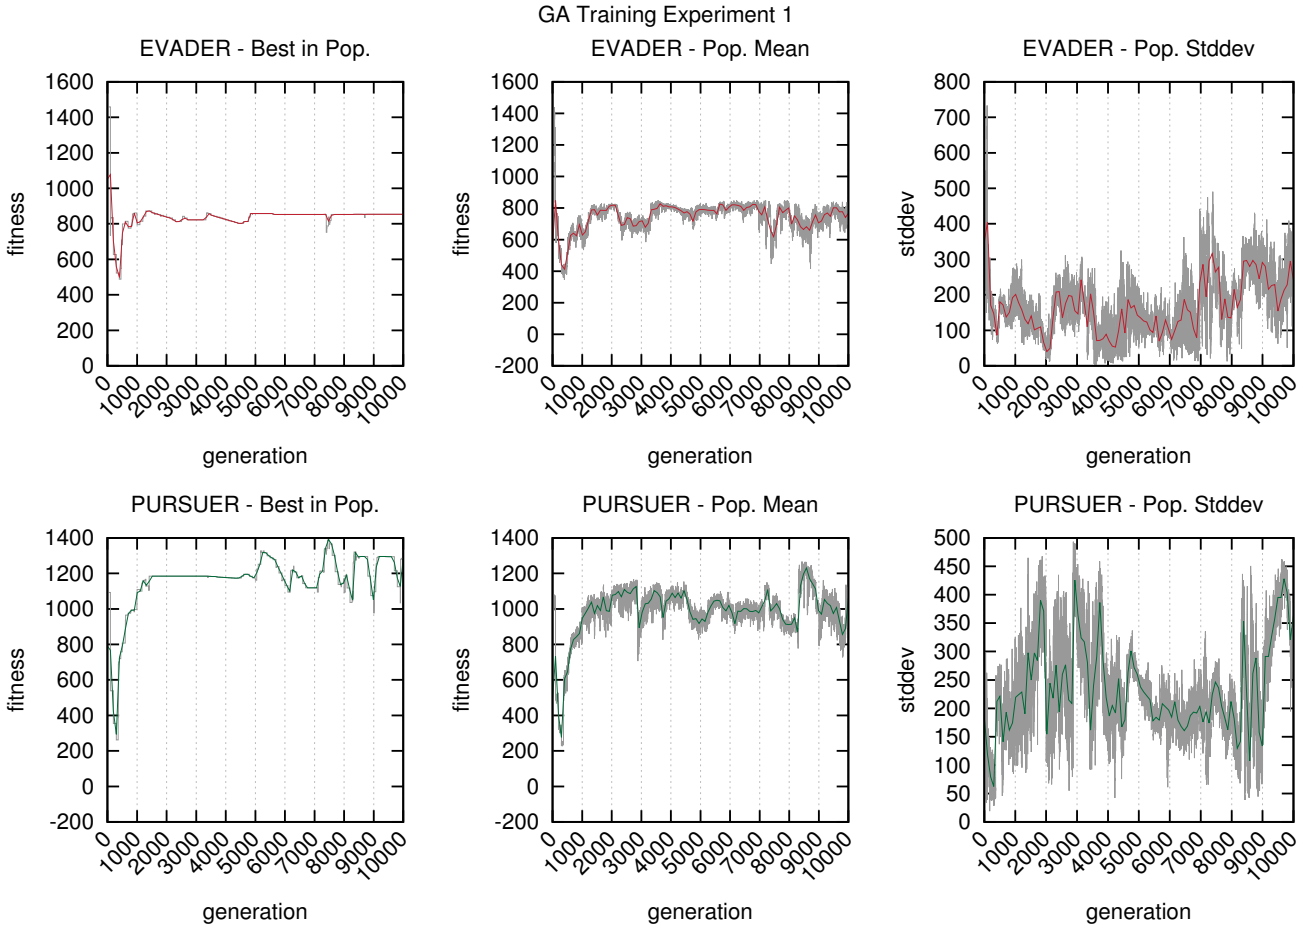

Fig. 7. A long training run 1.

be tested on actual hardware. Preparation of a reliable strategy requires a well-organized training process. The training should therefore introduce more realistic environmental parameters and cover various game scenarios including different player and mission arrangements. It should also simulate noisy and misleading information. Therefore, one of the primary goals is employing an accurate model of underwater signal propagation. It should be emphasized that the quality of the system must be evaluated according to the military knowledge and real-life scenarios.

***Abstract*—The exploration of a data set consists in grouping similar data. The classical statistical methods often fail when there is is no minimal assumption on the clusters. Our approach is based on the links between data, but the pairwise comparison between data and the importance of the links depend heavily on context where data lies. We propose to analyze a dataset through methods of the social choice theory where data plays both the role of a candidate and the role of a voter. The candidates are ranked by the voters and each voter gives a score to each candidate according to his ranking. We propose one specific election for each voter based on his preferences. The voters of these elections have weights computed according to their respective behaviors. In this approach, the conventional similarity indices between data are used to define the electoral behavior of each data.**

***Index Terms*—exploratory data analysis, social choice theory, representatives, vote, data reduction**

I. Introduction

ONE OF the first steps in the exploration of a data set consists in grouping similar data. For this purpose, lot of clustering methods are proposed in literature to detect clusters within a dataset. The methods often fail when there is neither a minimal assumption on the clusters nor a minimal model of the clusters. For instance the classical k-means method [8] assumes both that data could be grouped around mean values or mean vectors and that the number of clusters is known. Unfortunately the first assumption leads to important constraints on the shape of the clusters in the data space and this condition is seldom corroborated. Other approaches of clustering are based on links between data. The hierarchical agglomerative clustering methods are probably the most known methods for exploring the datasets using such links. The links are usually drawn from pairwise comparisons between data and they are based on distances or pseudo-distances [4]. But the pairwise comparison between data and the importance of the links depend heavily on context where data lies. Indeed the ranges of values of a comparison index could change when data are not in the same clusters. In other words, the links could be well suited to connect two data in one cluster and they are not adapted for the other clusters. Thus this paper proposes a new way to define the links between data through the ranks to overcome this constraint of cluster context.

We propose to analyze a dataset through methods of the social choice theory where data plays both the role of a candidate and the role of a voter [5]. The social choice inspired approach brings a metaphorical meaning that help to understand the concepts (as in bioinspired or human-inspired algorithms [10]).

The candidates are ranked by the voters and each voter gives a score to each candidate according to his ranking. Then the scores of the voters are aggregated using generally the sum of scores obtained by the candidates. In the classical procedure of election, each voter has the same weight in the aggregation. Thus this procedure is the same for all clusters. In this paper the election procedures differ from one cluster to another. We propose one specific election for each voter based on his preferences (i.e. one election per voter). The voters of these elections have weights computed by comparison of their respective behaviors. The weights differ from one election to another. The links between data are defined using these elections where each voter selects one candidate for representing itself within the dataset. The chainings between the voters and their representatives define data communities. Thus the partitions of the dataset with these communities give us a new way to explore the dataset.

The following section describes the procedure of election that we propose in this paper. It leads to a graph that permit us to structure the dataset. Then we study and we assess this method for structuring a dataset. Finally we discuss and we conclude this work.

II. Dataset and Voters

A. Collective preference

Let Ω be a dataset with n elements:

$$\Omega = \{X_1, X_2, ...X_n\}$$

In the framework of the social choice theory [9] [3], Ω is both a set of n voters and a set of n candidates. Thus each data is a voter of Ω and it also becomes an alternative that the other voters could prefer as a representative in Ω (i.e. an elected candidate of Ω).

The dataset is provided with a pairwise comparison index between data. We call D this index. In this paper, we use Euclidean distance as pairwise comparison index. But we need only two properties of D. When X_i, X_j, and X_k are three data in Ω, we should have:

- $D(X_i, X_i) \leq D(X_i, X_j)$,
- $D(X_i, X_j) \leq D(X_i, X_k)$ if X_j is more similar to X_i than X_k is (in other terms : X_j is prefered to X_k by X_i)

978-83-60810-90-3/$25.00

In the following, any pairwise comparison index should respect these two properties.

With using such a pairwise comparator, each data X_i is considered as a voter which can rank the other data. The ranks of X_i are defined between 1 and n. The ranking function is called R_{X_i} and we have:

- $R_{X_i}(X_i) = 1$,
- $R_{X_i}(X_j) \leq R_{X_i}(X_k)$ if $D(X_i, X_j) \leq D(X_i, X_k)$.

The data X_i is a voter that selects the candidates using R_{X_i} as preference indicator. The vote of X_i is realized with a score of Borda which is a classical method of social choice theory [6] [1]. In this paper, the score of Borda given by the voter X_i to the candidate X_j is defined as:

$$S_{X_i}(X_j) = \frac{n - R_{X_i}(X_j)}{(n-1)}$$

where X_j is a candidate and X_i is a voter.

The classical election procedure attributes the sum of the scores of the voters for each candidate. Thus the candidate X_j obtains the global score $S(X_j)$ defined by:

$$S(X_j) = \sum_{i=1}^{n} S_{X_i}(X_j)$$

This procedure leads to nominate the best candidate as the one with the highest score. But each voter has the same weight in this overall vote. This overall election does not take into account that two voters could belong to two different clusters.

In the following, we will change the paradigm. We consider that each voter has his own election procedure that is adapted to itself. The following describes the specific procedure for each voter.

B. Individual preference

Each voter will choose its candidate with its own election procedure. Let X_i be a voter that chooses the candidates. Each data X_j is also a voter of the election that X_i proposes. All the voters of Ω have weights that are specific of the election procedure of X_i. The weight of X_i itself is equal to one. The more similar to X_i a voter X_j is, the higher the weight of X_j is in this election. The weights are based on the similarity between the voters and the similarities with X_i are used for the election that X_i proposes.

Let us describe the similarity of the behaviors of two voters. We consider that two voters X_i and X_j are similar when their respective ranking function R_{X_i} and R_{X_j} are similar. The correlation of Spearman [11] is classically used to evaluate the correlation between ranks. The higher the correlation is close to 1, the more ranks are correlated. In this paper the correlation gives us an index of the similarity of the behavior of two voters. Spearman correlation between X_i and X_j is defined by:

$$Cor(X_i, X_j) = 1 - \frac{6 * \sum_{k=1}^{n} (R_{X_j}(X_k) - R_{X_i}(X_k))^2}{n^3 - n}$$

$Cor(X_i, X_j)$ lies between -1 and 1. We consider that X_i and X_j have similar behavior when the Spearman correlation is greater then a positive threshold which is a significance level. If we call t this level, then X_i and X_j become similar when $Cor(X_i, X_j) \geq t$.

Let $w_{X_i}(X_j)$ be the weight given to the voter X_j for the election based on the preferences of X_i.

We define this weight by:

$$w_{X_i}(X_j) = max(0, \frac{Cor(X_i, X_j) - t}{1 - t})$$

The weight lies between 0 and 1. It is equal to zero when X_i and X_j are not similar.

In the election based on the preferences of X_i, each candidate X_j obtains a score $Score_{X_i}(X_j)$ defined by:

$$Score_{X_i}(X_j) = \sum_{k=1}^{n} w_{X_i}(X_k) \times S_{X_k}(X_j)$$

Thus this election is based on a sum of scores weighted by the similarity of the voters with X_i. Other voters similar to X_i participate in the election of the representative of X_i.

C. Communities of voters

The representative of X_i becomes the one which have the highest score within Ω for the election based on the preferences of X_i. So each voter X_i has one representative in Ω elected by the specific election of X_i : $Rep_{Score}(X_i)$.

$$Score(Rep_{Score}(X_i)) = \max_{k=1}^{n}(Score_{X_i}(X_k))$$

We define a graph in Ω where the vertices are the voters and the edges are the links between the voters and their representatives. Each connected components of this graph defines a community of voters. The more we claim a high correlation between voters, the more the size of communities is reduced. In other words, the higher the threshold t is close to 1, the more the communities are small and the number of communities increases within Ω. These communities give a data structuration to study a dataset when we have neither assumption nor model for the clusters.

If the threshold t is close to 1, the representative of each voter X_i is based only on the preference of X_i. If this threshold decrease, other voters similar to X_i participate in the election of the representative of X_i.

Each data Xi has two representatives: the favorite candidate of Xi and the elected candidate of the local election of Xi. For each data X_i we define an individual loss indicator, wich represents the correlation loss between X_i and theses two representatives. The collective $loss$ indicator for the data is the sum of all the individual loss.

$$loss = \sum_{k=1}^{n} loss_{Ind}(X_k)$$

$$loss_{Ind}(X_i) = Cor(X_i, Rep_S(X_i)) - Cor(X_i, Rep_{Score}(X_i))$$

with

$$S(Rep_S(X_i)) = \max_{k \neq i}(S_{X_i}(X_k))$$

$$Score(Rep_{Score}(X_i)) = \max_{k \neq i}(Score_{X_i}(X_k))$$

III. Experimental Study

This section is devoted to the study of our method for structuring a dataset with a pairwise comparator. First let us present an example of the different steps of the dataset structuration with our method. In a second section, we assess the quality of this structuration using simulated data. Third the quality is assessed when using one real dataset.

A. Workflow for structuring a dataset

We propose to explore a dataset with 20 simulated data in dimension 2 (see Fig.1-A). The pairwise comparisons are based on Euclidean distance. We conduct the overall election with a classical Borda's procedure. This overall election permits us to propose the best candidate which could be considered as the representative of the whole dataset (see Fig.1-B). Then we proceed to the elections based on the individual preferences for obtaining linking each data with another one. These links allow to define communities of voters. The procedure of the election with the individual preferences is based on a threshold of correlation. Fig.1-C shows the number of communities when the correlation threshold increases.

The higher the threshold, the higher the number of communities is. The highest threshold leads to the highest number of unique representatives. The higher the threshold, the lesser the losses are (both individual and collective). When the threshold is equal to 0.5, 0.95 and 0.99 (Fig.1-D, Fig.1-E, Fig.1-F) :

- the number of communities is 2, 5 and 6 (resp.)
- the number of unique representatives is 4, 14 and 15 (resp.)
- the collective loss is 0.78, 0 and 0 (resp.)

This number of communities is less than the number of data. That gives a new way for the exploration of a dataset.

B. Assessment of the links structuring a dataset

TABLE II: Number of communities of voters, number of unique representatives and loss, using the three classes of Fig.2 and criterion of assessment when the threshold of correlation varies between 0 and 1.

	t	nbcom	nbrep	loss
1	0.00	3	20	6.99
2	0.05	3	19	6.65
3	0.10	3	19	6.37
4	0.15	3	18	6.49
5	0.20	3	16	6.23
6	0.25	3	17	6.09
7	0.30	3	17	6.00
8	0.35	3	16	6.01
9	0.40	3	16	6.03
10	0.45	3	16	5.95
11	0.50	3	16	5.82
12	0.55	3	17	5.70
13	0.60	3	19	5.47
14	0.65	3	21	5.00
15	0.70	3	24	4.58
16	0.75	3	31	4.04
17	0.80	3	35	3.03
18	0.85	4	47	2.32
19	0.90	7	58	1.37
20	0.95	10	74	0.52
21	1.00	150	150	0.00

In this paper, we place ourselves resolutely in the context of the exploratory analysis of data without any a priori assumption on eventual classes, we only use an index of pairwise comparison. But the use of classes gives the most classical way to evaluate a structuration of a dataset. So this paper uses classes to assess only the links that we propose between data. The detection of classes (i.e. the clustering) is out of the scope of this paper.

The assessment of our method for structuring a dataset is performed using a dataset with known classes. Each data belongs to one class and it has the label of its class. Using our structuration each data is also linked to a representative in the dataset. A data is well represented when its own label is equal to the label of its representative. In such case the link between a voter and its representative remains inside a class of the dataset. We propose a structuration of the dataset with graphs. The vertices of the graph are labeled and the edges are labeled when their extremities have the same label. We compute the number of the labeled edges.

The percentage of such edges could assess the quality of the structuration through a graph. Unfortunately the classes are unknown in the first step of data exploration. Thus we propose to use the loss indicator instead of this percentage of labeled links.

The higher is this quality criterion and the lower the number of communities is, then the better the structuration is.

Table II gives the values of this criterion when the threshold of correlation lies between 0 and 1. The dataset is simulated in dimension 2 (see Fig.2) and the number of detected

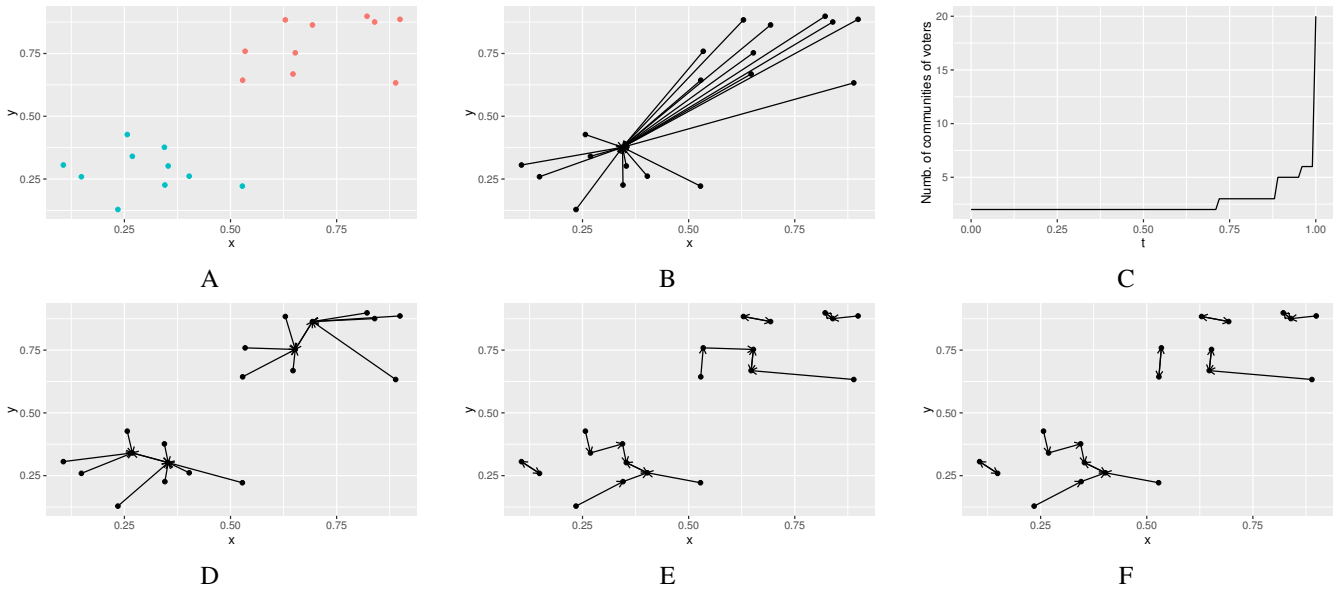

Fig. 1: Twenty simulated data in dimension 2 (A), the overal election selecting one representative (B) and elections based on individual preferences leading to several communities whose number depends on the correlation threshold (C). 2, 5, and 6 communities respectively obtained with a correlation threshold equal to 0.5, 0.95, 0.99 (D, E, F).

communities of voters is displayed when the threshold of correlation between voters increases from 0 to 1. Fig.2 gives also three examples of the communities when the threshold is respectively equal to 0, 0.5 and 0.9.

TABLE III: Number of communities of voters, number of unique representatives and loss, using the three classes of Fig.3 and criterion of assessment when the threshold of correlation varies between 0 and 1.

	t	nbcom	nbrep	loss
1	0.00	1	74	35.49
2	0.05	1	70	32.88
3	0.10	1	69	30.32
4	0.15	1	72	28.65
5	0.20	1	69	26.90
6	0.25	1	70	24.89
7	0.30	1	74	23.56
8	0.35	4	79	21.55
9	0.40	4	75	19.58
10	0.45	3	76	17.25
11	0.50	3	82	15.09
12	0.55	5	92	11.73
13	0.60	7	101	9.50
14	0.65	7	107	7.94
15	0.70	11	118	6.54
16	0.75	13	128	5.27
17	0.80	14	134	3.99
18	0.85	19	149	3.10
19	0.90	25	166	1.96
20	0.95	36	186	0.88
21	1.00	380	380	0.00

In the following we simulated a dataset with three classes that are hardly distinguishable because of their shapes and their overlapping. The dataset ($n = 380$) is simulated in dimension 2 with three uniform distributions in two rectangular crowns with 200 and 80 data and one rectangle with 100 data (see Fig.3). The number of voter communities is displayed when the threshold of correlation between voters increases from 0 to 1. Fig.3 gives also three examples of the communities when the threshold is respectively equal to 0.5, 0.8 and 0.99,

- the number of communities is 3, 14 and 71 (resp.)
- the number of unique representatives is 82, 134 and 212 (resp.)
- the collective loss is 15.09, 3.99 and 0.11 (resp.)

the number of communities are respectively equal to 8, 16 and 106. In such a case the classical clustering methods fail to detect meaning clusters. Indeed classical clustering methods are often based on statistics such as means or medoids. They use these statistics to determine the clusters and they make the assumption that data could be well represented with such statistics. Unfortunately these statistical approaches are unadapted in this case. Table III gives the values of our assessment criterion when the threshold of correlation lies between 0 and 1.

C. Assessment with real data

We use the databases from Machine Learning Repository of UCI [2] to assess our method with real data. Iris is the classical database that has 150 iris plants with 4 attributes and three clusters. Table IV gives the results we obtain with this dataset. Fig.4 displays the number of voter communities and the percentage of labeled links when the correlation threshold increases from 0 to 0.99, and the loss indicator.

IV. Discussion and Conclusion

In this paper we describe and we implement a method for exploring a data set. The main originality of this method lies in

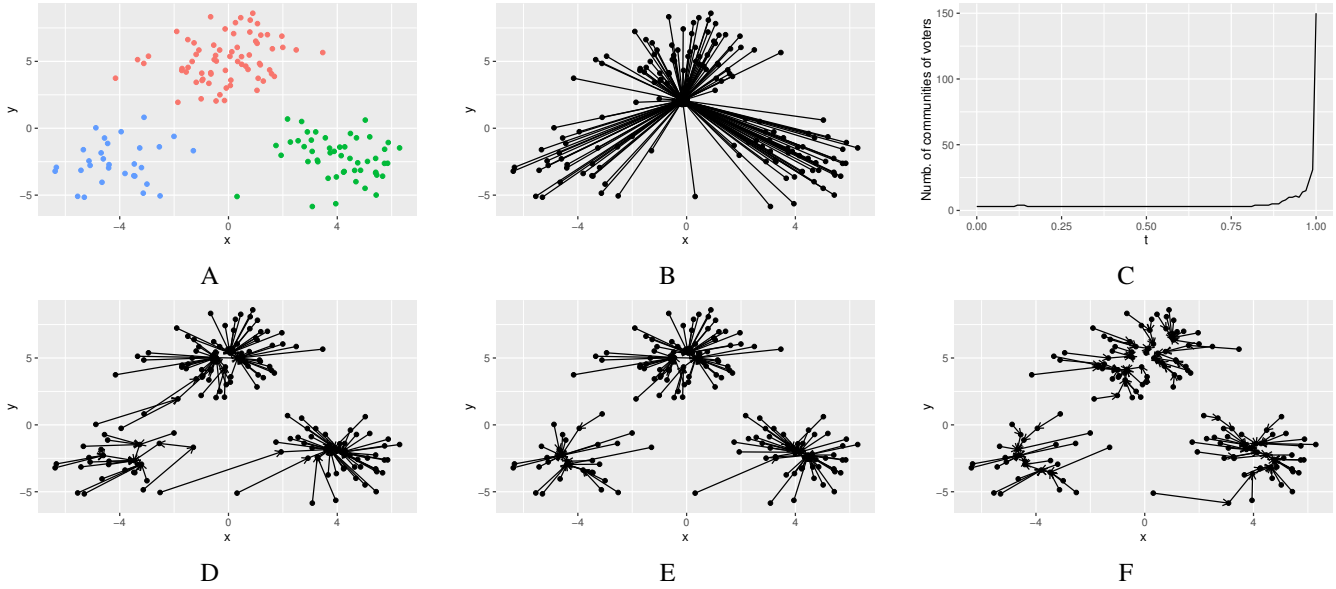

Fig. 2: Simulated data with three classes (three multinomial distributed subsamples)

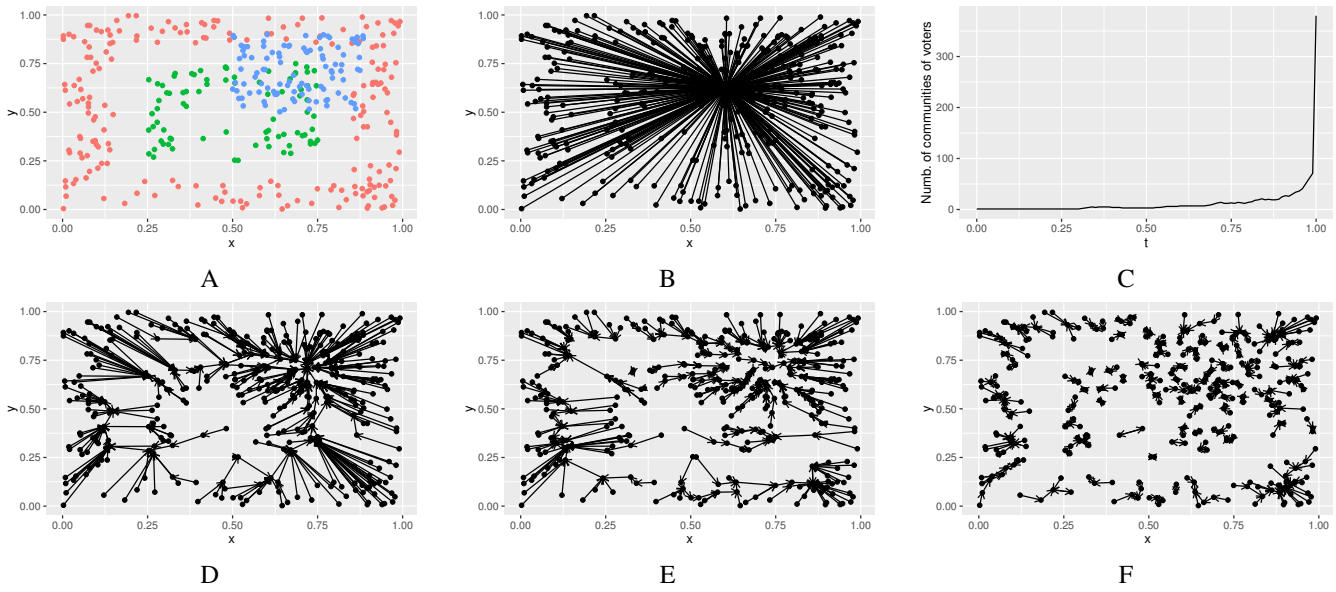

Fig. 3: Simulated data with three uniform distributions in two rectangular crowns of respectively 200 and 80 data and one rectangle of 100 data. The three classes are hardly distinguishable with classical clustering methods.

the definition of links between data. These links are based on a local election mechanism with individual preferences that connects each data to another data designated by the local election process. In this approach, the conventional similarity indices between data are used to define the electoral behavior of each data. As the preferences of the users in a recommender system, the voters then have weights corresponding to the similarity of electoral behaviors. However this approach by recommender systems is not used in this paper and the robustness of our method when data is incomplete or imperfect could be studied in future work.

Another important contribution of this work is to reduce the size of a data set from the exploration of a set of n data to a set of p communities where p is much smaller than n. This approach of dimensionality reduction has the advantage that it makes no assumption about the shape or the exact number of communities. It thus constitutes a preliminary step to a more meaningful clustering and it leads to select a more suitable method for the exploring dataset. This extension of our work could also be involved in further work.

***Abstract*—Fishing activity detection is important for fishery management to maintain abundant oceans. This paper presents a novel approach to identifying fishing activities from Automatic Identification System (AIS) data using Conditional Random Fields (CRFs). CRFs are popular for solving structured prediction problems such as sequence labeling in natural language processing. To model the conditional probability distributions that can identify fishing activities of the vessel points, we treat attributes of vessel points as observed variables and the fishing and non-fishing labels as hidden variables. We present three experiments and two comparisons to demonstrate the stability and effectiveness of the resulting models.**

I. Introduction

GLOBAL overfishing causes a dramatic decline in the fish population. Several major commercial fish species are endangered which threatens the ocean ecosystem. This affects millions of people who depend on fish for food and living. According to a 2014 report by the United Nations Food and Agriculture Organization[1], more than 90 percent of global fisheries are over exploited. Unfortunately, these fishing activities are often illegal, unreported and unregulated (IUU), which makes tracing them a challenge. Thus, in order to make fishing activities more transparent for practicing sustainable fisheries, fishing activity detection is urgently needed.

In 2000, International Maritime Organization (IMO) firstly introduced the Automatic Identification System (AIS) to enhance the security and safety of maritime navigation. Ships equipped with AIS can automatically broadcast information, including unique identification (Maritime Mobile Service Identity, MMSI), position, speed, course and further details of the vessel to its nearby ships and coastal authorities. AIS data are openly accessible and not encrypted. In 2008, satellites AIS technology was implemented, enabling the collection of massive and reliable information of vessels in global areas within seconds. Consequently, satellites AIS data could be used as an ideal source to monitor vessel movements and detect fishing activities around the world.

In this paper, we present a novel approach for identifying fishing activities using Conditional Random Fields and demonstrate its stability of performance using three different evaluation experiments and two comparisons. The remainder of the paper is organized as follows: In Section 2, we describe relevant literature; in Section 3, we explain conditional random fields (CRFs) and then elaborate on how to apply them to identify fishing activities; in Section 4, we present three experiments and two comparisons and their results on historical AIS data to demonstrate the stability and effectiveness of our models; finally, in Section 5, we discuss practices and provide direction for future work.

[1]Food and Agriculture Organization of the United Nations, 2014. http://www.fao.org

II. Background and Related Work

CRFs are prevalent in solving structured prediction problems [1]. It has been applied to many tasks in natural language processing (NLP) such as part-of-speech (POS) tagging [2], [3], shallow parsing [4] and name-entity recognition (NER) [5], [6]. In addition, Hierarchical CRFs [7] has been applied to extract human activities. We find similarity between these tasks and fishing activity detection from the following perspective. In POS tagging, the goal is to label words in sentences using word-category tags. The labels depend on both the word's meaning and context. This task involves two random variables, X and Y, where X is a sequence of words, and Y is a sequence of POS tags. Linear-chain conditional random fields can model the conditional probability distribution $p(\mathbf{y}|\mathbf{x})$ to predict POS tags. Similarly, the task of fishing activity detection involves two random variables, X and Y, where X is the observed random variable (which represents sequences of coordinates and speeds), and Y is the hidden random variable to be predicted (Y is a sequence of fishing and non-fishing labels). Consequently, it is reasonable to test whether the linear-chain conditional random fields can model the conditional probability distribution $p(\mathbf{y}|\mathbf{x})$ of fishing–non-fishing to detect fishing activities.

Most studies of fishing activity detection focus on Trawlers. For example, Mazzarella et al. identified fishing events using a clustering method [8], and Peel and Good recognized vessel activities using Hidden Markov Model [9]. It is found that trawler fishing activities are highly related with speed, meaning speed can provide useful information to aid the classification of fishing activities. However, for longliners, Souza et al. found that there is no obvious pattern to distinguish fishing activities using speed information alone [10]. Souza et al.

applied Lavielle's unsupervised trajectory segmentation algorithm, inspired by animal movements, to identify the longliner fishing behavior. Jiang et al. applied a deep learning approach using autoencoders (AE) that are pretrained with restricted Boltzmann Machines [11]. To the best of our knowledge, [10] was the first paper that we can find to apply Machine Learning to the task of fishing and non-fishing detection. Here we apply a supervised machine learning method (CRFs) to detect longliner fishing activities.

III. Linear-Chain Conditional Random Fields

A. Basic Principles of Linear-Chain Conditional Random Fields

Linear-chain conditional random fields are undirected graphical models that represent conditional probability distributions of random variables $V = X \cup Y$ that take the form

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \prod_{j=1}^{n} \psi_j(\mathbf{x}, \mathbf{y}), \tag{1}$$

where X is a set of observed variables, Y is a set of labels that we need to predict, and $Z(\mathbf{x})$ is a normalization or partition function

$$Z(\mathbf{x}) = \sum_{\mathbf{y}'} \prod_{j=1}^{n} \psi_j(\mathbf{x}, \mathbf{y}'), \tag{2}$$

where $\psi_j(\mathbf{x}, \mathbf{y})$ are compatibility functions over a subset of random variables $A \subset V$, and n is the number of compatibility functions $\psi(\mathbf{x}, \mathbf{y})$ that factorize the probability distribution. Given compatibility functions in the form

$$\psi_j(\mathbf{x}, \mathbf{y}; \lambda) = exp(\sum_{i=1}^{m} \lambda_i f_i(y_{j-1}, y_j, \mathbf{x}, j)), \tag{3}$$

the conditional probability distribution can be written as

$$p(\mathbf{y}|\mathbf{x}; \lambda) = \frac{1}{Z(\mathbf{x})} exp(\sum_{j=1}^{t} \sum_{i=1}^{m} \lambda_i f_i(y_{j-1}, y_j, \mathbf{x}, j)), \tag{4}$$

where m is the number of feature functions, t is the length of sequence $\mathbf{y}$, and λ is a set of weight parameters that help provide weighted average over these feature functions.

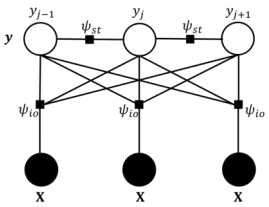

Fig. 1. Factor graph of linear-chain conditional random fields. $\mathbf{x}$ denotes a sequence of input data, $\mathbf{y}$ denotes a sequence of labels and ψ_{st} and $\psi_{\mathbf{i}o}$ denote two compatibility functions.

In (3), the parameter λ_i of compatibility functions $\psi_j(\mathbf{x}, \mathbf{y}; \lambda)$ does not depend on the index j, which means the parameters are shared along the linear chain. Fig. 1 visualizes the factor graph of linear-chain conditional random fields with two compatibility functions. In (4), the first sum runs over each position of the linear chain and the second sum runs over each feature function. The conditional probability $p(\mathbf{y}|\mathbf{x}; \lambda)$ can be represented as a mapping function from features to labels. Thus, the selection of feature functions is of great significance for the performance of a model. The parameters can be estimated using maximum-likelihood. The log-likelihood can be estimated with the Forward-Backward Algorithm. The inference of finding the most likely sequence $\mathbf{y}$ given observations $\mathbf{x}$ is performed using the Viterbi Algorithm [1]. The remainder of this section demonstrates how we adapt CRFs to identifying fishing activities.

B. Discretization

Compared with POS tagging where the input is a sequence of discrete words, AIS trajectory consists of real-valued features that are continuous by nature, such as longitudes and latitudes. Conditional random fields can model real-valued features, but they typically require proper normalization so that the value of the feature function is a linear function of the conditional probability $p(\mathbf{y}|\mathbf{x})$. However, since the relationships between AIS features and fishing activity labels are non-linear, we discretize the features to relax the normalization constraints and allow the conditional random fields to learn $p(\mathbf{y}|\mathbf{x})$ with a more flexible representation. We use a variant of equal interval binning discretization in our work. Each bin is associated with a set of parameters to fit the model.

C. Feature Functions

We use two sets of compatibility functions ψ_{st} and $\psi_{\mathbf{i}o}$ to factor $p(\mathbf{y}|\mathbf{x})$:

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} (\psi_{st}(\mathbf{x}, \mathbf{y}) \cdot \psi_{\mathbf{i}o}(\mathbf{x}, \mathbf{y})). \tag{5}$$

The first compatibility function ψ_{st} is transition compatibility function, which models the transition probability of the labels from one state to another and takes the form

$$\psi_{st}(\mathbf{x}, \mathbf{y}; \lambda) = exp(\lambda_{st} f_{st}(y_{j-1}, y_j, \mathbf{x}, j)), \tag{6}$$

where $f_{st}(y_{j-1}, y_j, \mathbf{x}, j)$ is transition feature function that takes the form

$$f_{st}(y_{j-1}, y_j, \mathbf{x}, j) = 1_{\{y_{j-1}=s\}} 1_{\{y_j=t\}}, \tag{7}$$

and st are all possible combinations of labels, y_{j-1} and y_j are the labels of the $(j-1)$-th and j-th position of the linear chain and $\mathbf{x}$ is the input sequence. More concretely, if the labels can only take two values: 0 and 1, the feature functions can be rewritten as

$$f_{00}(y_{j-1}, y_j, \mathbf{x}, j) = 1_{\{y_{j-1}=0\}} 1_{\{y_j=0\}}, \tag{8}$$

$$f_{01}(y_{j-1}, y_j, \mathbf{x}, j) = 1_{\{y_{j-1}=0\}} 1_{\{y_j=1\}}, \tag{9}$$

$$f_{10}(y_{j-1}, y_j, \mathbf{x}, j) = 1_{\{y_{j-1}=1\}} 1_{\{y_j=0\}}, \tag{10}$$

$$f_{11}(y_{j-1}, y_j, \mathbf{x}, j) = 1_{\{y_{j-1}=1\}} 1_{\{y_j=1\}}, \tag{11}$$

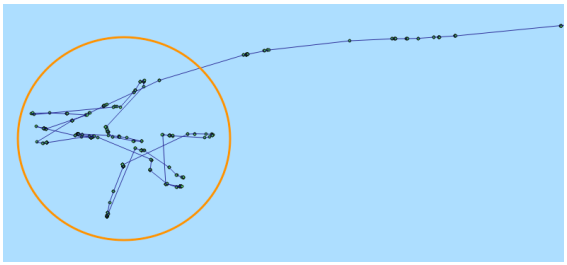

Fig. 2. Differences of fishing and non-fishing tracks. Tracks in the orange circle are fishing tracks and the rest are non-fishing tracks.

which are parameterized by $\lambda_{0,0}, \lambda_{0,1}, \lambda_{1,0}, \lambda_{1,1}$ respectively.

The second compatibility funciton $\psi_{\mathbf{i}o}$ is state-observation compatibility function, which models the probability distribution of the labels given a set of observations. The subscript $\mathbf{i}$ within $\psi_{\mathbf{i}o}$ represents a set of input observations, which is different from the index i of parameter λ in (4). The state-observation compatibility function can be written as

$$\psi_{\mathbf{i}o}(\mathbf{x}, \mathbf{y}; \lambda) = exp(\lambda_{\mathbf{i}o} f_{\mathbf{i}o}(y_{j-1}, y_j, \mathbf{x}, j)), \tag{12}$$

where $f_{\mathbf{i}o}(y_{j-1}, y_j, \mathbf{x}, j)$ is state-observation feature function that takes the form

$$f_{\mathbf{i}o}(y_{j-1}, y_j, \mathbf{x}, j) = 1_{\{y_j = o\}} 1_{\{\mathbf{x}=\mathbf{i}\}}, \tag{13}$$

where $\mathbf{i}o$ are all possible combinations of input features and its corresponding labels. The state-observation feature functions are parameterized by a set of parameters $\lambda_{\mathbf{i}o}$.

IV. Experiments

A. Data Preprocessing

AIS data contain attributes including MMSI, time, longitude, latitude, speed over ground (SOG) and course over ground (COG). In the experiments, we use historical AIS data from 14 longliners around the world collected from June 1st 2012 to Dec 31st 2013. The fishing and non-fishing activities of these data are labeled by a marine biology expert. Fig. 2 shows the differences between fishing and non-fishing tracks that are recovered from discrete AIS signals. The fishing tracks are in the form of a zigzag. The non-fishing tracks tend to follow smooth lines. To preprocess the data, we perform data cleansing to remove uninformative data, data conversion from absolute values to differential values (i.e. difference with to the previous point), data discretization to transform continuous value into nominal counterparts, and feature selection to fit the model with the most relevant features.

1) Data Cleansing: We sort the data points of each longliner in chronological order. We then remove repetitive data points as well as data points with incomplete features. We further detect and remove outliers if the speed exceeds the normal range and the location deviates from its normal trajectories. After data cleansing, we have 505893 longliners data points in total. On average, 77% of the data points are labeled as fishing. Table I shows a summary of the 14 longliners after cleansing.

TABLE I
Summary of the 14 vessels data

Track ID	Track Size	# of Fish Points	% of Fish Activity
1	21556	17148	79.6
2	8829	6326	71.7
3	30166	24422	81.0
4	6086	4226	69.4
5	28184	22153	78.6
6	37710	32977	87.4
7	24715	16857	68.2
8	2032	1755	86.4
9	12111	8470	69.9
10	17161	14277	83.2
11	2670	1761	66.0
12	90429	78765	87.1
13	108826	73005	67.1
14	115418	86256	74.7
Mean	36135	27742	76.5

2) Differential longitude and latitude: In our early experiments, we trained our predictive models using absolute value of longitudes and latitudes. However, we find the resulting models overfitting on the training data and cannot generalize to different locations. In order to generalize the model into other areas, we use differential longitude, that is the difference of absolute longitudes between the current and previous data points. Thus the absolute longitudes $L = [l_1, l_2, ..., l_n]$ are transformed to differential longitudes that takes the form $L_d = [l_2 - l_1, l_3 - l_2, ..., l_n - l_{n-1}]$. Similarly, we transform absolute latitudes to its differential form.

3) Discretization: As mentioned in Section 3, we discretize the attributes of data using a variant of equal interval binning. Early experiments indicate different features require different sizes of intervals. For differential longitudes and latitudes, the interval size m takes the form

$$m = \begin{cases} 0.05 & l \in [-1, 1] \\ 20 & l > 1, l < -1 \end{cases} \tag{14}$$

where fine intervals are selected in the range $[-1, 1]$. Because most differential longitudes and latitudes are between -1 and 1, fine intervals provide a larger number of parameters to fit the model compared to coarse intervals, when l is greater than 1 or less than -1. For SOG, we set m to 0.5. For COG, we set m to 20.

4) Feature Selection: In early experiments, we built the model using different combinations of features, such as differential longitude, differential latitude, SOG and COG. We find the model built with differential longitude, differential latitude, and SOG performed the best. We use these features in the following three experiments of this paper, shown in Fig. 3. More precisely, we use the following feature functions in our experiments: 1) pairs of longitudes and latitudes are selected to represent the positions of data points (colored in orange); 2) pairs of neighbouring longitudes are selected to represent the changes of longitudes over time (colored in red); 3) pairs of neighbouring latitudes are selected to represent the changes of latitudes over time (colored in green); 4) speed and pairs of neighbouring speed are selected to represent speed information

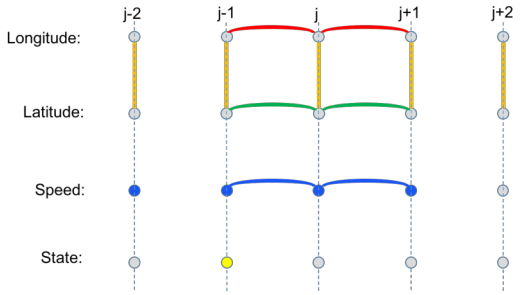

Fig. 3. Feature functions. When predicting the label of index j, the values of colored dots as well as the paired values connected by solid lines are selected as feature functions.

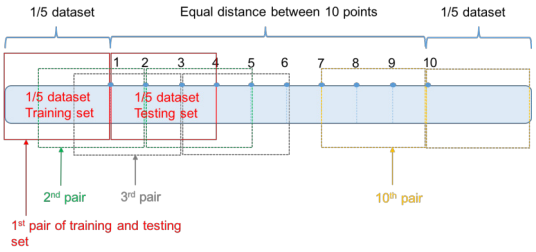

Fig. 4. Modified Monte Carlo. Choose 10 points as split point, obtain 10 pairs of training and testing sets.

(colored in blue); 5) label of the previous state is selected to help model the transition probability between states (colored in yellow). These feature functions employ spatial and temporal information to aid the classification task.

B. Results

We train CRF models using CRF++ [12]. We design three experiments to evaluate the model: Modified Monte Carlo methods, Iterative Leave One Batch Out (LOBO) and Stratified LOBO. We then compare CRFs with autoencoders and a data mining approach.

1) Modified Monte Carlo: Here, we concatenate all the data and apply Monte Carlo methods to get 10 pairs of training and testing data sets. The size of the training and testing set is $\frac{1}{5}$ of the total number of data points. To find the dividing points of the ten Monte Carlo experiments, we first set aside $\frac{1}{5}$ of the whole data set in the front and back respectively, then select 10 dividing points with identical intervals that can cover the entire dataset. For each selected point, the $\frac{1}{5}$ portion of the data set to the left of the point and the $\frac{1}{5}$ portion to the right constitute one pair of training and testing set. Fig. 4 shows the way we obtain our 10 pairs of training and testing sets.

TABLE II
EVALUATION USING MODIFIED MONTE CARLO METHODS .

Expt ID	Accuracy	Sensitivity	Specificity	PPV	NPV
1	0.868	0.481	0.959	0.730	0.888
2	0.872	0.460	0.947	0.610	0.906
3	0.959	0.826	0.985	0.916	0.966
4	0.973	0.876	0.991	0.953	0.976
5	0.860	0.622	0.941	0.785	0.879
6	0.765	0.821	0.739	0.598	0.897
7	0.851	0.743	0.908	0.809	0.871
8	0.944	0.885	0.965	0.900	0.960
9	0.939	0.735	0.981	0.892	0.947
10	0.946	0.835	0.983	0.940	0.947
Mean	0.898	0.728	0.940	0.813	0.924
SD	0.065	0.157	0.075	0.131	0.040

For each Monte Carlo experiment, the model is evaluated using accuracy, sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV), as shown in Table II, where the positive class is non-fishing. These measurements provide us with information about the overall performance of the model. Also, we present the mean and standard deviation (SD) of the metrics.

2) Iterative Leave One Batch Out: Here, we first split the 14 vessels into 2 groups, group one with 10 vessels for iterative LOBO, and group two with four vessels for stratified LOBO. To split the vessels into two groups, we first take four vessels from the 14 longliners as group two and then take the rest 10 vessels as group one. To get an accurate evaluation of the model, we need the four selected vessels to be representative of the entire data set. Therefore, we use trajectory size as a criterion to help select these vessels. Since the trajectory sizes of the 14 vessels vary from thousands to hundred thousands, as shown in Table I, we categorize the 14 trajectories into three sets based on their sizes. For the three sets, the sizes of trajectories are in the range of thousands, ten thousands and hundred thousands respectively. We then randomly select vessels that are proportional to the cardinality of each set, one vessel in set one, two vessels in set two, and one vessel in group set as the four testing vessels.
For the set of 10 vessels, in each iteration, we consider one vessel as one batch to be the test vessel and build one model on the rest of 9 vessels, and repeat this for 10 times. The results of Iterative Leave One Batch Out for the 10 test vessels are shown in Table III.

3) Stratified Leave One Batch Out: We use the selected four vessels from experiment 2 as independent test vessels and we train the model using the 10 vessels from experiment 2, and evaluate on the rest four vessels individually. The performance of the model on the four testing vessels are shown in Table IV. We further visualize the classification results in Fig. 5.

4) Comparisons with autoencoders and Data Minging approach: We reproduce the autoencoders [11] and the data mining approach [10] on the same set of data in previous ILOBO experiment. We compare the performance of CRFs with these two methods as shown in Table III. We perform paired-samples t-test to compare the classification accuracies of CRFs with autoencoders and the data mining approach. The resulting p-value from the comparison of CRFs and autoencoders is 0.057. For the comparison of CRFs and the data mining approach, the p-value is 0.032 which is less than significance level 0.05 so that we can conclude these two methods are significantly different.

Blue points mean both the label and the prediction are non-fishing. Red points mean the label is fishing while the prediction is non-fishing. Yellow points mean the label is non-fishing while the prediction is fishing. Zoomed-in region gives details of classification results in the Atlantic ocean area.

C. Discussion

The results of the three experiments are consistent. The average accuracy of the three experiments is 88.7% with 6.1% average standard deviation. By comparing the results of the second and the last experiments, we found that the models built using Iterative Leave One Batch Out perform as good as the model built in Stratified Leave One Batch Out. This further proves the stability and potential of the model in future fishing activity detection.

Through comparisons, we find CRFs can have better classification accuracy, in terms of mean and standard deviation. We also find CRFs do not suffer from imbalanced data as autoencoders: in experiment 7, autoencoders label all data points as positive class with 0% of sensitivity, whereas CRFs have 53.4% of sensitivity. According to our t-test results, despite the fact that the CRFs and autoencoders are not systematically different on significance level 0.05, CRFs can perform as well as and sometimes better than autoencoders and the data mining approach.

V. CONCLUSIONS AND FUTURE WORK

This paper presents an approach to detecting fishing activities from historical AIS data using Conditional Random Fields. Data cleaning, discretization and transformation followed by feature selection are performed to preprocess data. We then specify proper feature functions to train CRF models. The resulting models are further evaluated in three different ways. In terms of efficiency, we find CRFs can be trained efficiently than complex models such as deep learning. In terms of effectiveness, the three evaluation experiments suggest the model can generalize well in future fishing activity detection problems.

As for future work, we will investigate better ways of developing additional features, such as density and angle. We also consider systematic approaches to incorporate additional density and angle information into feature functions to aid the development of the model.

***Abstract*—The paper concerns automatic recognition of emotion induced by music (MER, Music Emotion Recognition). Comparison of different sparse coding schemes in a task of MER is the main contribution of the paper. We consider a domain-specific categorization of emotions, called Geneva Emotional Music Scale (GEMS), which focuses on induced emotions rather than expressed emotions. We were able to find only one dataset, namely Emotify, in which data are annotated with GEMS categories, this set was used in our experiments. Our main goal was to compare different sparse coding approaches in a task of learning features useful for predicting musically induced emotions, taking into account categories present in the GEMS. We compared five sparse coding methods and concluded that sparse autoencoders outperform other approaches.**

I. Introduction

MUSIC information retrieval has been gaining an increased amount of attention in machine learning community over the past decade due to the increasing popularity of new musical services and a huge amount of music data available on the internet, annotated using imperfect systems such as community tagging and description supplied by producers. With the increasing amount of files, automated music analysis and content-based retrieval becomes increasingly relevant.

One particular subset of music information retrieval tasks is music emotion recognition (MER) [1]. Emotion recognition, besides the potential use in recommendation systems and search engines, poses an interesting theoretical problem for artificial intelligence researchers due to its high subjectivity and the fact human emotions are still not fully understood by psychologists. For music emotion recognition, even the set of emotions employed to annotate the dataset and use as a ground truth in machine learning is still subject to discussion. Emotional categories and scales in popular datasets are often not domain-specific.

Another important issue in automated emotion recognition is that emotion can often be related to musicological concepts such as chords and tempo [2], which from a machine learning standpoint correspond to high-level features that require specialized algorithms to extract them from the music files. However, these algorithms can be imperfect and affect the performance significantly. Meanwhile, current trends in deep learning suggest that algorithms which learn to extract more complicated features from low-level features in an unsupervised manner can achieve even better results than hand-crafted features designed for a specific domain [4]. In music information retrieval, this kind of approach has become popular in the context of genre recognition [5][6] and generalized auto-tagging task [7][8], which includes simple emotional tags, but is more focused on semantic categories such as genre, male/female vocalist, etc.

In this paper, we describe a machine learning approach based on aggregation of sparse vectors constructed from the low-level description of a sound file and apply it to Emotify, a publicly available MER dataset. It is different from usual emotion recognition datasets in that it uses Geneva Emotional Music Scale, an emotional scale designed specifically for music-induced emotion. We compare different sparse coding approaches in order to find out whether these methods can reliably learn features useful for recognition of musically induced emotion, especially the highly subjective and hard to define emotional categories present in GEMS, for which the usually employed emotional scale with Valence-Arousal dimensions does not account.

The paper is organized as follows: Section II summarizes literature related to our paper. Section III describes GEMS emotion categorization and the dataset we used in our experiments. Section IV describes different sparse coding methods which can be used interchangeably in our approach. Section V explains our representation of music files, create using sparse vector pooling, and the rationale behind it. In Section VI, we report the results of our experiments on the Emotify dataset.

II. Related work

Music emotion recognition is an important part of automated music information retrieval and as such, it has been covered extensively in existing literature. Typically, an MER task in artificial intelligence research takes one of two forms: a multi-class annotation task in which each song in a dataset is annotated with a subset of a predefined set of tags [9][10], or a regression task multiple continuous values representing different dimensions of perceived emotion are assigned to a song [11][12]. In the case of multi-class annotation, there is no single consistent system of emotional categories. The set of tags can be based on one of existing emotion categorization

978-83-60810-90-3/$25.00

systems in psychology [13] [14]. However, these are not domain-specific and can be imperfect for describing music.

A common concept in work focusing on dimensional scales is the Valence-Arousal space [15], in which only two continuous dimensions are considered. Valence differentiates between positive and negative emotions while Arousal describes the intensity of perceived emotion. E.g., music described as "energetic" or "joyful" could be placed on the V-A scale in the high valence, high arousal area while music described as "calm" will be in the low arousal, middle valence area. It should be noted that the concept of placing specific emotions on the V-A scale was not designed specifically for describing emotions concerning music. Another criticism of this scale is that its two dimensions are insufficient to describe more complex emotions and discern pairs of emotions such as fear and anger (both of which are negative emotions with high arousal). The question whether V-A scale should be extended with a third dimension is an important subject of discussion among both MIR researchers and psychologists [16].

An important aspect of music emotion is the differentiation between *induced* and *expressed* emotions. Since one of the basic purposes of music is influencing the listener's mood, that differentiation should be a subject of interest when researching emotion modelling. A domain-specific emotion categorization system called Geneva Emotional Music Scale which takes the distinction between induced and expressed emotion into account was proposed in [17]. We describe it in more detail in section III, along with Emotify, the first MER dataset annotated with GEMS categories. The dataset was researched from a machine learning viewpoint in [18], which examined the performance of available features from multiple existing MATLAB toolboxes in combination with SVR algorithm. However, more complicated approaches such as stochastic process modelling or codebook methods have not been applied to GEMS-annotated data yet.

Among existing music information retrieval approaches, we chose to examine codebook methods. Codebook methods rely on building a *dictionary* of discernible patterns appearing in sample data on a short time-scale and then expressing the contents of a music file using contents of the dictionary. In recent years, papers concerning codebook methods reported good results in music information retrieval tasks [5][8] using the Restricted Boltzmann Machine algorithm [19]. In [8], results on the state of the art level were achieved in generalized music auto-tagging using temporal pooling of sparse vectors to represent a music file. We apply the same pooling approach to music emotion modelling. The authors established that sparse RBM can learn features better than sparse coding methods used for codebook generation in the past. Another promising coding method that, unlike RBM, has not been tested extensively in this context is an autoencoder neural network. Autoencoders without sparsity constraints have been tested as an emotion recognition method in [20], using a separate network for each modelled emotion. They have been applied to chord recognition [21] with good results. Hence, in our experiments we test autoencoder with a sparsity inducing loss function as an alternative to RBM.

III. GEMS Emotion Recognition

Geneva Emotional Music Scale is a categorical model of emotion designed specifically for the music domain, based on psychological research [17]. GEMS authors propose a hierarchy with three levels, with three general categories on the top level, nine emotions in the middle and 45 specific emotions at the bottom. The emotional categories were created using surveys concerning music-induced emotion. It is important to note that the difference between emotions expressed by music and induced by music is relevant to the choice of terms. Surveys explicitly asked separate questions about emotions participants felt and emotions they perceived in music.

In [22], nine emotions from the middle level of GEMS hierarchy were chosen to annotate the Emotify dataset, consiting of 400 songs from 4 genres. These middle-level categories are: amazement, solemnity, tenderness, nostalgia, calmness, power, joyful activation, tension, and sadness. The annotations were gathered using a Facebook game Emotify, and thus can represent the task of modelling a community consensus. For each song, annotations in the form of vectors consisting of zeroes (emotion not felt) and ones (emotion felt) were gathered from multiple subjects. Overall annotation of a song can be calculated as a mean of the annotation vectors corresponding to it, resulting in a vector of 9 continuous values ranging from 0 to 1, where zero means a complete agreement that the song does not evoke a particular feeling and one complete agreement that it evokes said feeling.

The dataset was analysed from a machine learning viewpoint in [18]. Authors compared three different sets of automatically extracted features and a set of manually annotated musicological features. First analysed feature set was features designed for music description available in MIRtoolbox, a MATLAB toolbox for music information retrieval. The second one used Mel-frequency Cepstral Coefficients (MFCC) [23] and statistical functionals applied to them such as mean, variance, skewness, etc. Third feature set consisted of harmonic features proposed by the authors used in combination with MIRtoolbox features. The authors concluded that while certain emotions can be modelled with decent accuracy, the performance of machine learning is heavily limited by the issue of subjectivity. The most subjective emotional categories identified by the authors were amazement, solemnity, and tension.

IV. Sparse Representation of Data

Sparse coding is the idea of approximating data drawn from a multidimensional space by representing it in another space in a way that encourages sparsity, i.e. a vector in the output space should consist mostly of zeroes. In its simplest form, the problem of approximating a vector y with its sparse representation x in a base D (called a dictionary), can be defined as:

$$x^* = \arg\min_x \|x\|_0 \quad s.t. \quad \|y - Dx\| < \lambda \tag{1}$$

where λ is a parameter dictating the desired accuracy of reconstruction and $\|x\|_0$ is the number of non-zero elements of vector x. However, this optimization problem is NP-hard and assumes a linear transformation between two spaces, which can sometimes be insufficient to create sparse representations for complex data. Below we describe approaches practically applicable to the problem of sparse representation for any given set of data.

A. K-means Clustering

K-means clustering [24] is a well-known unsupervised learning algorithm in which a dataset is divided into clusters, and each cluster is represented by a single point in the data space, which is the centroid of the cluster. The algorithm assigns any vector in the dataset to the cluster represented by a point closest to it. This enables us to treat K-means clustering as a very restrictive form of sparse coding. A vector y in the original data space assigned to n-th cluster can be represented by a vector x in which every component except n-th is 0, and the n-th component is 1. The dimensionality of x is equal to the number of clusters. Note that this is equivalent to minimizing $\|y - Dx\|$ with constraints $\|x\|_0 = 1$ and $\|x\|_1 = 1$, where the dictionary D is a matrix which n-th column is the centroid of the n-th cluster.

For any vector which is not present in the dataset used for dictionary training, its sparse representation can be calculated by simply choosing the centroid closest to it, and creating a vector of zeros with n-th component being one, where n is the closest centroid. This allows us to express the popular Bag-of-Words model [3] as a specific case of our approach, which will be explained in section IV. This model is known for its simplicity and efficiency regarding the dictionary building process.

B. L1 Regularized Least Squares

A basic way of solving the sparse representation problem in polynomial time is to use L1 norm regularization:

$$x^* = \arg\min_x \|y - Dx\| + \lambda\|x\|_1 \tag{2}$$

L1 norm is known to encourage sparsity [25] and there has been a significant amount of research dedicated to fast solvers for both L1 regularized least squares and its nonnegative variant. Nonlinearity is possible to achieve using the kernel trick [26], the problem then becomes:

$$x^* = \arg\min_x \|\Phi(y) - \Phi(D)x\| + \lambda\|x\|_1 \tag{3}$$

where Φ denotes a mapping function from the original data space to a space of larger dimensionality, implicitly defined by a kernel function $K(a, b)$ which replaces dot product.

Variants of regularized least squares are commonly used in sparse coding problems. They can achieve better reconstruction than a K-means based dictionary approach, at the cost of more complicated dictionary building process. Another issue is that the encoding of a vector is not explicitly given and requires solving (2), which is the main disadvantage of this approach.

C. Sparse Autoencoder

Autoencoders [27] are a type of neural networks developed mostly for use in deep learning. In its basic form, an autoencoder is simply a standard feedforward neural network in which the number of input neurons is equal to the number of output neurons. The network is trained using a backpropagation algorithm [28], in which the network is given a matrix of training vectors X and a matrix desired outputs Y. In the case of autoencoders $Y = X$, meaning the objective of learning is to create an encoding in hidden layer that enables the network to reconstruct later input vectors with maximum possible accuracy.

Without additional modifications to a standard loss function used in backpropagation (e.g. mean squared error), data compression is achieved by using a hidden layer with a low number of neurons, relatively to the number of input neurons. However, it is possible to encourage sparsity [29] by modifying the loss function for hidden layer. Denoting a loss function in relation to data matrix X and desired output matrix Y as $L(X, Y)$, the new loss function minimized by the backpropagation algorithm becomes:

$$L'(X, Y) = L(X, Y) + \lambda \sum_i (\rho \log \frac{\rho}{\hat{\rho}_i} + (1 - \rho) \log \frac{1 - \rho}{1 - \hat{\rho}_i}) \tag{4}$$

where ρ is a parameter indicating the desired average activations in the hidden layer, and $\hat{\rho}_i$ is the average activation of i-th neuron in that layer over the whole dataset. This encourages neuron activations in hidden layer to be 'sparse' in the sense that only a few neurons relevant to recognizing a particular data pattern are 'active' in response to a given input, i.e. they should exhibit significantly higher activations than all the others. However, the vector of hidden layer outputs is not sparse in a strict sense, as most of the 'inactive' neuron outputs are not equal to 0, and it is nearly impossible to achieve zero activations through backpropagation. We will explain why this is not an issue in our model when discussing the representation of music by pooling sparse vectors.

D. Sparse RBM

Restricted Boltzmann Machine [19] is a stochastic neural network model consisting of a set of visible units and a set of hidden units. These layers are fully connected to each other, however, there are no connections inside a layer. Assuming Gaussian visible nodes and binary hidden nodes (which is sufficient to model real-valued inputs) a configuration of network (x, h), where x is the vector of visible values and y is the vector of hidden values, is associated with an energy function:

$$E(x, h) = \frac{1}{2\sigma^2} x^T x - \frac{1}{\sigma^2} x^T W h - a^T x - b^T h \tag{5}$$

where W is the weight matrix, a and b are bias terms. σ is a scaling parameter. This energy function is inversely proportional to the log-likelihood of observing a particular

configuration. Probability distribution of $x^{(i)}$, the value of i-th visible neuron, assuming a hidden layer configuration h is Gaussian with mean $a_i + w_i^T h$ and standard deviation σ:

$$p(x^{(i)}|h) = \mathcal{N}(a_i + w_i^T h, \sigma^2) \tag{6}$$

where w_i denotes the i-th row of W and a_i the i-th component of bias vector a. Probability for j-th hidden layer unit being active is given by:

$$p(h^{(j)}|x) = sig(\frac{1}{\sigma^2}(b_j + w_j x)) \tag{7}$$

where b_j is the j-th component of bias vector b, w_j is the j-th column of W and sig is the logistic sigmoid function. Given these definitions, a model of (W, a, b) can be learned by maximizing the log-likelihood of visible values x using the contrastive divergence learning [30].

A penalty term can be added to the objective function to encourage sparsity. Given a sequence of training vectors in which i-th vector is x_i, the penalty term is:

$$penalty = \lambda \sum_j (\rho - \frac{1}{m} \sum_i \mathbf{E}(h^{(j)}|x_i)) \tag{8}$$

where ρ is the desired average activation of hidden layer and λ is a scaling parameter.

Encoding of a given input vector can be calculated using equation (7), which is similar to coding in autoencoder networks. Restricted Boltzmann Machines are known for their efficiency in building deep neural network architectures, however, these deep networks are usually fine-tuned after the initial learning, using backpropagation. In our approach, this fine-tuning in a supervised manner is not possible.

V. Music Representation by Pooling Sparse Vectors

We apply a method of representing music files described in [8], in which a machine learning scheme based on the sparse representation of data was employed to great success. Proposed approach achieved state-of-art results in the generalized music annotation task, in which the goal is to select a subset from a set of predefined tags for each music file in the dataset. These tags included genre tags, simple categorical emotion tags and other descriptive tags such as 'female vocalist'. It is important to note that emotion recognition does not necessarily rely on the same features of music as genre recognition. For emotion recognition, it is significantly more important to take rhythmic, tempo and harmonic features into account. For example, the differentiation between major and minor chords, while not very important when differentiating between classical and rock music, becomes crucial when attempting to differentiate sad and happy songs due to strong cultural associations between major-minor scales and emotions of happiness-sadness.

In our approach, firstly we calculate the spectrogram of a music file, using log scale for frequency. A sequence of vectors is built in which every vector represents a spectrogram patch of l consecutive frames of the spectrogram, with maximum overlap between patches (i.e. for a window length l a vector x_i in the sequence contains frames from i to $i+l-1$, then the next vector x_{i+1} contains frames from $i+1$ to $i+l$). This way, each vector represents a $f \times l$ patch of the spectrogram, where f is the number of frequency bins. Overall, a spectrogram of t time-frames with f bins results in a sequence of $t - l + 1$ vectors with fl components each.

For each vector in the resulting sequence, a sparse representation is calculated. We aggregate the information from the sequence of sparse vectors via pooling, two methods of pooling are considered: max pooling and average pooling.

In max pooling, a sequence of n-dimensional vectors is aggregated to a single n-dimensional vector by choosing the maximum value of i-th dimension among all vectors in the sequence as the i-th component of the resulting vector. In average pooling, we simply sum vectors in the sequence and divide the result by the number of vectors. For both pooling methods, the length of resulting vector representing the music file will be equal to the size of sparse representation vector. It is possible to use one of the methods over the entire file, or to mix them by first splitting the sequence of vectors into fragments of length m, use one type of pooling over the fragment, resulting in a sequence that is m times shorter, and then aggregate that sequence using the second type of pooling. The process is shown in Fig. 1.

The intuitive rationale behind using pooling for a sequence of sparse vectors is that every dimension in sparse representation corresponds to a particular pattern which can be found in the data used in the process of dictionary building or learning the encoding neural network. With this interpretation, we should understand max pooling as a method to find out whether a particular pattern appeared in a given part of a song at all. If maximal value of i-th element over multiple vectors in a sequence is low, there was no vector that could be reconstructed using i-th dictionary element or a vector that would result in a strong activation of i-th neuron. Similarly, average pooling gives the information of a particular dictionary element (or a pattern detected by the neural network) appearing consistently over the course of the entire song.

One useful property of max pooling is that it eliminates the drawback of autoencoders possibly creating non-sparse representation of data in the strict sense. The notion of 'sparse' vectors in which most neurons are 'inactive', while not precise, is not a problem here because the low activation values of 'inactive' neurons are mostly lost in the process of pooling regardless of whether or not they equal 0.

VI. Experiments on Emotify Dataset

The main goal of our experiments was to compare the performance of different sparse coding methods in creating features for emotion regression task (subsection VI-B). Additionally we tested the influence of the pooling window size on the result (subsection VI-C. Our third experiment shows the spectrogram patterns recognized by sparse coding methods (subsection VI-D. At the beginning we present what is common across all performed experiments. The used tools and

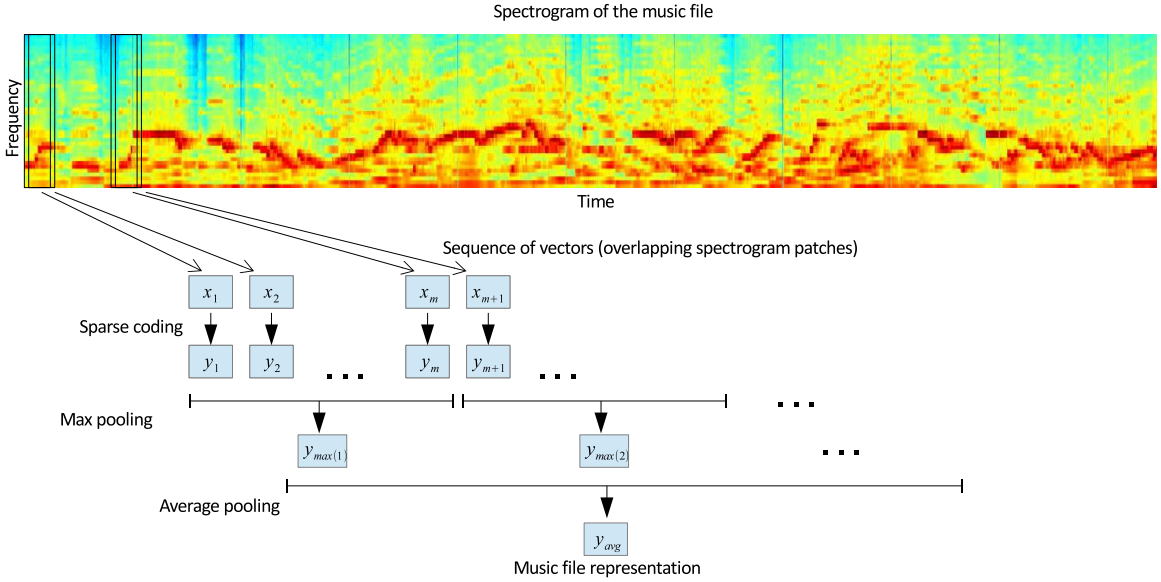

Fig. 1. Representation of a music file by pooling sparse vectors

the learning of sparse representation as well as the regression algorithm is presented in subsection VI-A.

A. Common conditions of the experiments

All performed experiments were performed using MATLAB/Octave toolboxes: MIR Toolbox [31] for spectrogram extraction from music files, Sparse Representation Toolbox [32] for the L1 regularized least squares implementation and DeeBNet [33] for the implementation of autoencoder and sparse RBM.

Sparse Representation Learning

Representation of music files we used in our experiments was based on spectrograms. Spectrogram of each file in the dataset was extracted using 50 ms frames with 25 ms overlap, using mel scale with $f = 40$ bins for frequency axis. The resulting values were logarithmized. Spectrogram patches were $l = 10$ frames long. This means vectors of length $fl = 400$ were used as an input for sparse coding algorithms.

We report the results for sparse representation size of $k = 200$ to emphasize tested methods' capabilities to build compact representations of musical files. In comparison, the best-performing feature set in previous research on the Emotify dataset consisted of 6535 features [18]. Testing sparse representation sizes 200, 500 and 1000 we found that increasing the vector size beyond 200 does not improve the performance significantly. For efficiency, both dictionary building and neural network training were performed on a randomly selected set of 40000 spectrogram patches from the whole dataset.

For kernelized version of L1-regularized least squares algorithm, we use radial basis function kernel defined as:

$$K(x, y) = \exp(-\gamma \|x - y\|^2) \tag{9}$$

Scaling parameter λ, which governs the weight of sparsity constraints relatively to reconstruction accuracy, is present in all methods except K-means. For this parameter we considered values of $\{0.01, 0.1, 1, 10, 100\}$. For parameter ρ, the desired average activation of neurons in sparse autoencoder and sparse RBM, values $\{0.01, 0.05, 0.1, 0.2, 0.5\}$ were considered. These parameters were optimized using grid search, and we report the best results.

Regression algorithm

We approached music emotion recognition as a regression problem: the input was the representation of the file calculated by pooling sparse vectors, i.e. a vector with 200 elements, and the value we were attempting to predict was a real number within [0,1] range, corresponding to the level of agreement that the music file evokes a certain emotion in the listener, as described in section III. A separate Support Vector Regression (SVR) [34] model was trained for each emotion. SVR is a model in which data is fit by a hyperplane, however, due to the possibility of using kernel trick one can accommodate for non-linear data. In our experiments we found that radial basis function kernel, defined as in (9), performs the best.

B. Experiment 1: Performance of different sparse coding methods

Obtained results are collected in Table 1. In order to compare them with [18], which is the only MER paper that reported results of research on Emotify dataset so far, we use the same performance measure, namely Pearson's correlation coefficient R. We compare proposed sparse coding methods to the results achieved using a feature set consisting of features available in MIRToolbox and harmonic features based on chord detection and interval detection.

TABLE I
SPARSE CODING METHODS COMPARED WITH A HIGHER-LEVEL FEATURE SET (PERFORMANCE MEASURED BY PEARSON'S R)

	K-means	L1 Least Squares	Kernel L1LS	Autoencoder	Sparse RBM	MIRtoolbox+Harmonic [18]
Amazement	0.27	0.20	0.18	**0.29**	0.21	0.16
Solemnity	0.41	0.43	0.36	**0.50**	0.48	0.43
Tenderness	0.30	0.46	0.38	0.54	0.49	**0.57**
Nostalgia	0.47	0.40	0.37	**0.50**	0.40	0.45
Calmness	0.47	0.47	0.45	**0.56**	0.53	0.50
Power	0.47	0.46	0.44	0.53	0.50	**0.56**
Joyful activation	0.48	0.50	0.50	0.53	0.54	**0.66**
Tension	0.32	0.47	0.26	**0.48**	0.43	0.46
Sadness	0.30	0.32	0.27	0.33	0.27	**0.42**
Average	0.39	0.43	0.37	**0.47**	0.43	**0.47**

For pooling, we first use max pooling over fragments of music file corresponding to 100 spectrogram patches (around 3 seconds), and then average pooling over the resulting sequence. Results were measured using 10-fold cross-validation.

It can be seen that on average, a sparse coding based approach can achieve performance comparable to that of hand-crafted features. However, autoencoder-based music representation outperforms hand-crafted features features in modeling highly subjective emotions, such as amazement and solemnity. At the same time, the results are significantly worse for "simple" emotions highly correlated with occurrence of major and minor chords, i.e. joyful activation and sadness.

Out of all examined methods, only autoencoders achieved this level of performance. The addition of radial basis function kernel to the L1 least squares not only did not improve the results, but worsened them. Sparse RBM performs better than most approaches, but does not achieve the performance of a sparse autoencoder. Interestingly, K-means based approach, equivalent to the simple bag of words model, achieves performance comparable to autoencoder. However, it does so only for specific emotions, while being significantly worse for others.

Under-performing in terms of recognizing joyful activation and sadness can be interpreted as a sign of difficulty in learning harmonic features. While an unsupervised dictionary learning method can recognize a pattern corresponding to a particular chord, it may be hard to generalize them to the concept of major and minor chords, and further to key detection for the entire song.

C. Experiment 2: Influence of pooling window size on the results

Using previous parameters and choosing autoencoder as the best performing method of sparse coding, we performed a second experiments with the goal of estimating the influence of selected pooling window size on the prediction of specific emotions. Usually, in music information retrieval, model parameters such as window sizes for any type of operation are constant and tuned for best overall performance. However, with a specific set of differing emotions, it is interesting to see how recognition of each emotion is affected by the time-frame considered.

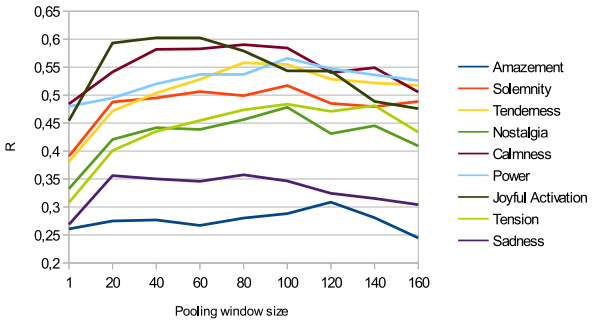

Fig. 2. Performance depending on pooling window size

As in the experiment 1, we use max pooling over small windows first, and average pooling over the resulting sequence of vectors afterwards. We consider pooling window sizes of $\{1, 20, 40, 60, 80, 100, 120, 140, 160\}$. Note that window size equal to one is equivalent to average pooling over the entire file, which is commonly used in dictionary learning. Similarly to the main experiment, results are measured using 10-fold cross-validation.

Fig. 2 shows the changes in performance for different window sizes of max pooling. It can be seen that peaks in performance appear at different window sizes for different emotions. For detection of joyful activation and sadness small window sizes seem optimal, while detection of tension can be improved with sizes close to 140 vectors.

D. Experiment 3: Encoding patterns

Since our sparse representations are built from spectrogram patches and spectrogram is a visual representation of how sound evolves, it is possible to visualize spectrogram patterns which sparse coding methods recognize. In case of autoencoder neural network, a response of a hidden layer neuron depends on the vector of input-hidden weights associated

with that particular neuron. For each neuron in the hidden layer, there are 400 weights, each corresponding to one input neuron. Since a vector given as an input to the neural network represents a 40×10 spectrogram patch, we use the same 40×10 dimensions to visualize the input weights. We want to see if the response patterns are possible to interpret by a human observer and relate to concepts existing in music. For visualization of encoding patterns, we learned an autoencoder network with the best-performing set of parameters found in previous experiments: $\lambda = 10$, $\rho = 0.1$.

Fig. 3 shows sample response patterns of single neurons in the encoding layer, with the highest weight values coloured red and lowest coloured blue. Neuron should respond with a high activation to spectrogram patches similar to these patterns.

We found certain types of response patterns appearing consistently in unsupervised training of autoencoders. In Fig. 3, leftmost pattern shows high weights in distinct narrow frequency bands, responding in high activation when the amplitude is high in these bands. Patterns like this respond well to specific music intervals, which makes them useful in extracting harmonic features. A combination of them could approximate chord detection. Second leftmost pattern shows an example of high weights in a wider frequency band, in this case responding to high amplitude in low frequency bins. Neurons responding to patterns like this for different wide bands can enable detection of overall amount high, mid and low tones, which in turn could be used e.g. in recognizing songs with a heavy bass line. Third pattern shows small weights for inputs corresponding to initial frames and high weights for inputs corresponding to latter frames in the low frequency band, indicating the neuron will respond with high activation to an onset of a musical phrase. Rightmost pattern can detect increases in amplitude separated by a specific interval of time, which gives the possibility of beat frequency detection.

We can see that through unsupervised training, autoencoders could learn features that are interpretable using concepts related to high-level features of music.

VII. Conclusions and future work

We applied a machine learning approach based on pooling of sparse vectors built from spectrograms of sound files to Emotify, first publicly available music emotion recognition dataset annotated with Geneva Emotional Music Scale categories. We compared 5 sparse coding methods and measured their performance in the task of predicting a community consensus concerning emotions induced by a music piece. We found out that sparse autoencoders significantly outperform other approaches.

The results show that a sparse coding approach based on autoencoders can achieve satisfying performance in recognizing certain very subjective emotions hard to detect using higher level features. On the other hand even the best sparse coding method applied to this problem cannot outperform harmonic features in recognizing joyful activation and sadness. However, the results show that performance is significantly affected by the choice of the size of pooling window and it appears that different window sizes are optimal for detecting different emotions. These results suggest that analysing sound using fixed and constant time scales is a significant limiting factor in predicting music-induced emotions.

The main limitation of our research was the dataset, which unfortunately is the only one so far using the GEMS system for emotion classification. Generalizations based on our results should be confirmed on other datasets, possibly including more varied music types.

Future research in the area of induced emotion modelling can focus on a number subjects. First, a thorough examination of properties of the sparse autoencoder in the context of music emotion recognition can be useful. Second possible area of research is developing methods that can simultaneously consider multiple time-scales since there is no optimal selection of time windows for pooling, and maximizing average prediction performance does not guarantee maximizing performance for every emotion. Finally, building new datasets annotated with domain-specific emotional models such as GEMS should be a subject of interest.

***Abstract*—This paper is aimed at presenting some general construction method of the hybrid plan controller for some task of temporal planning with preferences. This construction is multi-stage and it begins with a description of a chosen robot environment and its plan in some extended version of Linear Temporal Logic. This description is later transformed to the appropriate preferential Büchi automaton. In the same way, the real plan performing by the robot is encoded by the similar automaton. Finally, both automata are exploited to construct its product automaton, which is later described in** PROLOG**.**

***Index Terms*—the hybrid plan controller, temporal planning, preferences, the robot motion environment, PROLOG, automata, Linear Temporal Logic, Halpern-Shoham logic**

I. Introduction

A *Plan Controller* constitutes a machine (sometimes only abstract) suitable for controlling how different tasks are performed in comparison with the initially developed plans or schedules. The plan controller construction is often a multi-stage activity and it begins with a description of the robot environment and tasks in the appropriate formal language. This description should be later translated into the appropriate automata which encode the initial part of information in terms of automaton states and admitted transitions between them. Such controllers[1] satisfy many different features, and – depending on the proposed approach to the robot's motion representation – are usually rendered in terms of Linear Temporal Logic (LTL), but may be also rendered in terms of the motion description language [9] or of the control and computation language [14].

An interesting approach to the plan controller construction was presented in [4], [20], which is based, however, on the known idea of the environment triangulation. The classical approach to the controller construction leads just from a triangulation of the robot's/agent's environment and the appropriate finite transition system by a representation of this environment in terms of LTL. In the next step, the LTL-formulas are represented by the appropriate Büchi automaton[2]. Its construction is later complemented by the construction of the appropriate product automaton for LTL-specification and for the considered transition system – suitable for a grasping of the basic dynamism in the robot's environment. This product automaton ensures acceptance of certain desired transitions only, see: [4], and it forms a 'core' of the hybrid plan controller representation.

The method of the Büchi automaton construction alone for a use of different planning situations was presented in [6] and – w.r.t. formulas of some extended LTL — earlier in [21], [22]. The applicability of the formalism of temporal logic for specification of the robot's motion environment is a commonly known and widely discussed fact; see for example: [1], [2]. Indeed, such systems as Linear Temporal Logic (LTL) and Computation Tree Logic (CTL) have a satisfying expressive power to give a relatively detailed description of components of robot's motion planning such as action sequencing or objectives, the properties of the robot's environments. This utility of LTL was suggestively demonstrated in [2]. The robot's environments specification in terms of temporal logic constitutes the first fundamental step for planner and plan controller construction.

We intend to extend these recent approaches in two ways: we introduce an additional preferential component to the considered transition system and we extend the language for the robot's environment specification by introducing Halpern-Shoham logic (HS) – introduced in [7] – with single operators $\langle D \rangle$ and $\langle L \rangle$ for relations: 'during' and 'later' (*resp.*). Such a radical restriction of HS is dictated by formal requirements of the conversion to the automaton, which can be realized in this case.

Motivation. Majority of approaches to plan controlling of the robot behavior in polygonal environment – such as the presented in [1], [2], [4], [20] – discuss this issue rather in a form of extended outlines and without (often needed) technical details. By contrast, some formal papers such as [21], [22],

[1]They are often called "hybrid controllers" as they join different automaton types and they refer to different features and 'entities' such as plans and the motion environements.

[2]This useful formal tool was invented in 1962 and described in [**?**].

[6] are aimed at presenting a purely meta-logical face of the construction of automata in a language of temporal logic. In result, there is no real coincidence between these approaches. Moreover, no of them take into account preferential aspects of planning, which introduce a portion of 'rationality' to performing tasks and, its management and controlling.

These lacks constitute a main motivation factor of this paper investigations. The next motivation factor stems from an additional lack of some correlation between research on the real expressive power of temporal logic systems – such as Halpern-Shoham logic in [18], [19] – and some engineering tendency to exploit temporal logic systems in (almost) all possible contexts and without restrictions.

Against this state of the art, we intend to propose such a new preferential extension of the current approaches to the plan controller construction for a robot in polygonal environment which respects last arrangements about temporal logic and its expressive power. This intention determines a choice of the appropriate subsystems of Halpern-Shoham logic: its restriction to the modal operator $\langle D\rangle$ and $\langle L\rangle$ for representation "during' and 'later'-relations (*resp.*). In fact, these operators can be effectively transformed to the appropriate automata in the light of recent observations from [19], [17]. Some conceptual background of the automaton construction for combined formulas of some multi-valued extension of HS-logic has been presented in [13], [10].

Moreover, the authors of this paper give venture of their enthusiasm with respect to some utility of the proposed construction in different areas of utility of temporal logic systems: in engineering or – for example – in business processes and their management. Some applicability of temporal logic systems for engineering has been recently discussed in [12], [11], for a use of business management – in [15], [16]. Last, but not least, expected future implementation of the automaton construction in languages of a declarative paradigm such as PROLOG or ASP forms some additional motivating factor of this paper's analysis.

Objectives of the paper. According to these motivation factors, rendered above, objectives of this paper – in a chronological order – are the following :

1) proposing a new preferential extension of the concept of the hybrid plan controller– based on product automata,
2) construction of hybrid plan controller for a robot performing task in a polygonal environment in the block world,
3) an outline of the PROLOG-representation for some fragments of the constructed plan controller.

We also associate to these main objective some additional goal to extend the used specification language from LTL to LTL extended by Halpern-Shoham logic with $\langle D\rangle$ and $\langle L\rangle$-operators, symb. HS^D.

Organization of the paper. This paper is organized as follows. In section 2 we present a terminological background of the analysis. In section 3 we present the main problem of the paper analysis and we give a general algorithm of our hybrid controller specification. Section 4 forms the main conceptual part of the paper, where we describe in details the steps of the controller construction *via* the Büchi automaton for LTL and for the considered transition system. In section 5 we briefly describe the implementation area of this construction and HS logic with operators: $AB\bar{A}\bar{B}$. In section 6 we formulate conclusions and some remarks on the future research direction.

II. Preliminaries

Before moving to main paper body, we present a terminological framework of this paper analysis, introducing a new concept of *preferential automata* and *preferential transition system*. The recalled definitions of a (finite) transition system and a Büchi automaton are incorporated from [7].

Definition 1. . *A (finite) transition system FTS is a n-tuple $FTS = (W, W_0, Act, Tran, \Pi, Obs)$, where:*

1) *W is the finite set of states (worlds),*
2) *$W_0 \subseteq W$ is the distinguished set of initial states,*
3) *Act denotes the set of possible actions,*
4) *$Tran : W \times Act \mapsto W$ is a transition function, i.e such a total function that returns the next stage for a given state an an action,*
5) *Π denotes the set of possible observations,*
6) *$Obs : W \mapsto \Pi$ is the observability function, which returns the observable part of the current state.*

We define an *execution* on FTS as an infinite sequence of states $w_0, w_1, \ldots$, such that $w_0 \in W_0$ and $w_{k+1} = Tran(w_k, a)$ for some action $a \in Act$. The observable part of the execution will be called a *trace*.

Definition 2. *A Büchi automaton is a tuple $A = (\Sigma, S, S_0, \rightarrow, \rho, \mathcal{F})$, where:*

1) *Σ is the alphabet of the automaton,*
2) *S is the set of states of the automaton,*
3) *$S_0 \subseteq S$ is the set of initial states of the automaton,*
4) *$\rho : S \times \Sigma \mapsto 2^S$ is the transition function of the automaton and*
5) *$\mathcal{F}$ is the set of accepting words.*

We expand this definition to a definition of preferential Büchi automaton by specification of the set of accepting words by introducing some degrees/parameters α's from an interval $[0, 1]$. The role of them is to measure a *degree of a preference* of the accepting words from F, indexed by such an α.

Definition 3. *A A Preferential Büchi automaton is a tuple $A = (\Sigma, S, S_0, \rightarrow, \rho, \mathcal{F}, \alpha_1, \alpha_2 \ldots)$, where:*

1) *Σ is the alphabet of automaton,*
2) *S is the set of states of automaton,*
3) *$S_0 \subseteq S$ is the set of initial states of automaton,*
4) *$\rho : S \times \Sigma \mapsto 2^S$ is the transition function of automaton and*
5) *$\mathcal{F}^\alpha$ is the set of accepting words with associated α-degree preferences.*

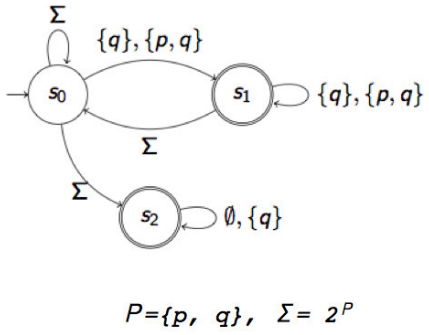

Fig. 1. Fragment of the Büchi automaton with states s_0, s_1 and s_2 over an alphabet Σ.

6) $\alpha_1, \alpha_2, \ldots$ *are values of functions* $f :\mapsto \mathcal{F}^\alpha \rightarrow [0,1]$ *called preferences.*

We assume that a set of α degrees is finite as they index accepting words from set F^α. Naturally, F^α should be finite as a a set of accepting words of a finite automaton.

For such a defined automaton we define a *run* of $\mathcal{A}$ (on an infinite words $a_0, a_1, a_2, \ldots$) is an infinite sequence of such states $s_0, s_1, \ldots \in S^\omega$ that $s_0 \in S_0$ and $s_{i+1} \in \rho(s_i, a)$. We say that a run r is *accepting* iff a set $\{s|s$ occurs in r infinitely often $\} \cap F \neq \emptyset$. If F is finite, this general condition means that there exists at least one state s that occurs in a run r infinitely often.

Linear Temporal Logic (LTL).

Syntax. Bi-modal language of LTL is obtained from standard propositional language (with the Boolean constant $\top$) by adding temporal-modal operators such as: *always in a past* (H), *always in a future* (G), *eventually in the past* (P), *eventually in the future* (F), *next and until* ($\mathcal{U}$) and *since* ($\mathcal{S}$) – co-definable with "until". The set FOR of LTL-formulas is given as follows:

$$\phi := \phi|\neg\phi|\phi \vee \psi|\phi\mathcal{U}\psi|\phi\mathcal{S}\psi|H\phi|P\phi|F\phi|Next(\phi) \qquad (1)$$

Some of the above operators of temporal-modal types are together co-definable as follows: $F\phi = \top\mathcal{U}$, $P\phi = \top\mathcal{S}\phi$ and classically: $F\phi = \neg G\phi$ and $P\phi = \neg H\phi$.

Semantics. LTL is traditionally interpreted in models based on the point-wise time-flow frames $\mathcal{F} = \langle T, <\rangle$ and dependently on a set of states S. In result, we consider pairs (t, s) (for $t \in T$ representing a time point and $s \in S$) as states of LTL-models. Anyhow, we often consider a function $f : T \mapsto S$ that associates a time-point $t \in T$ with some state $s \in S$ and we deal with pairs (t, f) instead of (t, s). Hence the satisfaction relation $\models$ is defined as follows:

1) $(t,f) \models G\phi \iff (\forall t^{'} > t)t^{'} \models \phi$, $(t,f) \models H\phi \iff (\forall t < t^{'})t^{'} \models \phi$.
2) $(t,f) \models F\phi \iff (\exists t^{'} > t)t^{'} \models \phi$, $(t,f) \models P\phi \iff (\exists t < t^{'})t^{'} \models \phi$.
3) $(t_1,f) \models \phi\mathcal{S}\psi \iff$ there is $t_2 < t_1$ such that $t_2, f \models \psi$ and $t, f \models \phi$ for all $t \in (t_1, t_2)$

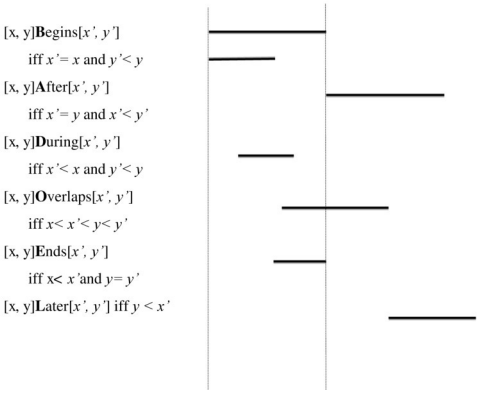

Fig. 2. Visual presentation of temporal interval relations of Allen

4) $(t_1,f) \models \phi\mathcal{U}\psi \iff$ there is $t_2 > t_1$ such that $t_2, f \models \psi$ and $t, f \models \phi$ for all $t \in (t_1, t_2)$
5) $(t_k,f) \models Next(\phi) \iff (t_{k+1}, f) \models \phi, k \in \mathcal{N}$.

Halpern-Shoham logic. HS forms a modal representation of the following temporal relation between intervals, defined by [7]: **a**fter" (or **m**eets"), (**l**ater"), **b**egins" (or **s**tart"), **d**uring", **e**nd" and **o**verlap". These relations are intuitive and their visualization can be easily found in many papers, so we omit their visual presentation, they correspond to the modal operators: $\langle A\rangle$ for **a**fter", $\langle B\rangle$ for **b**egins", $\langle D\rangle$ for **d**uring", etc. The syntax of HS entities ϕ is defined by:

$$\phi := p|\neg\phi|\phi \wedge \phi|\langle X\rangle|\langle \bar{X}\rangle\,, \qquad (2)$$

where p is a propositional variable and $\langle \bar{X}\rangle$ denotes a modal operator for the inverse relation with respect to $X \in \{A, B, D, E, O, L\}$ If $\phi \in \mathcal{L}$(HS), M is a model, and I is an interval in the M-domain, then the satisfaction for the HS-operators looks as follows:

$$M, I \models \langle X\rangle\phi \iff \exists I^{'} that\ IXI'\ and\ M, I^{'} \models \phi. \qquad (3)$$

Example 1. *Some simple spatial-temporal requirements imposed on the robot's environment E can be expressed by formulas:*

- *Always if you take a block A, take B, as well:* $G(take(A) \rightarrow take(B))$,
- *For any intervals: if you take A, than you also put B:* $[D](HOLDS(take(A)) \rightarrow HOLDS(put(B)))$.

III. Problem formulation and a general algorithm of the controller construction

Assume that E is a polygonal environment of robot motion operations. All possible admitted holes of E have to be enclosed by a single polygonal chain. The motion of robot is expressed as follows:

$$x(t) \in E \subseteq R^2, u(t) \in U \subseteq R^2, u(t) \cap x(t) \neq \emptyset \qquad (4)$$

where $x(t)$ is a trajectory of robot's motion (position of a robot in a time t) in E and $u(t)$ is a control input. Non-emptiness of the above intersection $u(t)$ and $x(t)$ ensures that a controller detects the robot's trajectory. In such a framework, the goal of the paper is to give an outline of a construction of a hybrid controller that generates controllers inputs $u(t)$ for a trajectory $x(t)$ and environment with a specification given by formulas of LTL and – partially – by HS restricted to D-operator.

A general path of our controller construction looks a follows. We begin with the environment E and its triangulation. Secondly, we consider some transition system FTS to describe a basic dynamism of E. The next, we specify E in terms of LTL (ϕ-formula) and of some subsystem of HS logic. In the next construction step, we transform FTS to the appropriate Büchi automaton $\mathcal{A}_{FTS}$ for it. The similar automaton $\mathcal{A}_{LTL,HS}$ is constructed for representation of a specification of E (with a chosen point x_0) in terms of the considered temporal logic. Having these automaton, we construct some product automaton $\mathcal{A}$ to 'reconcile' the activity of both automata. Assume that some environment E of a robot and a formula $\phi \in \mathcal{L}(LTL \cup HS^{D,L})$ – describing this environment or the robot motion are given. Thus, the algorithm of the hybrid controller construction could be given as follow – as a specified version of algorithm from [4]:

Algorithm: The Hybrid Controller Construction

Procedure: CONTROLLER(E, ϕ)

1) $\triangle \leftarrow Triangulate(E)$
2) $FTS \leftarrow TriangulationToFTS(\triangle)$
3) $\mathcal{A}_{FTS} \leftarrow FTS\ to\ Bchi\ Automaton$
4) $\mathcal{A}_{LTL,HS^D} \leftarrow LTL \cup HS^D to\ Bchi\ Automaton$
5) $\mathcal{A} \leftarrow Product \mathcal{A}_{FTS}, \mathcal{A}_{LTL,HS^D}$
6) **return**: $Controller(\mathcal{A}, \triangle, \phi)$

End procedure

IV. Controller construction for path temporal planning with observability

A. From triangulation to the FTS system

In order to propose an exact construction of our path temporal planning controller we will represent a polygonal environment E as a finite set of partitions. One can use many methods of the initial polygonal environment's decomposition, presented in [4], [5].

The main idea of such a triangulation consists in a mapping of each point $x \in E$ to a one of the disjoint equivalence classes determined by an equivalence relation $\sim$. The natural way is to define $\sim$ as follows: $\forall x, y \in E : x \sim y \iff x, y \in \triangle$, i.e each of such an equivalence class forms a triangle, what allows us to represent a quotient set $E| \sim$ as a sum of triangles. Assume now that $T : E \to Q$ for $Q = \{\triangle_1, \ldots \triangle_k\}$. Than each $T^{-1}(\triangle_i)$, for $i \in \{1, 2, \ldots, n\}$ contains some states $x \in E$ and a set $\{T^{-1}(\triangle_i) | \triangle_i \in Q$, for $i \in \{1, 2, \ldots, n\}\}$ of all such triangle anti-images is a desired partition of the initial motion environment E. In order to preserve a consideration generality, we do not impose any special requirements on E (concerning the temporal or spatial coverage etc.)

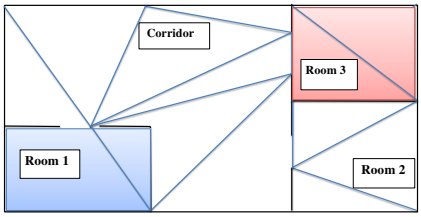

Fig. 3. An example of a triangulation of some polygonal robot environment

In this framework we can introduce a *finite transition system with preferences*– FTS, modifying a definition of of FST with observability from [4], [20] as follows:

Definition 4. *We define the finite transition system FTS with preferences as a tuple* $FTS = \langle Q, Q_0, Act, tran_{FTS}, Pref, P \rangle$, *where:*

1) Q *is the finite set of states (triangles),*
2) $Q_0 \subseteq Q$ *is the set of initial robot states,*
3) Act *is the set of actions,*
4) $tran_{FTS} : Q \times Act \mapsto Q$ *is defined as a 'move' from* $\triangle_i \to \triangle_j$ *iff the cells* $T^{-1}(\triangle_i)$ *and* $T^{-1}(\triangle_j)$ *share a common edge,*
5) P *is the set of objects called preferences,* $Pref : Q \to P$ *is a preferential map which associates to a* $\triangle_1 \in Q$ *some preference* $pref$ *such that* $pref(\triangle_1) \in P$ *if* $P \subset [0, 1]$ *and* $Pref$ *is a function.*

Example 2. *One can consider such a transition system with preferences as a system –depicted on a Fig. 2 with a function PREF, which satisfies a condition:* $PREF(\triangle(room3)) = \frac{1}{2}$. *(All triangles from a room 3 are preferable (in a sense of a robot task as places to visit) with a degree* $\frac{1}{2}$*).*

B. From FTS system to the Büchi automaton

It easy to observe that the finite transition system FTS naturally models a basic structure of the motion environment. It can play this role independently of a way of its presentation – in the standard form: $FTS = (W, W_0, Act, Tran, \Pi, Obs)$ or in the "triangle" tuple $FTS = \langle Q, Q_0, Act, tran_{FTS}, Pref, P \rangle$. Moreover, their structure – as it has been said – is similar to a structure of automata, so they seems to be a natural base of a construction of the required automata. In essence, (finite) automata may be considered as (finite) transition systems with labeling functions, connected with the appropriate language which delivers an alphabet as a required component of the automaton structure. Due to some practice in this area – expressed in [4], [20] – we will consider the standard repre-

sentation of FTS as more suitable for an expected automaton construction.

Authors of the approach from [4], [20] recommended to an immediate use a structure of such an FTS for this construction. We only partially make use of this advise. Of course, we will base the automata construction on the FTS-structure with its states as transitions as states and transitions of the newly constructed automaton. Nevertheless, we decide for a more"descriptive" solution: we firstly describe a robot environment (FTS) in terms of LTL and we construct states of desired automaton from sets of the used formulas. For that reason, one need now a mechanism of such a description. Its presentation will be given below.

C. From LTL and $HS^{L,D}$ to its Büchi automaton

The next step of our construction will consist in a constructing of the appropriate Büchi automaton for LTL- and HS-formulas expressing the robot's motion environment E and the action sequencing. This situation is, however, not so comfortable as in the FTS-case for three purposes. First, both LTL and HS form formal languages, so their translation for the Büchi automaton should be more sophisticated. Moreover, we deal with two languages: LTL and HS of a different temporal and a modal-temporal nature. Last, but not least, HS logic (in generality) cannot be expressed by the Büchi automaton because of the enormous expressive power of this logic. Fortunately – as it was already mentioned – it was proven in [17] that the subsystem of HS with an operator D can be represented by a finite state automaton. Unfortunately, it is not clear whether there exists any extension of this subsystem with the same property. Nevertheless, it is known that a subsystem $A\bar{A}B\bar{B}$ is too strong, because ω-regular languages can be embedded in this system, but not in the inverse direction [19]. According to these remarks on the Büchi automaton construction in section 2, we begin with defining of a closure of formulas of LTL and HS^D.

Definition 5. *Let assume that $\phi \in \mathcal{L}$(LTL). We define its closure $cl(\phi)$ as follows:*

1) $\phi \in cl(\phi), \neg(\phi_1) \in cl(\phi)$, *than* $\phi_1 \in cl(\phi)$,
2) $\phi_1 \wedge \phi_2 \in cl(\phi)$ *than* $\phi_1, \phi_2 \in cl(\phi)$,
3) $A(\phi_1, \ldots, \phi_k) \in cl(\phi) \rightarrow A_{sub}(\phi_1, \ldots, \phi_k) \in cl(\phi)$ *for* A_{sub} *denoting a sub-formula of A.*

In the similar way we will define a closure for $\phi \in \mathcal{L}$(HS^D). For a distinction of these languages and their formulas we will denote them as: ϕ_{LTL} and ϕ^D_{HS}.

Definition 6. *In accordance with the earlier statements we define an automaton $\mathcal{A}_{LTL,HS^D}$ as n-tuple:*

$$\mathcal{A}_{LTL,HS^D} = (2^{cl(\phi_{LTL} \cup \phi^D_{HS})}, \rho, S_0^{\phi_{LTL}}, S_0^{\phi^D_{HS}}, \mathcal{F}) \quad (5)$$

where $(2^{cl(\phi_{LTL})}$ is the set of states of the automaton as the collection of all sums of (disjoint) sets of formulas in $cl(\phi_{LTL})$ and $cl(\phi^D_{HS})$, ρ is the transition and $S_0^{\phi_{LTL}}, S_0^{\phi^D_{HS}}$ are sets of initial states of automaton containing for ϕ_{LTL} and $\phi^{D,L}_{HS}$ and $F \subseteq 2^{cl(\phi_{LTL})} \cup 2^{cl(\phi^D_{HS})}$ is a set of accepting words of automaton[3]*. (resp.).*

One can expand this definition – based on [21], [22] to the definition of a preferential automaton as follows:

Definition 7. *A preferential automaton (for words of $\mathcal{L}(LTL \cup HS^{D,L})$) is defined as n-tuple:*

$$\mathcal{A}_{LTL,HS^D} = (2^{cl(\phi_{LTL} \cup \phi^{D,L}_{HS})}, \rho, S_0^{\phi_{LTL} \cup \phi^{D,L}_{HS}}, \mathcal{F}^\alpha, \alpha_1\alpha_2, \ldots) \quad (6)$$

where $(2^{cl(\phi_{LTL} \cup \phi^{D,L}_{HS})}$ is the set of states of the automaton as the collection of all sums of (disjoint) sets of formulas in $cl(\phi_{LTL})$ and $cl(\phi^D_{HS})$, ρ is the transition,

$S_0^{\phi_{LTL} \cup \phi^{D,L}_{HS}}$ are sets of initial states of automaton containing for ϕ_{LTL} and $\phi^{D,L}_{HS}$ and $\mathcal{F}^\alpha \subseteq 2^{cl(\phi_{LTL}) \cup \phi^D_{HS})}$ is a set of accepting words of automaton, and each of $\alpha_1, \alpha_2 \ldots$ is a function $f : \mathcal{F}^\alpha \mapsto [0, 1]$.

Example 3. *Let us consider $\phi = \neg\phi_1$ for some ϕ_1 as a LTL-formula and $\psi = \langle D\rangle\psi_1$ (for some ψ_1) as our HS^D-formula.We show how to construct a Büchi automaton in a case of these formulas.*

Due to definition of a closure of the formula we obtain: $cl(\phi) = \{\phi_1, \neg\phi_1\}$ and $cl(\psi) = \{\psi, \neg\psi, \langle D\rangle\psi, \neg\langle D\rangle\psi\}$ and thus $2^{cl(\phi)} = \{\emptyset, \{\phi_1\}, \{\neq \phi_1\}, \{\phi_1, \neg\phi_1\}\}$ and $2^{cl(\psi)} = \{\emptyset, \{\psi\}, \{\neg\psi\}, \{\psi, \langle D\rangle\psi\}, \{\psi, \neg\langle D\rangle\psi\}, \{\neg\psi, \langle D\rangle\psi\}, \{\neg\psi, \neg\langle D\rangle\psi\}\}$. $N_\psi = \{\neg\phi_1, \{\phi_1, \neg\phi_1\}\}$ (because these sets contain ϕ) and $N_\psi = \{\{\psi_1, \langle D\rangle\psi_1\}, \{\neg\psi_1, \langle D\rangle\psi_1\}$ (because these sets contain $\langle D\rangle\psi_1$). Transitions ρ_{LTL} and ρ_{HS^D} are defined in such a way that sets from N_ϕ are initial in ρ_{LTL} and N_ψ are initial for ρ_{HS^D}.

D. Product automaton $\mathcal{A}_{FTS} \times \mathcal{A}_{LTL,HS^D}$

We have already defined the automaton $\mathcal{A}_{FTS}$, which describes the finite transition system and the automaton $\mathcal{A}_{LTL,HS^D}$ that represents the initial temporal logic-based specification of the motion environment. There is a need to reconcile both automata in order to construct our open-loop hybrid controller. For this purpose, it seem to be reasonable to restrict a *spectrum* of the possible transitions to these of them, which can ensure some form of observability.

For this purpose we introduce a product automaton $\mathcal{A} = A_{FTS} \times \mathcal{A}_{LTL,HS^D}$ with a new transition $\rightarrow_{\mathcal{A}}$ between pairs: $(q_i, w_i) \rightarrow_{\mathcal{A}} (q_j, w_j)$. We assume that this transition holds between such pairs if and only if $q_i \rightarrow_{FTS} q_j$ and $(w_i; \pi(q_j)) \rightarrow_{LTL} w_j$. This last condition means that the last transition has an input that contains an action $\pi(q_j)$ being an observation of the newly achieved (in sense of $\rightarrow_{FTS}$) state q_j.

Definition 8. *Let $\mathcal{A}_1 = \langle \Sigma_1, S, S_0, \rightarrow_{A_1}, \mathcal{F}^\alpha, \alpha_1, \alpha_2 \ldots\rangle$ and $\mathcal{A}_2 = \langle \Sigma_2, T, T_0, \rightarrow_{A_2}, \mathcal{F}^\beta, \beta_1, \beta_2 \ldots\rangle$ are preferential*

[3]Let us observe that defining of $\mathcal{F}$ as accepted words determines, somehow, a set of final states by this way of state definition – just by formulas, what seems to justify $\mathcal{F}$ as a subset of $2^{cl(\phi_{LTL}) \cup cl(\phi^D_{HS})}$.

automata, than their preferential product automaton is the automaton of the form:

$$\langle \Sigma_1 \times \Sigma_2, S \times T, S_0 \times T_0, \rightarrow_{A_1 \times A_2}, \mathcal{F}^{\alpha} \times \mathcal{F}^{\beta}, \alpha_1, \alpha_2, \beta_1, \beta_2 \ldots \rangle, \tag{7}$$

where $\rightarrow$ is a product transition defined such that: $(s_i, t_i) \rightarrow (s_{i+k}, t_{i+k})$ holds for natural $i \in I$ and $1 \leq k$ if and only if $s_i \rightarrow_{A_1} s_{i+k}$ and $t_i \rightarrow_{A_2} t_{i+k}$ and $\alpha_1, \alpha_2, \beta_1, \beta_2 \in [0, 1]$ are fuzzy values expressing preference degrees of accepting words from $\mathcal{F}^{\alpha}$ and $\mathcal{F}^{\beta}$ (resp.)

(For simplicity, we will shortly write $\rightarrow$ instead of $\rightarrow_{A_1 \times A_2}$, when it will not lead to any confusion.)

E. Complementation of conditions for a product automaton

After the product automaton construction the design of an open-loop hybrid controller for motion planning reduces to the finding problem the accepting execution of this automaton. Nevertheless, this construction requires a small complementation. In fact, some components of $\mathcal{A}$ being singletons can have no outgoing transitions. In order to ensure a normal work of the automaton, we add the so-called stutter extension [8] rule, which adds a self-transition on the blocking states. More formally: for all states $s \in$ domain of $\mathcal{A}$ we define a new transition $\rightarrow_{\mathcal{A}^*} = \rightarrow_{\mathcal{A}} \cup (s \rightarrow_{\mathcal{A}} s)$, where $\rightarrow_{\mathcal{A}}$ is the transition of the automaton $\mathcal{A}$ [4], earlier defined. In such a framework it holds the following:

Theorem 1. *(adopted from [6]) An execution of FTS that satisfies the specification in terms of LTL and HS-formulas exists iff the language of A is non empty.*

We omit the proof details. For a case of LTL-specification it can be found in[7]. For a case of HS^D it follows from the existence of the automaton accepting formulas of this logic from [17].

V. Part II: Implementation

In last part of the paper we gave a theoretic outline of the hybrid controller construction – based on some product automaton. In addition, a description of the robot motion environment and the robot plan have been rendered in LTL extended by some fragment of HS-logic. In this part we intend to illustrate these ideas by proposing a concrete construction of such a controller. According to the earlier arrangements – this construction will be multi-stage and it will contain the following stages:

1) a presentation of the robot motion environment,
2) a formal description of the environment and the plan of the robot in terms of $LTL \bigcup HS^{D,L}$,
3) a formal description of the environment and a real plan performing by the robot in terms of $LTL \bigcup HS^{D,L}$
4) a construction of the appropriate Büchi automata for both the cases (the first one – for a desired plan, the second one – for a real plan performing by the robot) ,
5) a construction of a product automaton built up from automata from a point (4).
6) a PROLOG-description of the product automaton in order to detect eventual discrepancies between a plan and its performing by the robot.

[4]In essence we consider a projection of $\rightarrow_{\mathcal{A}}$ for the set of s-states, because $\rightarrow_{\mathcal{A}}$ works for pairs of states.

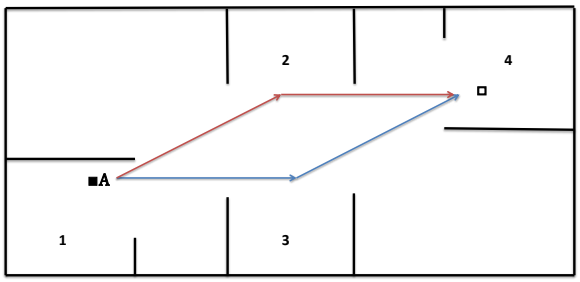

Fig. 4. The polygonal environment of the robot's motion with 4 rooms. The blue broken line illustrates the planned trajectory of the robot's move from a room no. 1 to the room no. 4. The red one illustrates the deviated trajectory of the robot's move.

A. The motion robot environment and its $LTL \bigcup HS^{D,L}$-specification

Let us consider a robot, say R, in some polygonal environment with 4 rooms as depicted on a picture below. Assume that R performs a task to dislocate a black block A from a room 1 to the room 4 and put in on a block B there and the planned (preferred) move trajectory leads from the room 1 by a neighborhood of the room 3 to the room 4 (the blue line on a picture). Let also assume that our robot exchanged this trajectory for another one (marked by a red line).
Therefore, the robot motion environment and plan specification in $LTL \cup HS^{L,D}$ may be rendered as follows:

- **Plan + Preferences**:
  1) Take a block A.
  2) Move from R_1 to R_3 (more preferable) or Move from R_1 to R_4 (less preferable).
  3) If you are in R_3, move from R_3 to R_4.
  4) Go to the room R_4).
  5) Put a block A on the block B.

We can also extract the following 'behavioral' rule for the robot as a condition of an effective plan performing.

- **Condition for the plan performing/behavioral rules**:
  1) Always in a future, if you take a block A, go to the room R_3.

Finally, we should give a short description of the polygonal robot motion environment.

- **The robot environment**:
  1) Environments consists of 4 rooms ,
  2) In a room R_1, block A is initially located ,
  3) In a room R_4, block B is initially located ,
  4) In rooms R_2, R_3 no blocks are located ,
  5) In room R_4, block A is finally located ,
  6) The robot motion area is always located on the left of a room R_1 ,
  7) The robot's motion area is always located on the right of a room R_4 .

All these conditions may be regarded now in terms of $LTL \bigcup HS^{D,L}$ in the corresponding way as follows:

- **Plan + Preferences**:
  1) $Take(A)$.
  2) $Move(R_1^A, R_3) \vee Move(R_1^A, R_4)$.
  3) $HOLDS(R_3^R) \rightarrow Move(R_3, R_4)$.
  4) $Put(A)$.
  5) $HOLDS(R_4^A)$.
- **Condition for the plan performing/behavioral rules**:
  1) $G(take(A) \rightarrow \langle L \rangle go(R_3)$.
- **The robot environment**:
  1) $R_1 \wedge R_2 \wedge R_3 \wedge R_4$,
  2) $R_1^A \wedge R_4^B$ $(HOLDS_{Init}(R_1^A))$,
  3) R_4^A $(HOLDS_{Fin}(R_1^A))$,
  4) $[D](R_1 \rightarrow Left)$
  5) $[D](R_4 \rightarrow Right)$.

Let us return now the initial assumption that the robot deviated from the planned path and has chosen a red line from $R_1 to R_4$, so via R_2. We can trace this deviation for the following juxtaposition of two formal descriptions in terms of $LTL \bigcup HS^{D,L}$ for both situations.

plan of the robot	**the real plan performing**
$Take(A)$	$Take(A)$
$Move(R_1^A, R_3) \vee Move(R_1^A, R_4)$	$Move(R_1^A, R_2)$
$HOLDS(R_3^R) \rightarrow Move(R_3, R_4)$	$Move(R_2^A, R_4)$
$Put(A)$	$Put(A)$
$HOLDS(R_4^A)$	$HOLDS(R_4^A)$
behavioral rule	**behavioral rule**
$G(take(A) \rightarrow \langle L \rangle go(R_3)$	?

B. From $LTL \cup HS^L$ to the Büchi automaton

The next stage of the plan controller construction consists in a translation of $LTL \cup HS^L$-formulas to states of an automaton which usually is not given *a priori*, but it must be constructed in the appropriate way. The automaton in our case will be constructed due to [21], [22] *via* such that states are identified with subsets of closures of the $LTL \cup HS^L$-formulas. In order to illustrate this procedure let us consider a case of a single LTL-formula Take(A). Due to definition 5 from p. 5 a closure of a formula ϕ contains all of its sub-formulas and its negations. In this case we get the following sets of formulas: $\emptyset$, $\{\neg A\}, \{A\}$, $\{TAKE(\neg A)\}$, $\{A, TAKE(\neg A)\}, \{TAKE(A)\}, \{A, TAKE(A)\}$ – as depicted on a fig. 3.

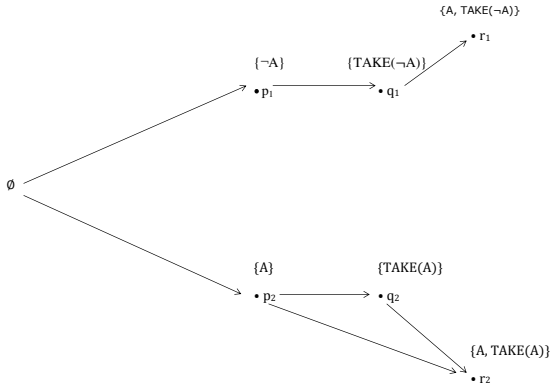

Fig. 5. Fragment of the Büchi automaton with states for a closure of the LTL-formula Take(A).

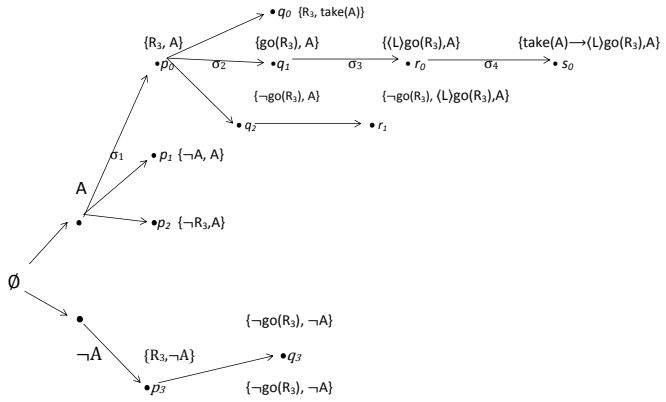

Fig. 6. Fragment of the Büchi automaton with states for a closure of the LTL-formula $Take(A) \rightarrow \langle L \rangle go(R_3)$.

The fragment of Büchi automaton for a more complicated formula $LTL \cup HS^L$-formula $take(A) \rightarrow \langle L \rangle go(R_3)$ was presented on a diagram 4.

The fragment of the Büchi automaton, say $\mathcal{A}$, for LTL-formula $Move(R_1^A, R_3)$ expressing the second step of the robot's plan is more complicated and it looks like depicted on fig.3. The same principle determines a construction way

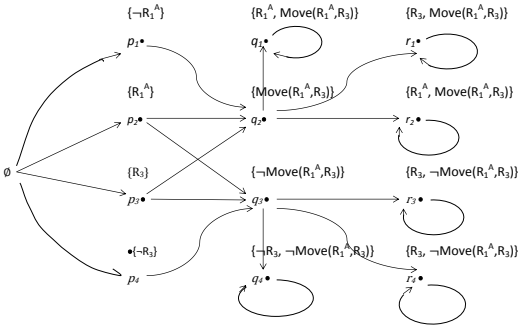

Fig. 7. Fragment of the Büchi automaton with states for a closure of the LTL-formula a$Move(R_1^A, R_3)$.

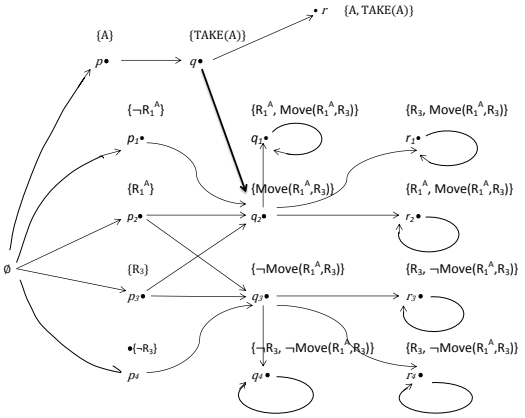

Fig. 8. Fragment of the Büchi automaton with states for a closure of the LTL-formulas $Take(A)$ and $Move(R_1^A, R_3)$.

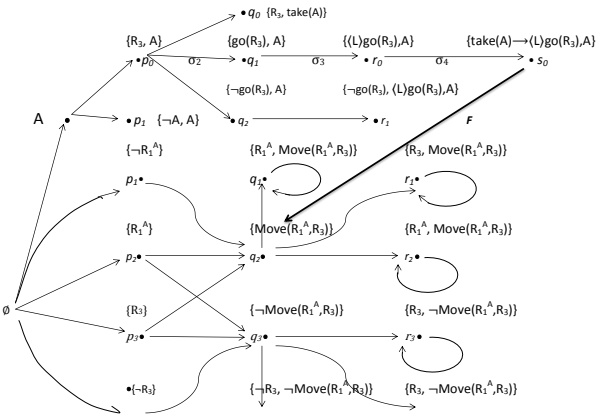

Fig. 9. Fragment of the Büchi automaton for $Move(R_1^A, R_3)$ and for a fragment of a formula $take(A) \rightarrow \langle L \rangle go(R_3)$.

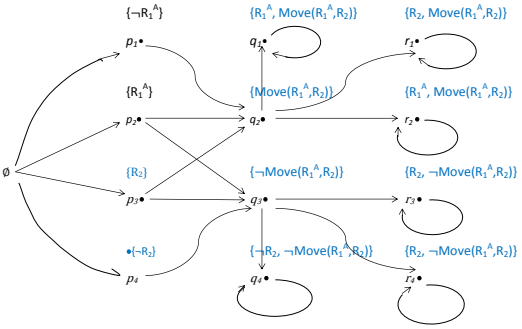

Fig. 10. Fragment of the Büchi automaton for the real task performing for the closure of LTL-formula $Move(R_1^A, R_2)$.

of the automaton fragment for $Move(R_1^A, R_3)$ – as depicted on a Fig. 5. In addition, the fragment of automaton for both formulas: $Take(A)$ and $Move(R_1^A, R_3)$ (taken together) is demonstrated on a Fig. 6. Finally, a more extended fragment of this automata for $Move(R_1^A, R_3)$ and the 'behavioral rule' of the robot $Take(A) \rightarrow \langle L \rangle go(R_3)$ – providing the plan performing – was presented on a Fig. 7.

It is not difficult to observe that a 'global size' of such automata for a complete plan of the robot and its motion environment is very large and its complete presentation would be difficult and non-suggestive. It is enough to observe that the full automaton is a composition of the appropriate fragments enriched by some 'move-lines' (the dark line on a Fig. 7) in order to connect the appropriate fragments of this automaton.

In order to detect discrepancies between the plan-automaton (for $Move(R_1^A, R_3)$ and for the 'behavioral rule' $take(A) \rightarrow \langle L \rangle go(R_3)$) with the corresponding part of automaton for the real performing of the plan, it is enough to compare both pictures. (The different states, i.e. with different formulas satisfied in them, are marked in a blue color.) Moreover, the plan-automata is larger as it also contains the transition 'branch' for the 'behavioral rule' of the robot. This branch cannot be added to the second automaton – due to observations from last section.

It has emerged that a discrepancy on the level of $LTL \cup HS^L$-formalism can be naturally reflected by its corresponding automata – as depicted on the Fig. 8. and Fig. 6.

C. The product automaton

As it has already been mentioned – each product automaton preserves some portion of information encoded by two automata: by the plan-automata, say $\mathcal{A}^{plan}$ and by its 'rival' for the real task performing, say $\mathcal{A}^{perf}$. As each product structure, the product automaton $\mathcal{A}^{plan} \times \mathcal{A}^{perf}$ is built up from pairs of states of the form: (s_1^{plan}, s_2^{perf}), where each $s_1^{plan} \in \mathcal{A}^{plan}$ and each $s_2^{perf} \in \mathcal{A}^{perf}$. [5] The similar pairs can be constructed with respect to transitions taken from $\mathcal{A}^{plan}$ and their equivalents from $\mathcal{A}^{perf}$ (if there are)[6].

The product automata – due to the earlier definition of preferential product automaton – $\mathcal{A}^{plan} \times \mathcal{A}^{perf}$ must have a general form:

$$\langle \Sigma_1 \times \Sigma_2, S^{plan} \times S^{perf}, S_0^{plan} \times S_0^{perf}, \rightarrow, \mathcal{F}^{\alpha} \times \mathcal{F}^{\beta}, \alpha_1, \alpha_2 \ldots \rangle . \tag{8}$$

Assuming that the choice of $Move(R_1, R_3)$ is preferable with a degree, say $\frac{2}{3}$ and the choice of $Move(R_1, R_4)$ – with a degree $\frac{1}{3}$ in the robot plan, the fragment of product automata $\mathcal{A} \times \mathcal{A}^{pref}$ for formulas $Move(R_1, R_3) \vee Move(R_1, R_4)$ and $Move(R_1, R_2)$ – due to definition – will have the following algebraic representation:

$$\Sigma_1 \times \Sigma_2 = \mathcal{L}(LTL \cup HS^L) \times \mathcal{L}(LTL \cup HS^L),$$
$$S^{plan} \times S^{perf} = 2^{cl(Move(R_1,R_3) \vee Move(R_1,R_4)} \times 2^{cl(Move(R_1,R_2)},$$
$$S_0^{plan} \times S_0^{perf} = \{\emptyset, \{R_1\}, \{\neg R_1\} \ldots\}^2,$$
$$\mathcal{F}^{\alpha} \times \mathcal{F}^{\beta} = \{R_1, R_3, R_4, Move(R_1, R_3)^{\frac{2}{3}}, Move(R_1, R_4)^{\frac{1}{3}}\} \times \{R_1, R_2, Move(R_1, R_2)\},$$
$$\alpha_1 = \tfrac{2}{3}, \alpha_2 = \tfrac{1}{3}.$$

The diagram presentation of the product automaton $\mathcal{A} \times \mathcal{A}^{pref}$ is simple and much more suggestive. For example, a diagram of the product automaton fragment for formulas $Take(A), Move(R_1^A, R_3)$ 'produced' with $Move(R_1^A, R_2)$ would be a product of single automata from Fig.6 and Fig. 8. (Both these automata – so to speak – combined together). The preferences imposed on some transition paths must be only marked by the appropriate values such as $\frac{2}{3}$, $\frac{1}{3}$ [7].

D. PROLOG-description of the product automaton

The last step of our plan controller construction is to encode the product automaton – earlier described in details – in a declarative language such as PROLOG. An idea of encoding is simple: a 'status' and localization of automaton states will be described by such predicates as: final(x), initial(x), but the transitions between them may be rendered by 3-argument predicates arc(x,y,z).

In this framework the PROLOG-description of the fragment of $\mathcal{A}^{plan}$-automaton for two formulas: $Take(A) \cup Move(R_1^A, R_3)$ may be as follows:

```
initial(0).
  final(r3).    final(r1).    final(r2).
final(r3).    final(r4).    final(q4).
arc(0,p1). arc(0,p2). arc(0,p3).
arc(0,p4).
arc(p1,q2). arc(p2,p2). arc(p2,q2).
arc(p2,q3). arc(p3,q2). arc(p3,q3).
arc(p4,q3).
arc(q1,q1). arc(q2,q1). arc(q2,r1).
arc(q2,r2). arc(q3,r3). arc(q3,r4).
arc(q3,q4).
arc(r1,r1). arc(r2,r1). arc(r3,r3).
arc(r4,r4).
arc(0, p). arc(p,q). arc(q,r). arc(q,q2).
```

In the similar way one can encode the fragment of the second automaton $\mathcal{A}^{pref}$ for $Move(R_1^A, R_3)$. Since each state is determined by a set of formulas satisfied in it and most of states of this automaton is determined by formulas different from the earlier ones, one should denote the corresponding states – when needed – by capital letters: R_1, R_2, Q_1, Q_2 etc. In order to encode them in PROLOG we will represent them by $'stateR_1', 'stateR_2'$ etc.[8] Thus the PROLOG-description of the required fragment of $\mathcal{A}^{pref}$ looks as follows:

```
initial(0).
final(r3).    final(r1).    final(r2).
final(r3).    final(r4).    final(q4).
arc(0,p1). arc(0,p2). arc(0,P3).
arc(0,P4).
arc(p1,Q2). arc(p2, stateP2).
arc(p2,stateQ2). arc(p2,stateQ3).
arc(stateP3,stateQ2).
arc(stateP3,stateQ3).
arc(stateP4,stateQ3).
arc(stateQ1,stateQ1).
arc(stateQ2,stateQ1).
arc(stateQ2,stateR1).
arc(stateQ2,stateR2).
arc(stateQ3,stateR3).
arc(stateQ3,stateR4).
arc(stateQ3,stateQ4).
arc(stateR1,stateR1).
arc(stateR2,stateR1).
arc(stateR3,stateR3).
arc(stateR4,stateR4).
```

In order to better elucidate differences between both PROLOG-encodings, let us write in the lines which differentiate both codes:

[5] It is not completely correct, because we should pedantically state that s_1^{plan} belongs to some set S^{plan} of states of $\mathcal{A}^{plan}$, but we will omit this distinction for a simplicity and some suggestiveness of analysis.

[6] Of course, both automata $\mathcal{A}^{plan}$ and $\mathcal{A}^{perf}$ are defined over the same alphabet $\Sigma = \mathcal{L}(LTL \cup HS^{L,D})$.

[7] Naturally, these paths (with associated values) could by also distinguished among other ones in other way on a diagram representation of the automaton.

[8] This encoding follows from the fact that capital letters in PROLOG are variables.

```
arc(stateQ1,stateQ1).
arc(stateQ2,stateQ1).
arc(stateQ2,stateR1).
arc(stateQ2,stateR2).
arc(stateQ3,stateR3). arc(stateQ3,R4).
arc(stateQ3,statesQ4).
arc(tateR1,stateR1). arc(stateR2,stateR1).
arc(stateR3,stateR3).
arc(stateR4,stateR4).
```

In addition, the third line of this first code for $\mathcal{A}^{plan}$ is partially incompatible with the corresponding line of the second code. The lack of the last line of the first code in the second code is accidental, since it follows from the automaton construction for $Move(R_1^A, R_2)$ only, but the "branch" for $Take(A)$ could be also added to this fragment of $\mathcal{A}^{pref}$. Nevertheless, the branch for $Take(A) \rightarrow \langle L \rangle go(R_3)$ cannot be added to is as the robot did not respect this 'behavioral rule' in its real task performing what it is reflected by $\mathcal{A}^{pref}$.

It remains to enrich these PROLOG–descriptions by some preferential component – as it it has been made with respect to automata. Due to our convention – preferences are denoted by rational numbers from a fuzzy set $[0, 1]$ and they are associated to paths/arcs between automaton states. For simplicity of the PROLOG-representation, we can assume that they can be associated to final states of such paths/arcs. Assume, however, that we do not know how they are associated to concrete formulas or states, but we only known that each of formula can take one of values from the set $\{0, \frac{1}{2}, \frac{2}{3}, 1\}$. If we define the automaton branches for a $Take(A)$-formula by PROLOG lists, say X and Y, we also need to add a piece of information about possible fuzzy values that can be considered:

X ins $0, \frac{1}{2}, \frac{2}{3}$, 1, and Y ins $0, \frac{1}{2}, \frac{2}{3}$, 1.

These coding examples do not exhaust the list of possible ways of PROLOG-encoding, but they are used for illustration and can be extended and specified in many ways.

VI. Conclusions

It has just been demonstrated how the hybrid plan controller can be constructed beginning with a formal description of the robot motion environment. As it could be observed – we were mostly interested in a theoretic side of a construction of such a controller, putting aside its real robotic materialization. This issue could constitute a subject of further research direction.

Anyhow, it has emerged that the initial discrepancy between a plan and its real performing by a robot can be encoded at each stage of the controller construction without losing of any portion of information. In fact, the same discrepancy at the stage of the LTL-description can be transformed to the stage of the automaton construction and – finally – could be visible at the stage of its PROLOG-representation, too. One could venture a thesis that attempts with other languages of a declarative paradigm give the similar results.

Naturally, the preferential extension of automata and the whole construction of the plan controller that we have just proposed forms a kind of an 'external' extension. In fact, we have not introduced any explicit preferential language to LTL extended by HS-language with $\langle D \rangle$ and $\langle L \rangle$. It seems that this task could be feasible in some preferential extension of HS or LTL.

***Abstract*—Mood of music is considered as one of the most intuitive criteria for listeners, thus this work is focused on the emotional content of music and its automatic recognition. The research study presented in this work contains an attempt to music emotion recognition including audio parameterization and rough sets. A music set consisting of 154 excerpts from 10 music genres was evaluated in the listening experiment. This may be treated as a ground truth. The results achieved indicated a strong correlation between subjective results and objective descriptors and on that basis a vector of parameters related to mood of music was created. On the other hand, rough set-based processing was applied to derive reducts containing the most promising features in the context of mood recognition, as well as confusion matrices of the mood recognition. Both approaches indicate strong relationship between objective descriptors and subjective evaluation of mood of music.**

Introduction

In music perception studies many different classifications and systems that describe music components are defined. Levitin [1] observed that from the listener's perspective there are seven major elements of music: loudness, pitch, melody, harmony, rhythm, tempo, and meter. These components are significant for discussion related to emotions included in music. The conventional approach to studying music emotion perception or to assigning music genre consists in subjective tests, in which a number of listeners evaluate a given music excerpt, and then these results are analyzed using statistical processing. This process is very lengthy and arduous, and does not always return reliable results, as mood and emotion are often treated by the listeners as interchangeable terms. Even such a notion as "music genre" may not precisely be defined, but still it plays an essential role in music appreciation and cognition. Mood plays an important role in music interpretation and annotation. Still, even though mood is an intuitive way of music describing, it is very difficult to find an exact correlation between physical features and perceived mood, which is necessary to make the annotation process automatic. This way, mood could automatically be added to music recommendation systems [2], [3].

Music as a form of art is perceived and interpreted in many different ways. It contains layers of music composition elements, emotions that may elicit different meanings, references to other pieces and other elements that are difficult to define and interpret. On the other hand, music can be treated as an audio signal and parameterized according to its temporal and spectral characteristics. The relationship between music described by music features and parameters derived from the signal is very difficult to find. The researchers' task is to identify parameters that are related to those features.

As already mentioned, with the growth of accessible digital music libraries over the past decade, there is a need for research into automated systems for searching, organizing and recommending music. Therefore, the aim of this study is to find a correlation between subjective evaluation of music mood and objective data processing. For that purpose, the rough set-based [4], [5] analysis is carried out, employing the Rough Set Exploration (RSES) system [6], [7].

The paper is organized as follows; Section II presents the mood model used in this study, list of labels and the principles of the listening tests carried out by the authors, as well as results of mood perception-based evaluation. In Section III correlation analysis is performed for data gathered in the listening tests and in feature vectors that are assigned to the set of 150 music excerpts. As a result, a table is created that contains the most significant parameters correlated to two mood-related features, namely: valence and arousal. Next, the same data are analyzed using the rough set-based processing and then results obtained compared to those presented in Section III. Finally, a short summary is included in Conclusion Section.

Subjective Evaluation

A. Model of Mood of Music

This section includes information with regard to the main experiment that aimed for subjective emotional content evaluation of larger set music. Outcomes from previous experiments [8]–[12] were taken into consideration and affected the final form of this experiment including the model of emotions, music dataset and the experimental procedure.

The test was executed to collect subjective mood evaluation results of a large set of songs using specially

This work was supported by Gdansk University of Technology

designed graphical interface (Fig. 1, for translation see Table I). The model of mood of music used in the experiment was proposed by the authors. The main assumptions were that the model has to be intuitive for users and compatible with dimensional models consisting of two dimensions as proposed by Thayer [13].

Fig. 1 Graphical interface dedicated for mood of music evaluation

Since previous stages of the research showed that 2-dimensional model is not very intuitive for listeners, an alternative solution was proposed [10]. The set of mood labels was selected from the Mood Dictionary Associated with Music proposed by the authors [10] Mood labels (originally in Polish) along with their translation can be found in Table I.

Mood descriptors were placed on a 2-dimensional plane, with regards to dimensions retrieved from Multidimensional Scaling (MDS) experiment [11]. This placement is coherent with Thayer's model [13] and Russel's [14] emotion representation. It is also consistent with findings of Brinker *et al*., [15] and Hevner [16], who placed mood descriptors on Valence/Arousal (VA) plane.

TABLE I.
LIST OF MOOD LABELS USED IN GRAPHICAL INTERFACE DESIGNED FOR MOOD OF MUSIC REPRESENTATION

No.	Mood label (Polish)	Mood label (English)
1	Agresywny	Aggressive
2	Depresyjny	Depressive
3	Ekscytujący	Exciting
4	Energiczny	Energetic
5	Neutralny	Neutral
6	Relaksujący	Relaxing
7	Smutny	Sad
8	Spokojny	Calm
9	Wesoły	Joyful

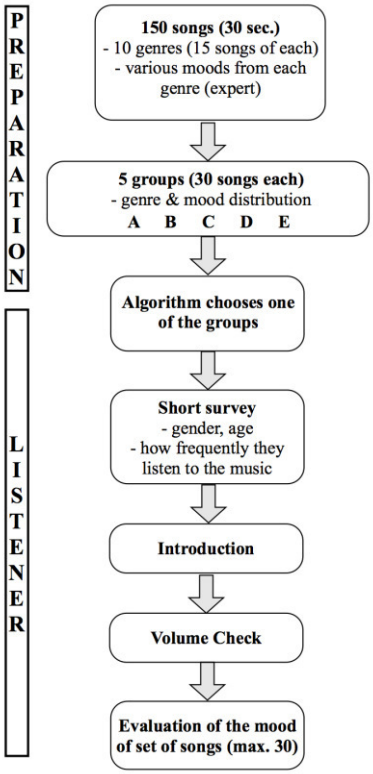

Fig. 2 Listening test arrangement related to music mood evaluation

The intensity of color corresponds to the intensity of the particular emotion contained in music. The "white" area placed in the center is considered as a neutral, where no emotional content is included. This concept is also strongly related to fuzzy logic and the concept of "degrees of truth". It includes various states of truth in between 0 (false) and 1 (truth), which is very intuitive, when it comes to evaluation of such a subtle substance as emotions.

B. Listening Procedure

The stages of the test are presented in Fig. 2. The main part of the test consisted of a series of musical excerpts presented one after another, where listeners were asked to evaluate the mood of music by clicking at the graphical mood representation. It was preceded by a short survey and the level check. The experiment was performed in Polish and its total average duration was approximately 12 minutes. The test was performed using a WEB-based interface. 112 listeners (57 women and 55 man) within age from 16 to 56 (average age 28) participated in the experiment. Majority of the audience reported that they listen to music everyday.

150 tracks were chosen from 10 different music genres, to obtain a diversified set. Chosen music styles were as follows: Blues, Classical, Country, Dance & DJ, Hard Rock & Metal, Jazz, Pop, R&B, Rap & Hip-Hop, Rock. It is worth noting, that styles chosen are easy to distinguish between each other and cover various music material. 30-sec music excerpts used in the experiment came from the SYNAT music database

[17], [18]. A detailed list of music files used in the experiments is available in [9].

C. Results

Answers provided by subjects were pre-processed and only valid entries were included in the result analysis. A submission was considered as valid, if consisted of 5 to 30 evaluated songs.

Results were analyzed with both dimensional and label approaches. In the dimensional approach answers were analyzed in the polar coordinates. To each field on the graphical interface, the number value was assigned according to the mood intensity (from 0 to 3) and the angle was assigned according to the position of the label. This allowed mapping onto 2D Energy/Arousal plane (Fig. 3). Achieved results were used as polar and Euclidean coordinates depending on the employed method. Selected results are listed in Table II.

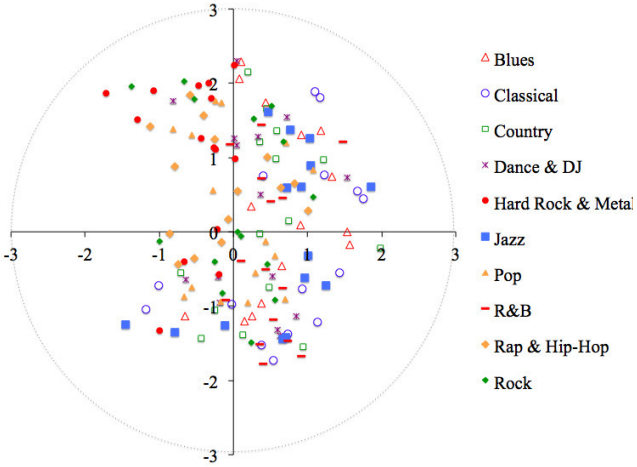

Fig. 3 *Mapping of 150 songs (divided by the genre) onto mood plane based on the listening test results*

Averaged ratings are mostly within range [0,2]. Only for aggressive mood a stronger result was obtained. In this case mood of music might be strongly related to the perceived emotion. Also distribution of music pieces sorted by genre is very interesting.

For pop and rock music, excerpts are distributed in all quadrants of the AV plane. There is no jazz songs in III quadrant. Blues was placed by listeners mostly on the right half of the VA plane (positive) as well as classical, where only two pieces were placed in quadrant III. A similar tendency is observed for country excerpts. Rap & Hip-Hop was considered mostly as music with high arousal and appeared mostly in quadrants I and II but some excerpts are placed in quadrant III.

Distribution of Blues and R&B was quite similar (mostly quadrants I and IV), which might be related to musical similarities and common roots of both genres. Although blues is often considered as very sad music, it was placed on the "positive" half of VA plane.

What is interesting, Dance & DJ excerpts are distributed among all quadrants as well as Pop and Rock. These music genres are very frequent in popular culture, therefore are not strongly related to one and only esthetics or topic but are mixtures of different trends. That is also reflected in values of the standard deviation, which are highest for these genres. Averaged results for each genre are listed in Table II. This table was used in the rough set-based analysis further on. Detailed results of the listening test are presented in [9].

TABLE II.
AVERAGED RESULTS FOR VARIOUS MUSIC GENRES

Music genre	Averaged Valence	Averaged Arousal	St. Dev. Valence	St. Dev. Arousal
Blues	0.60	0.33	1.11	1.16
Classical	0.68	-0.25	1.28	1.25
Country	0.44	0.10	1.05	1.02
Dance & DJ	0.25	0.26	1.06	1.15
Hard Rock & Metal	-0.55	1.03	0.99	1.09
Jazz	0.60	-0.10	1.19	1.33
Pop	0.04	0.22	1.04	1.20
R&B	0.49	-0.32	0.99	1.12
Rap & Hip-Hop	-0.17	0.62	1.10	1.12
Rock	0.00	0.43	1.24	1.13

All observations listed above are important cues for conducting experiments with decision systems. Although they are related to the specific music set, they might represent more general trends due to carefully selecting excerpts for the performed evaluation.

Contrarily, the label analysis was performed, where the number of occurrences of each label was calculated for every song. As a result, each song is described with a 9-element vector, where each position refers to the mood label (Table I). The value describes the percentage of occurrences of each label. Some songs are described by all listeners with mainly one label, while for other evaluations is spread among the labels. Examples of songs along with their label description are shown in Fig. 4.

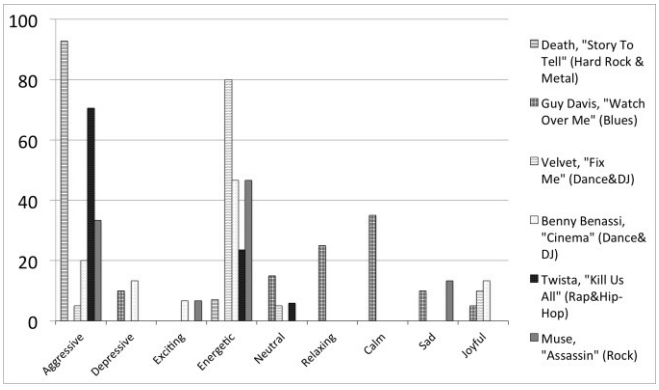

Fig. 4 *Example of results of mood labels assigned to particular songs. The vertical axis describes the percentage of occurrences of each label*

CORRELATION ANALYSIS

The starting point of the feature vector (FV) content creation for the purpose of automatic mood recognition was examination of previous studies performed in MIR by the authors and their collaborators. Resulted from them was FV applied to two databases, namely ISMIS [18] and SYNAT [9], [19]–[25], thus its content may be treated as very thoroughly analyzed. Moreover, the same FV was used in the ISMIS'2011 conference in music competition [18], in which more than 100 teams participated, thus it may also be treated as a kind of benchmarking. ISMIS is a database of approx. 1300 music excerpts of high quality audio excerpts, collected and divided into six music genres. On the other hand, the SYNAT database is a collection of 52532 pieces of music described with a set of descriptors obtained through the analysis of mp3-quality recordings. For the SYNAT database, the analysis band is limited to 8kHz. The database stores 173-feature vectors, which in majority are the MPEG-7 standard parameters (109). The vector has additionally been supplemented with 20 Mel-Frequency Cepstral Coefficients (MFCC), 20 MFCC variances and 24 time-related 'dedicated' parameters. The SYNAT database was realized by the Gdansk University of Technology (GUT) [19] and music was collected from the Internet. The vector includes parameters associated with the MPEG-7 standard, melcepstral coefficients (MFCC) and is supplemented by the so-called dedicated parameters which refer to temporal characteristic of the analyzed music excerpt. Full list of parameters was shown in the earlier study [12], [20].

In addition, parameters from the MIR Toolbox [26] were calculated. This set of parameters contains a lot of information but not necessarily related to mood of music. At previous stages of this study a selection of parameters based on correlation analysis was performed and returned good results, therefore this approach was also applied. Correlation between subjective values of Valence and Arousal and parameters was calculated and therefore a set of features strongly related to mood was created. Only parameters with correlation coefficient higher than 0.50 were included in the final feature vector. Eventually, the feature vector describing mood of music consisted of 16 parameters from SYNAT, listed in Table III and 16 parameters from MIR Toolbox Table IV. It is worth noting that correlation is slightly stronger with parameters based on music characteristic than from SYNAT, which describe general properties of an audio signal. Description of parameters included in SYNAT can be found in [9], [12] and features from MIR Toolbox in the MIR manual [26].

TABLE III.
PARAMETERS CORRELATED WITH SUBJECTIVE MOOD OF MUSIC EVALUATION SELECTED FROM 173-SYNAT FVS

Valence		
No.	**Parameter**	**Corr.**
1	ASE2	-0.72

14	Spectral Rolloff 185	0.52
15	Spectral Kurtosis	0.51
16	Spectral roughness	0.50

ROUGH SETS-BASED ANALYSIS

A. Input Data for Rough Sets

As mentioned earlier, the RSES was used in this study. The system generates interpretable results in the form of reducts,

classification measures, etc., thus it is very useful for the analysis and classification of data.

Data for the rough set-based analysis were prepared in various configurations. Table V gathers datasets in a form of decision tables, in which: "Mood label I", " Mood label II", and "Music Genre" are the decision attributes. Averaged values of Valence and Arousal were calculated, and averaged position on the Valence/Arousal plane indicated Mood label I. Mood label II was chosen according to the label analysis, where the number of occurrences of each label was calculated for every song and the label with maximum number of occurrences was chosen. The last column shows music genres. As seen from Table V, not always labels from Mood labels I and II are consistent between each other. Moreover, it is interesting that the position in VA plane does not condition music genre assigned.

Datasets from Table V were analyzed by the RSES system, the returned results are shown in a form of confusion matrices (Tables VI-VIII), containing true positives (TP), as well as coverage and accuracy measures. Data were randomly split into 60% and 40% subsets for training and testing the classifier. For every dataset a separate set of rules was created by the following procedure:

1. Every parameter value range was discretized by a local variant of Maximum Discernibility discretization method.
2. Reducts were calculated from training subset by the genetic method available in RSES software.
3. Reducts were tested against training subset to create decision rules, based on every object in the subset.
4. Testing subset was classified and accuracy was expressed by calculating a confusion matrix.

TABLE V.

LISTENING EXPERIMENT RESULTS USED IN THE RSES-BASED PROCESSING

Song No.	Valence	Arousal	Mood Label I	Mood Label II	Music Genre

Another set of data containing FVs and assigned Mood label I, Mood label II and music genre for the same 150 music excerpts was called FVs. These data returned confusion matrix (see Table IX). This dataset was classified by the following 10 reducts, with sizes ranging from 8 features to 11 features, each with positive region of 1.0 (i.e. percentage of objects from training set accurately classified), see Table X.

It should be of interest that reducts contain rhythm-related features belonging to "dedicated" features, such e.g. 1RMS_TCD_10FR_VAR, 2RMS_TCD_10FR_VAR, etc. This confirms a notion that music genre and related mood rely heavily on rhythmic features of music. Moreover, when comparing the correlation analysis performed (Table III), it may be seen that similar parameters were derived from this analysis for Valence and Arousal, which are features corresponding to mood of music.

Total number of tested objects: 60, Total accuracy: 0.3, Total coverage: 1.

As mentioned before other datasets combinations were tested. Two more attempts were made to classify songs:
- mood based on "Valence", "Arousal", and music genre features,
- genre based on "Valence", "Arousal", and "Mood Label I" features.

Even though, confusion matrices did not bring very satisfying results, i.e. the total accuracy was at level of 0.25 and the total coverage was approx. 0.56, still, the classification performed, based on a majority voting, returned adequate results.

TABLE X.
REDUCTS DERIVED FROM THE RSES SYSTEM FOR FVS

No.	Parameters
1	1RMS_TCD_10FR_VAR, 2RMS_TCD_10FR_VAR, ASC_V, ASE12, ASE27, ASEV14, MFCC20, SFMV6
2	1RMS_TCD, 1RMS_TCD_10FR_VAR, 2RMS_TCD_10FR_VAR, 3RMS_TCD, ASC_V, ASE_MV, ASE10, ASE17, ASE27
3	1RMS_TCD, 1RMS_TCD_10FR_VAR, 2RMS_TCD_10FR_VAR, 3RMS_TCD, ASC_V, ASE_MV, ASE10, ASE27, SFM7
4	1RMS_TCD_10FR_VAR, 2RMS_TCD_10FR_VAR, 3RMS_TCD_10FR_MEAN, ASE_MV, ASE10, ASE12, ASE20, ASEV22, MFCC20, SFM8

8	1RMS_TCD, 1RMS_TCD_10FR_VAR, 2RMS_TCD_10FR_VAR, ASC_V, ASE10, ASE12, ASEV14, MFCC7, SFM15, SFM8, SFMV6
9	1RMS_TCD, 2RMS_TCD_10FR_VAR, 3RMS_TCD_10FR_MEAN, ASC_V, ASE12, ASE22, ASE27, ASEV14, ASEV17, SFM5, SFM7
10	1RMS_TCD, 2RMS_TCD_10FR_VAR, 3RMS_TCD, ASC_V, ASE_MV, ASE12, ASE17, ASE27, ASE9, ASEV1, ASEV17

Finally, the last experiment used a decision table consisted of the joint Synat and MIR Toolbox parameters (derived from the correlation analysis as the ones correlated with mood of music). The decision attribute was Mood Label I. The confusion matrix for this dataset is presented in Table XI. 44 reducts resulted from the processing, each containing 6 to 8 attributes (Fig. 5).

TABLE XI.

CONFUSION MATRIX FOR CLASSIFICATION OF MOOD

Total number of tested objects: 60, Total accuracy: 0.383, Total coverage: 1.

Omitted attributes:
Tonal_hcdf1_HarmonicChangeDetectionFunction_Mean, Spectral_irregularity1_Spectral irregularity_Mean2, Spectral_kurtosis1_Spectral_kurtosis_Mean.

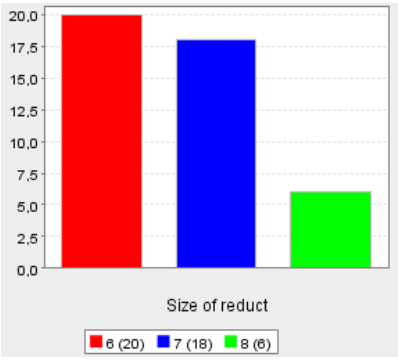

Fig. 5 *Histogram of reduct sizes*

An attribute called Spectral irregularity_mean was the most often used (see Fig. 6), also Spectral brightness is among those most often occurring, which confirm the results derived from the correlation analysis (see Table IV).

Based on these attributes and all training cases a set of rules was generated, containing 2583 rules (Fig. 7), aimed at precise classification of all 90 training objects. Such a disproportion indicates low quality of approximations, and low generalization, as the test set is classified with total accuracy of only 0.383.

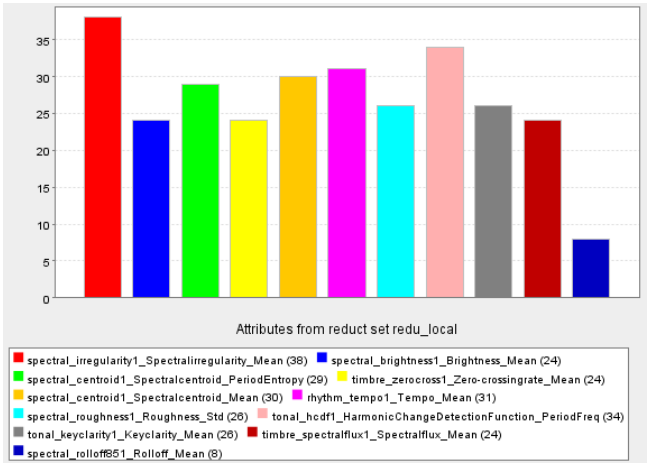

Fig. 5 *Histogram of occurrence of attributes in reducts*

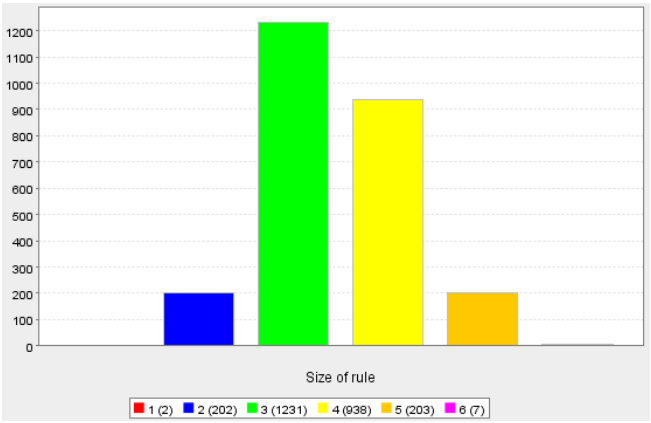

Fig. 7 *Histogram of rule lengths*

CONCLUSION

Several subsets were created for mood classification within the study presented. Gathered data contain results of subjective evaluation, which may be treated as ground truth in this type of classification. This means that we treat listeners' opinions, derived from a meaningful statistical analysis, as the starting point in such analyses. However, it should be remembered that listeners may impose their own emotions on those intended by the composer. That's why it would be preferable if the composer's perspective on the emotion content is known. However from the results obtained, distribution of music objects on the VA plane is coherent with findings available in the literature of the subject

[27], reflected by the prior concepts on musical expressiveness.

Data were carefully analyzed using correlation analysis, as well as the rough set-based processing. In the experiments conducted, the authors used the RSES application for testing the effectiveness of recognizing music genres using the rough set theory. It should be observed that reducts containing only a small number of parameters brought very similar results to those obtained in the correlation analysis, among them spectral irregularity mean and spectral brightness features may be found. The latter analysis was performed for two important features describing mood of music, namely valence and arousal. High accuracy and coverage achieved in rough sets processing confirm consistency between dimensional and label interpretation of the proposed model of mood of music.

***Abstract*—This paper describes a new approach to metaheuristic-based data clustering by means of Krill Herd Algorithm (KHA). In this work, KHA is used to find centres of the cluster groups. Moreover, the number of clusters is set up at the beginning of the procedure, and during the subsequent iterations of the optimization algorithm, particular solutions are evaluated by selected validity criteria. The proposed clustering algorithm has been numerically verified using twelve data sets taken from the UCI Machine Learning Repository. Additionally, all cases of clustering were compared with the most popular method of k-means, through the Rand Index being applied as a validity measure.**

I. Introduction

EXPLORATORY Data Analysis is essentially centred upon tasks of clustering, classification, data reduction and outliers detection. The procedure of clustering consists of dividing a large data set into smaller subsets called 'clusters'. This partition is achieved through developing a function which assigns individual elements of the data collection into each subset. This technique has been applied to a wide range of problems, including various technical tasks [1], robotics [2] and control approaches [3], to aspects of economics [4], as well as to many agricultural issues [5].

This procedure is considered to be an unsupervised method, therefore, the division of the data is based on information directly discovered (derived) from the data itself. Hence, the separation into clusters is made in such a way that the elements within the clusters are very similar to each other, but show a difference to that held in other clusters. [6].

In data clustering procedures, a few main groupings of algorithms can be distinguished. The first of these are hierarchical [7]. In this case, the process consists of phases in which available set of clusters are merged or divided. An example of an algorithm implementing the aforementioned task, is the "bottom up" approach of Agglomerative Clustering [8]. It starts from a division in which every object is a separate cluster. In each subsequent iteration, the various groups are combined on the basis of the adopted criteria. Finally, all tested elements are placed within one cluster. A further example, albeit an opposite, is the "top down" approach of Divisive Clustering Algorithm [9]. Here, all data items start in one cluster, and this splits recursively, as one element represents one cluster.

A second algorithm group is that called 'centroid-based clustering'. This is based on minimizing variance within the clusters. Here, the best known and most commonly employed method is 'k-means procedure' [10].

The application of fuzzy-logic-based techniques [11] are a still further way of completing a clustering task. In so doing, the individual elements of a considerate data set are assigned to more than one cluster. This feature imparts a significant difference to this category of algorithms, when compared to the other procedures. The most popular algorithm of this group is 'C-fuzzy-means' [12].

Density based methods are included within another group of clustering procedures. One of the more recently introduced algorithms is that referred to as the Complete Gradient Algorithm [13]. It based on the nonparametric methodology of statistical kernel estimators as used for the recognition of data set density. This information provides the number, as well as the shape of the proposed clusters. An interesting feature of this algorithm is that it possibilities of adjustment to the authentic structure of data, and, consequently, the achieved

978-83-60810-90-3/$25.00

results are more justifiable with regard to natural point of view.

A further, but similar group of procedures of clustering tasks are those of algorithms based on grid technique. These methods are based on the assumption that data space can be partitioned into a finite number of cells - the grid structure. Subsequently, each cell density is calculated, and, after sorting the cells according to their densities, the clusters centres are determined. What is interesting herein is that this group of algorithms allows for the traversal of neighbour cells. The first algorithm in this group was introduced by Warnekar and Krishna [14]. Nowadays, the most well-known algorithms in this group are CLIQUE, MAFIA, ENCLUS, OptiGrid, O-cluster and CBF. It should be noted that such algorithms can be used for high-dimensional tasks [15].

Yet one more group of clustering algorithms is that based on an optimization algorithm inspired by Nature [16], [17]. In this approach, some metaheuristics are applied for the optimization of adopted division criteria. This action enables the coming about of great similarity of items inside the clusters, and, simultaneously, vast diversity between clusters. The mentioned criteria can be expressed as a specific mathematical formula, using a variety of statistical measures. These criteria are called 'clustering indexes', and their properties are used to assess the quality of the assignment of individual elements of the test set to the appropriate clusters.

Because the task of clustering is a NP-hard problem of combinatorial optimization [18], here – in natural manner – we apply KHA [19] as an optimization technique. This is so as to find the best location for placement of the centre point of cluster. Based on these position of centres, the individual elements of the data set are then assigned to defined groups. Completion of the thus defined clustering method is achieved using the selected three indices separately, and the obtained results are compared with the outcomes of k-means method application, taking into account the Rand Index [20] as a common evaluation criterion.

In next section, the reader will familiarize with some general information concerning optimization tasks and KHA. In Section III, the details of the application of the clustering approach, as well as selected clustering validity measures are being covered. The experimental results of our work are discussed in Section IV. Finally, in the last section of this paper, the reader will find some conclusions regarding the application of the proposed clustering algorithm, as well as intended further research and studies.

II. Optimisation based on Krill Herd Algorithm

KHA is an iterative heuristic procedure inspired by the natural phenomena of krill heard behaviour. This technique is mainly used for solving optimization problems in continuous space. Here, the solution of this problem comes about by finding such an argument x° of space under consideration $S \subseteq R^N$, which satisfies the following formula

$$f(x^\circ) = \min_{x \in S} f(x) \tag{1}$$

where $f(x)$ describes value of cost function.

The KHA originally proposed by Amir Hossein Gandomi and Amir Hossein Alavi in the paper [19], imitates the behaviour of the individual krill moving together as a herd. Such herds, move accordingly to environmental factors such as proximity to neighbours (herd density), dispersion of swarm, food position and any other biological and environmental phenomena.

In order to solve the optimization problem, we apply KHA metaheuristic. Herein, particular elements $x_i = x_i^1, \ldots, x_i^N$ of N dimensional solutions space in the form of P herd's individuals are represented. In the kth iteration, the best solution of the optimization problem as represented by the pth individual is given alternatively by these two equations:

$$x^\circ(k) = arg \max_{p=1,\ldots,P} f(x_p(k)) \quad \text{/for maximalization task/} \tag{2}$$

or

$$x^\circ(k) = arg \min_{p=1,\ldots,P} f(x_p(k)). \quad \text{/for minimalization task/} \tag{3}$$

The above best solution are corresponding with extremal value of cost function $f^\circ = f(x^\circ)$ given as (2) or (3).

The full KHA procedure in flow chart form is shown as Figure 1. This algorithm starts from an initialization of all its parameters, and positions of all P individuals are generated randomly ❶. In next step ❷, the cost function values are calculated for all initial P individuals using (2) or (3). The subsequent stage ❸ is of great importance and is characterized by KHA technique. It consists of formulas describing the movement of particular individuals. Such motion viv-a-vis each individual krill is determined by three main components. They are:

- movement induced by other krill individuals,
- foraging activity,
- random diffusion.

In subsequent time units, vector of movement of ith krill in KHA technique is based on the by Lagrangian formula:

$$\frac{dx_i}{dt} = N_i + F_i + D_i, \tag{4}$$

where N_i is the motion induced by other krill individuals, F_i denotes the foraging motion and D_i is the physical diffusion of the krill individuals, respectively.

The first factor ❹ is a reflection of the social inspiration of the swarm's individual members. In the herd, individuals are maintained at a high density. Hence, the velocity of each individual is influenced by the movement of others. Thus, the direction of movement by the α_i parameter is induced by the presence of other herd members. This parameter is determined on the basis of the following components: local effect and target effect. The fraction of motion is formulated as:

$$N_i^{new} = N^{max}\alpha_i + \omega_n N_i^{old}. \tag{5}$$

Here N^{max} represents the maximum possible speed that can be induced, ω_n in the range $[0, 1]$ is the inertia weight of a particular krill and N_i^{old} is the motion induced in the previous turn. The α_i parameter is defined as:

$$\alpha_i = \alpha_i^{local} + \alpha_i^{target}, \tag{6}$$

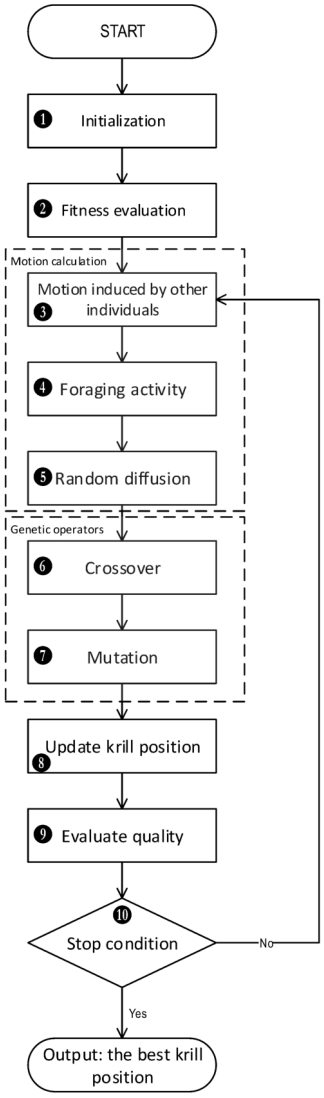

Fig. 1: Flowchart of KHA

where α_i^{local} is the local influence of the neighbours of any particular krill, whereas α_i^{target} is the target direction. The latter is determined by the position and movement of the best individual in a herd.

The α_i^{local} parameters are calculated according to the following formula:

$$\alpha_i^{local} = \sum_{j=1}^{NN} \hat{f}_{ij}\hat{X}_{ij}, \tag{7}$$

where

$$\hat{X}_{ij} = \frac{x_j - x_i}{\|x_j - x_i\| + \epsilon}, \tag{8}$$

and

$$\hat{f}_{ij} = \frac{f_i - f_j}{f^{worst} - f^{best}}. \tag{9}$$

In equation (9), f in describes the fitness value (1) of any investigated krill. Therefore f^{worst} and f^{best} represent, respectively, the worst and the best fitness of individuals in swarm. Additionally, NN provides the identification of the number of reachable krill neighbours, and ϵ is a positive number introduced to avoid singularities in the formula (8).

For determination of distance between particular krills and their neighbours, a parameter designated as being the sensing distance d_s, is introduced. This parameter may be formulated as:

$$d_{s,i} = \frac{1}{5P}\sum_{j=1}^{P}\|x_i - x_j\|. \tag{10}$$

Each individual incorporates its own target vector. This is determined as follows:

$$\alpha_i^{target} = C^{best}\hat{f}_{i,best}\hat{x}_{i,best}, \tag{11}$$

where

$$C^{best} = 2\Big(rand + \frac{k}{K^{max}}\Big). \tag{12}$$

Herein, k, K^{max} designate, respectively, the current iteration number and the maximum number of iterations. Moreover, $rand$ is a random value between 0 and 1, whereas $\hat{f}_{i,best}$ describes the best value of fitness function, while $\hat{x}_{i,best}$ provides the position of the best ith krill individual form the previous iterations.

The next main factor F_i of equation (4), is connected with the food foraging task. This F_i is defined as:

$$F_i = V_f\beta_i + \omega_f F_i^{old}, \tag{13}$$

where V_f is the food foraging speed and ω_f, denotes the inertia of the movement. In this previous equation (13), the food fitness of the ith individual is determined as follows:

$$\beta_i = \beta_i^{food} + \beta_i^{best}. \tag{14}$$

The aforementioned food aspect is determined by way of its location. Therefore, the virtual centre of food concentration is defined via KHA. This conception by the "centre of mass" approach is inspired. Hence, the food concentration in each iteration is calculated according to following formula:

$$X^{food} = \frac{\sum_{i=1}^{P}\frac{1}{f_i}x_i}{\sum_{i=1}^{P}\frac{1}{f_i}}. \tag{15}$$

Moreover, the food attraction for the ith krill individual is described via:

$$\beta_i^{food} = C^{food}\hat{f}_{i,food}\hat{X}_{i,food}. \tag{16}$$

The food coefficient in (16), expresses the global attraction of the food centre (15), and may be calculated as:

$$C^{food} = 2\Big(1 - \frac{k}{K^{max}}\Big). \tag{17}$$

The second part of equation (14) is as follows:

$$\beta_i^{best} = \hat{f}_{i,best}\hat{x}_{i,best}. \tag{18}$$

In this equation, $f_{i,best}$ is the best fit achieved by a given ith krill individual so far. This is characterised by its position $\hat{x}_{i,best}$.

The last element of the Lagrangian equation (4) is related to random physical diffusion ❺, notated as D_i. In essence, this component is of fully random character. This sub-part of movement is focused upon the diversity of population. In addition, it allows the individual krill to escape krill swarm in a situation of local optimum. Moreover, this part of equation (4) represents a trade-off between exploration and exploitation. The following formula describes this aspects of a random diffusion:

$$D_i = D^{max}\Big(1 - \frac{k}{K^{max}}\Big)\delta, \tag{19}$$

where, D^{max} is the maximum diffusion factor and δ describes the random directional vector.

Finally, the motion process can be formally summarized. This employs all the above effective parameters. The position of ith krill during the interval t to $t + \Delta t$ is, thus, determined by the following formula:

$$x_i(t + \Delta t) = x_i(t) + \Delta t \frac{dx_i}{dt}. \tag{20}$$

Here, it must be emphasized that parameter Δt is very sensitive to the speed and accuracy of optimisation task. In this respect, the Δt may be interpreted as being a scale factor of krill movement. This parameter can be obtained by way of the following equation:

$$\Delta t = C_t \sum_{j=1}^{N} (UB_j - LB_j). \tag{21}$$

In this equation, C_t is an empirically found constant number from the interval $[0, 2]$. What is more, UB_j and LB_j are, respectively, the upper and lower bounds of the jth feature $(j = 1, \ldots, N)$ of data set $X = x_1, \ldots, x_P$.

In the next stage of the KHA, the implementation of two basic evolutionary operators is applied. Firstly, in step ❻ the crossover function is considered. This operator is controlled by the crossover probability of the Cr parameter. In this approach, this operator is defined randomly. The crossover results in a change of the mth coordinate of ith krill as shown below by the formula:

$$x_{i,m} = \begin{cases} x_{r,m} & \text{for} \quad \gamma \le Cr \\ x_{i,m} & \text{for} \quad \gamma > Cr \end{cases}, \tag{22}$$

where $Cr = 0.2\hat{K}_{i,best}$; $r \in \{1, 2, ..., i-1, i+1, ..., P\}$ denotes a random index, and γ is a random number drawn from the interval $[0, 1)$ generated according to the uniform distribution. In this approach the crossover operator is calculated upon a single individual.

The last part of the main loop of the KHA employs the mutation operator ❼. This modifies the mth coordinate of the ith krill, doing so via the following formula:

$$x_{i,m} = \begin{cases} x_{gbest,m} + \mu(x_{p,m} - x_{q,m}) & \text{for} \quad \gamma \le Mu \\ x_{i,m} & \text{for} \quad \gamma > Mu \end{cases}, \tag{23}$$

wherein $Mu = 0.05/\hat{K}_{i,best}$; $p, q \in \{1, 2, ..., i-1, i+1, ..., P\}$ and $\mu \in [0, 1)$.

This operation completes the evolutionary procedures. Subsequently, we can now obtain individuals that are readily utilizable within the next iteration. In so-doing, in the last stage ❽ of the main loop, we should calculate the cost function for all the swarm members. Herein, the algorithm's stop condition ❿ decides whether the next iteration or the optimization algorithm is to be completed. The form of stop condition could be that of a time limit, or the reaching of a desired fitness level or a combination of these two.

More information about KHA can be found in [19]. Regarding KHA parameters, the tuning of the KHA is described in publications: [21], [22] and [23]. Notably articles [24] and [25] include other proposed modifications of the algorithm. The KHA procedure has been verified positively in discrete optimization tasks [26]. Furthermore, a parallel version of this algorithm can be found in [27]. It should also be underlined that this heuristic procedure has been applied in data base domains [28], medical tasks [29], in mechanism and machine theory [30], and also in neural learning process [31], e.t.c.

III. Clustering and Selected Clustering Indices

In this section a fusion of KHA with a variety of clustering task assessment methods is to be presented. The stated validation methods are based on characterisation indexes.

Consider a Y as being a data set matrix with dimensions D and M, respectively

$$Y = [y_1, \ldots, y_M]. \tag{24}$$

Herein, each data set element is represented by one column of this matrix. Moreover, the D feature describes each data item. The goal of the clustering task is to devise the particular division of the data set (24) into the individual C subsets, including the assignment of individual elements $y_1, \ldots, y_M$ to clusters $CL_1, \ldots, CL_C$,. In such process, as a rule, the number of clusters C is considerably smaller than the cardinality of set Y, i.e. $C \ll M$.

Individual clusters, along with their associated elements of the set Y, are characterized by points deemed the centroid of clusters $O = O_1, \ldots, O_C$. Each of these is calculated as:

$$O_c = \frac{1}{\#CL_c} \sum_{y_i \in CL_c} y_i, \tag{25}$$

where $\#CL_c$ denotes the number of elements assigned to the cth cluster. In a similar way, the center of gravity for all the investigated elements (24) is defined:

$$O_Y = \frac{1}{M} \sum_{i=1}^{M} y_i. \tag{26}$$

In this paper, the assignment of individual elements of the data set Y (24), to the clusters, is made through employing the KHA procedure. In undertaking this, krills are encoded as vectors that contain the centroid of clusters O_c. In this case, the number of clusters is established in advance, and the grouping of the individual elements of the data set is made on the basis of the rules of the nearest centroid. Thus, for

each point y_i (for $i = 1, \ldots, M$) the distance to each cluster centre O_c is calculated. In so-doing, the ith element belongs to cluster CL_c if the distance $dist(y_i, O_c)$ is the smallest of the tested distances.

Furthermore, the division of elements of the set Y, is evaluated in such a way as to minimize the cost function (1). This aspect is individually determined for each of the clustering index. The formula pertaining to individual functions will be described later in this work.

A. Rand Index

The Rand Index is the first in the sequence that will be presented. This is considered to be a so-called supervised method for validating clustering procedures. To use this index, it is assumed that the reference distribution of membership of individual elements of the data set Y with regard to the pertinent cluster, is known to be similar as that in the case of handling the data for the classification task. This index is expressed as:

$$I_R = \frac{a+d}{a+b+c+d}, \tag{27}$$

where a is the number of elements placed in the same reference group that in the cluster grouping, b denotes the number of elements that are placed in the reference group and in the different cluster sets, c defines the number of elements placed in other reference groups and in the same cluster, and, finally, d indicates the number of elements placed in the different reference groups and in the different cluster's groups.

Building upon above definition, it can be observed that I_R can yields value between 0 and 1. Furthermore, its maximum value points out the degree of full compliance of the clustering division result, with a reference set. In the reported studies, this index is employed for comparing the division by way of applying the clustering procedure that is based on KHA, with the division arising from the structure of the reference data (i.e. the label of classes). With this index, it is possible to compare the obtained results with the reference data, as well as with other clustering indices applied in the optimization cost function.

More information about the Rand Index can be found at [20], [32].

B. Calinski-Harabasz Index

The following indexes are designated as being unsupervised methods for validating clustering procedures. In such, the assessment of the quality of the division stems from the properties of the dataset and the individual clusters. Consequently, such induces, in terms of measuring ability, can be utilized within the evaluation function (1) at the KHA stage.

The Celinski-Harabasz criterion has its foundation within the concept of data set variance. This index is defined as:

$$I_{CH} = \frac{V_B}{V_W}\frac{M-C}{C-1}, \tag{28}$$

where V_B and V_W denote overall between-cluster and within-cluster variance respectively. These are calculated according to the following formulas:

$$V_B = \sum_{c=1}^{C} \#CL_c \|O_c - O_Y\|^2, \tag{29}$$

and

$$V_W = \sum_{c=1}^{C} \sum_{y_i \in CL_c} \|y_i - O_c\|^2, \tag{30}$$

here, $\|\cdot\|$ is the L^2 norm (Euclidean distance) between the two vectors.

It must be underlined that high values of Celinski-Harabasz Index designate well-defined partitions. More information about this index can be found at [33].

C. Davies-Bouldin Index

The Davies-Bouldin Index is one of the more commonly utilized unsupervised evaluations of clustering results criteria. This function consists of a ratio of within-clustering and between-clustering distances. This index is described via:

$$I_{DB} = \frac{1}{C}\sum_{c=1}^{C} \max_{c \neq p}\{D_{c,p}\}, \tag{31}$$

where $D_{c,p}$ denotes within-to-between cluster distance for the cth and pth cluster

$$D_{c,p} = \frac{\overline{d_c} + \overline{d_p}}{d_{c,p}}. \tag{32}$$

In (32) notation $\overline{d_p}$ designates the average distance between each element of the pth cluster and centre point of this group. Moreover $d_{c,p}$ is the distance between the centres of the cth and pth clusters. In this case,the smallest value of the Davies-Bouldin Index delineates a well-defined clustering solution. More information about this measure is obtainable in [34].

D. Silhoutte Value Index

The Silhouette Value Index (SH) is the last clustering index to be dealt within this part of this paper. Herein, for each ith point of data set Y, the distance between all points in the same cluster and the separation distance presented by the nearest neighbours, are calculated. This criteria is defined as follow:

$$I_{SV} = \frac{1}{M}\sum_{c=1}^{C} \sum_{y_i \in CL_c} \frac{b(i,c) - a(i,c)}{max(a(i,c), b(i,c))}. \tag{33}$$

Here, $a(i,c)$ describes the mean distance of the ith point to other points in the same cluster CL_c, while $b(i,c)$ represents a minimum of average distance from the ith point in cluster pth to points in other clusters. These values are obtained through the following formulas:

$$a(i,c) = \frac{1}{\#CL_c} \sum_{y_j \in CL_c \& j \neq i} dist(y_i, y_j), \tag{34}$$

and

$$b(i,c) = \min_{CL_l \in C \setminus CL_c} \frac{1}{\#CL_l} \sum_{y_j \in CL_l} dist(y_i, y_j). \quad (35)$$

For a single ith data point, a high value of the component of this criteria denotes that this element y_i is well-matched to its group, and, simultaneously is weakly-match to other clusters. What is interesting, is that a low value of I_{SV} index reveals that the number of clusters is overestimated.

By way of formulas (33)-(35), one can observe that this criteria yields a value between -1 and $+1$. Of note: a well-defined clustering solution is represented by a value close to 1.

More information concerning the SH Clustering Index can be found in [35], [36]. With regard to clustering quality measures as a whole, more information is obtainable in [37], [38].

IV. Numerical results

This section is intended to inform the reader of several numerical verification procedures that are useful in assessing the quality of the proposed clustering methods. In order to verify the quality of the clustering algorithm, 12 sets of data obtained from the UCI Machine Learning Repository were taken into consideration [39]. With regard to these, Table I provides a characterization of all the data sets that were applied in generating a numerical verification within this paper. Evident in this table is that it includes names, abbreviations, numbers of items, dimensionality, number of classes and references to the description of the presented data sets. Herein, synthetic data collection is placed within the first four rows. These data sets are two-dimensional, and, therefore, they serve as being very good explanatory examples upon which Figure 2 is outlined.

In the presented approach, the vector of cluster centre represents the solution in state space for KHA. Thus, the product value $D{\cdot}C$ expresses the dimensionality of a particular optimization task.

In this work, a quite difficult task that the researcher must undertake is to determine a suitable set of KHA parameters. Thus, for several data sets, pilot-tests are calculated. In each test, one parameter of the KHA optimisation procedure is made variable. In addition, in these studies, the CH Index is applied as a validation parameter. As a result of this research, it is found that for almost all data set cases, the same suboptimal sets with best parameters values are calculated. Indeed, it has been discovered that it is only in the case of the Sonar and Ionosphere data sets that the achieved parameters differ. The reason for this is thought to be the higher dimension of these datasets. The following parameters of KHA were established after pilot-tests:

- $P = 20$,
- $K^{max} = 200$,
- $N^{max} = 0.01$,
- $\omega_n = 0.5$,
- $V_f = 0.02$,
- $D^{max} = 0.01$,
- $C_t = 0.5$.

Each clustering test is made of only 200 iterations of the KHA optimization procedure. For this task, three clustering indexes CH, DB and SV are employed, and these validity measures are applied in assessing the value of the cost function (1) for KHA. Because of their different properties (described in Section III), for the indices used here, the following forms of cost functions are formulated

$$f_{CH} = \frac{1}{I_{CH}} + \#CL_{\text{empty}}, \quad (36)$$

$$f_{DB} = 2I_{DB} + \#CL_{empty}, \quad (37)$$

and, finally,

$$f_{SV} = \frac{1}{I_{SH} + 1.01} + \#CL_{empty}. \quad (38)$$

In the investigation presented here, it is assumed that, firstly, a clustering procedure based on KHA is performed by way of one selected index at a time. The result of this experiment is the clustering of the explored data set. In the next step of the test, the Rand Index calculated versus class labels is employed, as this is a commonly used evaluator of clustering performance. Thus, the obtained KHA optimization procedure solution is compared with the reference label of the class (cluster) which came from the data set. Additionally, for comparison purposes, outcomes from utilizing the k-means algorithm are also reported (with corresponding Rand Index values). Results generated by means of aforementioned steps can be seen in Table II. Throughout the testing runs, both KHA-based clustering procedures, as well as the k-means clustering algorithm were performed 30 times.

Table II consists of two parts. The first incorporates the 2nd and 3rd columns, and it contains the mean values $\overline{R}$ and the standard deviations σ_R of the Rand Index that was obtained while using the k-means clustering function. The second part of the table lists the Rand Index results (as in the first part). However, these were obtained by the way of following the KHA-clustering procedure. Here, each of three subparts provides the application results for Celinski-Harabasz ($\overline{R_{CH}}$ and $\sigma_{R_{CH}}$), Davies-Bouldin ($\overline{R_{DB}}$ and $\sigma_{R_{DB}}$) and Silhoutte Value ($\overline{R_{SV}}$ and $\sigma_{R_{SV}}$) Indexes, respectively.

While comparing all the obtained results, it can be seen that it is only in the case of the ION data set when Rand Index of clustering that was performed with k-means procedure achieves better quality then the one attained by the application of the KHA-clustering procedure. In all other cases, the results obtained via the KHA clustering method yield much better evaluation notes. These cases in Table II are emphasized with a bold font.

Based on presented results, one can observe that the Celinski-Harabasz Index clustering validation measure proved to be the best evaluation index applicable in metaheuristic procedures used in clustering. However, with regard to the other indexes, the results generated by way of the Davies-Bouldin Index are better than that obtained via the k-means

algorithm in only three of the applications, and that of the Silhouette Value Index, four.

Looking closely at all the results obtained by way of an application of the KHA procedure, it can be stated that for data collections S1, S2, S3, S4, Iris, Seeds, VH and Wine, the employment of the Celinski-Harabasz Index as a part of the cost function in KHA-clustering procedure gives the best results. Similarly, for the data set SON, applying the Davies-Bouldin Index, and, for the TH data set, using the Silhouette Value Index, yield the best result. Furthermore, in the situation of tests with use the WBC data collection, clusterings incorporating all three indexes provide the same result.

V. Summary

This paper is a presentation of research describing various clustering methods based on metaheuristic procedures and several validation measures. Here, in optimizing the cluster centroid locations, the biologically-inspired KHA procedure was employed. For the evaluation of particular KHA generated solutions, the paper assessed the quality of using Celinski-Harabasz, Davies-Bouldin and Silhouette Value Indexes as three clustering variants. Moreover, the Rand Index was calculated so as to evaluate the quality of the derived solutions of the analyzed clustering procedures. The proposed algorithm, in its three versions, was also confronted via the application of the well-known and commonly enrolled k-means method.

As a result of the study, it was established that the results obtained via the KHA-clustering method are much better than for that which were generated via k-means clustering procedure. What is more, the Celinski-Harabasz Index, as well as the KHA-clustering method, qualify for being considered superior for clustering tasks.

Future research will be targeted on deeper analysis of new clustering quality validation methods, as well as on applying the new procedures of swarm intelligence to the task of clustering.

***Abstract*—Ensemble learning is being considered as one of the most well-established and efficient techniques in the contemporary machine learning. The key to the satisfactory performance of such combined models lies in the supplied base learners and selected combination strategy. In this paper we will focus on the former issue. Having classifiers that are of high individual quality and complementary to each other is a desirable property. Among several ways to ensure diversity feature space division deserves attention. The most popular method employed here is Random Subspace approach. However, due to its random nature one cannot consider this approach as stable one or suitable for real-life applications. Therefore, we propose a new approach called Deterministic Subspace that constructs feature subspaces in a guided and repetitive manner. We present a general framework and three dedicated measures that can be used for selecting diverse and uncorrelated features for each base learner. This way we will always obtain identical sets of features, leading to creation of stable ensembles. Experimental study backed-up with statistical analysis prove the usefulness of our method in comparison to popular randomized solution.**

***Index Terms*—Machine learning, ensemble classification, feature subspaces, diversity, deterministic methods.**

I. Introduction

CONTEMPORARY machine learning deals with the ever-increasing complexity of problems, directly connected to the era of big data and data flood. Standard classifiers cannot properly capture the properties of analyzed data or by trying to do so finally become subject to the overfitting process. Therefore, methods that can take advantage of combining several learners to get at the same time advantages of complex decision boundary and simplified models are of high interest for both researchers and practitioners. Such approaches are known as ensemble learning, multiple classifier systems or classifier committees [1] and are being considered as one of the most efficient tools to handle pattern analysis process. It is assumed that we have at our disposal a number of models and combine their predictions in order to get a more efficient recognition system, as a set of weak models may overcome the limitations of using a single strong one.

For the ensemble to work efficiently one needs to supply a pool of diverse classifiers [2]. The diversity itself can be ensured on several different levels. One of the most popular is to train each learner on the basis of different features, in hope that such an embedding into lower dimensions will at the same time simplify the training procedure and allow classifiers to explore different properties of supplied feature space [3]. Random Subspace (RS) [4] is the most popular implementation of this paradigm. This method assumes that each base learner is trained with a subset of randomly selected features, with the assumption that feature subsets may overlap. This provides simple, but efficient way of managing the diversity in the ensemble. However, there exist a significant drawback of this method, rooted in its randomized nature. Due to lack of any guidance when creating feature subspaces we obtain different sets for each run (e.g., when using cross-validation or repeating experiments). This significantly limits the usability of RS in real-life applications as we are not sure exactly what kind of model we should be using and how stable it is.

To overcome this limitation we introduce a novel approach for forming classifier ensembles based on feature subset named Deterministic Subspace (DS). It is based on the same idea as RS, namely creating a pool of diverse classifiers on the basis of reduced number of features. However, we remove the randomization from it and replace it with a fully guided search approach that guarantee a high stability and repetitiveness of the entire procedure. To obtain a number of equally-sized subspaces we propose a set of metrics dedicated to evaluating the discriminative power of each separate feature and the diversity among created subspaces. A round robin strategy is being employed to evenly distribute features with greedy approach. This leads to the creation of deterministic feature subsets of suitable discriminative power that lead to a creation of efficient ensemble in a guided and deterministic manner. Finally, the created classifiers are combined using a majority voting strategy. The proposed method is as flexible as original RS approach and can work with any kind of base learner.

The main contributions of this works are as follow:

- Novel Deterministic Subspace method for forming classifier ensembles.
- Set of metrics suitable for evaluating the quality and diversity of features being used.
- Greedy round robin approach for creating subspaces of evenly distributed features.
- Thorough experimental evaluation of the proposed approach backed-up by statistical tests.

978-83-60810-90-3/$25.00

The rest of the paper is organized as follows. Next section gives the necessary background in recent advances in ensemble classification. Section III gives the full details regarding the proposed DS method. Section IV, while the final section concludes the paper.

II. Related works on ensemble classification

Ensemble classifiers have several desirable properties for the process of pattern classification system design:

- Ensemble techniques allow to exploit local competencies of base learners, thus leading to a potential gain in accuracy of the combined system.
- Due to their structure they are highly flexible methods that could be easily adjusted by the user according to specific needs.
- They prevent us from selecting the worst model from the pool.
- They are easy to implement in parallel and distributed high-performance commuting environments.

These properties made them highly regarded approaches for a variety of tasks including classification, regression and clustering. In this paper we will concentrate on their usage in supervised classification.

There are three major issues in designing multiple classifier systems:

- How to create a pool of classifiers characterized by a high individual accuracy and diversity [5].
- How to chose the topology of the ensemble.
- How to efficiently combine the outputs of individual classifiers in order to obtain better final predictions [6].

We will focus on the first issue, as this paper deals with the problem on how to form an efficient pool individuals. For such a group of learners to work well we must ensure that they display differing characteristics, as adding similar or identical models to the pool would not contribute to the quality of the ensemble, but would only increase its computational complexity.

There are three main approaches for introducing diversity into a pool of classifiers, depending whether we work with heterogeneous or homogeneous models:

- Different learning algorithms (different models or different parameters for the same model).
- Different inputs (training base classifiers on different data set partitions or choosing different attributes during training) .
- Different outputs (decompose the classification task e.g. into binary tasks).

Heterogeneous ensembles assume that using varying classifier models is enough to properly diversify the pool. By applying different learning paradigms we will get varying decision boundaries that combined together may promote their strong sides, while reducing their weaknesses. However, in some situations different classifiers may return similar or identical boundaries, thus making the selection process crucial. An entire family of dynamic classifier and ensemble selection methods deserves mentioning, as they offer a flexible ensemble line-up for each incoming sample [7].

However, when the considered pool is homogeneous one needs to find an alternative way of introducing diversity. Input manipulation for each base classifier is the most straightforward approach. One can either work in the data or feature space. Former approach assumes that we introduce variance into training instances in order for classifiers to capture properties of different subsets of objects. Here Bagging [8] and Boosting [9] are the most popular solutions, but one can also train ensembles on the basis of clusters to preserve spatial relations among instances [10]. Latter solution introduces diversity by splitting the feature space. This can be done in either randomized manner [11] or in a guided way with the usage of feature selection [12] or global optimization methods [13].

Alternatively one may manipulate the outputs of classifiers in order to get a diverse set of learners. Here the most common solution is a multi-class decomposition, where a divide-and-conquer approach is being used to obtain simplified learners specialized on a reduced number of classes. Then a dedicated combination method like Error-Correcting Output Codes is being used to reconstruct the original multi-class task [14]. Two approaches deserving mentioning are binarization (in one-vs-one or one-vs-all manner) [15] and hierarchical decomposition [16].

Finally when using the same model one may initialize it with different or randomized parameters in hope that training process for each method will return diverse classifiers. This approach is based on the assumption of a complex search space during the classifier training procedure, as multiple starting points could end up in different local extrema, thus offering better coverage of the considered problem. Most popular examples are prematurely stopped neural networks or ensembles of Support Vector Machines with varying kernels [17].

III. Deterministic feature subspace approach

Random Subspace method, while being hugely successful approach for ensemble classification [4], does not avoid some of the pitfalls associated with methods randomly selecting their inputs. Specifically, randomly selected subspaces may lack the discriminant power necessary for proper separation of different classes, which in turn can harm performance of whole ensemble. Additionally, even if individually strong subspaces are produced, we still do not have any guarantees on their diversity. In this section we present a novel approach of creating feature subspaces in a fully deterministic way, with the aim of, at least partially, mitigating mentioned issues.

A. Deterministic subspace algorithm

The idea behind DS approach we propose is to assign features evenly between the subspaces, with some preference of individually strong predictors. To achieve this, we employ separate metrics of both individual feature quality and diversification between subspaces. We then greedily assign features to subspaces using round robin strategy, based on weighted

average of two above metrics. Pseudocode for the proposed method is presented in Algorithm 1.

Algorithm 1 Deterministic Subspace algorithm

```
create k empty subspaces

repeat
  for all subspaces do
    for all features not in current subspace do
      score = α feature quality + (1 − α) diversity
    end for
    add feature with highest score
  end for
until every subspace has n features

return subspaces
```

B. Subspace diversity measure

Many different approaches of measuring diversity in classifier ensembles exist in the literature. Most of them, however, are fairly computationally expensive, as they usually require to train classifiers and compute predictions [18]. We instead propose naive but fast approach of measuring evenness of feature spread between subspace.

Let us denote the set of created so far subspaces by S and current subspace, for which we are considering selecting additional feature f, by S_c. We define metric of diversity d as an average of two components: ratio of subspaces already containing considered feature d_f and nearest distance between subspaces after selecting said feature d_s.

$$d_f = 1 - \frac{|\{S_i : f \in S_i\}|}{|S|} \tag{1}$$

$$d_s = 1 - \max_{i \neq c} \frac{|S_c \cap S_i|}{|S_c|} \tag{2}$$

$$d = \frac{d_f + d_s}{2} \tag{3}$$

Using defined above metrics in the framework of deterministic subspace algorithm ensures even spread of features between subspaces. Furthermore, since its values are bound in range from 0 to 1, it naturally extends to the case in which we consider feature quality as well.

C. Feature quality measures

Ideally, we would like to be able to measure the quality of whole subspace considered. It is especially important taking into account the fact that it can be easily shown that multiple weak features can have increased predictive power when combined. However, due to computational considerations such measures tend to be out of our reach: we have to either employ much less demanding search strategy for subspace creation or rely on rough estimations.

Instead, we propose alternate strategy: giving higher preference to individually strong predictors. While it is not true that using individually stronger features must improve quality of subspace, and even more so whole ensemble, we hypothesize that reducing frequency of appearance of particularly weak features may result in increased performance, especially in cases when classifier used is not resistant to being trained on uninformative features. Furthermore, such strategy is relatively inexpensive, requiring only single computation of ranking between features.

During the experimental study, we evaluate performance of three different measures of features predictive power: accuracy on validation set, mutual information between the feature and target vector, and correlation between the two.

IV. EXPERIMENTAL STUDY

In this section we present detailed description of conducted experiments, together with obtained results. Our goal was to compare the performance of proposed deterministic method with random subspace approach. We try to assess whether deterministic method can achieve at least as high accuracy without introducing randomness into the algorithm. We also investigate under what conditions, if any, deterministic approach may actually outperform random subspace method.

A. Datasets

During the experiments 22 datasets with varying number of features and objects were used. All datasets were taken from UCI[1] and KEEL[2] repositories and are publicly available for download. Details of datasets used are presented in Table I.

[1]http://archive.ics.uci.edu/ml/datasets.html
[2]http://sci2s.ugr.es/keel/datasets.php

B. Set-up

All experiments were implemented in Python programming language with usage of scikit-learn machine learning library[3]. In particular, all classification algorithms were taken from dedicated scikit-learn modules to ensure correctness of implementation. Repository with remaining code, sufficient to repeat conducted experiments is publicly available[4].

Throughout the experiments, performance of three different classifiers was tested: linear Support Vector Machine, CART decision tree and k-nearest neighbors. For every classification algorithm default parameters, provided in corresponding scikit-learn modules, were used.

During the experiments number of features in single subspace n was fixed at half the total number of features, rounded down. Different numbers of subspaces $k \in \{5, 10, ..., 50\}$ were evaluated for both random and deterministic method. Additionally, parameter values $\alpha \in \{0.0, 0.1, ..., 0.9\}$ were tested for deterministic subspace approach. Three different feature quality metrics were evaluated, namely: 5-fold cross-validation accuracy on training set, mutual information between features and targets, and absolute correlation between the two. Simple majority voting was used in every case, for both methods. All tests were done employing 5×2 cross-validation with combined F-test [19] performed to assess statistical significance of results.

C. Results and discussion

Summary of the obtained results is presented in Figure 1. It shows averaged classification accuracy across different classifiers and measures of feature quality, with baseline accuracy achieved by random subspace method presented for reference. Figure 2 shows the number of datasets on which deterministic subspace achieved statistically significantly better results than random subspace method minus the number of datasets, on which results were significantly worst. Detailed tables showing the number of statistically significantly better and worse results are presented in Appendix A.

Results of experiments indicate a slightly better performance of proposed method against RS approach for small values of $\alpha \in \{0.0, 0.1, ..., 0.5\}$ and CART, k-NN and SVM classifiers, regardless of feature quality metric chosen. Using larger values of α parameter, however, leads to significantly worse results. This indicates that whereas taking into account individual feature quality may have slight positive influence of quality of subspaces, there exist a threshold after which whole ensemble suffers due to lack of diversity.

V. Conclusions and future works

Method of deterministic feature subspace creation was presented and tested throughout this paper. During the experimental study, its performance was evaluated and compared to random subspace approach. Proposed method, on average, achieved slightly better results compared to its random counterpart.

[3]http://scikit-learn.org/stable/

[4]https://github.com/michalkoziarski/DeterministicSubspace

It is worth noting that both individual feature quality and evenness of feature distribution measures are simplified means of estimating subspace quality and diversity of ensemble, respectively. Proposing alternative, computationally feasible metrics presents possible venue of further investigation. Additionally, different search strategies for feature selection could be considered, allowing using established, more computationally expensive metrics at the cost of depth of the search.

***Abstract*—In this article, the modified probabilistic neural network (MPNN) is proposed. The network is an extension of conventional PNN with the weight coefficients introduced between pattern and summation layer of the model. These weights are calculated by using the sensitivity analysis (SA) procedure. MPNN is employed to the classification tasks and its performance is assessed on the basis of prediction accuracy. The effectiveness of MPNN is also verified by analyzing its results with these obtained for both the original PNN and commonly known classification algorithms: support vector machine, multilayer perceptron, radial basis function network and k-Means clustering procedure. It is shown that the proposed modification improves the prediction ability of the PNN classifier.**

I. Introduction

PROBABILISTIC neural network (PNN) is a data classifier proposed by Specht in [1] and [2]. It attracts researchers from the field of machine learning. In literature, one can find PNN's applications mainly in medical diagnosis and prediction [3], [4], [5], [6] and image classification and recognition [7], [8], [9]. However, a very good classification performance allows PNN to be utilized in other tasks, e.g.: earthquake magnitude prediction [10], multiple partial discharge sources classification [11], interval information processing [12], [13], phoneme recognition [14], email security enhancement [15] or intrusion detection systems [16].

In its conventional form, PNN is a multilayered feedforward network composed of four layers: input layer (represented by data features), pattern layer (consisting of as many neurons as training patterns), summation layer (with one neuron for each class) and output layer where a single neuron produces a classification result. In majority of cases, the connections between layers in PNN are not equipped with weight coefficients (or all the weights are equally set to 1). Therefore, the output response is not influenced by an impact of a particular class.

In literature, a subtle attention has been paid to determining the weights of PNN. The work of [17] is the first contribution where the weights are introduced to PNN. However, the coefficients are not computed directly; the network operates by using anisotropic Gaussians, i.e. the covariance matrix is utilized, instead of a single smoothing parameter, to compute the output for a particular class. In [18] and [19], the weighted PNN is proposed in the way it adds weighting factors between pattern and summation layer. These factors are calculated from soft labeling probability matrix to carry out a classification. The authors of [20] and [21] create weighted PNN based on their class separability. A single weight is defined as the ratio of 'between-class variance' and 'within-class variance' for a particular training pattern. As in [18], the weighting coefficients are used to connect the pattern and summation layer.

In this study, we propose the use the SA procedure in the computation of the weights for the PNN model. Similar to [18], [19], [20] and [21], the coefficients are inserted between pattern and summation layer. Their values are equal to the aggregated sensitivities normalized to $[0, 1]$ interval. The formulas for the weights are analytically derived. The idea is applied to PNN activated with a product Cauchy kernel. The proposed MPNN is tested in the classification problems of University of California, Irvine machine learning repository (UCI-MLR) data sets [22] by computing a 10-fold cross validation accuracy. The obtained outcomes are thoroughly compared to the ones obtained for original PNN. Furthermore, we verify MPNN accuracy with the accuracy of four reference classifiers: support vector machine, multilayer perceptron, radial basis function neural network and k-Means clustering algorithm.

This work is structured as follows. In section II, the SA procedure is highlighted. Section III, presents the fundamentals of the PNN model. In section IV, the procedure of computing the weights for PNN is proposed. Section V describes the input data sets and the reference classifiers used in current study. Here, the discussion regarding the results obtained in the simulations is also presented. Finally, section VI concludes the work.

This work was supported in part by the Rzeszow University of Technology under Grant No. U-596/DS

II. Sensitivity analysis

SA, in general, is one of many approaches used in determining the importance of particular inputs of a neural network. Therefore, it can be applied in the task of elimination of the irrelevant features in the input vectors. The main idea of SA is based on computing the influence of input features on a neural network output signal after a training process. This influence is characterized by real coefficients [23]

$$S_{j,i}^{(p)} = \frac{\partial}{\partial x_i} y_j \left(x_1^{(p)}, x_2^{(p)}, \ldots, x_N^{(p)} \right), \tag{1}$$

where x_i denotes an input feature and y_j stands for an output signal. In (1), $i = 1, \ldots, N$, $j = 1, \ldots, J$, where N and J indicate the number of features and outputs, respectively.

More specifically, equation (1) represents the sensitivity of the jth neural network output on the ith feature of the input vector $\mathbf{x}$ determined based on the pth training pattern $\mathbf{x}^{(p)}$ for $p = 1, \ldots, P$ where P is a data set cardinality. Taking into account N dimensional data set, (1) can be presented as the following matrix

$$\mathbf{S}^{(p)} = \begin{bmatrix} S_{1,1}^{(p)} & S_{1,2}^{(p)} & \ldots & S_{1,N}^{(p)} \\ S_{2,1}^{(p)} & S_{2,2}^{(p)} & \ldots & S_{2,N}^{(p)} \\ \vdots & \vdots & \ddots & \vdots \\ S_{J,1}^{(p)} & S_{J,2}^{(p)} & \ldots & S_{J,N}^{(p)} \end{bmatrix}. \tag{2}$$

Once $\mathbf{S}^{(p)}$ is computed for all P training patterns, it is possible to find aggregated parameters after application of various types of norms. In the research, one usually utilizes the parameter of the mean square average sensitivity

$$S_{j,i}^{\text{mean}} = \sqrt{\frac{\sum_{p=1}^{P} \left(S_{j,i}^{(p)} \right)^2}{P}}. \tag{3}$$

The absolute value average sensitivity and the maximum sensitivity parameters are also frequently applied in input significance estimation [24]. The appropriate impact of $S_{j,i}^{(p)}$ on the aggregated outcome of $S_{j,i}$ implies the selection of a particular norm.

III. Probabilistic neural network

PNN is composed of four layers. The coordinates of an input vector $\mathbf{x} = [x_1, \ldots, x_N]$ constitute the first input layer. The second layer, called a pattern layer, consists of as many neurons as training examples. Pattern neurons feed their output to the next summation layer. In the summation layer, there are J neurons, however each jth neuron sums the inputs from the neurons of jth class. In literature, two approaches are usually utilized to compute the signals of the summation neurons: the additive Gaussian kernels and the product kernels. In this work, we use the second approach, therefore the summation neuron output is defined as follows

$$f_j(\mathbf{x}) = \frac{1}{P_j \det(\mathbf{h})} \sum_{p=1}^{P_j} \frac{1}{s_p^N} K \left(\frac{\left(\mathbf{x} - \mathbf{x}_j^{(p)} \right)^T \mathbf{h}^{-1}}{s_p} \right), \tag{4}$$

where:

- $K(\cdot)$ is the kernel function calculated in the following way

$$K(\mathbf{x}) = \mathcal{K}(x_1) \cdot \mathcal{K}(x_2) \cdot \ldots \cdot \mathcal{K}(x_N), \tag{5}$$

for which

$$\mathcal{K}(x_i) = \frac{2}{\pi(x_i^2 + 1)^2} \tag{6}$$

denotes the one-dimensional Cauchy multiplicand;
- P_j stands for the number of cases in the jth class ($j = 1, \ldots, J$);
- $\mathbf{x}_j^{(p)} = [x_{j,1}^{(p)}, \ldots, x_{j,N}^{(p)}]$ is the pth training vector of the jth class.

If one regards (5) and (6) as the pattern neuron activation function, the summation layer output for the jth class is determined as follows

$$f_j(\mathbf{x}) = \frac{1}{P_j \det(\mathbf{h})} \sum_{p=1}^{P_j} \frac{1}{s_p^N} \prod_{i=1}^{N} \frac{2}{\pi \left(\left(\frac{x_i - x_{j,i}^{(p)}}{h_i s_p} \right)^2 + 1 \right)^2}. \tag{7}$$

Finally, using the Bayes theorem [2], the output layer of PNN determines the label for a new test vector $\mathbf{x}$

$$C(\mathbf{x}) = \underset{j=1 \ldots J}{\operatorname{argmax}} \, f_j(\mathbf{x}), \tag{8}$$

where $C(\mathbf{x})$ denotes the predicted class. The training algorithm for this network amounts to the appropriate choice of the smoothing parameter h_i by means of the plug-in method [25], and the computation of the modification coefficient s_p [26]. The structure of the PNN model is illustrated in Fig. 1.

IV. Proposed algorithm

In Fig. 2, we present the step-by-step data classification algorithm with the use of modified PNN model. We start with the calculation of the sensitivity coefficients for all $r = 1, 2, \ldots, P_j$ neurons in the pattern layer

$$S = \frac{\partial \hat{f}_j \left(\mathbf{x}_j^{(p)} \right)}{\partial \mathbf{x}_j^{(r)}}, \tag{9}$$

were $\mathbf{x}_j^{(p)} \in \left\{ \mathbf{x}_j^{(1)}, \mathbf{x}_j^{(2)}, \ldots, \mathbf{x}_j^{(P_j)} \right\}$ is the vector argument from jth class. Thus, $\mathbf{S}$ for jth class takes the matrix form

$$\mathbf{S}_j = \left\{ \frac{\partial \hat{f}_j \left(\mathbf{x}_j^{(p)} \right)}{\partial \mathbf{x}_j^{(r)}} \right\}_{P_j \times P_j}. \tag{10}$$

In (10), the elements of rth column represent the sensitivities of KDE in jth class in regard to each rth pattern neuron computed for a specific input pattern p. Since the denominator of each item of $\mathbf{S}_j$ is a vector, the following gradient has to be determined

$$\nabla \hat{f}_j^{(p,r)} = \frac{\partial \hat{f}_j \left(\mathbf{x}_j^{(p)} \right)}{\partial \mathbf{x}_j^{(r)}} = \left[\frac{\partial \hat{f}_j \left(\mathbf{x}_j^{(p)} \right)}{\partial x_{j,1}^{(r)}}, \ldots, \frac{\partial \hat{f}_j \left(\mathbf{x}_j^{(p)} \right)}{\partial x_{j,N}^{(r)}} \right], \tag{11}$$

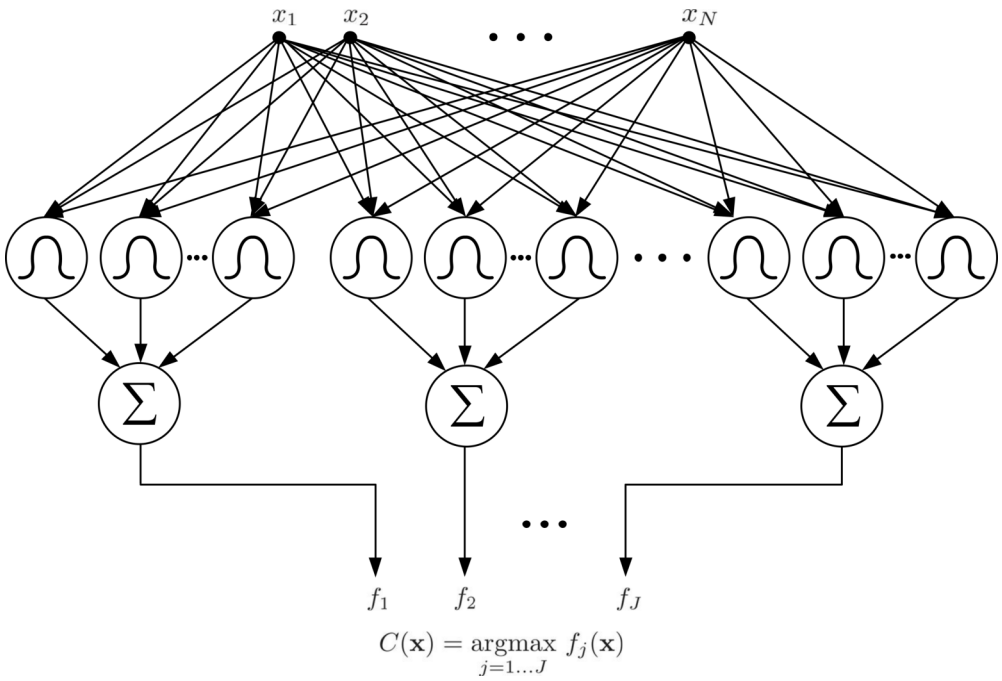

Fig. 1. The architecture of probabilistic neural network.

where

$$\frac{\partial \hat{f}_j\left(\mathbf{x}_j^{(p)}\right)}{\partial x_{j,i}^{(r)}} = \frac{1}{P_j \det(\mathbf{h})} \frac{1}{s_r^N} \frac{\partial}{\partial x_{j,i}^{(r)}} K\left(\frac{\left(\mathbf{x}_j^{(p)} - \mathbf{x}_j^{(r)}\right)^T \mathbf{h}^{-1}}{s_r}\right). \tag{12}$$

The product form of KDE in (5) expands (12) into the following formula

$$\frac{\partial \hat{f}_j\left(\mathbf{x}_j^{(p)}\right)}{\partial x_{j,i}^{(r)}} = \frac{1}{P_j \det(\mathbf{h})} \frac{1}{s_r^N} \mathcal{K}\left(\frac{x_{j,1}^{(p)} - x_{j,1}^{(r)}}{h_1 s_r}\right) \cdots \frac{\partial}{\partial x_{j,i}^{(r)}} \mathcal{K}^\star\left(\frac{x_{j,i}^{(p)} - x_{j,i}^{(r)}}{h_i s_r}\right) \ldots \mathcal{K}\left(\frac{x_{j,N}^{(p)} - x_{j,N}^{(r)}}{h_N s_r}\right). \tag{13}$$

The Cauchy kernel in (6) allows us to determine the ith coefficient of (13)

$$\frac{\partial}{\partial x_{j,i}^{(r)}} \mathcal{K}^\star\left(x_{j,i}^{(p)}\right) = \frac{8\left(x_{j,i}^{(p)} - x_{j,i}^{(r)}\right)}{\pi h_i^2 s_r^2 \left(\left(\frac{x_{j,i}^{(p)} - x_{j,i}^{(r)}}{h_i s_r}\right)^2 + 1\right)^3}. \tag{14}$$

We can see that $\nabla \hat{f}_j^{(p,r)}$ is a vector field, therefore, in order to extract an information on sensitivity of KDE of jth class for a given rth pattern neuron, it is necessary to determine the norm of (11). Thus, $\mathbf{S}_j$ in (10) must be generalized to the following matrix

$$\mathbf{S}_j = \left\{ \|\nabla \hat{f}_j^{(p,r)}\| \right\}_{P_j \times P_j}, \tag{15}$$

where

$$\|\nabla \hat{f}_j^{(p,r)}\| = \sqrt{\sum_{i=1}^{N} \left(\frac{\partial \hat{f}_j\left(\mathbf{x}_j^{(p)}\right)}{\partial x_{j,i}^{(r)}}\right)^2} \tag{16}$$

for the Euclidean norm. The matrix $\mathbf{S}_j$ is computed for $j = 1, \ldots, J$.

Now it is necessary to aggregate all $p = 1, \ldots, P_j$ entries in each rth column of $\mathbf{S}_j$ to obtain the aggregated sensitivity vector. For the mean square average sensitivity measure, this vector takes the following form

$$\mathbf{a}_j = \left[\sqrt{\frac{\sum_{p=1}^{P_j} \left(S_j^{(p,1)}\right)^2}{P_j}}, \ldots, \sqrt{\frac{\sum_{p=1}^{P_j} \left(S_j^{(p,P_j)}\right)^2}{P_j}} \right]. \tag{17}$$

Finally, the normalization of the elements of $\mathbf{a}_j$ to some interval introduces the weight vector for each jth class. In this work, we propose simple "max" normalization

$$\mathbf{w}_j = \left[\frac{a_j^{(1)}}{\max(\mathbf{a}_j)}, \frac{a_j^{(2)}}{\max(\mathbf{a}_j)}, \ldots, \frac{a_j^{(P_j)}}{\max(\mathbf{a}_j)} \right], \tag{18}$$

where $\max(\cdot)$ operator returns the maximum value of the argument.

Including the weights' coefficients, the summation layer output (7) is redefined as

$$f_j(\mathbf{x}) = \frac{1}{P_j \det(\mathbf{h})} \sum_{\{p,r\}=1}^{P_j} w_j^{(r)} \frac{1}{s_p^N} K\left(\frac{\left(\mathbf{x} - \mathbf{x}_j^{(p)}\right)^T \mathbf{h}^{-1}}{s_p}\right), \tag{19}$$

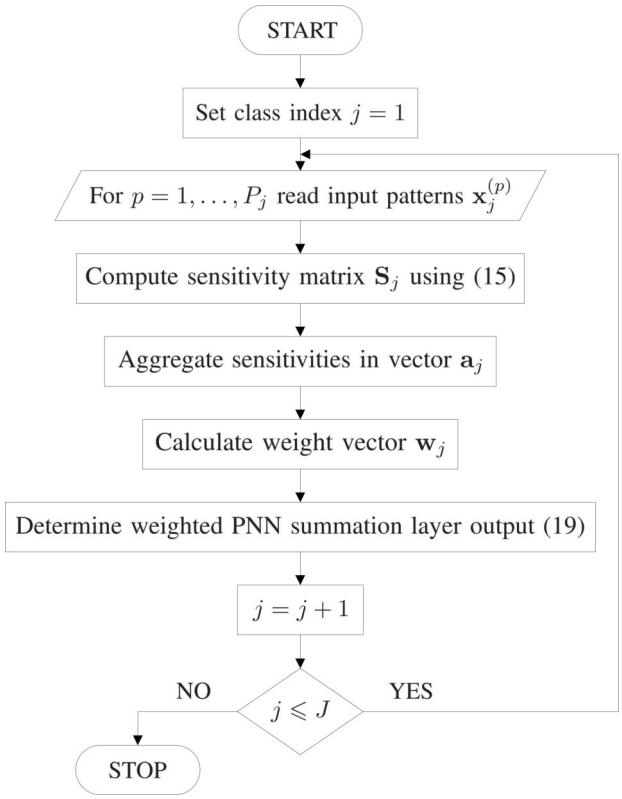

Fig. 2. The algorithm for the computation of the weights in PNN between pattern and summation layer.

where

$$w_j^{(r)} = \frac{\sqrt{\frac{1}{P_j}\sum_{p=1}^{P_j}\left(S_j^{(p,r)}\right)^2}}{\max(\mathbf{a}_j)}, \tag{20}$$

where r refers to rth element of $\mathbf{a}_j$.

V. Experiments

In this section, we present the classification results obtained by PNN with introduced weights and the original network. These results are compared with the outcomes achieved by other classifiers: support vector machine (SVM) algorithm, multilayer perceptron (MLP), radial basis function neural network (RBFN) and k-Means method. Both, input data sets and the reference classifiers used in the simulations are also described.

A. Input data sets

The performance of the proposed MPNN, original PNN and the reference methods (SVM, MLP, RBFN and k-Means) is evaluated on UCI-MLR data sets. Ten well known and commonly tested databases are included: Wisconsin breast cancer (WBC), Statlog heart (SH), Pima Indians diabetes (PID), Ecoli (E), Parkinsons (P), Iris (I), breast tissue (BT), monk (M), seeds (S) and cardiotocography (CTG). The cardinality, dimensionality, number of classes and the class distributions for the utilized databases are presented in Table I.

B. Reference methods

In this subsection, the reference classification models are highlighted. Additionally, we provide the parameter settings used for these classifiers in the simulations.

1) SVM: SVM is the classification algorithm proposed by Vapnik [27]. To perform the classification, SVM requires the solution of the quadratic programming optimization problem. For this purpose, various kernel functions need to be explored. In the current study, we verify the following ones:

- radial basis kernel

$$K(\mathbf{x}_i, \mathbf{x}_j) = \exp\left(-\frac{\|\mathbf{x}_i - \mathbf{x}_j\|^2}{2\sigma^2}\right), \tag{21}$$

- polynomial kernel

$$K(\mathbf{x}_i, \mathbf{x}_j) = \left(\alpha\left(\mathbf{x}_i \cdot \mathbf{x}_j\right) + \beta\right)^k. \tag{22}$$

In the classification tasks, the parameters of the kernels (21) and (22) and capacity control parameter C must be appropriately selected.

2) MLP: MLP is a feedforward neural network [28]. This network is composed of an input layer, hidden layers, and an output layer. The number of hidden layers, the optimal number of neurons in hidden layers and the appropriate activation functions must be determined for this model. In this work, the following functions are tested:

- linear identity

$$f(x) = x, \tag{23}$$

TABLE I
UCI-MLR DATA SETS USED TO TEST ALL COMPARED MODELS

Data set	Records	Attributes	Classes	Class distribution
WBC	683	9	2	444–239
SH	270	13	2	150–120
PID	786	8	2	500–268
E	327	5	5	143–77–35–20–52

M	432	6	2	216–216
S	210	7	3	70–70–70
CTG	2126	22	3	1655–295–176

- logistic sigmoid

$$f(x) = \frac{1}{1 + e^{-\alpha x}}, \tag{24}$$

- hyperbolic tangent

$$f(x) = \frac{2}{1 + e^{-\beta x}} - 1, \tag{25}$$

where α and β are the coefficients used to control the slope of (24) and (25).

3) RBFNN: RBFNN, similar to PNN and MLP, is a feed-forward neural network [29]. However, this model consists of three layers: an input layer, a radial basis hidden layer and a linear output layer. The number of the neurons in the hidden layer and the parameters of the RBFNN training method must be appropriately selected.

4) k-Means: The k-Means clustering is an unsupervised learning algorithm. It partitions input data into k clusters and provides a center of each cluster [30]. As a result, the records within each cluster are similar to each other and distinct from records in other clusters. The predictions for the unknown cases are made by assigning them the category of the nearest cluster center. The parameter k is increased up to K, which depends on the number of input vectors of a given class (P_j). In the current study, K does not exceed 50% of P_j, $j = 1, \ldots, J$. The step for k is determined empirically.

The training methods and the parameters of the models are presented in Table II.

TABLE II
SIMULATION PARAMETERS OF THE EXAMINED REFERENCE CLASSIFIERS

SVM	
	kernel functions: – radial basis kernel (21) – polynomial kernel (22) The grid search is performed for σ, α, β and k Capacity control coefficient: $C = \{10^{-1}, 10^{0}, 10^{1}, 10^{2}, 10^{3}, 10^{4}, 10^{5}\}$

C. Results and discussion

In Table III, we present the accuracy (*Acc*) determined for MPNN, PNN and the reference methods in the classification problems of WBC, SH, PID, E, P, I, BT, M, S and CTG data sets. The accuracy is computed with the use of a 10-fold cross validation procedure. Table IV shows the optimal parameters of the reference classifiers for which the highest accuracy is achieved in particular classification problems. In the case of the SVM model, the capacity control parameter C and the spread constant σ are shown for the radial basis kernel (21) since for this function, a higher accuracy values are obtained in contrast to the results achieved with the use of kernel presented in (22). For MLP, the network structure is presented in the form *w–x–y–z*, where *w* and *z* denote the number of input and output neurons, respectively while *x* and *y* stand for the number of neurons in the hidden layers. The abbreviations "lin" and "log" refer to linear (23) and logistic (24) activation functions, respectively. For example, in the case of E data classification case, the string "5–13–4–5 log–log–log" describes MLP with 5 input neurons, 13 neurons in the first hidden layer, 4 neurons in the second hidden layer and 5 output neurons where the logistic activation function is applied in hidden and output layers. In the case of the RBFN and k-Means classifiers, n and k denote the number of neurons in the network's hidden layer and the number of cluster centers, respectively. The optimal parameters are obtained after vast number of simulations performed in DTREG software [32].

Comparing two first columns of Table III, one can definitely emphasize the fact that in almost all classification problems, the introduction of additional weight parameters to PNN

TABLE IV
THE PARAMETER VALUES FOR WHICH THE HIGHEST *Acc* IS OBTAINED FOR THE REFERENCE CLASSIFIERS

	SVM		MLP		RBFN	k-Menas
Data set	C	σ	structure	act. funct.	n	k
WBC	10^3	0.5	9–3–2	log–lin	50	57
SH	10^2	2.5	13–19–2	log–log	38	4
PID	10^3	0.3	8–7–2	log–lin	74	4
E	10^4	1.5	5–13–4–5	log–log–log	66	2
P	10^5	0.1	22–7–2	log–log	54	33
I	10^0	1.5	4–5–3	log–log	16	4
BT	10^1	27.1	9–3–6	log–log	34	11
M	10^2	0.7	6–14–8–2	log–log–lin	3	23
S	10^3	0.2	7–8–10–3	log–log–log	41	25
CTG	10^2	2.6	22–13–6–3	log–log–log	100	171

results in significant increase of its accuracy. Note, that in P data classification case, this increase is over 5% which is the highest investigated result. The above observation does not take place in S data set classification task. Here, the proposed modification of neural structure does not change obtained accuracy. Thus, the use of weights for original PNN is not beneficial in terms of prediction ability.

In general, one can note that only in three data set cases, i.e.: PID, M and CTG, the reference methods provide higher *Acc* value. However, among these cases, there is no unequivocal alternative classifier since SVM and MLP yield higher accuracy twice and once, respectively.

If we do not take the MPNN accuracy results into account, it is clear that the original PNN is an average quality classifier because in WBC, SH, E, P and I classification problems, higher *Acc* is obtained by the following methods: MLP, SVM, RBFNN, SVM, and SVM *ex aequo* MLP, respectively.

VI. CONCLUSION

In this paper, the modified probabilistic neural network was proposed. The modification relied on the introduction of the weights' coefficients between pattern and summation layers. The weights for PNN were computed by means of the SA procedure. Their values were equal to the aggregated sensitivities normalized to $[0, 1]$ interval. A PNN with product kernel estimator with Cauchy realization was used. The plug-in method was applied to determine the smoothing parameter. A 10-fold cross validation accuracies of MPNN were compared with the ones obtained for the original PNN and the reference classifiers in the UCI-MLR data sets classification tasks. The results showed, that among all tested models, MPNN achieved the highest *Acc* in seven out of ten classification cases. In contrast to the conventional PNN, the proposed network performed better in nine classification problems, while only in single task (S data set), the accuracies of MPNN and PNN were identical.

***Abstract*—This paper describes a method for spatial tracking of a strapdown device that can be used for design of human-computer interfaces. Inertial Measurement Unit (IMU) is used to obtain 6-dof position exploiting the so-called ZUPT technique by the means of the Kalman Filter. Additional corrections of position are done using magnetometer readings in the presence of static magnetic field induced by permanent magnet that overshadow geomagnetic field. This correction allows us to overcome drifting errors of integration of IMU readings. We have also presented comparisons of different models for magnetic field reconstruction that is crucial for this system.**

I. Introduction

HUMAN-Computer interfaces that uses hand gestures, object manipulation or any other pervasive technology always require position tracking subsystem. Recent developments in micro-electro mechanical systems (MEMS) enables researchers to build new wearable, position aware devices by utilization of miniaturized and low-power sensing devices. For example, inertial sensors are commonly used for construction of 6-dof (orientation and position) spatial tracking systems [1], [2]. Nevertheless, precision of such sensing devices is still very low, therefore it is needed to adopt more complex computations and signal filtering techniques. In this paper, we present an inertial position tracking system that uses additional correction by positioning in magnetic field induced by permanent magnet. Previous works exploited an array of magnetic sensors to unambiguously estimate position, while we propose a data fusion algorithm that uses just one magnetic sensor along with inertial sensor.

Data fusion algorithms are used commonly with inertial devices—in order to estimate orientation of the sensor, state-of-the art filter [3] integrate angular rate (obtained from gyroscope) in order to calculate rough quaternion rates and then uses gravitational force (obtained by accelerometer) to correct roll and pitch angles. Finally, magnetometer readings are exploited to correct yaw angle. The best known algorithm that can be used in this setup for position estimation exploits the so-called "zero-velocity" update (ZUPT). Second integral of acceleration outputs position with accumulative error. Additional statistics are used to test if the sensor is still—velocity, therefore, should be zero (most of the time it is not and one can use this information to correct position). This technique was proposed in [4] for inertial navigation using foot-mounted inertial measurement unit. We have extended the technique introducing Magnetic Update (MUPT) that introduces small correction of position if the sensor is exposed to magnetic field. In presented setup properties of magnetic field must be known beforehand, basing on extensive calibration procedure.

Contribution of this paper is as follow: (1) design and evaluation of position tracking system by fusion of inertial and magnetic sensing in the presence of magnetic field induced by permanent magnet, (2) evaluation of magnetic field reconstruction techniques, (3) positioning algorithm in that use

II. Related Work

Measurements of magnetic field have long been used in the problem of spatial tracking. Starting with the problem of locating buried magnet, one solution [5] used measurements of magnetic field generated by beacon device. In 1979 Raab et al. [6] proposed a complete system for relative position and orientation tracking using active 3-axis magnetic dipole source. Technique was further described and analysed on simulated data by Raab [7]. Similar methods are now used in commercial tracking solutions like *Polhemus Fastrack* or gaming controller *Razer Hydra*. Although these methods are useful in some situations, power requirements and high weight of magnetic coils disqualify it in context of wearable devices, with exception of specific usages as described in [8]. Since the advent of MEMS inertial and magnetic sensors, many solutions have been proposed for problem of position and orientation tracking using fusion of inertial and passive magnetic measurements [9], [10], [11]. Unfortunately, inertial systems suffer from systematic error accumulation. It is common [12], [13] to address this problem with ZUPT, as proposed in [4]. Although, as pointed out in [14], this solution suffers from many drawbacks and its usefulness is limited.

Geomagnetic field measurements are also susceptible to errors such as interference from ferromagnetic mass and electric devices. Zachmann tried correcting magnetic measurements by gathering calibration samples of magnetic field in a volume of tracking space [15]. Some authors tried using these distortions for detection and low accuracy tracking of metallic objects [16], [17]. Magnetic field produced by permanent magnets locally overshadow earth's, thus extensive research have been done on reverse problem of tracking permanently

978-83-60810-90-3/$25.00

magnetised markers with relation to magnetometer and (most often) arrays of magnetometers [18], [19], [20], [21].

Finally, in 2015 Kortier et al. [22] explored a system for tracking neodymium magnet paired with accelerometer and gyroscope with respect to array of four magnetometers in parallel with inertial sensor.

We propose a system where magnetometer is coupled with inertial sensors in a package and tracking is carried out with respect to neodymium magnet.

III. Modelling Vector Field Of A Permanent Magnet

In order to obtain the position of magnetic sensor in the presence of static magnetic field the straightforward idea is to use a model of the magnetic field and match the empirical measurement (obtained by magnetometers) to the theoretical one. The idea is to construct error function that will be minimized in order to find position of the sensor (or array of the sensors). This idea was investigated in many papers, e.g. [19], [21]. The technique requires finding a method for determining theoretical value of magnetic vector field.

More formally, we are searching for a function P such that

$$P_{\Theta_s^m}(x, y, z) = \vec{B}, \tag{1}$$

where $\vec{B}$ is a vector of magnetic induction in given position $(x, y, z) \in \mathbb{R}^3$ and Θ_s^m is an orientation of the sensing device s in the magnet frame of reference m (one can understand it as a transformation from sensor frame of reference to magnet frame of reference).

Magnetic induction vector in our case consists of three components: geomagnetic field $\vec{B}_{\text{geo}}$, field of permanent magnet $\vec{B}_{\text{mag}}$ and ferromagnetic part considered as environment noise $\vec{B}_{\text{env}}$. Therefore,

$$\vec{B} = \vec{B}_{\text{mag}} + \vec{B}_{\text{geo}} + \vec{B}_{\text{env}}. \tag{2}$$

For strong magnets, however, we can omit environmental and geomagnetic component, hence $\vec{B} \approx \vec{B}_{\text{mag}}$.

The model of the magnetic field is difficult to calculate in real time, so we are looking for some approximation of it. For this reason, we have investigated and compared different techniques: (1) dipole model, (2) integration from Maxwell equations using finite element method (FEM) simulators, and (3) field interpolation on empirical (and sparse) sampling. These methods are described below.

A. The Magnetic Dipole

Magnetic field of strong magnet can be approximated using *magnetic dipole* model [23]:

$$\vec{B}_{\vec{\mu}}(\vec{r}) = \frac{1}{\|\vec{r}\|^5}\left(3(\vec{\mu}\vec{r})\vec{r} - \vec{\mu}\|\vec{r}\|^2\right), \tag{3}$$

where μ is a *magnetic dipole moment* (that characterize magnetic field source) and $\vec{r}$ is a vector from the magnetic dipole source to the observation point. It is important to note that, since we assume that magnetic field source is infinitely small point, this model is accurate only when $\|\vec{r}\| \gg r_m$ (where r_m is a size of magnet).

We can rewrite Eq. (3) into components to obtain formulas that characterize components of $\vec{B} =: [B_x, B_y, B_z]$:

$$\begin{aligned} B_x &= 3|\mu|\tfrac{zy}{(x^2+y^2+z^2)^{\frac{5}{2}}}, \\ B_y &= 3|\mu|\tfrac{zx}{(x^2+y^2+z^2)^{\frac{5}{2}}}, \\ B_z &= |\mu|\tfrac{2(x^2-y^2)-z^2}{(x^2+y^2+z^2)^{\frac{5}{2}}}. \end{aligned} \tag{4}$$

From Equation (4) we see that in order to use the above model, we must carry out a calibration of the magnet (find the magnetic dipole moment μ for a particular magnet). This characteristic is included in the documentation that came with the magnet, nevertheless, we have found this parameter in the experimental section by defining an error function and making its optimization. In order to find this parameter, only one measurement in some known position is needed.

Usage of magnetic dipole moment for defining position estimation error function enables us to carry out the gradient function in analytical form. That makes minimization very fast.

B. Magnetostatic simulation using FEM

FEM (Finite Element Method) is a method of integrating differential equation used to find approximate solutions of many physical models. In our context it is used to solve the Maxwell equations. Magnetic dipole moment, which is a parameter for this FEM model, was calculated by experiment. The boundary conditions were chosen at far distance from field source in the manner that changing them will not affect the magnetic field in region of interest.

We used `QuickField`[1] library, that outputs the exact solution at some points and interpolates the rest. The position of the points are optimized.

C. Interpolation of a vector field

In this section, we propose a fast method to approximate the magnetic field using empirical readings—our magnetic field calibration procedure.

The method described below is based on measurements of magnetic field $\vec{B}$ at predetermined positions in the vicinity of the magnet, and then determining the interpolating function for any point in the area of interest D. For this purpose, we used the *Delaunay triangulation* (DT). The idea of this method is to find simplex, inside which there is a point of interest, and then counting the weighted sum of the vertices of the simplex (on which empirical measurement is known).

More formally, suppose we have made n measurements of magnetic field $\vec{B}(p_i)$, $i = 1, \ldots, n$, in points $p_i := (x_i, y_i, z_i)$, $i = 1, \ldots, n$.

Let us consider the division of space $\mathbb{R}^d$ on $(d+1)$-simplices $\{\sigma_j := \sigma(\{p_{i_k}\}_{k=0}^{K_j})\}_{j\in J}$, where $\sigma(\{p_l\}_{l=1}^{L})$ is the simplex determined by vertices p_l, $l = 1, \ldots, L$, such that:

- for $k \neq l$, k, $l \in J$, intersection of simplices $\sigma_k \cap \sigma_l$ is either a common wall of σ_k and σ_l, or is empty,

[1] http://www.quickfield.com/

- the interior of the circumscribed sphere on any simplex σ_j does not contain any point $\{p_i\}_{i=1}^n$.

Our area of interest D is the sum of all the above simplices. In the present context we only consider the division of $\mathbb{R}^2$ and $\mathbb{R}^3$, therefore, we can informally say that Delaunay triangulation divides the space into triangles and tetrahedrons, respectively, such that none of these objects is deformed (i.e. do not contain "very sharp" angles). A popular method for determining triangulation is based on the dual space (we show an example for $\mathbb{R}^2$): we consider the projection $(p_x, p_y) \mapsto (p_x, p_y, p_x^2 + p_y^2)$ and then calculate the convex hull of this set of points. Then the corresponding points will create DT.

Let $\vec{B}_{DT}(p)$ denotes the magnetic induction vector calculated by Delaunay interpolation at point p contained in the convex hull of p_i. For determining $\vec{B}_{DT}$ DT uses barycentric coordinates $\{\lambda_k\}_{k=1}^{d+1}$ of p with respect to $\{p_{i_k}\}_{k=1}^{d+1}$. In conclusion, we can represent it as a linear combination

$$\hat{\vec{B}}_{DT}(p) = \sum_{k=0}^{d+1} \lambda_k \hat{\vec{B}}(p_{i_k}) \tag{5}$$

such that $\sum_{k=1}^{d+1} \lambda_k = 1$ and $\lambda_1, \ldots, \lambda_{d+1} \geq 0$, where points p_{i_k} are vertices of simplex σ such that $p \in \sigma$. It is worth noting that calculation of coefficients λ_k for point $p = (p_x, p_y)$ in $\mathbb{R}^2$ (and, analogically, in $\mathbb{R}^3$) using reference points p^1, p^2, p^3, is limited to determining the solution of the following system of equations

$$\begin{bmatrix} p_x^1 & p_x^2 & p_x^3 \\ p_y^1 & p_y^2 & p_y^3 \\ 1 & 1 & 1 \end{bmatrix} \begin{bmatrix} \lambda_1 \\ \lambda_2 \\ \lambda_3 \end{bmatrix} = \begin{bmatrix} p_x \\ p_y \\ 1 \end{bmatrix}. \tag{6}$$

From the computational complexity point of view, the most expensive operation is finding a simplex, inside which the point is located. To do this, one can apply a hierarchical decomposition of simplices, which represents collection of simplices in the form of binary search tree. Asymptotic cost of finding simplex is, therefore, $\mathcal{O}(\log n)$, however, because of need for preprocessing and higher storage requirements, such representation may be not suitable for implementation on small microprocessors. Best alternative seems to be a classic *walking* algorithm [24]. As noted in [25], Mücke shows [26] that careful use of *walking* algorithm can bring down expected time close to $\mathcal{O}(n^{1/4})$ (for $d = 3$).

D. Magnetic Field Reconstruction

In order to check its reliability our methodology was as follows: we recorded vectors of magnetic induction in many places on common plane and compared it with the theoretical model. In this section, we will present experimental result of reconstruction of magnetic field.

The magnetic field was generated by arrangement of three cylindrical neodymium magnets ($\oslash = 22\,[\text{mm}]$, $h = 10\,[\text{mm}]$, direction of magnetization was along shorter axis). According to specification, at the distance of $0.7\,[\text{mm}]$ in the direction of magnetization the magnetic field strength was $\approx 0.380\,[\text{T}]$. Measurement was performed with MEMS magnetometer LSM303D, that is able to measure magnetic field of maximum strength of $\pm 1.2\,[\text{mT}]$ with 16 bits resolution (values with 16 meaningful bits). See Fig. 1 for our experimental setup.

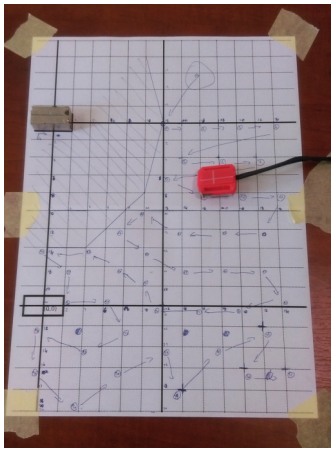

Fig. 1: Experimental setup.

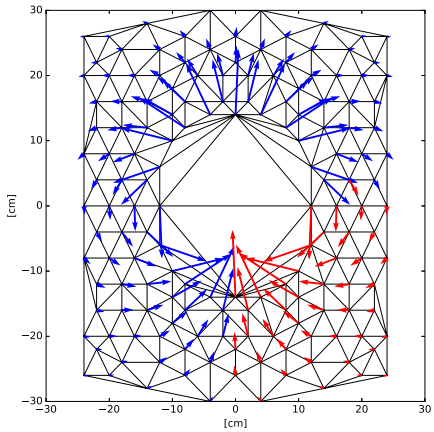

Fig. 2: Magnetic field by Delaunay triangulation. Red arrows depicts empirical measurements whereas blue arrows represent symmetrical reflection of those.

At the beginning, we checked properties of the field with magnets arranged in the above manner.

We've done several experiments, in order to show that magnetic field around the cylinders is symmetrical. Moreover, several experiments have been performed to check the accuracy of different models. Geomagnetic field was measured beforehand and discarded from both calibration dataset and test dataset. Experimental station is illustrated in Fig. 1. Table III-D shows the results of different tests.

Test 1 was divided into several subtest: Iq, IIq, IIIq, IVq, r<20, r>=20. It consists of measurements when magnet was not rotated.

Test 2, 3 and 4 consists of measurements with magnet rotated along magnetization axis by 90, 180 and 270 degrees, respectively, without changing its location. Each test consisted of 54 measurements in places which were different than

TABLE I: Comparison of magnetic field reconstruction using different models.

test 4 / 270°	19.08 ± 9.21	7.63 ± 5.05	3.77 ± 3.56	71.92 ± 71.63	113.67 ± 50.58	15.53 ± 17.49

calibration points. Since magnetometer has maximum range of measurements, readings were taken at distances of less that 12 [cm] from the magnet.

Left part of the table shows angle of deviation between model magnetic field $\vec{B}_m$ and experimentally measured magnetic field $\vec{B}_e$. Right part of the table shows means and standard deviations of norms between $\vec{B}_m$ and $\vec{B}_e$ (i.e. $|\,\|\vec{B}_m\| - \|\vec{B}_e\|\,|$).

In Table III-D one can see that error is similar in each model, indicating that the measured magnetic field is indeed symmetrical along the axis of magnetization. Differences between quarters of the coordinate system are larger, but this is probably due to inaccuracies of measurement. Dipole model (as expected) makes smaller error (in particular, when it comes to the norm of $\vec{B}$) when we measure at distant places ($r \geq 20$ [cm]) from the source field. Field calculated using FEM is, roughly speaking, two times better than the dipole model. Our method was marked as "interpolant" and is about five times better that dipole and about 2 times better that FEM.

Bearing in mind the above, we assume that around cylindrical magnetic the field is symmetrical, therefore calibration measurements were taken only on the one selected quadrant of a plane.

Delaunay triangulation is depicted in Fig. 2. We see there 42 measurements of $\vec{B}$ (depicted as red arrows) and 115 vectors (blue arrows) that were derived using symmetrical reflection of those 42.

IV. Positioning in empirically interpolated magnetic field

Positioning within the magnetic field using a magnetometer is usually performed using the layout of sensors and the dipole model. Dipole model considered for its own sake is biased by error. However, it can be compensated by using more readings and their relative positions. Additionally, a more accurate position can be determined with a greater number of sensors.

Therefore, in order to calculate the precise position it is usually necessary to use at least two sensors. However, in the paper we want to get rid of this constraint and estimate the position with a single magnetometer in the magnetic field. Hence, we cannot mitigate errors of the model by simultaneous readings and, therefore, we can find only one parameter: either the location (having a fixed orientation) or the orientation (having a fixed position). For that we will minimize the *cost function* defined as follows

$$f_{\vec{B}_e}(p) = |\vec{B}_m(p) - \vec{B}_e|^2 + (|\vec{B}_m(p)| - |\vec{B}_e|)^2, \qquad (7)$$

where $\vec{B}_e$ is experimentally measured magnetic field and $\vec{B}_m(p)$ is the value of model magnetic field at point p. Calculation of $\vec{B}_m(p)$ is the most computationally expensive operation.

Since this function is convex in a neighbourhood of current position, we know that (locally) the minimum value of function (7) is uniquely determined. As it was stated above, in the presence of at least two sensors we can use dipole model. Therefore, error function is smooth and minimization can be done by gradient descent algorithm which it terminates after just a few iterations. In the case of our model, the error function is created from DT and since the data is collected empirically we do not have smoothness any more. That is why we use nongradient methods, e.g. Nelder-Mead. This algorithm also terminates after few iterations, but it needs many more error function evaluations.

In Fig. 3 we show the magnitudes of error function (Eq. 7) with respect to number of evaluations during the execution of minimization, starting from two initial positions. For each minimization these were selected by first randomly choosing known destination point and then selecting random position from its neighbourhood within the range of 1 [cm] and 4 [cm], respectively. The thick line on the chart indicates the average and is surrounded by a plot of the standard deviation at each iteration.

V. Fusion of inertial positioning and magnetic

The fusion algorithm is implemented by the means of Kalman Filter which estimates the error state vector $\delta x_k = [\delta v_k\ \delta p_k\ \delta C_k]$, which represents velocity, position and orientation (roll, pitch, yaw) errors. Details of the algorithm are described in Alg. 1—as an input it takes readings from IMU (a, ω, m—which are acceleration, angular rates and magnetic induction vector respectively).

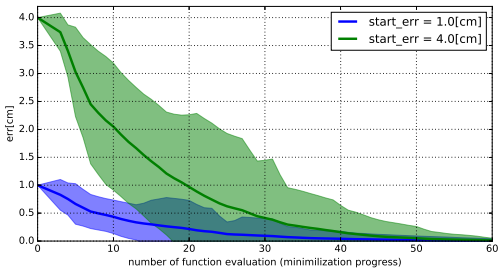

Fig. 3: Converge of minimization.

State transition matrix F_k is defined as follow:

$$F_k := \begin{bmatrix} I_{3\times3} & \Delta t I_{3\times3} & 0_{3\times3} \\ 0_{3\times3} & I_{3\times3} & 0_{3\times3} \\ \Delta t S_k & 0_{3\times3} & I_{3\times3} \end{bmatrix}, \tag{8}$$

where S_k is a skew-symmetric cross-product operator matrix given by:

$$S_k := \begin{bmatrix} 0 & -a^N_{z,k} & a^N_{y,k} \\ a^N_{z,k} & 0 & -a^N_{x,k} \\ -a^N_{y,k} & a^N_{x,k} & 0 \end{bmatrix}. \tag{9}$$

The S_k matrix is used for accumulating orientation errors with respect to velocity error estimates. This method is inspired by technique called "alignment transfer" [27] and was introduced to ZUPT-based inertial navigation systems by Foxlin [4]. In our algorithm we updated the orientation estimation from original Foxlin work by usage of complementary filter (line 6) which was developed by Madgwick [3]. In our previous work [28] we showed his setup works better for orientation estimation for the object in motion with zupt-based filters.

At line 11 two statistical test are performed: one for zero velocity hypothesis testing (`IsZUPT`) and one for position estimation error test (`IsMUPT`). For the zero-velocity hypothesis testing we apply the following formula at k-th reading:

$$\mathrm{Var}\left(\left\{\sqrt{\omega_x^2(t)+\omega_y^2(t)+\omega_z^2(t)} \mid t = k-w,\ldots,k\right\}\right) < \epsilon_1 \tag{10}$$

Simply speaking Eq. 10 is a windowing w-length function that checks if variance of gyroscope readings do not exceed certain threshold (ϵ_1). For zero-velocity hypothesis testing there exist lots of solution in the literature (see [29], [30], [31])

In order to check if the correction based on magnetic positioning observation need to be performed another test is executed: `IsMUPT`. This test checks if covariance error didn't exceed certain threshold:

$$\sum_{i=3}^{6}(P_{i\times i}) < \epsilon_2 \tag{11}$$

Eventually at lines 19-23 the Kalman Update is performed basing on two version of observation matrix H; one for velocity pseudo-observation update (line 13) and second one or true position observation (line 16).

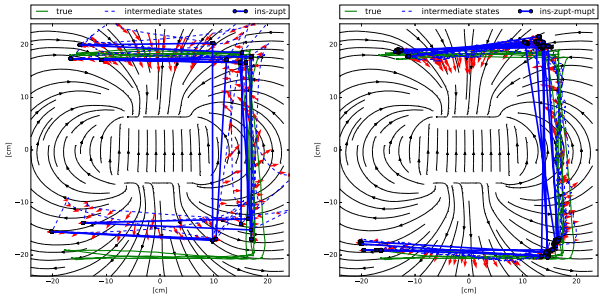
VI. EXPERIMENTAL RESULTS

Experiment was conducted using sensor and a magnet, which properties were described in section III-D. The sensor was moved freely over the table with moderate speed in various trajectories (with and without still phases). The true path was obtained using optical system, composed from two cameras that were observing diode mounted on top of the sensor. Example of such movement is depicted on the Fig. 4. Fig. 4b depicts trajectories computed by algorithm described in previous section (blue lines), whereas Fig. 4a shows the same algorithm in which no magnetic update has been made. Note that path is depicted only between zero-velocity phases—the *a posterori* states. The *a priori* states are depicted by the dotted line as "intermediate states". The read arrows indicates magnetic field measurements done at particular place and the green line is the true path observed by optical system. As a visual aid magnetic field was enclosed using interpolation method—black field lines.

Error drift in inertial navigation system describes the situation where there is a random inaccuracy introduced at each step of computation. It source lays in (1) sensor error and (2) floating-point computation. It is very challenging (or impossible) to model this error, therefore there is no method for position tracking basing only on IMU readings.



(a) Inertial System with zero-velocity updates.

(b) Inertial system with zero-velocity updates and magnetic positioning.

Fig. 4: Comparison of position tracking algorithms.

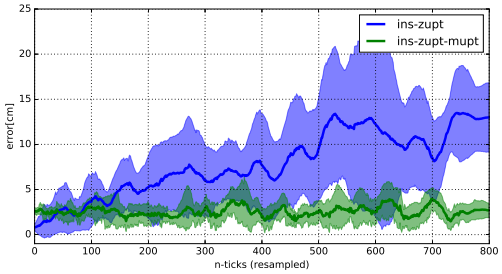


Fig. 5: Position estimation errors.

After prototyping a system with another source of correction the most important thing to check is if it's error does not accumulate over time.

The absolute error (measured as Euclidean distance between the true and estimated path of two methods over time) is depicted on Fig. 5. The error is computed as an average over all 10 samples of different trials along with standard deviation. The most important observation is that that ins-zupt-mupt does not drift over time ($p < 0.01$ using *Augmented Dickey-Fuller Test* for unit root testing of processes—stationary test), while ins-zupt accumulates errors over time. The trials without zero-velocity phases were not enclosed into the results since its error was too significant.

VII. Conclusion and Future Works

In this paper, position tracking system based on data fusion from inertial measurement unit and positioning in magnetic field was presented. Inertial navigation was performed using the so-called zero-velocity updates and modelled by the means of the Kalman Filter. The common problem with error accumulation of inertial system has been solved by positioning sensor in the presence of static magnetic field.

The presented method enables us to build more robust human-computer interfaces which requires positioning subsystem, because it requires just one sensor for magnetic field sensing. Static magnetic field can be easily generated with no energetic cost by various (in terms of size and strength) neodymium magnets and the magnetometer most of the time is already mounted into IMU unit.

The previous works consisted of array of sensor that was rigidly mounted, which can introduce some problem in real-life systems. Usage of just one sensor, however, introduces some drawbacks: (1) the field of magnet needs to be known precisely in advance, therefore a calibration procedure needs to be introduced in advance (2) from theoretical point of view the additional corrections that are made are not unambiguous—the cost function Eq. 7 minimizes position error with given orientation. The second problem could lead to error in yaw-angle estimation.

In this paper authors did not investigated orientation estimation errors. Nevertheless, the presented algorithm corrects the orientation estimates in zero-velocity phases. The estimates are sufficiently good for most applications because orientation estimation is less prone to errors since it can be corrected by data fusion filter and needs only one integration. Nevertheless, in future work promising idea is to estimate orientation errors taking the whole path into consideration by forming some lag-introducing corrections. The naive idea is to correct orientation minimizing the magnetic field vector derivation from theoretical model in more than one points, assuming some tuned springiness between the measuring points.

***Abstract*—This paper presents a comparison of different machine learning algorithms applied to automatic sleep detection which uses electroencephalogram signals as a differentiating basis. The Single-Layer Perceptron, Multi-Layer Perceptron, Support Vector Machine, Boosted Tree and the Multi-Agent (comprising of the earlier models) models are developed and analyzed with training and testing datasets. The results of the models are evaluated using a cross-validation technique. The models are compared with each other using the Cohen's index, the True Positive Rate and True Negative Rate. The models are very successful with sleep stage detection reaching up to 94 %, and Cohen's index reaching up to 0.69, showing considerable promise for deployment and future studies.**

I. Introduction

ROAD accidents are responsible for many deaths and economic losses around the globe. Drowsiness is a cause of about 40,000 non-fatal injuries and 1550 fatalities annually in the United States alone [1]. A press release by the National Sleep Foundation in 2009 indicates that 1.9 million American drivers have had a car crash or 'near-miss' due to fatigue or drowsiness [2]. The National Sleep Foundation has data which shows that even some flight and train accidents have drowsiness and fatigue as probable causes [3].

In general, to detect a driver's sleep stage the frequency spectra of brainwave signals are used as a differentiating factor. A good detection algorithm should accurately detect a drowsy driver, while not causing many false alarms. In principle, a model may detect drowsiness all the time, i.e., a success rate of 100 % for sleep detection, but this will create many false alarms, which would affect the driving behavior. A false alarm is triggered when a wake stage is detected as a sleep stage. For our classification purposes, a sleep stage is defined as the first stage of sleep. Earlier work using multichannel electroencephalogram (EEG) signals obtained 92.8 % internal sleep stage classification accuracy [4]. This work did not classify wake stages, which would be included in our models. The aim of our project is to obtain similar or better results for sleep detections using only one channel, i.e. fewer data input parameters. It is more important for us to detect a sleep stage than have fewer false alarms, which is why the sleep detection success rate has a high benchmark.

To train and test the algorithms before grading them, the dataset used was obtained from the DREAMS project [5]. This dataset consisted of raw polysomnographic (PSG) signals. A data-mining plan was designed for transforming the dataset, for training and testing the models, and for evaluation of the models. This plan expanded on the existing widely-used CRISP-DM model [6].

In the DREAMS project, PSG data was collected from sleeping patients, which included the electroencephalograph signals, the backbone of our project. Automatic classification of the sleep stages and sleep disorders was a major part of the different studies performed by the DREAMS project team. They showed that it is possible to perform automatic classifications using machine learning algorithms.

In 2001, Van Hese P. *et al.* [7] performed an automatic detection of the sleep stages using only EEG data. They used a modified K-means algorithm, and the parameters they used for classification were the parameters of Hjorth – Activity, Mobility and Complexity – expressed in terms of the frequency spectrum. The mobility was a measure of the central frequency, the complexity was a measure of the bandwidth of the signal, and the activity was a measure of the variance. They showed that clusters were created and it was possible to distinguish between the different stages, but that extra information, like electrocardiograph (ECG) and electrooculograph (EOG) data, was necessary for a clear discrimination between the stages.

Zhovna I. and Shallom I. proposed in 2008, an automatic sleep stage detection and classification of multichannel EEG signals [4]. They used a method based on the Multichannel Auto Regressive (MAR) model, which incorporated the cross-correlation information existing between the different EEG signals. Their approach involved training and testing phases, including a continuous unknown 7-hour subject dataset. They obtained a promising rate of detection of 92.8 %. However, they had not trained the system to detect wake stages or movements.

A more recent study in 2013 by Malaekah E. and Cvetkovic D. tried to perform an automatic detection scheme to classify the sleep stage 1 and the wake stage using the EEG sub-epoch approach [8]. They divided 30 second epochs into 6 second sub-epochs from which the Relative Spectral Energy Band (RSEB) was calculated and used to create the feature space. The RSEB for a given frequency band is defined as the ratio of the Power Spectral Density (PSD) of the band divided to the total power (sum of PSD of all bands). Their best results showed an average of 77 % and 55.8 % success of detecting the wake and first sleep stages respectively.

978-83-60810-90-3/$25.00

The work done by different research groups shows that EEG signals are good indicators of sleep and wake stages. For manual classification, there are two references, [9] and [10], both of which rely on the frequency of the EEG signals. Following up on the works of [7] and [8], it seems that using the complete frequency spectrum instead of few parameters might improve the classification accuracy.

The main goal of the paper is to create an automatic detection mechanism using data mining approach. In the project, the standard CRISP DM methodology was applied [6]. The first step is to understand the important physiological processes of sleep and their mathematical representation as signals. The following section provides a brief description of the brainwave signals along with their classification based on the frequency range. Then the data preparation phase is explained followed by an introduction to the classification models used in this project. In the third section, the experimental results for the different models are tabulated in terms of the true positive and true negative rates, also known as sensibility and specificity respectively. The paper ends with the conclusions drawn from our work and perspectives to continue research in this domain.

II. Data Sources and Classification Models

A. EEG signals

An electroencephalograph (EEG) represents electrical signals which reflect the elec-trical activity of the neurons. Based on their frequency range, an EEG signal is divided into bands denoted by Greek letters [11]:

- Beta waves – β-waves are brainwaves with frequencies between 13 and 30 Hz. They indicate full awareness and high brain activity.
- Alpha waves – α-waves have frequencies between 8 and 13 Hz. These are generally linked to relaxed states.
- Theta waves – θ-waves lie in the frequency range of 4 to 8 Hz. These are connected to Non-Rapid Eye Moment (NREM) sleep.
- Delta waves– δ-waves are below 4 Hz in the frequency spectrum. They generally correspond to slow wave sleep stages.

There are two standards to classify EEG data into sleep stages. The older Rechtschaffen and Kales (R&K) standard is composed of the following stages – Wake stage, REM stage, Sleep stage S1, Sleep stage S2, Sleep stage S3, and Sleep stage S4 [9]. In the more recent American Academy of Sleep Medicine (AASM) standard, the stages are classified as – Wake stage, REM stage, Sleep stage N1, Sleep stage N2, and Sleep stage N3 [10]. However, the DREAMS dataset contains additional stages. There is one sleep stage movement (transition) present in the R&K classification. The additional sleep stages are defined as *unknown sleep stages* by the classifying experts. The terminology used to denote the sleep stages is defined as:

- 0 = Wake stage or REM (R&K and AASM)
- 1 = Sleep stage 1 (R&K and AASM) or Sleep stage 2 (R&K and AASM)
- 2 = Sleep stage 3 (R&K and AASM) or Sleep stage 4 (R&K) or unknown sleep stage (R&K)
- 3 = Sleep stage movement (R&K) or an unknown sleep stage (AASM)

The reason why data points which might not seem as a wake stage or sleep stage S1/N1, are included is that when one model predicts a sleep stage 1, the other model might predict a sleep stage 3, an unknown sleep stage, or a sleep stage movement (transition).

B. Data Preparation

The dataset used in the current work was collected as part of the DREAMS project in Belgium and consists of 32-channel polygraph whole-night polysomnographic readings of 20 healthy subjects [5]. At least three of the 32 channels were EEG channels. The data was collected with a sampling frequency of 200 Hz and stored in the standard European Data Format (EDF). The channel chosen by us for the project was the channel CZ-A1, a central lobe channel. Only the first sleep and wake stages were selected from the files along with the corresponding EEG data. Points, which did not have sleep stage 1 or the wake stage in one rating model but in the other, were included, and the total number of data points after this phase was 32924. Each data point consists of one hypnogram rating based on the R&K model, and one hypnogram rating based on the AASM model and 1000 raw EEG signal points corresponding to a manual rating of a 5-second time-window.

These data points were then read into the statistical software R for further pro-cessing. This is a very large volume of data (32924×1000) to be provided for a machine learning algorithm. To reduce the size, feature selection was performed. Each data point was first transformed as per the Fourier transform to obtain the frequency spectrum from 0 Hz to 100 Hz (half the sampling frequency) with an accuracy of 0.2 Hz (inverse of the length of the signal). The sleep manuals indicate that frequencies above 30 Hz do not provide information for sleep stages and thus frequencies above 30.5 Hz were rejected. The size of the data was still large (32924×153). The frequencies were then averaged to the nearest integer frequency to reduce the dimension of the problem. After the data selection, transformation, and feature selection, the size of the data was 32924×31 (31, including the 0 Hz value). This final data was passed to the R platform, a statistical software package extensively used for analyzing large data.

C. Quantitative Indicators Used for the Models

It is important to describe the quantitative indicators used to grade the models in this work. Two models for each machine learning algorithm were created, one corresponding to the AASM scoring method and the other to the R&K scoring method. Thus, for consistency purposes, it is vitally important to *not* compare the AASM models with the R&K models.

There are many indicators, which can be used to grade a classification model. In our paper, the confusion matrix (see Table I) is first created, where TN stands for *True Negatives*, TP for *True Positives*, FN for *False Negatives* and FP for

TABLE I
EXAMPLE OF A CONFUSION MATRIX

		Model's Output 0	Model's Output 1
Manual Rating	0	TN	FP
	1	FN	TP

False Positives. These values can be used to grade the models, however they depend directly on the number of sleep and wake states. Since the database consists of unequal number of sleep and wake states, and to thus properly normalize the results, the following indicators, along with the Cohen's Index, were used:

- *True Positive Rate* (TPR) – This value is known as the sensitivity of the model, and provides an estimate for the successful sleep detection rate by the model. It is defined,
$$\mathrm{TPR} = \frac{\mathrm{TP}}{(\mathrm{TP} + \mathrm{FN})}, \tag{1}$$
and is also linked to the *False Negative Rate* (FNR) through TPR = 1 - FNR [12].
- *True Negative Rate* (TNR) – This value is known as the specificity of the model, and provides an estimate for the successful wake detection rate by the model. It is defined as,
$$\mathrm{TNR} = \frac{\mathrm{TN}}{(\mathrm{TN} + \mathrm{FP})}, \tag{2}$$
and is also linked to the *False Positive Rate* (FPR) through TNR = 1 - FPR [12].
- Cohen's Index (κ) – κ is an indicator that measures the inter-rater agreement for categorical objects, and that takes into account the agreements (TP and TN) occurring by chance [13]. It is defined as:
$$\kappa = \frac{p_o - p_e}{1 - p_e}, \tag{3}$$
where p_o is the observed agreement between the raters, given as:
$$p_o = \frac{\mathrm{TP} + \mathrm{TN}}{\mathrm{TP} + \mathrm{TN} + \mathrm{FP} + \mathrm{FN}}, \tag{4}$$
and p_e is probability of chance agreement, described as:
$$\begin{aligned} p_e = &\frac{(\mathrm{TP} + \mathrm{FN})(\mathrm{TP} + \mathrm{FP})}{(\mathrm{TP} + \mathrm{TN} + \mathrm{FP} + \mathrm{FN})^2} \\ &+ \frac{(\mathrm{TN} + \mathrm{FN})(\mathrm{TN} + \mathrm{FP})}{(\mathrm{TP} + \mathrm{TN} + \mathrm{FP} + \mathrm{FN})^2}. \end{aligned} \tag{5}$$
It can be easily verified that $\kappa = 1$ when the two raters are in complete agreement. In general, a value of $\kappa > 0.6$ indicates a good level of agreement between the raters.

In classification models, there is a trade-off between the TPR and TNR, since increasing one generally reduces the other. Thus it is necessary to study both simultaneously, making the TPR and TNR important indicators of the models. These are simple indicators and to consider random agreement, κ was also used to grade the models.

The following subsections will present the classifying algorithms used in our experiments – Single-Layer Perceptron, Multi-Layer Perceptron, Support Vector Machine, XGBoost and Multi-Agent model – whose classification accuracies were compared, in order to choose the best model. The SLP is a simple linear classifier that calculates the sum of the weighted input variables. It is simple to implement and forms a good reference model. The MLP, also known as neural networks, consists of layers of neurons. This provides the next level of complexity and allows for non-linear behavior to be captured. The SVM models have better predictive performance than the MLP, since they create multiple support vectors, which provide more flexibility in the classifying criterion. The XGBoost model is a variation of the gradient boosting model, an ensemble model that is a collection of decision trees added to minimize a loss function. The Multi-Agent classifiers are two algorithms proposed by us that consists of all the previous models to better classify the EEG data, one by a majority vote and the other by treating the sleep and wake states on a more equal footing.

D. Single-Layer Perceptron

E. Malaekah and D. Cvetkovic [8] had used the ratios of the EEG bands to perform classification of the sleep and wake states. The classifying criterion was manually tuned in their case. Instead of using the ratios of the EEG bands and manually tuning the ratio to match a specific quantity, we used an automatic learning algorithm that can find the classifying criterion without any human interference.

A Single-Layer Perceptron (SLP) is an algorithm for binary classification of an input vector. It is a linear classifier that makes its decisions by a scalar product of the input vector with a set of weights. In machine learning, a perceptron is considered to be the simplest neural network consisting of one neuron. Mathematically, the SLP algorithm can be expressed as:
$$y(\overrightarrow{x}) = \begin{cases} 1 & \text{if } \overrightarrow{w} \cdot \overrightarrow{x} + b > 0 \\ 0 & \text{otherwise} \end{cases}. \tag{6}$$
Here, $\overrightarrow{x}$ is the input vector, $\overrightarrow{w}$ is the weight vector and b is the bias. The output of the perceptron is either 0 or 1 and is determined by the condition provided by the scalar product. The bias alters the position of the decision line. The weight vector is changed by learning algorithms. The learning algorithm used here was the Particle Swarm Optimization (PSO) [14]. PSO optimizes a problem by having a set of candidate solutions (called particles), and moving these particles in the feature space by simple rules for updating the particles' positions and velocities. This optimization technique does not make assumptions about the parameters being optimized and so can be used for noisy and irregular problems. PSO possesses certain advantages of Monte Carlo techniques, where a large space of solutions is searched by the various particles, as well as the advantages of classical optimization techniques, such as gradient descent, where the particles are guided by a 'force' towards the final solution.

Each particle is attracted by its best known position, as well as the best position among all the particles. There is also an inertia term, which keeps the particle moving along a straight line. These three 'forces' act together in different proportions to guide the particle towards better solutions. A PSO algorithm consists of the following main steps, along with part of the code from our implementation in R:

- Initialize `N` particles' positions `particle_pos` and velocities `particle_vel` randomly within the boundaries of the feature space. `part` indicates the particle index, maximum `N`, and `i` the dimension, 31 dimensions in our case.
```
particle_pos[part,i] <- runif(1, min=-10,
max=10) #Random starting positions
particle_vel[part,i] <- runif(1, min=-5,
max=5) #Random starting velocities
```

- Update each particle's best position `best_particle_pos` with the randomly assigned starting position.
```
best_particle_pos[part,i] <-
particle_pos[part,i]
```

- Find the particle with the best position and update the global best position, `coeffs_aasm` or `coeffs_rnk`, with its position. This step depends on the error function and with random starting positions. In our case, the error function was the sum of absolute errors between the expected result and the actual result. This is similar to using the mean of squared errors, since only the absolute value of the error is considered. `#perr` is the particle error.
```
if(perr[part] < global_min_err) {
global_min_err <- perr[part]
coeffs_aasm <- particle_position[part,]
}
```

- Until the stopping criterion is satisfied, i.e. number of iterations run or error criterion is below threshold, do the following
  - Update each particle's position by adding the velocity to it.
```
particle_position[part,] <-
particle_position[part,] +
particle_velocity[part,]
```
  - Update each particle's best position with its current position if and only if the current position is better than the particle's best position. `#min_perr` is the particle's minimum error.
```
if (perr[part] < min_perr[part]) {
min_perr[part] <- perr[part]
best_particle_position[part,] <-
particle_position[part,]
}
```
  - Find the particle with the best current position and update the global best position if and only if this best current position is better than the global best position.
```
if(perr[part] < global_min_err) {
global_min_err <- perr[part]
coeffs_aasm <- particle_position[part,]
}
```
  - Update each particle's velocity as a sum of three contributions multiplied by factors indicating their proportions. The first contribution is the difference between the particle's best position and its current position. The second contribution is the difference between the global best position and the particle's current position. The final contribution is simply the previous velocity of the particle.
```
particle_velocity[part,] <-
particle_velocity[part,] +
runif(31,min=0,max=0.4) *
(best_particle_position[part,]
- particle_position[part,]) +
runif(31,min=0,max=0.7) * (coeffs_aasm
- particle_position[part,])
```
  - Update the number of iterations or calculate the error.
- The global best position is the best solution.

The factors which multiply the three contributions, the inertia term, the force due to the global best position and the force due to the particle's best position, are chosen by the user. These control the 'swarming rate' and hence the behavior and response of the system. In our implementation, the inertia term was multiplied by 1, the force due to the particle's best position was multiplied by a random number between 0 and 0.4 (excluding the extreme values), and the force due to the global best position was multiplied by a random number between 0 and 0.7. The inertia term was kept as a unit value because we wanted the particles to move to not stop swarming. The maximum values of 0.4 and 0.7 were chosen so that the particles were attracted towards their individual best positions and the global best positions, but the contribution of these attractions did not exceed the contribution of the inertia term. The higher average value of the attractive force towards the global best position indicated a preference of each particle to explore positions near the global best position, which is the best known solution so far. The non-zero value of the force towards the individual particle's best position ensured that the particles explored positions near their own best positions. The final values were chosen based on the "goodness" of the results.

E. Multi-Layer Perceptron

In our case, the data does not satisfy the condition of linear separability; therefore non-linear classifiers were considered.

A well-known neural network model, a Multi-Layer Perceptron (MLP) was chosen and its architecture was evaluated.

Neural networks contain at least two layers, with the possibility of additional *hidden* layers. Earlier experiments [15] were performed with two and three hidden layers, the latter of which gave maximum sleep and wake detection rates of about 69 % and 90 % respectively. Compared to the architecture with three hidden layers, this architecture drastically decreased the number of connections and thus the learning time for the neurons [15]. Based on these results, a neural network with two hidden layers 31-46-10-1 was chosen. The learning algorithm used for this project was the default algorithm, *resilient backpropagation* with weight back tracking. The error function minimized in this project was the mean squared errors.

Neural networks have one major disadvantage – risk of *overfitting*, when a model begins to describe the noise. The underlying relationship between the input variables and the output value may fail to have a predictive power completely. In our case 1,953 weights had to be found using 16,462 training points. Thus there is a high possibility of overfitting in our neural network models, which can lead to poor predictions. Unfortunately, reducing the number of neurons in the hidden layers led to a drastic decrease in the performance of the neural network, while increasing it led to overfitting, where the testing phase results were measurably poor as compared to the training phase results. Therefore, the data parameters for our neural network could not be classified correctly without increasing the risk of overfitting. Due to a lower number of sleep stages, the neural network models did better at detecting the wake stages.

F. Support Vector Machine

Support Vector Machines (SVMs) are supervised learning algorithms used for classification and regression analysis [16], [17]. An SVM model maps data points in the feature space as categories which are as far apart as possible, by constructing a hyperplane or a set of hyperplanes in a space, generally of a higher dimension than the feature space. Generally, two or more hyperplanes are selected with no points between them, and then the distances between these hyperplanes are maximized.

Two types of SVM models, a simple SVM model and a multi-class SVM model, were used. The first one interprets the hypnogram sleep stage rating as having a "meaning", i.e. this value can be expressed as the output of a mathematical function of the SVM. The second model merely assigns the hypnogram value as a label for a given SVM input vector. This model is hence more robust to clustering of data that is not linearly separable.

Before starting the training of the SVMs, tuning was performed for two parameters, `gamma` and `cost`, using the functionality provided in the package `e1071` through the function `tune.svm()` on 10 % of the data. The parameter `gamma` is internal to the implementation and is required for all the non-linear kernels, while *cost* is the cost of violating the constraints of the SVM model. The results of this tuning indicated a value of 0.1 for `gamma`, and a value of 1 for `cost`, which were recommended by the SVM implementation based on the 10 % of the data. The same values were obtained for both AASM and R&K classification methods, and were used for the final training of the models. In the multi-class variant of SVM (unlike in the default-SVM), the wake states were given a weight of 0.2 and the sleep states were given a weight of 1.0, to compensate the influence of the higher number of wake states in the dataset.

G. Extreme Gradient Boosted Model

Extreme Gradient Boosted Model (XGBoost) is a supervised machine learning algorithm used for classification and regression analysis, which comprises of an ensemble of 'weak' prediction models, generally in the form of decision trees. It is an efficient implementation of the gradient boosting framework, and has been known to be many times faster than standard implementations.

The boosting process deals with transforming the weak prediction models into a strong model. For example, decision trees with only one or two levels would be considered weak, since their accuracies are slightly better than random classification, and thus are more robust to overfitting. A boosted model creates an ensemble of these models with the intention of creating a strong learner. In many implementations, the weak learners are functions of the loss (error) functions, which the ensemble is trying to minimize. The gradient boosting model consists of calculating the loss function at each iteration and correcting itself by adding the gradient of the loss function in the next iteration [18], [19].

In this work, the maximum depth (nodes) was set to 5 to allow better decision trees at each level. This reduced the number of iterations, i.e. the number of additional trees required to correct the loss function, which was set to 40. The learning process was made more conservative (less overfitting) by scaling the contribution of each tree by 0.15, compared to the default value of 0.3. These values were selected after running multiple tests on the data, and were used for the AASM and R&K models.

H. Multi-Agent Model

To maximize the sleep and wake detection rates, two Multi-Agent (MA) models were developed. Typically, an MA model consists of many 'agents', each of which is an independent classification model. In our work, these MA models were constructed from all the aforementioned algorithms. There are different ways to implement such algorithms [20], and for this project, a democratic MA model and a weighted MA model were chosen. The democratic MA model determined the outcome of a given input by a majority vote, while the weighted MA model determined the outcome of a given input by weighing the outputs of each of the agents.

The democratic MA model did not have any training or testing phase, due to it directly relying on its component models. The outputs from the agents were directly used to

analyze this model on the training and testing data sets. Two models were made, one for the AASM classification and one for the R&K classification.

The training phase for the weighted MA model consisted of optimizing the weights using an error function, and the optimization was achieved with the Particle Swarm Optimization (PSO) as discussed in the SLP model. The error function chosen was the sum of the FNR and FPR. Since the rates are independent of the number of states, this error function is not biased towards one of the sleep or wake states. Minimizing this function would thus maximize the sleep and wake detections simultaneously (TPR = 1 - FNR and TNR = 1 - FPR).

The parameters of the PSO algorithm were identical to those used to determine the weights of the SLP, with the exceptions that the number of dimensions were reduced to 5 and the bias was not required. Two such models were made for each training set, one corresponding to the AASM classification and the other corresponding to the R&K classification.

III. Experimental Results

The data was divided randomly into training and testing sets for cross-validation purposes to check how well the model can perform under more general data. We performed 4-fold cross-validation, where the data was divided into four equal random sets. Earlier experiments [15] indicated similar results to 2-fold cross-validation results, and 4-fold cross-validation has more training and testing phases, which is why it was used to obtain more results. The final results (averaged) are presented for comparison purposes. To compare the models, all learning algorithms were provided the same data for training and testing.

Since there were two scoring models (R&K and AASM) for each data point, two models were made for each learning algorithm, e.g. MLP_Rnk and MLP_AASM. Because of the two *different* standards, it only makes sense to compare all the AASM models together and all the R&K models together. After splitting the data and dividing them as *train-sets* and *test-sets*, the data workspace in R is stored for future use and reference.

In the confusion matrix tables, two outlier points (Outlier 1 and 2) are obtained because of having the same data point classified as sleep stages other than 0 or 1 in one of the two models. These points were neglected to better analyze our results. The confusion matrix was reinterpreted for comparison purposes in terms of TPR, TNR and κ. These quantities are provided for the 4-fold cross-validation studies in table II.

A general observation is that the multi-class SVM (R&K) performs the best, followed closely by the multi-class SVM (AASM). In addition, the TPR for the multi-class SVM is about 94 %, better than previous results of 92.8 % classification accuracy obtained by I. Zhovna and I. Shallom [4], where the cross-correlation information existing between the multichannel EEG signals was used. The TNR, on the other hand, is about 75 %, slightly lower than the 77 % obtained by E. Malaekah and D. Cvetkovic [8]. This is not so far behind, and thus the multi-class SVM is a good choice for further study. As perspectives, the multi-class SVM might be improved by providing more data points corresponding to sleep stages so that the FPR is reduced.

Looking at the Cohen's indices for the different algorithms, we see that the MA, XGBoost, MLP and SVM models are at least 0.60. However, in our study, we place more emphasis on sleep detection, i.e. a TPR higher than 90 %. This is only achieved by the multi-class SVM. It should be pointed that the number of sleep states are lower than those of wake states, which is why the XGBoost and the MA models have a TNR greater than the TPR.

From the tables, we infer that the default SVM does better than the SLP and MLP methods. Both default SVM models (AASM and R&K) have a TPR of over 70 %, similar to the TNR of the multi-class SVM, and the same can be said for the TNR of the default SVM models. Thus, when compared with the results of the multi-class SVM, the TPR and TNR values appear to be swapped. This could be due to the larger number of the wake stages.

A value of $\kappa > 0.60$ indicates a good agreement between the different raters, and thus the SVM, XGBoost and MA models performed well. Comparison of the Cohen's indices shows that the default SVM, XGBoost and MA models perform well with $\kappa > 0.65$ for both scoring methods.

To better understand the trade-off between TPR and TNR, the Receiver-Operator Characteristic (ROC) curves for all the models were plotted as shown in Fig. 1. The FPR and TPR form the $x-$ and $y-$axes of the graph respectively, and a random guessing model would have TPR = FPR as shown with the blue dotted-dashed diagonal in the figure. Points above the diagonal have TPR $>$ FPR, indicating a better predictive performance and a 'perfect' classification model would be at the (0,1) point on the plot, i.e. FPR = 0 and TPR = 1.

Based on the ROC curve, we see that the weighted MA (PSO) model does the best in terms of the trade-off, being closest to the (0,1) point, followed closely by the democratic variant. This is due to the fact that the error function in the PSO algorithm treats sleep and wake stages on an equal footing. In the democratic MA model, there is no training beyond that for each of the individual agents. As a result, the bias towards the wake states exists due to the 'majority' of the models (MLP, XGB and SVM) being biased towards the wake states, a consequence of the previously mentioned larger number of wake states.

Depending on the requirement, detection of one stage might be more critical and the 'best' model has to be accordingly chosen. The purpose of this project was to focus on sleep detection over wake detection and thus, based on the Cohen's index and the requirement of TPR $>$ 90 %, the multi-class SVM is a better model.

It is important to underline that the R&K models have performed better than the AASM models. The R&K standard for sleep scoring was developed in 1968 [9], while the AASM standard was developed recently, in 2007 [10]. These standards have differences which might have affected the manual scoring of the dataset used. To choose between them, inputs from

TABLE II
COMPARISON OF RESULTS (4-FOLD CROSS-VALIDATION)

	AASM Criteria			R&K Criteria		
	TPR (%)	TNR (%)	Cohen's Index (κ)	TPR (%)	TNR (%)	Cohen's Index (κ)
SLP	72.3	76.9	0.47	73.0	77.1	0.46
MLP	69.0	88.2	0.58	70.5	89.3	0.61

a neuroscientist or more *in vivo* data based on a standard of quantifying drowsiness are required. In addition, using a more *balanced* dataset with similar numbers of wake and sleep stages might help develop the methods further.

IV. CONCLUSIONS AND PERSPECTIVES

The main objective of this work was to develop an automatic sleep detection system to warn a sleepy driver and prevent road accidents. With this purpose, the DREAMS database [5] was used and the Fourier transforms of the EEG signal formed the input vector space for the machine learning algorithms. Multiple experiments were performed on different models, such as SLP, MLP, SVM, multi-class SVM and XGBoost. A MA model was subsequently developed that treated the sleep and wake stages equally. This model was observed to be the closest to a perfect classification as can be confirmed with the ROC curve. In addition, the multi-class SVM model for the R&K scoring system maintains the benchmarks of TPR $\geq$ 90 % and TNR $\geq$ 70 %, and the AASM scoring system is not far behind. Using these benchmarks, the potential reduction in economic costs due to loss of human lives was calculated for France to be about 1,104 million EUR for the year 2014 [15].

For future work, the detection models will need to be tested across different datasets to confirm their reliability and to ensure that the models do not fail when presented with new data, either through future laboratory studies or *in vivo* experiments. Pragmatically, the models can be said to be relatively compatible with different datasets, a desirable property, which is useful in the event of retraining the models for certain medical cases where the EEG signals might not be the same as those in an average human being.

Furthermore, it might be fruitful to validate our results from a strictly medical perspective, with the ability to quantify *drowsiness* rather than the first sleep stages, preferably using EEG signals. Obtaining a more *balanced* dataset with equal wake and sleep stages would ensure that there is no bias of the models towards a particular stage. Including more physiological data, like body pulse or blood pressure, may improve the model, since they also decrease when a person tends to fall asleep.

***Abstract*—This paper presents the analysis of potential of the Kosinski's Fuzzy Number (KFN) idea in the modeling trends of the processes which are described imprecisely. KFNs conception is an alternative for the classical fuzzy numbers ideas as model to represent of the imprecise quantitative data. They introduces new feature into vagueness of the information - a direction. It is base for good arithmetical properties of calculations. Furthermore, a direction also extends a potential in the modeling of information by the additional interpretation, what is a subject of this article. This new potential is presented and explained basing on the example of modeling of quantity of liquid in a reservoir. The environment is changing dynamically what is described as the changes in inflow and outflow. Proposed example explains how to interpret the direction of KFN and how to understand the results of calculations and its influence.**

***Index Terms*—Ordered Fuzzy Numbers, Kosinski's Fuzzy Numbers, direction of imprecision, trend in the data, interpretation of fuzziness**

I. Introduction

THE CLASSIC idea of fuzzy sets and numbers is widely known methodology for modeling the imprecision of real world. It wins with statistical methods, especially in the problems where partial imprecision is needed.

Unfortunately the computational properties of classical fuzzy numbers (convex fuzzy numbers) have drawbacks connected with a rapidly growing imprecision after sequence of operations. To improve their arithmetics several additional solutions were introduced. They are usually connected with defining additional operations or constraints ([1][2][3]).

An alternative solution is the Kosinski's Fuzzy Numbers mathematical model [4], [5]. This model takes into account the order of the characteristic parts of a fuzzy number giving the fuzzy number an additional feature - direction. By the consideration of the order in calculations we get the opportunity to reduce the imprecision of the following operations. The KFN computational model have a number of properties which were presented in the publications [4], [6], [7].

This model was previously called 'Ordered Fuzzy Numbers'. However, to honor the late Professor Witold Kosiński, his work, the contribution and commitment to the development, analysis and popularization of this model since the 2015 [8] the name "Kosinski's Fuzzy Numbers" (KFN for short) is used instead.

New property - a direction - apart good properties in calculations also introduces new interpretative potential. We have additional information in processing imprecise data associated with the direction. The papers [9], [10] presents a practical use of KFNs in the modeling of financial data, and [11] applies them to the modeling of diversity of opinions in the social networks. Furthermore, in [12] is presented proposition of the application of KFNs for the ant colony optimization algorithm.

A direction is property which can contain an additional portion of information in the same object which also represents an imprecise fuzzy value. However, the interpretation of this new feature, should be consistent and intuitive with methods of the calculations/processing and also with the final results of them. Such coherent proposal how to understand a direction of KFN was presented in [13], [14]. This proposition connect this new feature with a representation of trend in a process. Despite the fact that in the literature can be found various proposals of applications of the model KFN, it lacks exact discuss and full consistent example how and where to get the direction and how it translates into results of operations. Thus the purpose of this publication is to provide such complete analysis of the quite simple and easy to understand process where actions are described by KFNs.

It will be presented on the example of process of changes in the level of liquid in the reservoir. Example presents a problem, in which we want to describe / determine the state of the liquid in the container, under conditions of high variability due to rapidly changing an inflow and an outflow. This publication demonstrates the effectiveness of KFNs in the modeling such problems. The example will show that by modeling the process with the KFNs, we can get more than imprecise description of situation, we can get also the informations about the trends of changes.

A. The Organization of the Paper

In next section the Kosinski's Fuzzy Number model is shortly introduced with the genesis of the idea. In subsections are also presented the definitions of arithmetic operations on KFNs and practical interpretation of the specific feature of the model - the direction. The following - third section contains the description of the process, which is modeled in this paper. First subsection presents assumptions of the model, next the

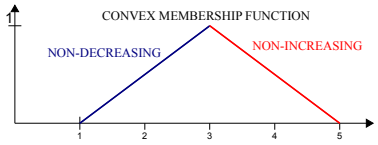

Fig. 1. Parts of the convex membership function

description of subsequent actions with use of KFN model. Third subsection presents the analysis of the appropriateness of using KFNs for modeling of actions of dynamic process. Next - fourth section provides some discussion about different ways for concerning of the direction in the model of process. Final section provides extended summary and conclusions for this paper.

II. Kosinski's Fuzzy Number (KFN)

Main concepts of the idea of Kosinski's Fuzzy Numbers were introduced and developed in the series of papers [15], [4], [5], [6], [13], [16], [14]. As it is an unusual model of imprecise information, before introducing a formal definition, it will be useful to clarify a background of concept.

At the beginning, very important fact must be emphasized. The KFNs are not the fuzzy sets. They are connected conceptually with the idea of fuzzy sets and they can be used in similar way, but, in formal, they are not Zadeh's fuzzy sets. Thus comparing the operations on KFNs with adequate operations based on Zadeh's extension principle [17] can be realized only in the context of the results of calculations, but not by the definitions.

It is also worth noting the fact, although KFNs by definition are other mathematical objects than fuzzy sets, they can represent the majority of situations, which can be described by the convex fuzzy numbers including calculations on them.

A. Genesis of the KFNs

Idea of KFNs have a source in the quasi-concavity of membership functions of fuzzy numbers [18]. It is not a new observation that the each convex membership function of fuzzy number can be split into two parts: first is non-decreasing and second is non-increasing (see fig.1). It is a base of widely known classical fuzzy numbers model called the (L, R) fuzzy numbers [19]. The KFNs idea also generally is based on such point of view. However, the new model treat separately non-decreasing and non-increasing parts of fuzzy number. Additionally, it defines an order between these parts as independent from the domain values. Such conditions leads to the new possibilities in calculations and also in processing of imprecise data.

B. Definition of the KFN

Following the papers [15], [4], [5], [6], [13], [20], [8], [21] fuzzy number will be identified with the pair of functions defined on the interval $[0, 1]$.

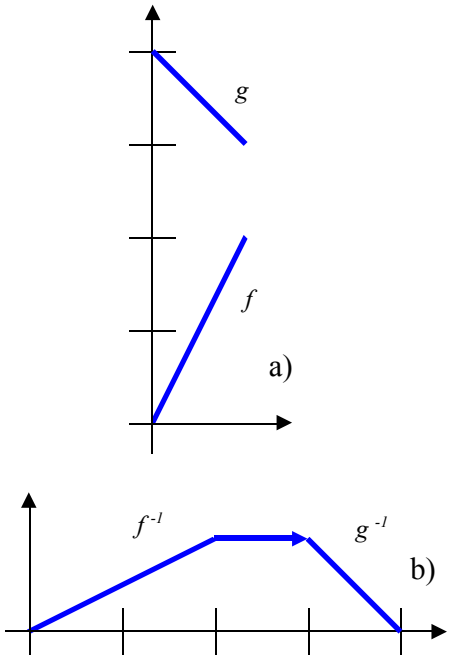

Fig. 2. a)Kosinski's Fuzzy Number, b)The Kosinski's Fuzzy Number as convex fuzzy number with an arrow.

Definition 1: The Kosinski's Fuzzy Number (KFN in short) A is an ordered pair of two continuous functions

$$A = (f_A, g_A) \tag{1}$$

called the up-part and the down-part, respectively. Both are defined on the closed interval $[0, 1]$ with values in **R**.

If the functions f and g are monotonic (Fig.2a), they are also invertible and possess the corresponding inverse functions defined on the real axis with the values in interval $[0, 1]$. If these two inversed functions are not connected, we linking them with constant function with the value 1. In such way we receive an object which directly represents the classical fuzzy number. For the finalization of transformation, we need to mark an order of f and g with an arrow on the graph (see Fig.2b). Notice that pairs (f, g) and (g, f) are the two different Kosinski's Fuzzy Numbers, unless $f = g$. They differ by their orientation or direction. We can distinguish two orientations giving them names. If the down-part g is greater than the up-part f we will call that "positive" orientation and opposite to it - "negative".

For the later use it will be more convenient to adopt the following general indications of the KFN boundaries:

$$\begin{aligned} UP &= (s, 1^-) \\ CONST &= [1^-, 1^+] \\ DOWN &= (1^+, e) \end{aligned} \tag{2}$$

These boundaries allow for simply representation of the KFNs where f and g (up-part and down-part) are linear functions. In such situation we can precisely represent a given KFN by four $(s, 1^-, 1^+, e)$. In fact in this paper in the example presented in

later sections the $CONST$ interval will be minimized to the one point $k = 1^- = 1^+$, thus the KFNs will be represented by triples (s, k, e) (see fig.3).

It should be emphasized that, these intervals can be improper intervals (see the KFNs B and C on the fig.3) in the sense of Kaucher's extended interval arithmetic [22] and called by him 'directed intervals', i.e. such $[a, b]$ where a may be greater than b.

For monotonous f and g we may point the membership function within the meaning of classical fuzzy numbers:

$$\mu(x) = \begin{cases} f^{-1}(x), \text{ if } x \in [f(0), f(1)] = [s, 1^-], \\ g^{-1}(x), \text{ if } x \in [g(1), g(0)] = [1^+, e], \\ 1 \text{ when } x \in [1^-, 1^+]. \end{cases} \quad (3)$$

It is worth to point out that a class of Kosinski's Fuzzy Numbers represents the very wide class of convex fuzzy numbers with continuous membership functions (regarding "classical fuzzy numbers" [18], [23], [3], [24]).

C. Arithmetic Operations

Operations on KFNs we define as calculations with the up-parts and down-parts as follows:

Definition 2: Let $A = (f_A, g_A), B = (f_B, g_B)$ and $C = (f_C, g_C)$ are mathematical objects called Kosinski's Fuzzy Numbers. The sum $C = A + B$, subtraction $C = A - B$, product $C = A \cdot B$, and division $C = A \div B$ are defined by the formula

$$f_C(y) = f_A(y) \star f_B(y) \qquad \wedge \qquad g_C(y) = g_A(y) \star g_B(y) \quad (4)$$

"$\star$" replaces "$+$", "$-$", "$\cdot$", and "$/$". The A/B is determined only if B does not contain zero. The $y \in [0, 1]$ is the domain of functions f and g.

The properties of these operations and their results have already been discussed and analyzed in various publications (for example see [25], [6], [7]). Additionally the paper [7] presents also a different examples of calculations. Nevertheless a brief description of the properties KFN calculations is needed for a better understanding of analysis included in the next sections of this paper. For example it is important property, that the subtraction is equal to the addition of the opposite number, where the opposite number is obtained by multiplying the given value by the -1 (real number - singleton). By using the above-mentioned method in calculation of $A - A$ we obtain exact zero (crisp number). Using the arithmetical operations on KFNs every simple equation type $A + X = B$, where A and B are fuzzy numbers with any membership functions, can be solved. We calculate result exactly the same way as with real numbers. Such possibilities are a consequence of adopting operations for KFNs directly from real numbers. After a closer investigation of the definitions 1 and 2 it can be noted that the operations on parts of the KFNs are executed through operations on functions representing these parts. Finally, the operations on the functions are, in fact, operations on their values. Thus, if space of values of function

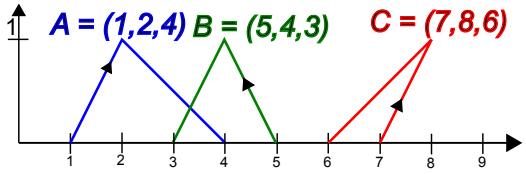

Fig. 3. Examples of KFNs represented by triples.

are the real numbers (as with all KFNs), then practically, calculations are executed as operations on the real numbers universe. Summarizing, the KFN model grants flexibility of calculating on imprecise data in a similar way like with real numbers on crisp data. It retains fuzzy quantitative character, but without necessity of growing an imprecision.

However, using the KFNs we should remember that their basics are different than the Zadeh's fuzzy sets and some objects like C on the fig.3 can appear (see also [14], [7]). Such elements are consistent with the definition of KFN (see def.1), although, their shape can not be defined as a membership function. Such objects are called improper KFNs. This aspect of model was commented in [4], [5], [7]. Despite the unusual shape (as for fuzzy numbers), such KFNs still contain important information needed for the calculations. In the example presented in next sections of this paper such object also will be part of analysis as an important portion of data about the modeled process.

D. Imprecision interpretation and direction of the KFN

The direction is a key element of the KFN model. Basically it is defined as an order of the parts of fuzzy number and is independent from the real numbers universe. Proposition of practical interpretation for this new property was presented in [13], [14]. KFNs are considered in these papers as the values representing an observation, which passes in time, regardless of the order of numerical values. So, the time dependence can be a natural interpretation of the direction. Such context is also used in this publication. Following [13], [14]imprecision here is interpreted as a consequence of dynamic changes. So the up-part represents, relatively short, past behavior of the value represented by given KFN, and the down-part indicate expected change of the value in the next step of process. However, it should be clarified that this is not the only possible interpretation of the direction, but this publication focuses just on such variant.

III. Modeling process using the KFNs

At start it should be noted, that there is a paper [26] that presents an example of calculations which context is connected with the water lever for the cofferdam. But that publication focuses on comparison of arithmetics of LR fuzzy numbers and KFNs based on solving simple equation. The issue of the direction's source is there minimized.

Possibilities of modeling an imprecision in the processes with use of the KFNs will be presented here on the simple intuitive example of reservoir with one outflow and one inflow.

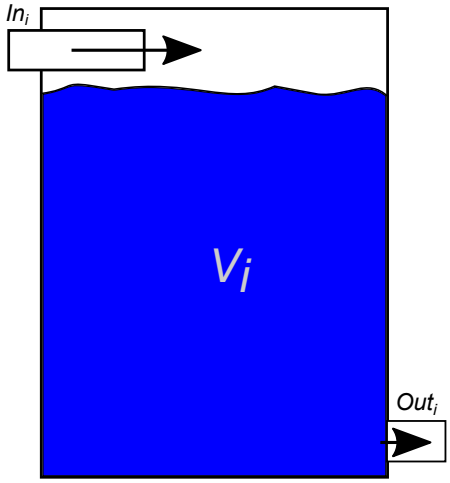

Fig. 4. General idea of the model.

KFNs are used here to describe a behavior of the inflow and the outflow, and also, to indicate the amount of liquid in the reservoir during each step of the process. Following [13], [14], here, the source of imprecision will be also connected strictly with a dynamic changes of parameters. Thus, when no changes are applied the situation will be considered as crisp and precise.

It is worth noting that the problem that we want to solve with this example is to find a simple method to determine the current state of the liquid in the tank in a high variability situation. The input data, in addition to the initial state, are the changes in inflow and outflow. Generally, the problem can be formulated as monitoring the status of the tank only on the basis of the monitoring of sources (an outflow is interpreted as a negative value).

A. Assumptions

General idea of the model is presented on the fig. 4. Before the analysis, some assumptions should be clarified. The time of analyzed example is discrete and divided onto intervals with a similar duration. The units are not specified, as it is not relevant whether they will be seconds, minutes or hours. The actions during the process will be described as changes of values (of inflow and outflow) which lasts by one time interval denoted by Δt. Similarly, the determination of the state of actual liquid level in the reservoir will be denoted by V_i without specifying units. As the natural consequence of these assumptions the performance of inflow In_i and outflow Out_i will be described as cumulative change ΔV_i during Δt with units adequate to the description of capacity of analyzed reservoir and time-steps. The index i will indicate the subsequent time-steps in the analysis.

B. The sequence of actions in the process

The exemplary of process starts with static situation. Inflow and outflow is zero. At the beginning, volume of liquid in the reservoir is described by the KFN singleton $V_0 = (20, 20, 20)$. The whole process will be divided onto time-steps numerated from 1 to 11. Each step is described by the changes in inflow and outflow which are usually consequent continuations of previous states. For each step, the actual volume of liquid will be calculated by the formula:

$$V_i = V_{i-1} + In_i + Out_i \tag{5}$$

where i - indicates the number of subsequent - actually analyzed - time interval. In general, the inflow values are positive numbers as they represent incoming liquid to the reservoir. So, for the outflow the values are negative.

Steps in the process are as follows:

1) The inflow starts slowly from 0 to 1. It is described by the KFN $In_1 = (0, 0, 1)$. The outflow is no changing so the value is $Out_1 = (0, 0, 0)$. The state of liquid in the reservoir is calculated $V_1 = V_{i-1} + In_i + Out_i = (20, 20, 21)$. As we can see the fuzziness is growing due to the changes in inflow. The result represents not only the actual state but also an information about a trend in the process (which is presently growing due to positive orientation of V_1).
2) The inflow is growing with the same speed $In_2 = (0, 1, 2)$. It means is increasing from 1 to 2 unit of volume in Δt. The outflow still is closed: $Out_2 = (0, 0, 0)$. The level of liquid: $V_2 = V_{i-1} + In_i + Out_i = (20, 21, 23)$. We can see that we again have reasonable imprecise information about actual volume of liquid. Summarizing, it started with 20 then in first time interval the inflow was about 0 however not precisely. During next time interval, the inflow is growing and is about 1. So after these two time intervals we have in result the content of reservoir about 21. The orientation is positive so this is increasing trend and as we can see, generally, it is the right conclusion for this moment.
3) The inflow is growing with the same speed $In_3 = (1, 2, 3)$. Now the outflow is activated and it is rapid: $Out_3 = (0, 0, -3)$. At this point it is worth to calculate the cumulative change: $\Delta V_3 = In_3 + Out_3 = (1, 2, 0)$. The level of liquid: $V_3 = (21, 23, 23)$. In this step we see, that the starting rapid outflow eliminates the effect of inflow. The KFN V_3 tells us that the growing trend in filling reservoir is stopping. More interesting however, is the cumulative change ΔV_3, which is in fact the improper KFN as it was earlier introduced. As we can see such object represents important information - sudden change of a trend.
4) The inflow is growing with the same speed: $In_4 = (2, 3, 4)$. The outflow is growing with the same high speed: $Out_4 = (0, -3, -6)$. The cumulative change: $\Delta V_4 = In_4 + Out_4 = (2, 0, -2)$. The level of liquid: $V_4 = (23, 23, 21)$. In this step we have a situation when the actual volume of content of reservoir changes orientation. Inflow and outflow are more or less balancing, however trend starts decreasing.
5) The inflow stops increasing at the level 4: $In_5 = (3, 4, 4)$. The outflow still is growing, however, much

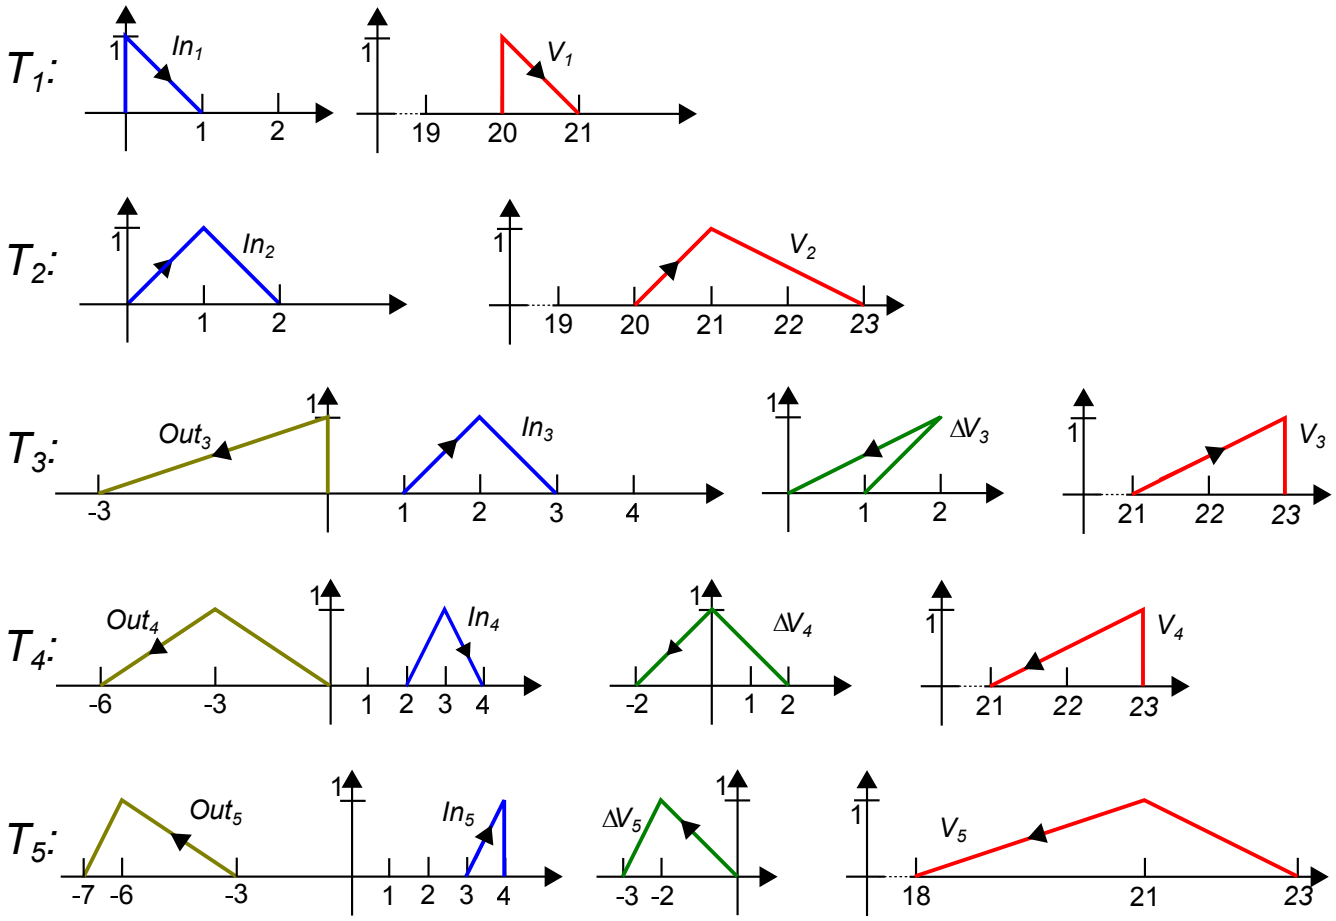

Fig. 5. KFNs in first five time intervals of the process.

more slowly than before: $Out_5 = (-3, -6, -7)$. The cumulative change: $\Delta V_5 = (0, -2, -3)$. The level of liquid: $V_5 = (23, 21, 18)$. Clearly as the V_5 posses negative orientation the liquid volume is about 21 in the decreasing trend.

6) The inflow is constant and equal 4: $In_6 = (4, 4, 4)$. The outflow stops growing at the value -7: $Out_6 = (-6, -7, -7)$. The cumulative change: $\Delta V_6 = (-2, -3, -3)$. The actual level of liquid: $V_6 = (21, 18, 15)$. At this moment we have a situation where the outflow and the inflow stabilizing. So, fuzziness of cumulative change is not high, however, the imprecision of actual volume of liquid is clearly greater. Although the cumulative changes are not too large, the situation in the reservoir is quite dynamic. In comparison with the initial value of 20, currently we have an income of liquid on the level 4 and outcome - about 6. This is generally quite big change, even if cumulatively it is not so significant.
7) The inflow starts decreasing with high dynamic: $In_7 = (4, 4, 2)$. The outflow is stabilized at -7: $Out_7 = (-7, -7, -7)$. The cumulative change: $\Delta V_7 = (-3, -3, -5)$. The level of liquid $V_7 = (18, 15, 10)$. Now we have clear decreasing trend and this decreasing is growing.
8) The inflow decreasing with the same speed: $In_8 = (4, 2, 0)$. The outflow starts rapidly decreasing: $Out_8 = (-7, -7, -4)$. The cumulative change: $\Delta V_8 = (-3, -5, -4)$. The level of liquid: $V_8 = (15, 10, 6)$. Once again we have to deal with the improper KFN as cumulative change.
9) The inflow is closing: $In_9 = (2, 0, 0)$. The outflow is decreasing with the same very high speed: $Out_9 = (-7, -4, -1)$. The cumulative change: $\Delta V_9 = (-5, -4, -1)$. The level of liquid: $V_9 = (10, 6, 5)$.
10) The inflow is cut off: $In_{10} = (0, 0, 0)$. The outflow is closing: $Out_{10} = (-4, -1, 0)$. The level of liquid: $V_{10} = (6, 5, 5)$. This KFN shows that situation in reservoir is stabilizing. The whole process stops, so a fuzziness/imprecision is low.
11) Finally, the inflow is cut off and also the outflow definitely ends: $Out_{11} = (-1, 0, 0)$. The final level of liquid: $V_{11} = (5, 5, 5)$. There is no change in the reservoir. Therefore, according to previous assumptions (a source of imprecision are changes), the result is not fuzzy.

C. The KFNs in the example

For a better understanding and analysis of the example the full graphical representation of KFNs which describes clue values for first five steps of the process are presented on fig.5. Summing up, we can identify the following general activities during the process:

- First, the inflow is slowly turning on and it is increasing steadily giving more and more income of the liquid during next few time intervals. After that it stabilizes for a moment.
- During slow increasing of inflow, the rapid outflow starts, which quickly slow down and stabilizes in short time.
- Then, the inflow is slowly closing and then, almost simultaneously, also the outflow is closing.

The KFN model can be represented, quite intuitively, by Japanese Candlestick Chart commonly used for financial data [10]. We can use it to present a set of KFNs which have a common context. This kind of chart is especially compatible with the KFNs because it can represent not only values, but also intervals and more important - a direction. It is not full precise description but gives general outlook about main character of such set. Figure 6 represents the chart for volume of liquid V_i in the reservoir during each time interval. The actual level of content during $i-th$ time interval is represented by the rectangles. Height of the rectangle represents the range of imprecision. Additionally, white color represents the increasing trend and black - the decreasing. So, we can read from the chart informations about the content of reservoir during subsequent time-steps as follows:

- The trend is positive in the first three time intervals. The fuzziness is not large as the changes are not so dynamic.
- From the fourth time-step the trend changes and becomes negative. Additionally the fuzziness is growing. If we refer back to the detailed description of the example, in third step the outflow starts rapidly and lasts for a while. So, its consequence is the change of trend in fourth step and growing imprecision during next few periods.
- From the ninth time interval, imprecision is decreasing, however trend of the liquid's volume is still negative. If we again refer back to the detailed description of the process, we notice that from ninth period the dynamics of inflow and outflow is decreasing so the imprecision is smaller.

IV. Determining direction of the KFNs

The source of a direction of KFNs used in the example is basing on the fundamentals of conception 'a change', which has generally two possible trends. It is either increasing or decreasing - thus positive or negative orientation for the KFNs. It is simple and intuitive.

In the linguistic description of actions in the example from previous section, we consider the inversion of ideas: the inflow and the outflow. Therefore, if the inflow means adding liquid to the reservoir, then enlarging an outflow means that, the KFN becoming more and more negative. The KFN model grants

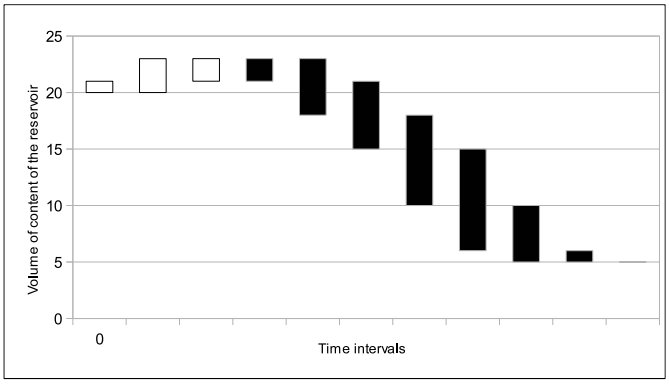

Fig. 6. Candlestick chart for the level of liquid in the subsequent time-steps.

flexibility of calculations, so we could describe outflow with absolute values. However, in such situation the opposition of outflow against inflow should be referred in the calculating of actual volume of content. Instead the formula 5 we should use:

$$V_i = V_{i-1} + In_i - Out_i. \tag{6}$$

Finally, the results would not change, due to the fact that subtracting the KFNs is, in real, adding the opposite number. We get the opposite number like in the real numbers (but unlike with classical fuzzy numbers) by multiplying the original number by -1.

V. Summary and Conclusions

The example in the previous section presents application of KFNs for the modeling of changes in the process of filling and outpouring content in the reservoir. Although this example is simply, it presents not only the changes of actual volume of liquid. In fact, the fuzziness of inflow and outflow refers to the 'change of changes'. As the In_i and Out_i represents $\Delta V_i/\Delta t$, so fuzziness of them is a change $\Delta(\Delta V_i)$ during Δt. It may be easier to understand if we compare this with the process of object's movement. If x is a position, then Δx is a velocity. And furthermore, change of speed is an acceleration. It generally shows a good potential of the KFNs as a good tool for modeling more complex dynamic action than just simple changes.

Presented process is analyzed step by step. It shows also particular usefulness of KFN model for a linguistic describing of changes. Although in the example we have one inflow and outflow, it is not difficult to expand conception to the multi-inflow/outflow situations. The formula 5 becomes as follows:

$$V_i = V_{i-1} + \Sigma In_i^j + \Sigma Out_i^k \tag{7}$$

where: j - subsequent number of the inflow, k - subsequent number of the outflow.

However, because the indication of source of changes, if it is either inflow or inflow, bases on the numerical values, we can simplify the notation. Instead In^j and Out^k we can use just Src:

$$V_i = V_{i-1} + \Sigma Src_i^m \tag{8}$$

where: $m \in (j + k)$ - subsequent number of the source of change of any kind.

If we analyze concrete values of actual level of liquid V_i in each time-step (let's look more closely at the fig.5) we can notice that KFNs accumulates the fuzziness of changes. However, if changes are opposite - they are canceling. This is right and consistent with the intuition. If the liquid is inflowing and simultaneously the same amount of content is outflowing, there is no change at all.

Furthermore we can see also on fig. 5, that KFNs representing actual volume of content can be referred to the classical fuzzy numbers. Such objects can be defuzzified or we can ignore a direction and use them, for example, as input values for the next stage of processing, even with use of classical fuzzy system. But these KFNs contains more information than only imprecision. We can read from them, the actual trend of the process. The papers [16], [27], [8], [21] describes the research of the methods of processing of KFNs where a direction is considered - Direction Sensitive Fuzzy Information Processing. So, instead ignoring orientation we can use full information and process it in a more effective way.

By application of KFNs we can distinguish a situation "about 5 in increasing trend" and "about 5 in decreasing trend". It is not hard to find many real life circumstances where these informations should generate significantly different reactions. An example can be the getting dressed for a trip. If we have "15 degrees of Celsius and temperature is decreasing" we should get more warm cloth than in opposite trend. More to that, there is also significance either a dynamic of changes is large or small.

The example presented in this paper can be easy transferred into other areas than the controlling content of reservoir. Balancing of the incomes and outcomes is very popular pattern. If it is inflow of liquid or income of money, or increasing number of some web-portal users, it can be described by the KFNs. So, if we need a tool for processing an imprecise data and we want to model a trend, the KFNs can be used.

ON closing, it should be stressed that, this publication presents the effectiveness of the use of KFNs in the situations where we focus on the dynamic changes as the source of the inaccuracy. However, there is many cases where a vagueness is more complex. In such situations a good idea is to design the hybrid methods which will consider all significant sources of an imprecision.

***Abstract*—In the paper issues related to the use of dispersed knowledge in medicine are discussed. The main aim of the article is to investigate the efficiency of inference of seven selected fusion methods in a dispersed decision-making system. The dispersed system was proposed by the author in previous papers. The examined fusion methods - the maximum rule, the minimum rule, the median rule, the sum rule, the probabilistic product method, the method that is based on the theory of evidence and the method that is based on decision templates - are well known from the literature. In the paper two medical data sets from the UCI repository were used. Based on the obtained results it was concluded that for one data set the maximum rule generates the best results, and for other data set better methods are the sum rule and the median rule.**

I. Introduction

IN THE paper issues related to the use of dispersed knowledge are considered. The use of dispersed knowledge is particularly important in medicine because many medical centers independently collect information on patients or studied cases. That means that we have access to dispersed knowledge. If this knowledge is from one field, for example, one disease entity, it is possible to use all of the collected information at the same time which should improve the efficiency of inference.

The use of dispersed knowledge was investigated by the author in the earlier papers [9], [10], [12], [13], [14]. In the paper [10] a dispersed decision-making system with dynamic structure was proposed. This system is used in this article. The use of dispersed knowledge in medicine was also considered by the author [8], [11]. The novelty that is proposed in this article is to apply the seven fusion methods in a dispersed system.

The issue of combining classifiers is a very important aspect in the literature [1], [2], [3], [4], [5], [6], [17]. The aim of the issue is to improve the quality of the classification by combining the results of the predictions of the base classifiers. One of the basic questions is what combination rule to use. In this article different fusion methods are considered. These methods are very popular and are described in numerous papers [1], [4], [5], [6], [7], [15], [16]. In this article, seven selected fusion methods were tested in conjunction with a dispersed system. The obtained results were compared and conclusions were drawn.

The paper is organized as follows. The second section briefly describes the dispersed decision-making system. The third section describes the fusion method that are used. The fourth section shows a description and the results of experiments. The article concludes with a short summary in the fifth section.

II. A dispersed decision-making system - brief overview

In the article [10] a dispersed decision-making system was proposed by the author. This system is also used in the paper. The main assumptions of the system are very briefly described below. A detailed discussion is omitted because it is not the goal of this article. A detailed description of the system can be found in the paper [10].

It was assumed that in the system the knowledge is available in a dispersed form. The dispersed form means that we have several decision tables. The set of local knowledge bases that contain data from one domain is pre-specified. One condition must be satisfied by the local knowledge bases. They must have common decision attributes. We assume that each local decision table $D_{ag} = (U_{ag}, A_{ag}, d_{ag})$ is managed by one agent, which is called a resource agent ag. We want to designate homogeneous groups of resource agents. The agents who agree on the classification for a test object into the decision classes will be combined in the group that is called a cluster. It is realized in a two step process with the negotiation stage. For more details, please refer to the paper [10]. For each cluster that contains at least two resource agents, a superordinate agent is defined, which is called a synthesis agent, as_j, where j is the number of cluster. The synthesis agent, as_j, has access to knowledge that is the result of the process of inference carried out by the resource agents that belong to its subordinate group. A formal definition of a dispersed decision-making system is as follows.

Definition 2.1: By a dispersed decision-making system with dynamically generated clusters we mean $WSD^{dyn}_{Ag} = \langle Ag, \{D_{ag} : ag \in Ag\}, \{As_x : x \text{ is a classified}$

object}, $\{\delta_x : x \text{ is a classified object}\}\rangle$ where Ag is a finite set of resource agents; $\{D_{ag} : ag \in Ag\}$ is a set of decision tables of resource agents; As_x is a finite set of synthesis agents defined for clusters dynamically generated for the test object x, $\delta_x : As_x \rightarrow 2^{Ag}$ is a injective function that each synthesis agent assigns a cluster generated due to classification of the object x.

On the basis of the knowledge of agents from one cluster, local decisions are taken. An important problem that occurs is to eliminate inconsistencies in the knowledge stored in different knowledge bases. In previous papers the approximated method of the aggregation of decision tables have been used to eliminate inconsistencies in the knowledge [9], [10]. In this paper, we also use this method. In the method for every cluster, a kind of combined information is determined. This combined information is in the form of aggregated decision table. Object of this table are constructed by combining relevant object from decision tables of the resource agents that belong to one cluster. Based on the aggregated decision tables global decisions are taken using the fusion method.

III. Fusion methods

In this study, seven fusion methods are used that belong to the measurement level group [1], [6]. In this group of methods each base classifier generates a vector that represents the probability of an observation belonging to different decision classes. Thus, for each synthesis agent, such a vector of probabilities is generated. This is realized in the following manner. A c-dimensional vector of values $[\mu_{j,1}(x), \ldots, \mu_{j,c}(x)]$ is generated for each j-th cluster, where c is the number of all of the decision classes. The value $\mu_{j,i}(x)$ determines the level of certainty with which the decision v_i is taken by agents belonging to the cluster j for a given test object x. This vector will be defined on the basis of relevant objects. From each aggregated decision table and from each decision class, the smallest set containing at least m_2 objects for which the values of conditional attributes bear the greatest similarity to the test object is chosen. The value of the parameter m_2 is selected experimentally. The value $\mu_{j,i}(x)$ is equal to the average value of the similarity of the test object to the relevant objects form j-th aggregated decision table, belonging to the decision class v_i. In this way, for each cluster the vector of probabilities is generated.

In the paper [5], it was proposed that the classifier outputs can be organized in a decision profile (DP) as the matrix. The decision profile is a matrix with dimensions $card\{As_x\} \times c$, where As_x is a finite set of synthesis agents defined for the test object x and c is the number of all of the decision classes. The decision profile is defined as follows

$$DP(x) = \begin{bmatrix} \mu_{1,1}(x) & \cdots & \mu_{1,c}(x) \\ \cdots & & \\ \mu_{card\{As_x\},1}(x) & \cdots & \mu_{card\{As_x\},c}(x) \end{bmatrix}$$

The j-th row of the matrix saves the output of j-th synthesis agents and the i-th column of the matrix saves support from agents As_x for decision class i.

The maximum rule and the minimum rule

The maximum rule and the minimum rule consist in the designation of the maximum or the minimum value of the probability values assigned to this class by each cluster for each decision class. The set of decisions taken by the dispersed system is the set of classes that have the maximum of these values. Thus, the sets of global decisions that are generated using these methods are defined as follows: the maximum rule

$$\hat{d}_{WSD_{Ag}^{dyn}}(x) = \arg\max_{i\in\{1,\ldots,c\}} \Big\{ \max_{j\in\{1,\ldots,card\{As_x\}\}} \mu_{j,i}(x) \Big\},$$

the minimum rule

$$\hat{d}_{WSD_{Ag}^{dyn}}(x) = \arg\max_{i\in\{1,\ldots,c\}} \Big\{ \min_{j\in\{1,\ldots,card\{As_x\}\}} \mu_{j,i}(x) \Big\}.$$

The median rule

In the median rule the median value of the probability values is determined for each decision class. The set of decisions taken by the dispersed system is the set of classes that have the maximum of these medians

$$\hat{d}_{WSD_{Ag}^{dyn}}(x) = \arg\max_{i\in\{1,\ldots,c\}} \Big\{ \mathrm{med}_{\mathrm{j}\in\{1,\ldots,\mathrm{card}\{\mathrm{As_x}\}\}}\ \mu_{\mathrm{j,i}}(\mathrm{x}) \Big\}.$$

The sum rule

The sum rule consists in the designation of the sum of the probability values assigned to this class by each cluster for each decision class. The set of decisions taken by the dispersed system is the set of classes that have the maximum of these sums. Thus, the set of global decisions that are generated using the sum rule is defined as follows

$$\hat{d}_{WSD_{Ag}^{dyn}}(x) = \arg\max_{i\in\{1,\ldots,c\}} \Big\{ \sum_{j=1}^{card\{As_x\}} \mu_{j,i}(x) \Big\}.$$

The probabilistic product method

The probabilistic product method was proposed in the paper [16]. For each decision v_i, the value is determined

$$\frac{1}{P(v_i)^{L-1}} \prod_{j=1}^{L} \mu_{j,i}(x), \tag{1}$$

where the probabilities $P(v_i)$ are estimates based on the training sets of the synthesis agents. $P(v_i) = \frac{N_i}{N}$, where $N = \sum_{as\in As_x} card\{U_{as}\}$ is the sum of the number of objects of the aggregated decision tables and $N_i = \sum_{as\in As_x} card\{X_{as}^{v_i}\}$ is the sum of the number of objects from the decision class v_i of the aggregated decision tables. The set of decisions taken by the dispersed system is the set of classes that have the highest value as calculated by Formula 1.

Method that is based on decision templates

The method that is based on decision templates was proposed in the paper [5]. The decision templates of each class are defined in this method. The decision template for class v_i is the average of the decision profiles of the objects of the training set labelled in class v_i. In the dispersed decision-making system the decision templates of the synthesis agents are constructed based on the decision templates of the resource agents that belong to its subordinate cluster. Therefore, the

decision profiles of the resource agents for the training objects were calculated

$$DP^{Ag}(x) = \begin{bmatrix} \bar{\mu}_{1,1}(x) & \cdots & \bar{\mu}_{1,c}(x) \\ & & \cdots \\ \bar{\mu}_{j,1}(x) & \cdots & \bar{\mu}_{j,c}(x) \\ & & \cdots \\ \bar{\mu}_{card\{Ag\},1}(x) & \cdots & \bar{\mu}_{card\{Ag\},c}(x) \end{bmatrix}$$

the values $\bar{\mu}$ are defined as follows:

$$\bar{\mu}_{j,i}(x) = \frac{\sum_{y \in U^{rel}_{ag_j} \cap X^{v_i}_{ag_j}} s(x,y)}{card\{U^{rel}_{ag_j} \cap X^{v_i}_{ag_j}\}},$$

where $U^{rel}_{ag_j}$ is the subset of relevant objects selected from the decision table D_{ag_j} of a resource agent ag_j and $X^{v_i}_{ag_j} = \{x \in U_{ag_j} : d_{ag_j}(x) = v_i\}$ is the decision class of the decision table of resource agent ag_j; $s(x,y)$ is the measure of similarity between objects x and y. Note that in order to construct the decision profiles of the resource agents for training objects, the same sets of objects must be included in the decision tables of the resource agents. Thus, the assumptions of a dispersed system must be narrowed slightly when we use this method, and therefore the system will no longer be so general. Based on the decision profiles of the resource agents, the decision templates of the resource agents are determined

$$DT^{Ag}_{v_i} = \frac{1}{card\{Z_{v_i}\}} \sum_{x \in Z_{v_i}} DP^{Ag}(x),$$

where Z_{v_i} is the set of objects from the training set that belong to the class v_i. The training process consists in determining the decision templates of the synthesis agents for each class $DT^{As_x}_{v_i}$, $i \in \{1, \ldots, c\}$. The decision templates of the synthesis agents are determined based on the decision templates of the resource agents in the following way. The j-th row of the decision template should save the output of the j-th synthesis agent. The j-th row of the decision template is calculated as the average of the rows of the decision templates of the resource agents that correspond to the resource agents that belong to the cluster that is subordinate to the j-th synthesis agent

$$DT^{As_x}_{v_i} = \begin{bmatrix} \frac{\sum_{ag_p \in \delta_x(as_1)} DT^{Ag}_{v_i}(p,1)}{card\{\delta_x(as_1)\}} & \cdots & \frac{\sum_{ag_p \in \delta_x(as_1)} DT^{Ag}_{v_i}(p,c)}{card\{\delta_x(as_1)\}} \\ \cdots & & \\ \frac{\sum_{ag_p \in \delta_x(as_k)} DT^{Ag}_{v_i}(p,1)}{card\{\delta_x(as_k)\}} & \cdots & \frac{\sum_{ag_p \in \delta_x(as_k)} DT^{Ag}_{v_i}(p,c)}{card\{\delta_x(as_k)\}} \end{bmatrix}$$

where $As_x = \{as_1, \ldots, as_k\}$ and $DT^{Ag}_{v_i}(p,l)$ is an element at the p-th row and the l-th column of the matrix $DT^{Ag}_{v_i}$.

The next step is to calculate the similarity measure between the decision profile of the test object and the decision templates $DT^{As_x}_{v_i}$ of each class $i \in \{1, \ldots, c\}$. Four different similarity measures were used in this study:

1) The similarity measure that uses the normalised Euclidean distance

$$s(DP(x), DT^{As_x}_{v_i}) = 1 - \frac{1}{card\{As_x\} \cdot c} \cdot \sum_{m=1}^{card\{As_x\}} \sum_{l=1}^{c} \left(DP_{m,l}(x) - DT^{As_x}_{v_i}(m,l)\right)^2,$$

where $DP_{m,l}(x)$ and $DT^{As_x}_{v_i}(m,l)$ is an element at the m-th row and the l-th column of the matrix $DP(x)$ or $DT^{As_x}_{v_i}$ respectively.

2) The similarity measure that uses the symmetric difference defined by the Hamming distance

$$s(DP(x), DT^{As_x}_{v_i}) = 1 - \frac{1}{card\{As_x\} \cdot c} \cdot \sum_{m=1}^{card\{As_x\}} \sum_{l=1}^{c} \left|DP_{m,l}(x) - DT^{As_x}_{v_i}(m,l)\right|$$

3) The Jaccard similarity coefficient

$$s(DP(x), DT^{As_x}_{v_i}) = \frac{\sum_{m=1}^{card\{As_x\}} \sum_{l=1}^{c} \min\{DP_{m,l}(x), DT^{As_x}_{v_i}(m,l)\}}{\sum_{m=1}^{card\{As_x\}} \sum_{l=1}^{c} \max\{DP_{m,l}(x), DT^{As_x}_{v_i}(m,l)\}}$$

4) The similarity measure that uses the symmetric difference

$$s(DP(x), DT^{As_x}_{v_i}) = 1 - \frac{1}{card\{As_x\} \cdot c} \cdot \sum_{m=1}^{card\{As_x\}} \sum_{l=1}^{c} \max\Big\{ \min\{DP_{m,l}(x), 1 - DT^{As_x}_{v_i}(m,l)\}, \min\{1 - DP_{m,l}(x), DT^{As_x}_{v_i}(m,l)\}\Big\}$$

All of these measures were also used by the authors of the method based on decision templates in the paper [5]. The set of decisions taken by the dispersed system is defined by selecting the decision that has the maximum value of similarity.

Method that is based on the theory of evidence

The method that is based on the theory of evidence was proposed in the paper [15]. In this method as in the decision templates method, the decision templates $DT^{As_x}_{v_i}, i \in \{1, \ldots, c\}$ are designated from the data. And like in the previous method, the same sets of objects must be included in the decision tables of the resource agents, which means that the assumptions of the system are a bit narrow. Instead of calculating the similarity between the decision template $DT^{As_x}_{v_i}$ and the decision profile $DP(x)$, the Dempster-Shafer theory is used in this method and the belief is calculated. The following steps are performed in the Dempster-Shafer algorithm:

1) Let $DT^{As_x}_{v_i}(m,\cdot)$ denote the m-th row of the decision template for class v_i and $DP_{m,\cdot}(x)$ denote the m-th row of the decision profile for the object x. The proximity between the prediction of the m-th synthesis agent $DP_{m,\cdot}(x)$ and the m-th row of the decision template for every class $v_i, i \in \{1, \ldots, c\}$ and for every synthesis agent $m \in \{1, \ldots, card\{As_x\}\}$ is calculated

$$\phi_{i,m}(x) = \frac{(1 + \|DT_{v_i}(m,\cdot) - DP_{m,\cdot}(x)\|^2)^{-1}}{\sum_{k=1}^{c}(1 + \|DT_{v_k}(m,\cdot) - DP_{m,\cdot}(x)\|^2)^{-1}}$$

where $\|\cdot\|$ is the norm. The Euclidean norm was applied in this study.

2) For every class $v_i, i \in \{1, \ldots, c\}$ and for every synthesis agent $m \in \{1, \ldots, card\{As_x\}\}$ the following belief degrees are calculated

$$Bel_i(DP_{m,\cdot}(x)) = \frac{\phi_{i,m}(x) \prod_{k \neq i}(1 - \phi_{k,m}(x))}{1 - \phi_{i,m}(x)[1 - \prod_{k \neq i}(1 - \phi_{k,m}(x))]}$$

3) The Dempster-Shafer membership degrees for every class $v_i, i \in \{1, \ldots, c\}$ are calculated

$$\mu_i(x) = K \prod_{m=1}^{card\{As_x\}} Bel_i(DP_{m,\cdot}(x))$$

where K is a constant that ensures that $\mu_i(x) \leq 1$.

The set of decisions taken by the dispersed system is defined by selecting the decision that has the maximum value of the Dempster-Shafer membership degrees.

IV. Experiments and results

In this section, experiments with two data sets from the medical field and seven fusion methods are described. The aim of the experiment is to compare the obtained results and, if possible, to choose the best fusion method from the methods that were examined. In the article data from the medical field are examined, as the use of dispersed knowledge is particularly important in this area. We consider a situation in which knowledge in the same field is stored independently in several medical centers (hospitals, laboratories). The use of all of this knowledge at the same time should improve the efficiency of inference.

A. Data

For the experiments the following data, which are in the UCI repository (archive.ics.uci.edu/ml/), were used: Lymphography data set, Primary Tumor data set. Both sets of data was obtained from the University Medical Centre, Institute of Oncology, Ljubljana, Yugoslavia (M. Zwitter and M. Soklic provided this data). Lymphography is a medical imaging technique in which a radiocontrast agent is injected, and then an X-ray picture is taken to visualize structures of the lymphatic system. In the Primary Tumor data set, on the basis of values of attributes such as histologic-type, supraclavicular etc. a decision is taken where (of 22 organs) the cancer cells are located. In order to determine the efficiency of inference each data set was divided into two disjoint subsets: a training set and a test set. A numerical summary of the data sets is as follows: Lymphography: # The training set - 104; # The test set - 44; # Conditional - 18; # Decision - 4; Primary Tumor: # The training set - 237; # The test set - 102; # Conditional - 17; # Decision - 22. The next step of data preparation consists in dispersion of datasets. The training set was divided into a set of decision tables. Divisions with a different number of decision tables were considered. For each of the data sets used, the decision-making system with five different versions (with 3, 5, 7, 9 and 11 resource agents) were considered. For these systems, we use the following designations: WSD^{dyn}_{Ag1} - 3 resource agents; WSD^{dyn}_{Ag2} - 5 resource agents; WSD^{dyn}_{Ag3} - 7 resource agents; WSD^{dyn}_{Ag4} - 9 resource agents; WSD^{dyn}_{Ag5} - 11 resource agents.

The dispersion of a data set proceeded in a random way but under certain conditions that were defined by the author of the paper. This process was carried out as follows. In the first step the cardinality of set of conditional attributes in each decision table of resource agent was determined, and the number of common conditional attributes of decision tables was defined. These values were defined by the author. Then the conditional attributes were assigned to the decision tables so that the conditions which were defined earlier were met. Each universe of decision tables includes all objects from the data set. However, after the dispersion the identifiers of objects are not stored in the decision tables, so it is not possible to reconstruct the original data set. The cardinalities of sets of conditional attributes of decision tables in the systems are given in Table I. Table II presents the cardinalities of all nonempty intersection of conditional attributes sets. The data set was dispersed in such a way to obtain a set of decision tables that could be collected independently by different medical centers. The author is aware that the results of experiments obtained for real data would be much more valuable, however, the author does not have access to such a data.

B. Quality measures and parameters

Some of the considered fusion methods have the property that the final decision may have ties. In order to analyze these properties the appropriate classification measures were applied, which are adapted to this situation. The measures of determining the quality of the classification are: *estimator of classification error* e in which an object is considered to be properly classified if the decision class used for the object belonged to the set of global decisions generated by the system; *estimator of classification ambiguity error* e_{ONE} in which object is considered to be properly classified if only one, correct value of the decision was generated to this object; *the average size of the global decisions sets* $\overline{d}_{WSD^{dyn}_{Ag}}$ generated for a test set.

In this article, the measures were applied that are adequate to the situation in which a set of decision instead of one decision is generated for a test object. Note that in the paper the classification problem is being considered but not in a standard version. Therefore, the standard measures, such as error rate, recall, precision and F-meaure are not appropriate. However the estimator of classification error and the estimator of classification ambiguity error can be considered as a modification of the standard error rate measure. If $\overline{d}_{WSD^{dyn}_{Ag}} = 1$ then e and e_{ONE} are equal to the standard error rate. During the experiments, the author tried to use measures such as precision and recall. The values were calculated based on the cases in which an unambiguous decision (only one decision) was generated by the system. Therefore, some test objects were not taken into account in these calculations. This caused that

Primary Tumor, WSD^{dyn}_{Ag3}	$\lvert A_{ag_1} \cap A_{ag_2}\rvert = 2, \lvert A_{ag_2} \cap A_{ag_3}\rvert = 2, \lvert A_{ag_4} \cap A_{ag_5}\rvert = 2, \lvert A_{ag_6} \cap A_{ag_7}\rvert = 1$
Primary Tumor, WSD^{dyn}_{Ag4}	$\lvert A_{ag_1} \cap A_{ag_2}\rvert = 1, \lvert A_{ag_3} \cap A_{ag_4}\rvert = 1, \lvert A_{ag_4} \cap A_{ag_5}\rvert = 1, \lvert A_{ag_6} \cap A_{ag_7}\rvert = 1, \lvert A_{ag_8} \cap A_{ag_9}\rvert = 1$
Primary Tumor, WSD^{dyn}_{Ag5}	$\lvert A_{ag_1} \cap A_{ag_2}\rvert = 1, \lvert A_{ag_3} \cap A_{ag_4}\rvert = 1, \lvert A_{ag_5} \cap A_{ag_6}\rvert = 1, \lvert A_{ag_6} \cap A_{ag_7}\rvert = 1, \lvert A_{ag_8} \cap A_{ag_9}\rvert = 1,$ $\lvert A_{ag_{10}} \cap A_{ag_{11}}\rvert = 1$

in some cases the calculation of precision and recall for a class was impossible because there was no test object from the class. For this reason, the calculation of micro-averaged and macro-averaged precision or recall would also be inappropriate. In the experiments the above-defined three measures were used.

In the description of the results of experiments for clarity some designations for parameters have been adopted: m_1 - which determines the number of relevant objects that are selected from each decision class of the decision table and are then used in the process of cluster generation; p - parameter which occurs in the definition of friendship, conflict and neutrality relations; m - parameter of the approximated method of the aggregation of decision tables; m_2 - parameter which determines the number of relevant objects that are used to generate decision of one cluster in the method of conflict analysis (the maximum rule, the minimum rule, the median rule, the sum rule, the probabilistic product method, the method that is based on the theory of evidence and the method that is based on decision templates).

C. Results

At the beginning of experiments the process of parameters optimization was carried out. A series of tests for different parameter values were performed: $m_1 \in \{1, 4, 7, 10, 13\}$, $m_2, m_3 \in \{1, \ldots, 10\}$ and $p \in \{0.05, 0.1, 0.15, 0.2\}$. From all of the obtained results, one was selected that guaranteed a minimum value of estimator of classification error (e), while maintaining the smallest possible value of the average size of the global decisions sets ($\overline{d}_{WSD^{dyn}_{Ag}}$). In tables presented below the best results, obtained for optimal values of the parameters, are given. In the tables the following information is given: the name of dispersed decision-making system (System); the selected, optimal parameter values (m_1/p/m_2/m_3); the three measures discussed earlier e, e_{ONE}, $\overline{d}_{WSD^{dyn}_{Ag}}$; the time t needed to analyse a test set expressed in minutes. In the tables below the best results in terms of the measures e and $\overline{d}_{WSD^{dyn}_{Ag}}$ are bolded.

The results of the experiments with the Lymphography data set are presented in Table III. Based on the results for the Lymphography data set it can be concluded that all of the examined methods generate almost unambiguous results - the average size of the global decision sets is very close to or equal to 1. On the basis of detailed analysis of vectors of probabilities generated by the individual classifiers, it was concluded that the reason of this situation is that for the Lymphography data there is very few dummy agents. That is undecided agents who assign the same probability value to many different decision values. For some test objects there

are dummy agents, therefore the maximum rule, the minimum rule and the median rule generate more ambiguous decisions. However, there is always a group of agents who assign different probabilities for decisions. Therefore, the sum rule generates unambiguous results. As can be seen, the analyzed methods can be divided into two groups due to the efficiency of inference. Better results are obtained by - the maximum rule, the minimum rule, the median rule and the sum rule, whereas worse results are obtained by - the probabilistic product method, the method that is based on the theory of evidence and the method that is based on decision templates. Among the first group of methods, definitely the sum rule produces better results than the minimum rule and the maximum rule and the median rule produces better results than the maximum rule. It is hard to choose the best method among the methods from the second group. Each of the methods at least once achieved the best result in this group.

The results of the experiments with the Primary Tumor data set are presented in Table IV. As can be seen, for the Primary Tumor data set only two from the analyzed methods produce unambiguous results - the method that is based on the theory of evidence and the method that is based on decision templates. Other methods generate results with the average size of the global decision sets that is close to 3. But it should be noted that the Primary Tumor data set has 22 decision classes and because of that even results with the average

number of global decisions sets less than 4 are interesting. On the basis of detailed analysis of vectors of probabilities generated by the individual classifiers, it was concluded that for some test objects there is a lot of dummy agents. Therefore, the maximum rule, the minimum rule, the median rule and the sum rule generate so ambiguous results. However, for about a third of the test objects unambiguous results are generated by these methods. Like before there are two groups of methods - those that generate better results (the maximum rule, the minimum rule, the median rule and the sum rule), and those that generate poorer results (the probabilistic product method, the method that is based on the theory of evidence and the method that is based on decision templates). In the first group of methods the best method is the maximum rule with the median rule in second place. The minimum rule and the sum rule obtain very similar results. In the second group of methods the best method is the probabilistic product method. From all of the analyzed similarity measures in the method that is based on decision templates the best results are generated by the similarity measure that uses the normalized Euclidean distance.

In conclusion, for both data the methods: the maximum rule, the minimum rule, the median rule and the sum rule produce significantly better results than the methods: the probabilistic product method, the method that is based on the theory of evidence and the method that is based on decision templates.

It is hard to say which method is the best, because for one data set the sum rule and the median rule generate better results, and for other data set the best method is the maximum rule. The reason for such results in the case of the probabilistic product method is that the method assigns greater weight to the smaller decision classes. The data sets that were analyzed have very diverse number of objects in the decision classes. Therefore, in this fusion method, the smaller decision classes are more awarded, which resulting in lower efficiency of inference. Therefore, the conclusion can be drawn that this is not the best method for data sets with very diverse, in terms of the number of objects, decision classes. For the method that is based on the theory of evidence and the method that is based on decision templates poor results are obtained, probably because a certain approximation was adopted during the training process. Due to the high computational complexity the decision templates of the synthesis agents are constructed based on the decision templates of the resource agents.

V. Conclusion

In this article, a significant problem that concerns the use of dispersed knowledge in medicine was considered. By dispersed knowledge in medicine we mean the set of knowledge bases that are accumulated independently in different medical centers. The knowledge base may contain information about various objects (patients), and may include various attributes (research methods). The use of dispersed knowledge will increase capabilities and efficiency in decision-making process.

In the paper a dispersed decision-making system with dynamic structure in conjunction with the seven fusion methods was considered. Dispersed medical data were used in the experiments: Lymphography data set and Primary Tumor data set. The conclusions, that were reached based on the results of experiments are as follows. The median rule, the sum rule, the maximum rule and the minimum rule generate the best results from the methods that were examined.

University of Lodz, Poland
Email: kpytel@uni.lodz.pl

***Abstract*—Clustering is a task of grouping a set of objects in such a way that objects in the same group (called a cluster) are similar to each other and dissimilar to objects belonging to other groups (clusters). The article presents the idea of the hybrid Fuzzy Logic-Genetic Algorithm (FLGA) system that supports solving clustering problems. The Genetic Algorithm (GA) realizes the process of multi-objective optimization - it aims at optimal distribution of clusters and correctly assigns each object to a cluster. The Fuzzy Logic Controller (FLC) is used for setting the number of clusters. The FLC uses additional fuzzy logic criteria obtained from experts. Experiments show that the proposed algorithm is an efficient tool for the clustering problem. The algorithm can be also used for solving similar optimization problems.**

I. Introduction

CLUSTERING (or cluster analysis) is the problem of classifying an unlabeled set of objects into groups of similar objects, called clusters. Each cluster consists of objects that are similar to one another and dissimilar to objects belonging to other clusters. Clustering is often based on similarity or dissimilarity measure. This measure is problem-dependent. The similarity or dissimilarity between the objects is usually computed, based on the distance between objects. The most popular distance measure is the Euclidean distance, but other measures, such as the Manhattan or Minkowski distances, could also be used. Clustering can be formally considered as a kind of NP-hard grouping problem. The main difficulty in a clustering problem is that it is an unsupervised task, so usually we do not know the number and the distribution of clusters, the shape of clusters or association of objects to clusters. Clustering is not one specific algorithm, but a general task. A classical clustering method is the k-means [1]. A k-means algorithm is sensitive to the choice of an initial partition, and this step can have a significant impact on the performance of algorithm. The algorithm could converge to a local minimum. A k-means algorithm needs determining a number of clusters in all data sets (parameter k), an inappropriate parameter k may yield poor results.

The Genetic Algorithm is an optimization method that simulates the process of natural evolution. They usually search for approximate solutions for composite optimization problems in a large search space. A characteristic feature of genetic algorithms is that in the process of evolution they do not use the knowledge specific for a given problem, except for the fitness function assigned to all individuals. Genetic algorithms can be used for solving wide range of optimization problems.

Clustering can be formulated as a multi-objective optimization problem. It consists of three different objective functions: looking for an appropriate number of centroids, optimal placeing of centroids in a given area, and assigning each object to a cluster, represented by the centroid, to minimize the distance between the objects in the same cluster.

II. Problem formulation

A clustering problem is one of practical examples of multi-objective optimization problems. The clustering problem can be defined as: let us consider a data set $X = \{x_1, x_2, ..., x_N\}$ be a set of N objects. Each object $x_i = [x_{i1}, x_{i2}..., x_{id}]$ has d dimensions. The goal of the clustering algorithm is to find k clusters $C_1, C_2, ..., C_k$ so that objects belonging to the same cluster are more similar to each other than to the objects belonging to other clusters. The Euclidean distance between each pair of objects is typically used as a similarity measure. Clustering must comply assigning constrains: each cluster must contain at least one object, and the object can be assigned to one cluster only.

$$\begin{cases} min \quad f_1(x_1, x_2, ..., x_N) \\ opt \quad f_2(n) \\ min \quad f_3(n, x_1, x_2, ..., x_N) \\ \text{subject to: } assigning\ constraints \end{cases} \tag{1}$$

where: f_1 - is the function representing the distance between the objects assigned to the same cluster,

f_2 - is the function representing the number of clusters,

f_3 - is the function assigning an object to a cluster,

$(x_1, , x_N)$ - are objects in d dimentional space,

$1 \leq n \leq n_{max}$ - is the number of clusters.

More information about cluster analysis can be found in publications [1][2].

III. Proposed Fuzzy Logic-Genetic Algorithm

The clustering problem is discussed in literature, eg. [8][9]. There are a lot of publications concerning different methods of solving this problem, for example k-means or genetic algorithms, but these methods work well if a number of clusters is known before running an algorithm. The proposed Fuzzy Logic-Genetic Algorithm (FLGA) consists of two modules: the Genetic Algorithm (GA) and the Fuzzy Logic Controller (FLC). The GA seeks for an optimal placement of centroids

and assigns objects to clusters. It delivers information concerning a current state of optimization to the FLC after a fixed number of generations. The FLC looks for an optimal number of clusters. The FLC is engaged between generations of the GA in fixed intervals of generations. The FLC modifies the number of clusters in dependence on information delivered from the GA. If the FLC changes the number of clusters, it sends information to the GA and modifies the individuals' genes to comply with the new constraints. The system is able to find the optimal number of clusters simultaneously with an optimization executed by the GA, so we do not need to know the number of clusters before running the algorithm.

In the proposed FLGA the individuals' genes (potential solutions) are encoded by the means of a composite data structure consisting of:

- the table describing the position of centroids by geographical coordinates - coordinates (x, y) of centroids are represented by real numbers, the number of genes in a table is equal to the number of clusters,
- the table describing an association of objects to clusters - association of objects to clusters are coded by integer numbers, eg. number i in position k means the association of object k to cluster i, the number of genes in a table is equal to the number of objects. This method of gene coding ensures assigning every object to one cluster only.

The value of the fitness function of an individual is calculated as a total distance between objects and centroids. Because clustering is a problem of minimization of the distance, we introduced additional constant C to transform the increasing fitness function into the decreasing function optimized. The value of constant C was chosen experimentally for every solved task. In our experiment different types of crossing-over of chromosomes were used. The standard one-point crossing is used when the number of clusters does not change. We introduce two new crossing-over operators, used when the number of clusters changes:

- CR1 - is used when the descendant's length of genotype is greater than the genotype's length of its parents. The descendant's genotype is obtained by copying all the genes from its first parent and lacking the genes of its second parent beginning from the end of the genotype.
- CR2 - is used when the descendant's length of genotype is smaller than the genotype's length of its parents. The number of the genes copied from every parent is diminished in proportion to the genotype's length to obtain the required length of the descendant's genotype.

Genetic Algorithms can be used for solving multi-objective optimization problems. They can be used in hybrid systems with other methods inspired by observation of nature. For example, the Fuzzy Logic Controller can effectively direct the process of evolution in the Genetic Algorithm toward a desired area of the search space [4][5].

A basic task of the FLC in the proposed system is evaluation of the solutions found till now. The FLC uses experts' knowledge and the knowledge collected by the GA and transferred to the FLC in fixed intervals of GA's generations. The FLC optimizes the number of clusters and is engaged in fixed intervals of GA's generations - it makes decisions about the diminution or the enlargement of the clusters' number. The FLC calculates the change of the clusters' number, based on two parameters:

- the relation of the distance between the centroids to the distance between the centroids and the objects assigned to these clusters,

$$rd_1 = \frac{\sum_{i=1}^{n}\sum_{j=1}^{n} d(i,j)}{\sum_{i=1}^{n}\sum_{k=1}^{m} d(i,k)} \tag{2}$$

  where:
  - rd_1 - the relation of the distance between the centroids to the distance between the centroids and the objects assigned to these clusters,
  - $\sum_{i=1}^{n}\sum_{j=1}^{n} d(i,j)$ - the distance between the centroids,
  - $\sum_{i=1}^{n}\sum_{k=1}^{m} d(i,k)$ - the distance between the centroids and the objects assigned to these clusters,
  - n - the number of clusters (centroids),
  - m - the number of objects.

  This parameter lets us determine a suitable number of clusters. The low value of this parameter can be due to a small number of clusters with relation to the number of objects. The large value of this parameter can be due to a big number of clusters with relation to the number of objects.
- the relation of the distance between the centroids and the objects assigned to these clusters to the distance between the centroids and the objects not assigned to these clusters,

$$rd_2 = \frac{\sum_{i=1}^{n}\sum_{k=1}^{m1} d(i,k)}{\sum_{i=1}^{n}\sum_{l=1}^{m2} d(i,l)} \tag{3}$$

  where:
  - rd_2 - the relation of the distance between the centroids and the objects assigned to these clusters to the distance between the centroids and the objects not assigned to these clusters,
  - $\sum_{i=1}^{n}\sum_{k=1}^{m1} d(i,k)$ - the distance between centroids and objects assigned to these clusters,
  - $\sum_{i=1}^{n}\sum_{l=1}^{m2} d(i,l)$ - the distance between the centroids and the objects not assigned to these clusters,
  - n - the number of clusters (centroids),
  - $m1$ - the number of the objects assigned to these clusters,
  - $m2$ - the number of the objects not assigned to these clusters,

  This parameter lets us determine a suitable density of objects in the clusters. The low value of this parameter can be due to a big number of clusters with relation to the number of objects. The large value of this parameter can be due to a small number of clusters with relation to the number of objects. The value of this parameter is 0

TABLE I
FUZZY VALUES OF CLUSTERS' NUMBER CHANGE

		rd_1		
		Small	**OK**	**Large**
rd_2	**Large**	Enlarge	Enlarge	Not change
	OK	Enlarge	Not change	Diminish
	Small	Not change	Diminish	Diminish

when every object belongs to its own cluster, the value 1 is when all objects belongs to one cluster only.

The knowledge of experts is expressed by the following rules:

- enlarge the number of clusters if the relation of the distance between the centroids to the distance between the centroids and the objects assigned to these clusters (rd1) is small and the relation of the distance between the centroids and the objects assigned to these clusters to the distance between the centroids and the objects not assigned to these clusters (rd2) is large,
- do not change the number of clusters if the relation of the distance between the centroids to the distance between the centroids and the objects assigned to these clusters (rd1) is suitable and the relation of the distance between the centroids and the objects assigned to these clusters to the distance between the centroids and the objects not assigned to these clusters (rd2) is suitable,
- diminish the number of clusters if the relation of the distance between the centroids to the distance between the centroids and the objects assigned to these clusters (rd1) is large and the relation of the distance between the centroids and the objects assigned to these clusters to the distance between the centroids and the objects not assigned to these clusters (rd2) is small.

As the result from the FLC we accepted:

- signal to enlarge the number of clusters (+1),
- signal to do not change the number of clusters (0),
- signal to diminish the number of clusters (-1).

The knowledge base (rule base) of FLC is shown in Table 1 (fuzzy values of clusters' number change).

Figure 1 show membership functions of the relation of the distance between centroids to the distance between the centroids and the objects assigned to these clusters, the relation of the distance between the centroids and the objects assigned to these clusters to the distance the between centroids and the objects not assigned to these clusters and the value of the clusters' number change respectively. The shape of the membership functions was established experimentally and user can adapt them to solved problem. The FLC uses the center of gravity as a defuzzyfication method. Similar systems were successfully applied to other multiobjective optimalization problems, such as the Connected Facility Location Problem (ConFLP) [6] or the Wireless Access Points Placement Problem (WAPP) [7].

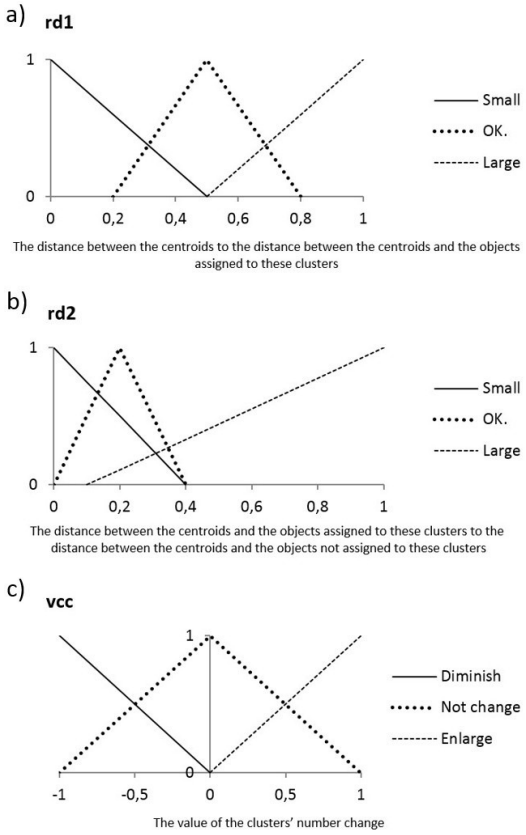

Fig. 1. Membership functions: a) the relation of the distance between the centroids to the distance between the centroids and the objects assigned to these clusters, b) the relation of the distance between the centroids and the objects assigned to these clusters to the distance between the centroids and the objects not assigned to these clusters, c) the value of the clusters' number change

IV. COMPUTATIONAL EXPERIMENT

The goal of our experiments is verification of the idea of the hybrid fuzzy-genetic algorithm to solving a clustering problem. In experiments we verify the ability of the FLC to optimize of the number of clusters, basing on experts' knowledge and data originated in the GA. Optimization of centroids' positions and optimal assigning of objects to clusters is realized by a genetic algorithm. For tests we used a set of data from "The Fundamental Clustering Problems Suite" (FCPS) [12] as a benchmark. We have chosen 4 two-dimensional problems from 400 to 4096 objects and from 2 to 3 clusters. Figure 2 show the distribution of objects in space and known a priori classifications in problems selected for our tests.

All tasks were solved by a k-means algorithm (we used the k-means method from the "rattle" library in R programming language [11]), proposed a hybrid genetic algorithm with the fuzzy logic (FLGA) and the simple genetic algorithm (SGA) - an algorithm proposed in [3], and modified by me to solve a clustering problem. The correct value clusters' number was used in a k-means and the SGA algorithms, the

Wingnut	1070	1815	1855	1821
EngyTime	4096	7912	9454	10093

FLGA was started from an incorrect number of clusters. Each algorithm was executed 10 times. In Table 2 and 3 there is the best distance between objects and centroids and the number of correctly assigned objects to clusters obtained by all algorithms. Figure 3 shows the distribution of objects in space obtained by the k-means algorithm and the FLGA algorithm.

V. CONCLUSIONS

The proposed Fuzzy Logic-Genetic Algorithm was able to find a solution near the optimum. However, looking at charts in Figure 3 presenting the distribution of objects after an optimization, it is easy to notice that improvement of this result is still possible. In Lsun task, the assignment of objects to clusters in the FLGA algorithm is more similar to known a priori classification, than in the k-means algorithm.

In all tasks proposed, the FLC correctly qualified the number of clusters.

The time operation of the FLGA on a PC computer did not exceed 10 minutes for the task of optimization of 4096 objects.

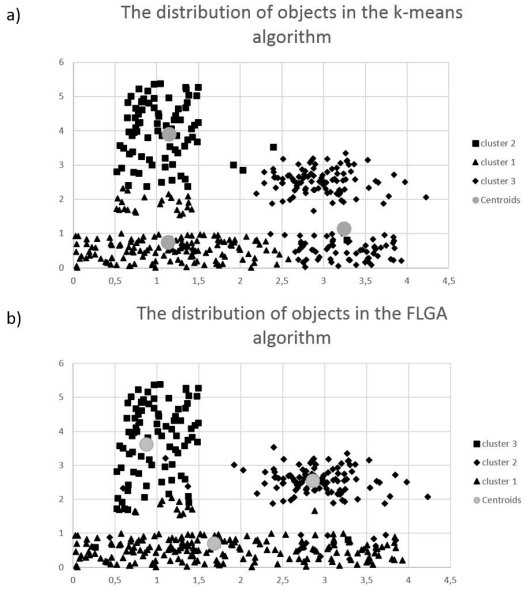

Fig. 3. The distribution of objects in space obtained by: a) the k-means algorithm, b) the FLGA algorithm

In tasks with a large number of objects, the time of calculations can be considerably longer. The parameters of an algorithm, eg. the number of generations, can be changed to fulfil the users' needs and reach a required accuracy of calculations.

The proposed algorithm is an efficient tool for solving clustering problems, where the number of clusters cannot be pre-determined. The proposed algorithm can be used for solving similar problems of multi-objective optimization.

***Abstract*—In the paper, the deep evolving neural network and its learning algorithms (in batch and on-line mode) are proposed. The deep evolving neural network's architecture is developed based on GMDH approach (in J. Schmidhuber's opinion it is historicaly first system, which realizes deep learning) and least squares support vector machines with fixed number of the synaptic weights, which provide high quality of approximation in addition to the simlicity of implementation of nodes with two inputs. The proposed system is simple in computational implementation, characterized by high learning speed and allows processing of data, which are sequentially fed in on-line mode. The proposed system can be used for solving a wide class of Dynamic Data Mining tasks, which are connected with non-stationary, nonlinear stochastic and chaotic signals. The computational experiments are confirmed the effectiveness of the developed approach.**

I. Introduction

Nowadays, artificial neural networks (ANNs) are widely used for solving a lot of Data Mining tasks. In these tasks initial information is presented in the form of both "object-properties" table and multivariate time series, which are generated by stochastic or chaotic nonstationary nonlinear objects. The advantages of these computational intelligence systems are, first of all, their universal approximation properties and learning abilities using real experimental data [1], [2].

Recent years Computational Intelligence specialists are interested in deep neural networks (DNN) [3], [4], [5], [6], [7]. The deep neural networks comparatively with conventional ANNs, also called shallow neural networks (SNNs), provide much higher quality of information processing. However, these networks are essentially tedious with relation to computational implementation, also are subjected to overfitting in case of short training samples and demand of high operation time and computational resources especially when operated with Big Data [8]. Both the standard neurons (which form set of layers) and shallow neural networks can be used as the basic elements of deep neural networks.

One of the most effective representatives of the shallow neural networks are support vector machines (SVM) [9], [10], [11], [12], [13]. The tuning of support vector machines is provided by using both lazy learning (the activation functions' centers tuning) and optimization procedures (the synaptic weights tuning). However, if the process of the lazy learning is implemented immediately, then optimization tasks solving using support vector machines with big training set is enough complex. In this connection deep neural networks, which are implemented using support vector machines [14], [15], [16], providing high quality of information processing are essentially tedious from the computational point of view.

It can be noticed, that tuning process of support vector machines can be essentially speed up if the least-squares support vector machines (LS-SVM) [17] are used instead of a conventional approach. The learning process of least-squares support vector machines reduces to a solution of the set of Karush-Kuhn-Tucker equations and the result of this learning can be written in an analytical form.

Among a great number of possible deep neural networks' architectures, the deep networks based on GMDH are one of the most effective networks, as it was mentioned in [6]. These networks are based on the group method of data handling [18], [19], [20], which allows automatically increasing a number of layers for information processing to achieve the required accuracy of the results. A combination of the GMDH approach with ANNs have led to synthesis of wide range of computational intelligence systems [21], [22], [23], [24], [25], [26], [27], [28] where different type of artificial neurons are used as nodes.

In this case unlimited increasing of layers in the sistem (using the GMDH paradigm) and simplicity of learning LS-SVM with two inputs (using their universal approximation properties) allow to efficiently information processing in on-line mode of the deep learning.

In the connection with mentioned above, it seems appropriate to develop deep neural networks' architecture based on GMDH and LS-SVM and its learning algorithm. The proposed approach is characterized by simplicity of a computational implementation and high speed learning for the solution of

978-83-60810-90-3/$25.00

wide range of Data Mining tasks, which are described by both short and large volume data set.

II. The architecture of deep evolving GMDH-SVM-neural network

An architecture of the proposed deep evolving GMDH-SVM-neural network is shown in Fig.1.

A $(n \times 1)$-dimensional vector of the input signals $x = (x_1, x_2, \ldots, x_n)^T \in R^n$ is fed to the zero (receptive) layer of the GMDH-SVM-neural network. Further, this input vector is passed to the first layer, which consists of $n_1 = C_n^2 = 0.5n(n-1)$ nodes that are the conventional LS-SVM with two inputs. It is obvious that learning process of the LS-SVM with two inputs has not any problem both in relation of a computational implementation and with regard for requirements to a volume of training set. The output signals $\hat{y}_l^{[1]}$ $(l = 1, 2, \ldots, n_1)$ are formed by the nodes' outputs of the $SVM^{[1]}$ of first hidden layer.

Further these signals are fed to the selection block $SB^{[1]}$ of the first hidden layer. This selection block SB^1 selects $n_1^*(n_1^* \leq n_1)$ signals from a range of signals $\hat{y}_l^{[1]}$. The selected signals are the best in the sense of accepted criterion, in more cases it is the mean square error $\sigma^2_{\hat{y}_l^{[1]}}$, but any other accuracy criterion can be used in relation to reference signal $y(k)$ $(k = 1, 2, \ldots, N$ is an observation number in a training set or a current discrete time, when a learning process and data processing take place in on-line mode).

From the n_1^* best output's signals of the first hidden layer $\hat{y}_l^{[1]*}$ (using the conventional GMDH approach) are formed $n_2(n \leq n_2 \leq 2n)$ pairwise combination of signals $\hat{y}_l^{[1]*}$, $\hat{y}_p^{[1]*}$, which are fed to the inputs of the second hidden layer. The second hidden layer is formed by $SVM^{[2]}$ nodes, which are similar to the elements of the first hidden layer.

From the output's signals $\hat{y}_l^{[2]}$ of this layer, the selection block $SB^{[2]}$ of the second hidden layer selects only that signals $\hat{y}_l^{[2]*}$, whose accuracy is better than the best signal $\hat{y}_l^{[1]*}$ of the first hidden layer. The third hidden layer with selection block $SB^{[3]}$ forms the signals, which have accuracy better than the best signal $\hat{y}_l^{[2]*}$ of the second layer.

In such way, the network's architecture is formed during learning process likewise evolving computational intelligence systems [29], [30].

The architecture's evolution process takes place until the selection block $SB^{[n-1]}$ forms only two signals $\hat{y}_1^{[s-1]*}$ and $\hat{y}_2^{[s-1]*}$ in its output. Just these two signals are fed to the single output nodes of $SVM^{[3]}$ where the output system's signal $\hat{y}^{[s]}$ is computed.

III. The learning of deep evolving GMDH-SVM-neural network

As it was previously noted an each node of the proposed system is the LS-SVM with single output and two inputs. Hence, two-dimensional vector $x_{ij}(k) = (x_i(k), x_j(k))^T$ $(i = 1, 2, \ldots, n; j = 1, 2, \ldots, n; i \neq j)$ is fed to the input of the first hidden layer and output of the each node is a scalar signal $\hat{y}_l^{[1]}$ $(l = 1, 2, \ldots, n_1)$. Therefore, the LS-SVM is the hybrid system, which combines a learning based on both an optimization and a memory [1], [2], [6], [7], [17], and implements minimization of an empirical risk criterion. It is necessary to notice, that the SVMs are the most effective under short data set conditions and are not subject to an overfitting and proved a high quality of approximation.

The mapping, which implements standard LS-SVM SNN, can be written in the form

$$\hat{y}_l^{[1]} = (w_l^{[1]})^T \varphi_l^{[1]}(x) + w_{0l}^{[1]} \tag{1}$$

where $w_l^{[1]} = (w_{1l}^{[1]}, w_{2l}^{[1]}, \ldots, w_{Nl}^{[1]})^T$, $\varphi_l^{[1]}(x) = (\varphi_{1l}^{[1]}, \varphi_{2l}^{[1]}, \ldots, \varphi_{Nl}^{[1]})^T$. The learning process reduces to setting the centers of activation functions (usually Gaussians) in the point, which are determined by a training sample x_{ij} $(k = 1, 2, \ldots, N)$ and minimization of squared criterion simultaneously in the form

$$E_l^{[1]}(N) = \frac{1}{2}\|w_l^{[1]}\|^2 + \frac{\gamma}{2}\sum_{k=1}^{N}(e_l^{[1]}(k))^2 \tag{2}$$

in the presence of N equality-constraints in the form

$$\begin{cases} y(1) & = (w_l^{[1]})^T \varphi_l^{[1]}(x_{ij}(1)) + w_{0l}^{[1]} + e_l^{[1]}(1), \\ \vdots & \\ y(N) & = (w_l^{[1]})^T \varphi_l^{[1]}(x_{ij}(N)) + w_{0l}^{[1]} + e_l^{[1]}(N) \end{cases} \tag{3}$$

where $\gamma > 0$ is a regularization parameter and

$$\begin{aligned} e_l^{[1]}(k) &= y(k) - \hat{y}_l^{[1]}(k) = \\ &= y(k) - (w_l^{[1]})^T \varphi_l^{[1]}(x_{ij}(k)) - w_{0l}^{[1]}. \end{aligned} \tag{4}$$

In this way, LS-SVM learning task is reduced to finding of a saddle point of Lagrange function

$$\begin{aligned} L_l^{[1]}(w_l^{[1]}, w_{0l}^{[1]}, e_l^{[1]}, \lambda_l^{[1]}(k)) &= E_l^{[1]}(N) + \\ &+ \sum_{k=1}^{N} \lambda_l^{[1]}(k)\Big(y(k) - (w_l^{[1]})^T \varphi_l^{[1]}(x_{ij}(k)) - \\ &- w_{0l}^{[1]} - e_l^{[1]}(k)\Big). \end{aligned} \tag{5}$$

This saddle point can be found by solving the Karush-Kuhn-Tucker equations set. In this case, besides $N + 1$ synaptic weights $w_l^{[1]}$, $w_{0l}^{[1]}$ the N indefinite Langrange multipliers $\lambda_l^{[1]}(k)$ have to be found.

The main disadvantage of SVM in the system under consideration is necessity of adding new synaptic weights in each nodes with rising of a training set volume. Therefore, if it is necessary to process Big Data than proposed system becomes too tedious. To avoid this problem it is possible by limiting a number of synaptic weights in each node by using, so-called, "sliding window" data processing. Such "sliding window" contains only h last observations.

Introducing the Lagrange function with "sliding window" instead of the expression (5) in the form

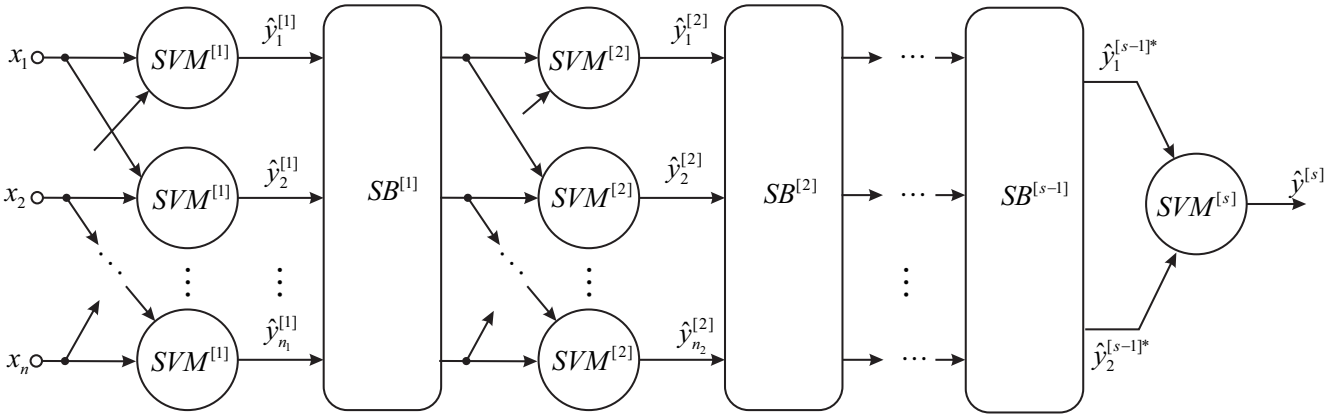

Fig. 1. The architecture of proposed deep evolving GMDH-SVM-neural network

$$
\begin{aligned}
&L_l^{[1]}(w_l^{[1]}, w_{0l}^{[1]}, e_l^{[1]}, \lambda_l^{[1]}(k), h) = \\
&= \frac{1}{2}\,\|w_l^{[1]}\|^2 + \frac{\gamma}{2}\sum_{\tau=k-h+1}^{k}(e_l^{[1]}(\tau))^2 + \\
&+ \sum_{\tau=k-h+1}^{k}\lambda_l^{[1]}(\tau)\Big(y(\tau) - (w_l^{[1]})^T\varphi_l^{[1]}(x_{ij}(\tau)) - \\
&- w_{0l}^{[1]} - e_l^{[1]}(\tau)\Big)
\end{aligned}
\tag{6}
$$

and solving Karush-Kuhn-Tucker equations set, we can write the result in the form

$$
\begin{pmatrix} 0 & I_h^T \\ I_h & \Omega(k) + \gamma^{-1} I_{hh} \end{pmatrix}
\begin{pmatrix} w_{0l}^{[1]} \\ \Lambda(k) \end{pmatrix} =
\begin{pmatrix} 0 \\ Y(k) \end{pmatrix} \tag{7}
$$

where $\Lambda(k) = (\lambda(k-h+1), \ldots, \lambda(k))^T$, I_h is a $(h \times 1)$ unity vector, I_{hh} is a $(h \times h)$ unity matrix, $Y(k) = (y(k-h+1), \ldots, y(k))$, $\Omega(k) = \{\Omega_{\tau l} = \varphi_l^{[1]T}(x_{ij}(\tau))\varphi_l^T(x_{ij}(t)) = K(x_{ij}(\tau), x_{ij}(t))\}$, $\tau = k-h+1, \ldots, k$, $t = k-h+1, \ldots, k$, $K(x_{ij}(\tau), x_{ij}(t))$ is the kernel function, which is satisfied to the conditions of Mercer theorem [17], and usually it is Gaussian function in the form

$$
K(x_{ij}(\tau), x_{ij}(t)) = \exp\left(-\frac{\|x_{ij}(\tau) - x_{ij}(t)\|^2}{2\sigma^2}\right). \tag{8}
$$

In this case, the transformation (1), which is implemented by the LS-SVM node, can be rewritten in the form

$$
\hat{y}_l^{[1]} = \sum_{\tau=k-h+1}^{k}\lambda_l^{[1]}(\tau)K(x_{ij}(\tau), x_{ij}(t)) + w_{0l}^{[1]} \tag{9}
$$

where parameters $\lambda_j^{[1]}(\tau)$, $w_{0l}^{[1]}$ can be defined from the system (7) in the form

$$
\begin{aligned}
&\begin{pmatrix} w_{0l}^{[1]} \\ \Lambda(k) \end{pmatrix} = \\
&= \begin{pmatrix} 0 & I_h^T \\ I_h & \Omega(k) + \gamma^{-1} I_{hh} \end{pmatrix}^{-1}
\begin{pmatrix} 0 \\ Y(k) \end{pmatrix}.
\end{aligned}
\tag{10}
$$

As a result, the learning of nodes in the proposed system reduces to a solving of linear equations set with fixed number of variables. It should be noticed, the "sliding window" learning allows managing the deep neural network tuning process, when information is fed to the system's input in on-line mode in the form of data stream. The nodes of second and next hidden layers are tuned absolutely likewise the expression (10).

IV. Simulation results

A. Identification of the mechanical system signal

Efficiency of proposed deep evolving GMDH-SVM-neural network was examined based on different benchmark data including the identification task using real data from mechanical system. Data is taken from a flexible robot arm. The arm is installed on an electrical motor. [We are grateful to Hendrik Van Brussel and Jan Swevers of the laboratory of Production Manufacturing and Automation of the Katholieke Universiteit Leuven, who provided us with these data, which were obtained in the framework of the Belgian Programme on Interuniversity Attraction Poles (IUAP-nr.50) initiated by the Belgian State - Prime Minister's Office - Science Policy Programming. http://homes.esat.kuleuven.be/ smc/daisy/daisydata.html].

Inputs number of deep evolving GMDH-SVM-neural network were taken as $n = 5$, that for input vector in the form $u(k-2), y(k-2), u(k-1), y(k-1), u(k)$ for identification value $y(k)$ where u is a reaction torque of the structure, y is an accelaration of the flexible arm . Node of deep evolving GMDH-SVM-neural network was training by proposed learning algorithm during 100 iterations. Initial parameters values of kernel functions were taken $\sigma = 0.1$. After 100 iterations the training process was stopped, and the next 50 points for $k = 101 \ldots 150$ we have used as the testing data

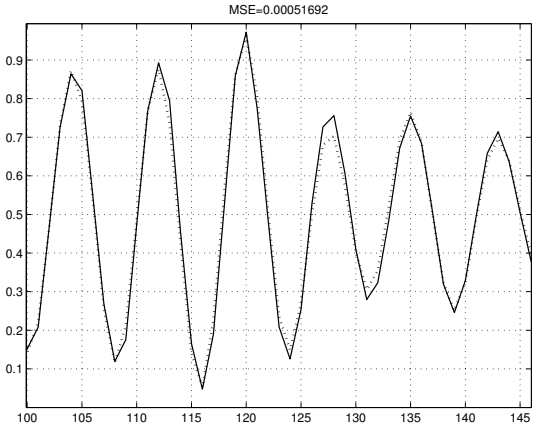

Fig. 2. Results of signal identification

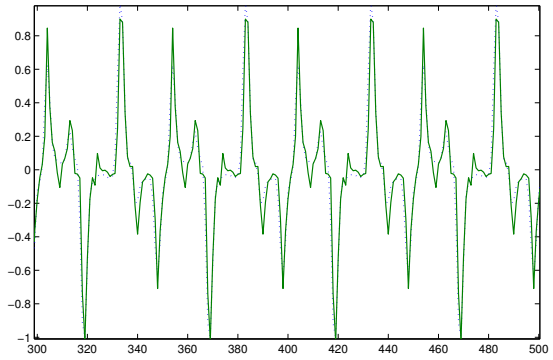

Fig. 3. Results of non-linear non-stationary system identification

set to compute forecast. Initial values of synaptic weights were taken equal to 0. As the quality criterion of forecasting root mean squared error (MSE) was used. Fig.2 shows the results of signal identification. The two curves, representing the actual (dot line) and identification (solid line) values, are almost indistinguishable.

Table I cotains comparative analysis of the signal identification based on different approaches.

Thus as it can be seen from experimental results the proposed approach provides the best quality of prediction in comparison with conventional GMDH-neural networks.

B. The identification of nonlinear nonstationary signal

Simulation of deep evolving cascaded GMDH-SVM-neural network was performed in the process of identification of nonlinear signal, which is described by equation in the form [31]

$$y(k+1) = \frac{y(k)}{1+y^2(k)} + u^3(k) \tag{11}$$

where $u(k) = sin(2\pi k/25) + sin(2\pi k/10)$ is control signal.

The inputs number of evolving cascaded GMDH-neural network were taken as $n = 4$, which correspond to the input vector $x(k-3), x(k-2), x(k-1), x(k)$ for the value $x(k+1)$.

LS-SVM-neuron was trained based on proposed procedures for 400 iterations (400 training samples for $k = 1 \ldots 400$). After 400 iterations the training process was stopped, and the next 100 points for $k = 401 \ldots 500$ we have used as the testing data set to compute signal value. Initial values of synaptic weights were taken equal to 0. As the identification quality criterion mean squared error (MSE) was used.

Fig. 3 shows the results of signal identification. The two curves, representing the actual (dot line) and identification (solid line) values, are very close. Table II shows the comparative analysis of nonlinear non-stationary signal identification based on different approaches.

V. CONCLUSIONS

In the paper, the deep evolving neural network and its learning algorithms are proposed. The architecture of the deep evolving neural network is developed based on GMDH and least squares support vector machines with fixed number of the synaptic weights are used as nodes. The proposed system is simple in computational implementation, characterized by high learning speed and allows processing of data, which are fed sequentially in on-line mode. The combining, in the context of the common deep learning system, the GMDH paradigm with unlimited increasing of the layers number and LS-SVM nodes with fixed sinaptic weights number allow to predetermine an on-line deep learning in Dynamic Data Mining tasks. The computational experiments are confirmed the effectiveness of developed approach.

***Abstract*—In this paper a convolutional neural network is applied to the problem of note onset detection in audio recordings. Two time-frequency representations are analysed, showing the superiority of standard spectrogram over enhanced autocorrelation (EAC) used as the input to the convolutional network. Experimental evaluation is based on a dataset containing 10,939 annotated onsets, with total duration of the audio recordings of over 45 min.**

I. Introduction

Onset detection is a well recognized and important problem in automatic music information retrieval. It directly addresses one of the most fundamental aspects of music – the time flow and novelty detection; abstracting from *what* and *how*, it concentrates on the *when* question and tries to answer it as precisely as possible. Interesting on its own, this problem is also fundamental in the analysis of many higher-level concepts, such as *rhytm*, *meter* or *tempo* [1]. In a broader context, sound attack analysis can also support other audio processing tasks, including i.a. audio to score alignment (score following), query-by-humming melody search, singing voice quality evaluation and speech analysis [2][3][4][5][6][7].

While trivial when looking at the musical score, note onset detection appears surprisingly complex when musical recordings with real instruments are considered, with all kinds of phenomena and effects like vibrato, glissando, varied dynamics, embouchure and articulation types, etc. As the result, the precise definition of the *onset time*, enabling to unambiguously locate it on the time axis may be difficult [8][1]. Various definitions, including Perceptual Onset Time (POT), Perceptual Attack Time (PAT), Acoustic Onset Time (AOT) and Note Onset Time (NOT) have been proposed [9][1] in order to highlight differences between the time when the onset is perceivable by a human listener, when it is measurable in the signal or when e.g. the *note-on* command is triggered by a MIDI synthesizer [10]. Presence of vibrato, glissandi or ornamentation, not to mention impulse noise or other distortions in low-quality recordings, may in fact render the problem ill-posed, which makes us resort to machine learning approaches for example-based definition of what an *onset* actually is.

This work was supported by the Faculty of Technical Physics, Information Technology and Applied Mathematics, Lodz University of Technology

II. Previous work

The classical approach to note onset detection is based on the *onset detection function* (ODF) constructed to detect novel events in the sound signal [8][11][12][13]. Typically, the signal waveform $x(t)$ is first split into a series of consecutive, usually overlapping time frames $x_n(t)$ with a windowing function applied to each of them:

$$x_n(t) = x(t)w(St - nh) \tag{1}$$

where $w(St - nh)$ is a windowing function stretched by a factor of frame size S and shifted by an integer, n-th multiple of the hop-size h between the consecutive frames. Discrete Fourier transform (DFT) is then computed, and the ODF construction may be based on either its magnitude spectrum [8], the phase spectrum [11] or both [12]. Obviously, the difference between the consecutive frames is considered, such as in the following simple example (ODF based on the *spectral flux* [1][14]):

$$ODF_{sf}(n) = \sum_k H(|X_k(n)| - |X_k(n-1)|) \tag{2}$$

where

$$H(x) = \frac{x + |x|}{2} \tag{3}$$

$$X_k(n) = \mathrm{DFT}(x_n(t))(k) \tag{4}$$

and where the half-wave rectifier function H is used to consider only positive differences, indicating new spectral components appearing in the signal. The onsets may be then easily detected by thresholding the ODF with a fixed threshold T or – more frequently – with a threshold based on moving mean or moving median.

978-83-60810-90-3/$25.00

It should be noted that some onsets (e.g. percussive ones) may be reliably detected also in the time domain by simply monitoring the signal energy. However, sound signal is generally better described in the frequency domain, as opposed to e.g. image processing, where the frequency domain methods have usually more limited and specialized applications [15][16]. For sound, spectral analysis if far more flexible and it opens possibilities of the construction of many specialized algorithms where the signal may be easily split into frequency bands, often distributed logarithmically according to human perception of the pitch. For example, Böck and Widmer proposed an onset detection algorithm with vibrato suppression called SuperFlux, where the input data is filtered with a bank of varying-length frequency domain triangular filters spaced equally in musical scale and where the maximum filter is applied to the resulting spectrograms in order to ignore minor pitch fluctuations [17]. It has been shown [18] that this approach enhances onset detection for bowed instruments playing both with and without the vibrato technique.

In contrary to classical onset detection methods, many recent works involve machine learning techniques – most notably the neural networks [19][20][21], although other data-driven techniques, such as Support Vector Machines (SVM) have also been applied [22]. The input data usually consists of a time-frequency representation of the sound signal, mapped non-linearly in the frequency domain according to a perceptual model. Böck *et al* [21] used a bank of triangular filters positioned at critical bands of the Bark scale to filter the STFT magnitude spectra, computed with three different window lengths in parallel. In this way the redundancy resulting from unnecessarily high frequency resolution of the STFT in the upper frequency range may be avoided. Hertz to Mel scale mapping [23] and constant-Q transform [20] have also been applied for similar reasons.

Several approaches have been proposed in which the *fusion* of many onset detection functions is applied. This is accomplished either on the feature-level by a set of pre-defined rules or a linear combination of ODFs [24], or in the form of the *score-level fusion* in which the decisions are taken on the basis of the already computed onsets [25][24]. Quintela *et al* [25] apply i.a. KNN- and SVM-based classifiers to the lists of pre-computed onset candidates and their locations in time. Recently, Stasiak *et al* [10] proposed to simultaneously use several ODF functions as the input to a multilayer perceptron with one output, playing *de facto* the role of a new "integrated" onset detector. In this way the neural network learns to merge the onset-related information from various sources, while not being forced to extract it explicitly from raw spectral data.

On the other hand, the recent progress in theory and practical applications of deep neural architectures enabled to successfully use the solutions developed by the image processing community also to directly process audio spectrograms, transforming the onset detection task into a problem similar to that of texture recognition. Apart from bidirectional long short-term memory neural networks (LSTM) [23] and recurrent neural networks (RNN) [21], the convolutional neural networks (CNNs) [26][27] proved to be especially useful here.

In this work we adopted the approach proposed in [27] to test the effectiveness of a convolutional network in the onset detection task using two different signal representations, namely the logarithmically scaled spectrogram and enhanced autocorrelation (EAC).

III. The proposed approach

A. Neural network architecture

The input to our network is a spectrogram fragment in the form of an image with 15 columns, representing 15 consecutive time frames and 80 rows, corresponding to 80 logarithmically distributed frequency bands (up to 16kHz). The initial audio files are sampled 44100Hz and the spectrogram parameters are: window size $N = 2048$, hop-size $K = 512$ samples, which yields time resolution of ca. 11.6 ms. The target is composed of a single value, indicating the distance of the onset from the middle frame of the current input image, similarly as in [10] (Fig. 1). If more onsets are present within the fragment, only the closest one is considered. In this way the network has to solve *regression* problem instead of binary classification (onset absent/present in the middle of the fragment). Preliminary experiments showed that it enhances the results significantly.

The network structure is as follows:

- Convolutional layer with ten rectangular filters of size: w×h = 7×3 with ReLU (Rectified Linear Unit) activation function and stride value of 1 in both directions (full overlap). Note that for input size of w×h=15×80 it yields w×h=9×78 output.
- Max-pooling layer with non-overlapping kernels of size: w×h = 1×3 (output size w×h = 9×26).
- Convolutional layer with twenty square filters of size w×h = 3×3 and stride value of 1 in both directions (output size w×h = 7×24).
- Max-pooling layer with non-overlapping kernels of size: w×h = 1×3 (output size w×h = 7×8).
- Inner product (i.e. fully connected) layer with 256 hidden neurons and ReLU activation function.
- Inner product (i.e. fully connected) layer with one output neuron and tanh (hyperbolic tangent) activation function.

The neural architecture basically follows the scheme proposed by Schlüter and Böck in [27] with some modifications concerning – apart from the aforementioned regression, replacing classification – mostly the type of nonlinearity of the layers. We agree with [27] that the rectified linear units in the first convolutional layer may play the role of the half-wave rectifier H function (cf. Eq. 3) helping to detect onset-related energy increases. Additionally, we use the same nonlinearity type for the fully connected layer, instead of sigmoidal units which proved to positively influence the learning process in our tests. We also change the unipolar sigmoid into tanh function in the output neuron, which leads to increasing the output range from $[0, 1]$ into $[-1, 1]$ (cf. Fig. 1, the top plot).

The last change influences the threshold which is applied to the output of the network in order to find the onset positions.

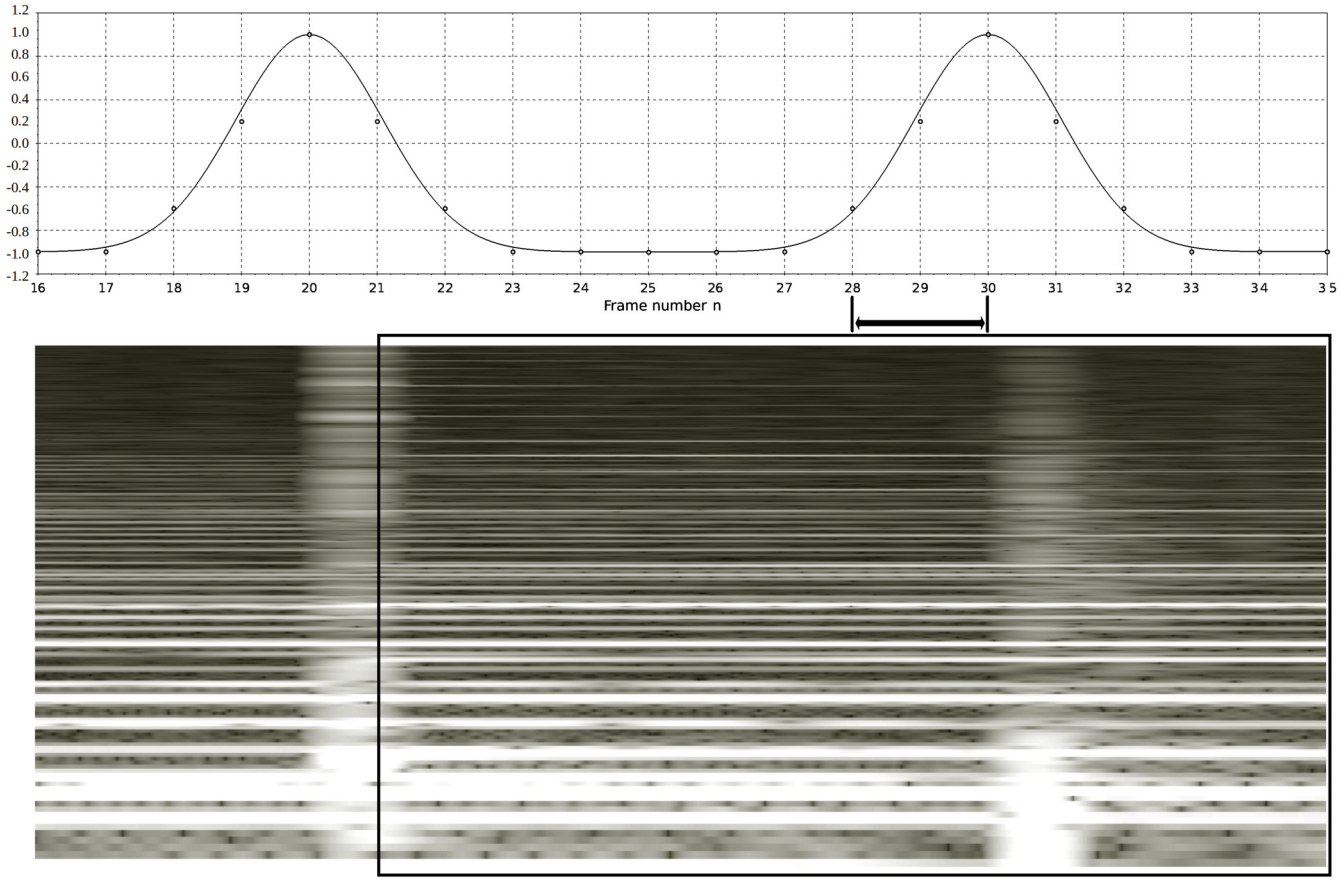

Fig. 1. *Spectrogram fragment enlarged (in a black box, lower plot) and the associated target values (top plot). The middle of this fragment (frame 28) is two frames apart from the onset (frame 30), so the target value for this fragment is -0.6 (top plot). Note, that the actual resolution of the image representing this fragment, that is fed to the network input is much lower (w×h=15×80 pixels)*

It should be mentioned here, that the output of the trained network may be treated as a classical ODF, with the difference, that a fixed threshold T may be used instead of moving mean or moving median, due to general lack of dependence on the signal energy. For the tanh activation function the optimal threshold value T_{opt} determined in our tests, i.e. the value maximizing the F-measure [27][10] was always lower than zero. After the thresholding, the peak-picking procedure is applied and peaks found within the range of 50ms relative to the actual onsets are treated as the properly detected ones.

Having denoted the correctly located onsets by **TP** (true positives), the assessment of the quality of the onset detection may be expressed in terms of *precision*, defined as the ratio: **TP/(TP+FP)**, and *recall*, defined as: **TP/(TP+FN)**. In our experiments we use the harmonic mean of precision and recall, known as the *F-measure*, as a "balanced" result of the onset detection procedure [10].

B. Audio material and data preparation

The dataset used in our experiments is a collection merged from several sources, including [8][28][29][20][30]. The total duration of all the audio files in our collection is over 45 min. and it contains 10,939 annotated onsets. The dataset has been divided at random into the train, test and validation subsets, containing 6236, 2520 and 2183 onsets, respectively. Complete files are assigned to either of the subsets (they are not split between the subsets).

For training, the spectrograms are cut into overlapping fragments which are then selected so that the obtained set is balanced, i.e. the number of "onset fragments" (for which the target value is non-zero) is equal to the number of "non-onset fragments". For testing, all possible fragments are used in an ordered sequence.

The main time-frequency representation (TFR) used in the experiments is the spectrogram, computed as explained in the previous section. In a separate test we use also enhanced autocorrelation (EAC) correlogram, calculated frame-by-frame in a similar way. EAC is an intermediate representation for the task of pitch estimation, thus also suitable for supporting onset detection with a degree of additional information on the input audio features related to melodic content. The procedure itself had been developed by Tolonen and Karjalainen [31] and (as the name implies) it is an extension of standard autocorrelation method. In our research we use EAC implementation operating in frequency domain for each frame of input signal using the

following processing scheme:

1) Transform a frame to frequency domain with Fourier transform. In this step, we use the same parameters as for the spectrogram computation – frame size of 2048 samples and frame step size (hop-size) of 512 samples.
2) Compute signal power
3) Take cube root of the resulting transform to compress magnitude in a non-linear manner. For normal autocorrelation the spectral coefficients are raised to the power of 2, however using the factor of 1/3 (cube root) of "generalised autocorrelation" is more suitable for the task of periodicity detection.
4) Clip all values below zero
5) Create a stretched copy (by factor of 2) of the values derived, and subtract it from the original (at step 4)
6) Clip all values below zero
7) Transform back to time domain with inverse Fourier transform

Steps 4-6 are performed for the purpose of peak pruning to improve pitch representation clarity, following Tolonen and Karjalainen's method. The procedure is applied to the signal frame-wise, yielding a correlogram, which can be processed further in a similar way as an ordinary spectrogram (Fig. 2).

C. Experimental evaluation

Caffe framework [32] has been used for training and testing the convolutional neural network presented in Sect. III-A. Separate validation set was used to determine the optimal model and to avoid overfitting. Stochastic gradient descent with momentum was used as the optimization strategy with mini-batch size of 1000 input spectrogram fragments. We used fixed momentum parameter of 0.4 and variable step size.

In the initial experiments we tested the influence of the activation function type on the results, as discussed in Sect. III-A. The results are presented in Table I.

TABLE I
THE RESULTS OF THE ONSET DETECTION TESTS

Experiment	F-measure
Original architecture based on [27]	82.13%
Our version with ReLU in the hidden layer and tanh in the output layer	83.35%
Our version trained on EAC correlograms instead of the spectrograms	73.10%

Although our modification enhanced the result by over one percent point, yet the EAC correlogram appeared definitely inferior to the spectrogram-based TFR. In the search of the potential reasons we conducted a series of additional tests in which we compensated for the potentially different annotation procedures in our heterogeneous dataset, by artificially shifting the onset positions by several multiples of the hop-size (from $-4 \times K$ to $4 \times K$). All the onsets in a given file were naturally shifted by the same displacement, but the displacement for each file was determined independently. Due to the latter fact, the figures presented in Table II obviously cannot be treated as the final objective results achieved by our network – they are rather indicators of its theoretical capabilities if some strict, uniform rules were applied for annotating the input files. They may also be used for a comparison of the spectrogram- and correlogram-based representations which again shows definite superiority of the first one. Figure 3 demonstrates the F-measure changes for varying values of the threshold T for the spectrogram-based input.

TABLE II
THE RESULTS OF THE ONSET DETECTION TESTS WITH ONSET SHIFTING

Experiment	F-measure
Our version with ReLU in the hidden layer and tanh in the output layer	88.62%
Our version trained on EAC correlograms instead of the spectrograms	81.13%

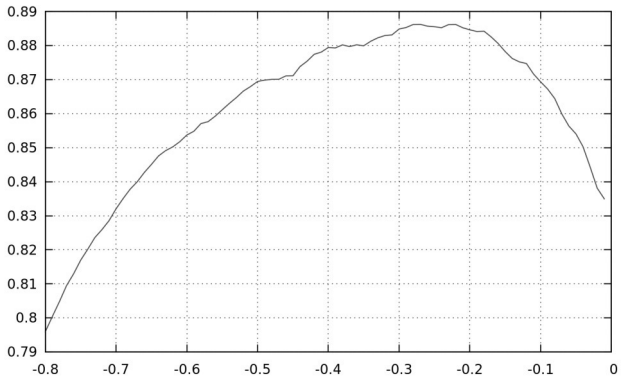

Fig. 3. *F-measure for varying values of the threshold T*

IV. DISCUSSION AND FUTURE WORKS

In this paper a convolutional neural network has been applied in the note onset detection problem. The obtained results demonstrate the superiority of the standard, spectrogram-based representation of the audio signal over the EAC correlogram. This observation confirms the potential of convolutional neural networks which are able to successfully extract useful information from the lower-level audio representation (spectrogram). The EAC correlogram, on the other hand, may be seen as a result of some more sophisticated processing, yielding more directly interpretable information related to pitch and melody content. However, this processing, although potentially useful from the human perspective, inevitably removes some information, which in consequence limits the potential of the convolutional neural network, eventually impairing the results.

The obtained results for the spectrogram-based input are satisfactory in terms of absolute onset detection rate. Enhancements might be searched for in increasing the precision of onset location (the annotations in the database used in the experiments should be manually checked and corrected to obtain more consistent annotation style [14]). Also, combining several time-frequency representations in a single spectrogram fragment, possibly computed with varied window size

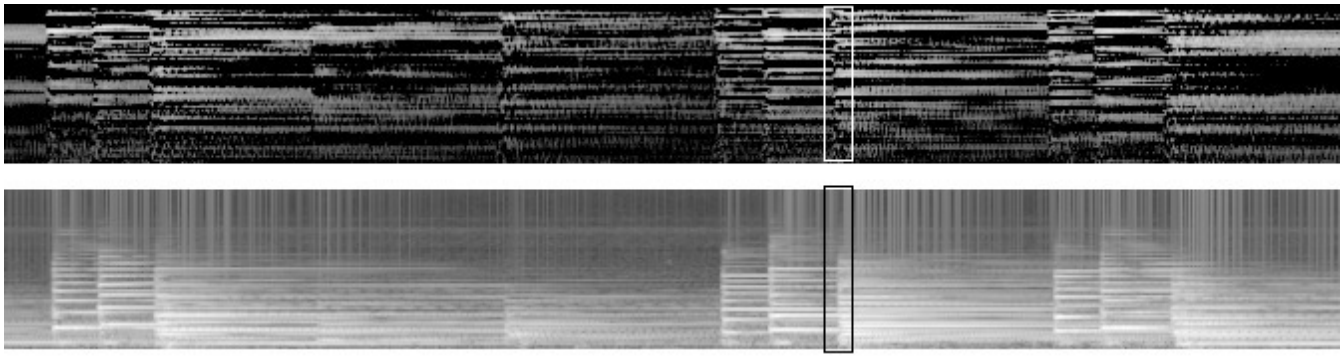

Fig. 2. *EAC correlogram (top) and spectrogram (bottom) of the same input file, with a bounding box around a fragment with an onset in the middle*

as proposed in [27], would probably lead to some further improvements.

ACKNOWLEDGMENT

We are truly grateful to Juan Pablo Bello, Sebastian Böck and Andre Holzapfel for making the annotated audio datasets available for our experiments.

***Abstract*—We present IQBEES, a novel prototype system for similar entity search by example on semantic knowledge graphs that is based on the concept of maximal aspects. The system makes it possible for the user to provide positive and negative relevance feedback to iteratively refine the information need. The maximal aspects model supports diversity-aware results.**

***Index Terms*—entity search; relevance feedback; interactive retrieval; aspect model; diversity**

I. Introduction

IN THIS paper we present *iQbees*, a prototype system for *Interactive Query-By-Example Entity Search* on semantic knowledge graphs. The system solves the following list completion problem: given one or more example entities (e.g. actors, movies, etc.) as representatives of a group of entities, find other entities in that group. Our system solves this task through a sequence of *interactive query refinement steps* based on positive or negative user feedback. The results in each step are selected according to our own model based on *maximal aspects* that supports diversity awareness of the results.

The target of our interactive prototype *iQbees* system are non-expert users searching for a well-defined group of entities, for example European scientists who won a Nobel prize in physics. We assume that the users are unaware of the structure of the knowledge base and are not familiar with powerful structured query languages like SPARQL, thus cannot formulate a precise query that would satisfy their need. For such users, it is much simpler to provide one or a few examples of entities within the target group; in our example, such entities could be Maria Skłodowska-Curie or Max Planck. Our system will then, in a sequence of steps, present candidate result entities, for some of which the user will be able to give positive or negative feedback, refining the initial query and moving closer to her search goal. Our system thus combines techniques from entity list completion and relevance feedback and interactive search. The *iQbees* is built on the model previously applied in our (off-line) QBEES system [1], equipped with the interactive approach for providing positive and negative feedback by the user.

The first author is also with Polish-Japanese Academy of Information Technology, Warsaw, Poland

An obvious issue in such a scenario is the *ambiguity* of the actual user information need that is imperfectly represented by the given set of example entities. This problem is particularly difficult when just a single example entity is given which may represent a large number of possible entity sets; more example entities make this somewhat easier, but still far from trivial to solve. In such a scenario, it is almost impossible to immediately retrieve the correct set of entities in a single step, as standard list completion systems would do. The QBEES system, which is used as the backbone of our interactive *iQbees* system, does not provide user interaction and thus, as other list completion systems too, does not always retrieve the results that match the user information need.

We model possible user information needs by the concept of *aspects* of an entity, i.e., subsets of the facts and types in the semantic knowledge graph that characterize the entity. This model is designed so that it naturally supports *diversity* of the retrieved entities in order to cover as many as possible potential aspects (and thus possible information needs). A user will therefore likely find at least one relevant entity among the results for which she can give positive feedback, refining her query for the next iteration. The result diversity is guaranteed by the properties of *maximal aspects* that will be shortly described later. The *iQbees* system relaxes the strict aspect-based retrieval model used in QBEES, focusing more on popular entities that a user may know instead of obscure entites that perfectly match a possible information need.

iQbees and its underlying rankers are based on the structural and statistical properties of the underlying semantic knowledge graph. Such approach is orthogonal to any other approaches using external data or textual features of the entities. Hence, our approach can be easily enriched or combined with other text-based approaches that have been havily researched before. Our model assumes the correctness and completeness of the data, treating the issue of missing and wrong facts as out of scope of this paper.

II. The QBEES Aspect-based Model

Our system is based on the *aspect model* that will be very shortly described in this section. The full description of the model can be found in [1].

978-83-60810-90-3/$25.00

A. Knowledge graph

A Knowledge Graph KG is a directed multi-graph that consists of three basic components, a *Fact Graph* FG, an *Ontology Tree* O, and a set of type assignment arcs TA connecting the two. Arcs in KG are labelled. We will use the notation `relation(arg1,arg2)` for any directed arc with label `relation` in KG that points from node `arg1` to `arg2`.

The *Fact Graph* $FG = (E, F)$ is a directed multigraph where nodes in E represent *entities* (e.g. `Fryderyk_Chopin`, `Warsaw`) and edges in F represent *facts* about the entities. For example, an arc `bornIn(Fryderyk_Chopin, Żelazowa_Wola)` represents the fact that a Polish composer Fryderyk Chopin was born in Żelazowa Wola or `hasWonPrize(Max_Planck,Nobel_Prize_in_Physics)` means that the German scientist Max Planck is a Nobel Prize awardee in Physics.

The *Ontology Tree* $O = (C, S)$ is a graph where each node (class) $c \in C$ represents some *type* of entities (e.g. person). The class nodes are connected by directed arcs labelled as `subClassOf`. For instance, `subClassOf(composer,musician)` indicates that every composer is also a musician. Because the only relation present in this ontology tree in our current setting is the `subClassOf` relation, it can be also viewed as just a *taxonomy* of types.

The *Type Assignment* TA is a set of arcs labelled `hasType` which connect entities from the Fact Graph and classes from the Ontology Tree. For example the arc `hasType(Chopin, composer)` means that "Chopin is a composer".

B. Basic aspects

A basic aspect represents an "atomic property" that describes a specific entity q. In our most general setting, we distinguish three types of basic aspects: *fact aspects*, *relational aspects* and *type aspects*.[1]

1) Fact aspects: are created from the arcs incident with the entity in the fact graph FG that represent a fact concerning this entity. For example: the arc `bornIn(Chopin,Poland)` induces the fact aspect `bornIn(.,Poland)`.

2) Relational aspects: are predicates obtained from arcs that represent facts in the fact graph FG concerning the entity but the remaining argument of a factual aspect is replaced by a free variable ?. For example, `actedIn(.,?)` indicates that an entity acted in at least one movie.

3) Type aspects: are obtained similarly as relational aspects but inside the type assignment TA set of edges. It is obtained by replacing the particular entity q in an arc that represents a type with a free variable. Intuitively it represents the type of the entity under consideration. For example, a type arc `hasType(Chopin,composer)` naturally induces predicates of the form `hasType(.,composer)` that represents the "basic property" of this entity of "being a composer".

The three kinds of basic aspects can be viewed as forming a 3-level hierarchy, from the most general type aspects to more specific relational aspects (since particular kinds of relations between entities can be bounded only to particular types of entities) to the most specific factual aspects (as being realisations of relational aspects by substituting the free variable with a particular value referring to other entity).

[1] In some particular practical tasks the general framework can be simplified by reducing the considered types of basic aspects to only fact aspects, for example.

C. Compound aspects

A set of basic aspects is called a *compound aspect*. For example, a property "being a composer born in Poland", which consists of two basic aspects - "being a composer" and "being born in Poland", is represented by a set of two basic aspects, i.e. a compound aspect: {`bornIn(.,Poland)`, `hasType(.,composer)`}.

It is easy to see that each entity can be characterised by its set of basic aspects and vice versa – each set of basic aspects represents some set of entities that share it.

For an entity $e \in E$ we will henceforth use A_e to denote a *set of all basic aspects of* e.

We will say that "entity e *satisfies* a compound aspect A" whenever $A \subseteq A_e$.

D. Entity set of an aspect

For each basic aspect $a_q \in A_q$, of some entity q, we naturally define its entity set $E(a_q)$ as the set of all entities $e \in E$ that share this aspect with q, i.e. contain a_q in their set of basic aspects A_e:

$$E(a_q) = \{e \in E : a_q \in A_e\}$$

We extend the above definition of entity set $E(a_q)$ (for a basic aspect a_q) to the concept of entity set $E(A)$ of a compound aspect A as the set of all entities that share *all* basic aspects in A.

E. Maximal aspects

Let q be a query example and A_q be its set of basic aspects. For any $e \in E, e \neq q$ consider the set of all basic aspects of e common with q, that is $A'_e = A_e \cap A_q$.

A compound aspect A_q for entity q is called a *maximal aspect* if and only if it satisfies the following two conditions:

1) it is satisfied by q and *at least one entity other than* q
2) A_q is maximal wrt inclusion (i.e., extending this set of basic aspects with any more basic aspect of q would violate the first condition).

In other words, the maximal aspects of q are maximal compound aspects satisfied by q and any other entity.

We assume that the concept of maximal aspect is defined with respect to the current content of the underlying semantic knowlege graph.

There may exist multiple different maximal aspects for a given entity.

The definition of maximal aspect for a single entity q extends to a set Q of query entities as follows. For a query entity set Q we say that a compound aspect A_Q is *a maximal aspect for* Q if and only if it satisfies the following two conditions:

1) it is satisfied by all entities in Q and at least one entity outside Q
2) A_Q is maximal wrt inclusion

We introduce the denotation of $E(A_Q)$ as the natural extension of the concept of $E(A_q)$ corresponding to a single entity q to the set of entities Q.

To illustrate the maximal aspect concept we will use the following example. Assume an entity set $Q = \{\texttt{Schwarzenegger}, \texttt{Stallone}\}$ is given. Then, consider two compound aspects for Q:

$A_1 = \{\texttt{hasType(.,ActionMovieActor)}, \texttt{livesIn(.,USA)}\}$

$A_2 = \{\texttt{hasType(.,ActionMovieActor)}, \texttt{livesIn(.,USA)}, \texttt{hasType(.,MovieDirector)}\}$

If, in the underlying knowledge base, there is at least one entity that is an action movie actor and director living in USA, other than Schwarzenegger and Stallone the first condition of the maximality definition holds. Moreover, if adding any other basic aspect of Q (e.g. additionally being a body-builder) would make the compound aspect satisfied only by the two mentioned entities, the set A_2 is a maximal aspect for Q while A_1 is obviously not since it subsumes A_2.

F. Diversity-awareness of Maximal Aspects

Maximal aspects have the following two crucial properties:

- (RELEVANCE) any entity that satisfies a maximal aspect is *maximally similar* (in terms of sharing maximally many basic aspects with the target entities)
- (DIVERSITY) each maximal aspect A_Q represents a *different* set of entities, i.e. they do not intersect except Q.

The last property can be expressed in the form of the following theorem:

Theorem: *Let Q be a (query) set of entities and $A_Q \neq B_Q$ be two different (non-empty) maximal aspects of Q. Then, $E(A_Q)$ and $E(B_Q)$ do not share any entities, except those in Q (i.e. $(E(A_Q) \cap E(B_Q) \setminus Q) = \emptyset$).*

Proof: *Assume, $e \in E(A_Q) \cap E(B_Q)$ for some entity $e \notin Q$. This implies that e shares all the basic aspects from both A_Q and B_Q. Let us introduce denotation $C_Q = A_Q \cup B_Q$. Thus, e shares all basic aspects from C_Q which implies that $e \in E(C_Q)$. But, since A_Q and B_Q are different and non-empty, C_Q strictly contains both A_Q and B_Q which would contradict the maximality property of them.*

Due to the above theorem, the set of candidate similar entities to be returned is *partitioned* by the entity sets of maximal aspects. Thus, the maximal aspects model supports *diversity* of the results, since they are non-redundant (i.e. different maximal aspects imply non-intersecting sets of entities).

G. Searching with basic QBEES approach

Given a set of query examples, the approach calculates all maximal aspects and generates results from them based on a two-step ranking scheme that first selects the most promising maximal aspect and then the most promising entity that satisfies this maximal aspect. This process is repeated until k results are retrieved. Entities are ranked based on various factors including graph properties (e.g. random-walk based) and importance (popularity). Maximal aspects are ranked based on their size and the popularity of their entities, hence retrieving (and thereby removing) an entity from a maximal aspect changes its score. We adapted the QBEES ranking system that is out of scope of this paper and is described in [1].

III. Interactive Search with *iQbees*

With *iQbees*, the static search procedure used by QBEES is extended with interactive feedback cycles.

Initially, the user provides an example entity.[2]. The system then returns an initial list of result entities using the ranking approach. If this answer is not yet perfect, the user can use the returned entities as *refinement suggestions* and select some of them as *positive* hints, some of them as *negative* hints. The system will then exploit this feedback and produce new, hopefully better, results. This interaction cycle proceeds until the user is satisfied with the results.

A. Positive feedback and Negative feedback

To shortly explain the mechanism of positive and negative feedback, let's introduce some ancillary concepts. Let *domain* be defined as the intersection of compound aspects of all initial entities and all positive feedback entities. Let *candidate aspects* be defined as the set of compound aspects that are contained in the *domain*. In the basic setting they are exactly *maximal aspects* contained in the *domain*. In the *relaxed* variant, that will be described below, *candidate aspects* are any compound aspects contained in the *domain*.

Filtered candidates are exactly those *candidate aspects* that are *not satisfied* by any entity from the negative hint set.

Then, we run the algorithm using *filtered candidates* only, i.e. only the entities that satisfy filtered candidates can be returned.

B. Relaxed Variant of Aspect Selection

The maximal aspect concept proved to perform well in the basic QBEES algorithm [1] where the user provided a set of entities in a "one-shot" mode.

However, in the interactive *iQbees* approach, if we applied the basic model described above, one can observe the following phenomenon. The more positive feedback entities are provided by the user, the more entities can be potentially returned which is counter-intuitive to the concept of *query refinement*. This phenomenon is due to the fact, that the more positive examples are provided, the smaller is their aspect intersection (*domain*). As a result, more entities can potentially satisfy such maximal aspect being the intersection of more entities, since it is easier to contain a smaller aspect set than a bigger one. This is counter-intuitive, since providing more positive examples should *refine* the query intent rather than make it more vague.

[2]Actually, our model can be easily extended to allow for any number of initial query entities. This can be also easily simulated by providing one entity and marking the others as positive feedback. The extension to multi-entity input is planned as a close future work

Hence, to "correct" such undesirable behaviour, in *iQbees* we "relax" the original QBEES mechanism by considering (as *candidates*) *all* compound aspects contained in the *domain* instead of considering only *maximal aspects* contained in the *domain* as *candidates*. Such "relaxed", non-maximal compound aspects are ranked using the base QBEES approach to promote the maximal or near-maximal aspects and only top-k are considered. After this "relaxation" the above phenomenon is removed, i.e. the more positive hints are provided, the fewer entities potentially satisfy (contain) any relaxed compound aspect.

IV. An example search session

A working demo application was built as a preliminary proof of concept, and as an experimental platform and to illustrate the approach studied in this paper. It is currently using YAGO [2] as the underlying semantic knowledge base[3]. By using the demo application a user, interested in a particular entity present in the semantic knowledge graph, can query the graph to find similar entities. *User Interface* UI of the demo application allows to mark each search result (entity) as relevant or not. This information is used in subsequent queries and allows the user to iteratively refine his initial query until he receives satisfactory results.

A. Preliminary Demo UI

Demo application UI consists of three main parts - *Query Input Field*, *Search Parameters Section* and *Search Results Section*. *Query Input Field* is a typical text input, where the user can type in the entity name which will be the subject of the query. *Search Parameters Section* contains UI controls which allow to change the number of expected search results and specific settings of the query algorithm.

Search Results Section, visible after performing the initial and subsequent queries, contains similar entities found in the previously executed query and *Feedback Subsection*. Each result entity has two buttons labeled "+" and "-". These buttons are used to mark a particular result entity as positive or negative feedback i.e. relevant or not to the initial user information need. Pressing one of these buttons results in moving the entity to the *Feedback Subsection* and marking it accordingly as "positive" or "negative" feedback for future searches. Each feedback entity has an additional "show debug" button which displays the set of all *basic aspects* satisfied by it. Likewise each search result entity has a "show debug" button which displays *maximal aspect* of query subject satisfied by this particular entity.

The "Calculate" button triggers query execution. The "Fresh Start" button restarts the searching session, clears the initial entity and previous search feedback. Screenshots of available "work in progress UI" are visible in Figures 1 and 2.

[3]Other semantic knowledge graphs are considered to be used as the underlying databes in our future work

B. Example usage scenario

Application user is interested in Arnold Schwarzenegger and entities similar to him in terms of political career. Notice the particular *ambiguity* of this entity, since it represents also many other aspects, e.g. famous body-builders, action movie actors, directors, etc. Assume the user applies the default search parameters visible in Figure 1 and inputs "Arnold Schwarzenegger"[4] in *Query Input Field* and clicks the "Calculate" button. The system verifies if "Arnold Schwarzenegger" entity is present in the underlying knowledge graph (demo application requires exact match of the entity name) and starts computing similar entities. After certain amount of time the results are visible in *Search Results Section*. In the results, among others, the user can see:

- Gray Davis: a former governor of California.
- Dany DeVito: an American actor who acted in a move "Junior" with Schwarzenegger.

User marks Gray Davies as positive feedback and clicks "Calculate" once again. The new result set contains only politicians. The user can further search for similar entities by providing new feedback.

If user eventually decides that entities similar to Arnold Schwarzenegger in terms of political career are not interesting to her, she can start a new searching session by clicking the "Fresh Start" button. This will clear previous search results and return *Search Parameters Section* settings to default values. User once more inputs "Arnold Schwarzenegger" in *Query Input Field* and *Search Results Section* gets populated by previously visible results. This time user marks Gray Davies as negative entity by clicking the "-" button next to it. Once the search is finished a new result set contains mainly actors and movie producers and does not contain any politicians. In the next step user chooses Sandahl Bergman as a positive entity. Sandahl Bergman is an actress who starred in "Conan the Barbarian" and "Red Sonya" together with Schwarzenegger. The final result set contains actors and actresses among whom three actors played in "Conan the Barbarian" (Gerry Lopez, James Earl Jones) and one actress starred in "Red Sonya" (Brigitte Nielsen).

V. Experiments

The prototype system has been implemented and is being tested. Besides experimenting with the on-line prototype, we made a preliminary experimental evaluation aiming at an objective comparison of the described variants of our system on publicly available benchmark data.

We used the YAGO semantic knowledge graph [2] as the underlying database. We used data from the INEX 2007 entity track to build a 163-query one-entity gold-standard dataset by mapping Wikipedia pages to YAGO and using list completion topics, following the approach sketched in [1]. Each topic

[4]In our current working demo the input is not preprocessed so that the user has to type the exact string as it is represented in the database. Obviously, in future we plan to add semi-automatic query correction using methods proposed in [3] or [4] to make the user interface more user-friendly

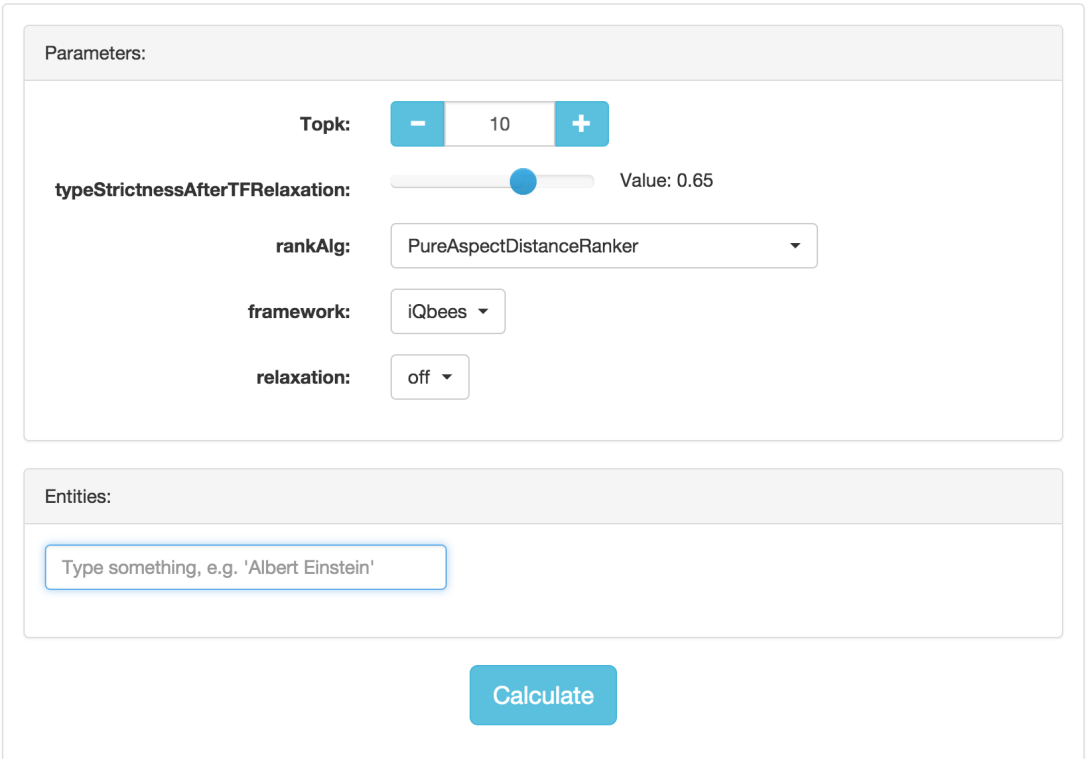

Fig. 1. Initial application view with default search parameters.

is provided with a set of relevant entities (called *ground truth*). As the basic back-end, we reused the existing QBEES engine that was extended by positive and negative feedback functionality and ranking all the candidate aspects (not only maximal aspects).

We simulated three simple 2-step strategies of the user. In each scenario the "simulated" user, in step 0, inputs one query entity to the system and then, in step 1, marks one (randomly) selected result entity that is relevant according to the ground truth as "positive" (p), or one (randomly) selected result entity that is irrelevant according to the ground truth as "negative" (n), or both (p+n). We simulate this by marking 1 *random* relevant or irrelevant entity, respectively.

Each combination of one of the three mentioned strategies (p, n, p+n) and one of the two extensions described above (FEEDBACK for positive and negative feedback, RELAX for additional consideration of non-maximal aspects) was run on each of the 163 one-entity queries. For all settings, we computed average MAP and MNDCG in step 0 and step 1 to measure and compare the performance of the system in each step and each setting. For each query and each setting the procedure of computation of measures is as follows: we run two steps; we remove the selected entieties from the ground truth and from both result list; then we calculate measures (MAP, MNDCG) for each step.

The presented experimental evaluation results indicate that in the two examined settings: marking positive (p) and positive and negative (p+n) entities observably improves the quality of the results in the next step (Tables I and III). Interestingly, we also found out that marking only 1 negative entity did not improve the results in the next step (Table II), in this particular experimental setting even if in our on-line experiments the negative feedback functionality seems to improve the results. This issue will be the matter of our further study.

Furthermore, one can observe that the relaxed variant of our approach (i.e. RELAX) performs consistently better than FEEDBACK in this setting.

VI. Previous and Related Work

The system is based on the *aspect model* described in detail in [1]. An early version of the *iQbees* system (without negative feedback functionality nor relaxation nor experimental evaluation) was presented in a short paper [5] that this paper is a substantial extension of.

Entity search has been considered extensively in the past, with a focus on finding related entities and list completion, and with extensive evaluation campaigns at TREC [6] and INEX [7]. We consider the specific scenario where entities

from a knowledge graph are searched. Existing systems usually build on entity similarity measures, exploiting the graph structure (e.g., SimRank [8]), the context of entities in the graph (e.g., Albertoni and De Marino [9]), or additional context outside the graph (e.g., Bron et al. [10], which combines a term-based language model with a simple structural model).

The problem of example-based entity search has been actively studied recently. Yu et al. [11] solve a slightly different problem where entities similar to a single query entity are computed, exploiting a small number of example results. Focusing on heterogeneous similarity aspects, they propose to use features based on so-called meta paths between entities and several path-based similarity measures, and apply learning-to-rank methods for which they require labelled test data. Wang and Cohen [12] present a set completion system retrieving candidate documents via keyword queries based on the entity examples. Using an extraction system additional entities are then extracted from semi-structured elements, like HTML-formatted lists.

Mottin et al. [13], [14] introduce the concept of exemplar queries. Similar to our setting, an example result is used instead of a query. However, the setting in their XQ system is strictly different since it considers examples in the form of a connected subgraph of entities, not single entities, and determines result subgraphs based on their similarity to the query graph. The problem is therefore in some sense easier, as more information can be exploited for identifying query results.

The GQBE system by Jayaram et al. [15] is similar to XQ, but does not use connected subgraphs, but just entities that form a query result as input; the meaningful connections between those entities are explored by the system. Again, the main difference to our system is that we consider only single entities as results, not combinations, and hence have less information for identifying relevant results.

Relevance feedback has seen surprisingly little use in entity search on knowledge bases. Only very recently, Su et al. [16] proposed exploiting relevance feedback for improving results of searching a knowledge graph, but not for entity search. For entity ranking using text or semi-structured information, relevance feedback has been more popular [17].

Diversity-aware entity summarization was originally proposed in [18] and further studied in [19], but we are not aware of any work on entity search that takes diversity into account.

VII. Conclusions and Further Work

We presented *iQbees* – a prototype interactive approach to the problem of entity list completion based on semantic knowledge graphs. This is an extension of the previously presented QBEES system [1] by adding positive and negative interactive feedback functionality. The prototype of the approach was preliminarily implemented as a proof of concept and demonstration available online. We also presented experimental results that indicate that the proposed approach outperforms on a publicly available benchmark the basic (non-interactive) QBEES system without the feedback functionality. The future work includes better understanding and modeling of the feedback functionality, in particular negative feedback, and ranking strategies since the current experiments indicate that there is room for improvement in the current model. It is also envisaged to further work on developing the on-line demo in order to improve its functionality and optimise it and to perform more experimental evaluation on other semantic knowledge graphs, e.g. DBPedia.

***Abstract*—In this paper are presented classification methods with use of two-dimensional three-state cellular automata. This methods are probabilistic forms of cellular automata rule modified from wide known almost deterministic rule designed by Fawcett. Fawcetts rule is modified into two proposed forms partially and fully probabilistic. The effectiveness of classifications of these three methods is analysed and compared. The classification methods are used as the rules in the two-dimensional three-state cellular automaton with the von Neumann and Moore neighbourhood. Preliminary experiments show that probabilistic modification of Fawcett's method can give better results in the process of reconstruction (classification) than the original algorithm.**

I. Introduction

In a classification problem, we wish to determine to which class new observations belong, based on the training set of data containing observations whose class is known. The binary classification deals with only two classes, whereas in a multiclass classification observations belong to one of the several classes. The well-known classifiers are neural networks, support vector machines, k-NN algorithm, decision trees, and others. The idea of using cellular automata (CA) in the classification problem was described by Maji et al. [4], Povalej et al. [7] and recently by Fawcett [1]. Fawcett designed the heuristic rule based on the von Neumann neighborhood (so-called voting rule) moreover, tested its performance on different data sets. Recently, GA was considered as a tool to select CA rules with von Neumann neighbourhood for binary classification problem by Piwonska et al. [6].

Despite the fact that CAs have the potential to efficiently perform complex computations [9]; the main problem is a difficulty of designing CAs which would behave in the desired way. One must not only select a neighborhood type and size, but most importantly the appropriate rule (or rules). In some applications of CAs one can design an appropriate rule by hand (e.g. the GKL rule designed in 1978 by Gacs, Kurdyumov and Levin for density classification task [2]) or can use partial differential equations describing a given phenomenon [5]. Since the number of possible rules is usually huge, this is the extremely hard task, and it is not always possible to select them by hand. Therefore, in the 90-ties of the last century Mitchell et al. proposed to use GAs to find CAs rules able to perform one-dimensional density classification task [3].

In this paper are used rules based on methods of classification like the Fawcett's [1] method, and new proposed modifications into a probabilistic form of such method. Above rules are applied to the rectangular grid with both neighbourhood types i.e. von Neumann and Moore neighbourhood, and the effectiveness of the modified rules is compared with the effectiveness of the original Fawcett's rule.

This paper is organized as follows. Section 2 describes two-dimensional CAs and binary classification problem. In section 3 are proposed new CA-based classifier as a modification of the Favcett's rule. Experimental results are presented in Section 4. Last section contains conclusions and future works.

II. Two-Dimensional Cellular Automata and Binary Classification Problem

A two-dimensional CA considered in this paper is a rectangular grid of $N \times M$ cells, each of which can take on k possible states. After determining initial states of all cells (i.e. the initial configuration of a CA), each cell changes its state according to a rule - transition function TF which depends on states of cells in a neighborhood around it. In this paper is considered finite CA with the periodic boundary conditions. This is usually done synchronously, although asynchronous mode is used too. Two types of the neighborhood are commonly used: the von Neumann neighborhood (the four cells orthogonally surrounding the central cell) and can be described as: $a_{i,j}^{(t+1)}=TF[a_{i,j-1}^{(t)}, a_{i-1,j}^{(t)}, a_{i,j}^{(t)}, a_{i+1,j}^{(t)}, a_{i,j+1}^{(t)}]$, where $a_{i,j}^{(t)}$ denotes the state of a cell at position i, j in the two-dimensional cellular grid, at time step t, and also the Moore naighbourhood (the eight cells around the central cell) and can be described as: $a_{i,j}^{(t+1)}=TF[a_{i-1,j-1}^{(t)}, a_{i,j-1}^{(t)}, a_{i+1,j-1}^{(t)}, a_{i-1,j}^{(t)}, a_{i,j}^{(t)}, a_{i+1,j}^{(t)}, a_{i-1,j+1}^{(t)}, a_{i,j+1}^{(t)}, a_{i+1,j+1}^{(t)}]$.

The evolution of a CA is usually presented using so-called 'space-time diagrams' displaying grid of cells at subsequent time steps, with each state marked with different color.

The square state of the data space in classification problem should be i.e. $[0,1] \times [0,1]$. Suppose that $N \times M$ data-points $p_{(i,j)}=(x_i, y_j)$, where i=1, 2, ..., N and j=1, 2, ..., M are given as a training set from two classes: class 1 and class 2. When each of $p_{(i,j)}$ data-points is known as one of two classes then we have the classification. On the other hand, when even one of the data-points is not one of two known classes we have the classification problem. Moreover, to answer the question, what kind of class 1 or class 2 are unclassified data points it should be applied the classification method. In CA the data space of such problem should be mapped from $[0,1] \times [0,1]$ into the

grid of $N \times M$ cells (in this paper $N \times N$ for the simplicity). Each of cells can take one of 3 states, classified the state 1 (class 1) and state 2 (class 2) and also unclassified state (class 0). Classifier - the rule of CA will analyze the unclassified cells and changes its states into one of two known.

III. Proposed CA-based Classifier

The classification problem described in [1] is the base of this paper. The rule of CA known as $n4\_V1\_nonstable$ and presented there was the starting point to create a better classifier. The classification with use this rule is defined as:

- classify as $class$ 0, if $class$ 1 neighbors + $class$ 2 neighbors = 0,
- classify as $class$ 1, if $class$ 1 neighbors > $class$ 2 neighbors,
- classify as $class$ 2, if $class$ 1 neighbors < $class$ 2 neighbors,
- classify as $rand(\{class\ 1, class\ 2\})$, if $class$ 1 neighbors = $class$ 2 neighbors.

The Fawcett's rule is productive enough for classification problems in little CA grids. This rule was presented in [1] as better than other, but it was tested and compared for only 81×81 wide CA grid. Therefore, in this paper are proposed modifications of Fawcett's rule into two patterns: partially and fully probabilistic. A proposed modification should strengthen an original and more accurate classify binary data, specially for large CA grid. The partially probabilistic modification ($n4\_V1\_nonstable\_PP$) is proposed as follows:

- classify as $class$ 0, if $class$ 1 neighbors + $class$ 2 neighbors = 0,
- classify as $class$ 1, with probability $p(1)$,
- classify as $class$ 2, with probability $p(2)$,

where probability are calculated form classified neighbours in the neighbourhood, i.e.: $p(i)=\frac{class\ i\ neighbors}{class\ 1\ neighbors+class\ 2\ neighbors}$, where $i=\{1,2\}$. It means that unclassified cell will change in to one of classified state with probability calculated from known states in the neighbourhood and suitable state.

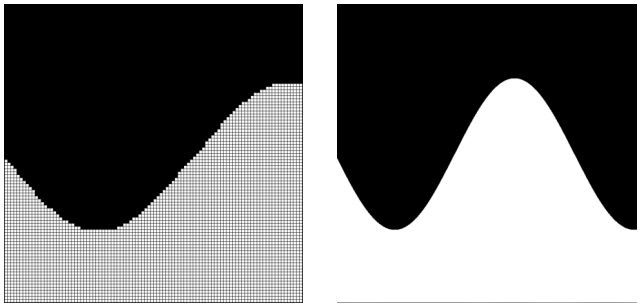
The full probabilistic modification ($n4\_V1\_nonstable\_FP$) is proposed as follows:

- classify as $class$ 0, with probability $p(0)$,
- classify as $class$ 1, with probability $p(1)$,
- classify as $class$ 2, with probability $p(2)$,

where probabilities are calculated form each class of neighbours in the neighbourhood, i.e.: $p(i)=\frac{class\ i\ neighbors}{\sum_{j=0}^{2} class\ j\ neighbors}$, where $i=\{0,1,2\}$. It means that unclassified cell could change in to one of classified state or stay unclassified with probability calculated from states of cells in neighbourhood.

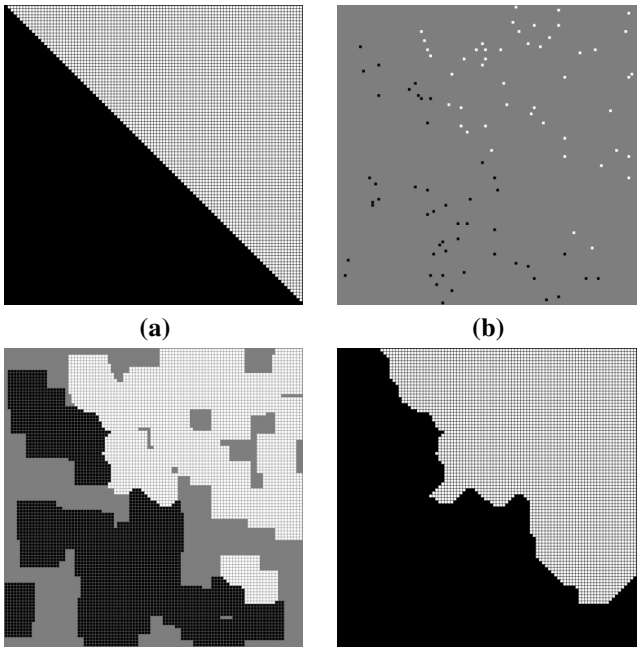
The $n4\_V1\_nonstable$ rule presented in [1] and newly proposed modifications will be examine on the sinusoidal testing sets (CA grids), shown in the Fig. 1.

In the Fig. 2(b, c and d) one can observe a classification process of the linear goal Fig. 2(a). In the classification was used $n4\_V1\_nonstable$ rule in CA size: 100×100. In the first step (see, Fig. 2(b)), 1% cells of known state (classified as class 1 - cells in black state or class 2 - cells in the white state) was randomly chosen from the linear goal. This initial configuration of CA was subject to the classification and the unclassified (cells in the gray state) with the use of $n4\_V1\_nonstable$ rule (temporary state of CA under classification process, see Fig. 2(c)). After the classification, the obtained result shows Fig. 2(d). The effectiveness of classification in presented example achieved level $93,38\%$ it means that 662 CA cells from 10000 CA cells have an incorrect classification.



(a) **(b)**

Fig. 1. Two-dimensional classifications of sinusoidal goals (examples): 100×100 **(b)** and 800×800 **(c)**.



(a) **(b)** **(c)** **(d)**

Fig. 2. An example of classification process with use of $n4\_V1\_nonstable$ rule in 2D CA with size 100×100 for linear goal **(a)**, initial configuration of CA - 1% of classified cells **(b)**, temporary CA state - classification in progress **(c)**, final CA state - after classification **(d)**.

Suppose, the $G_{N\times M}$ is the binary matrix of the classification goal. Also, the $F_{N\times M}$ is the binary matrix of the final configuration. The $E_{N\times M} = |G_{N\times M} - F_{N\times M}|$ is the absolute difference between two matrixes. Therefore, the Effectiveness (in %) is calculated by the formula: $Effectiveness = \frac{N*M-\sum_{i=1}^{N}\sum_{j=1}^{M} e_{(i,j)}}{N*M} * 100$, where $e_{(i,j)} \in E_{N\times M}$.

IV. Experimental Results

Proposed modifications of Fawcett's CA rule was tested and compared with original one. The results of analysis for the efficiency of classification are described above. During each test were used $N \times N$ CA, where $N \in \{100, 200, ..., 700, 800\}$, according to each of CA rules ($n4\_V1\_nonstable$, and newly proposed: $n4\_V1\_nonstable\_PP$, $n4\_V1\_nonstable\_FP$) with the von Neumann and Moore neighbourhood. In the goal, a 99% random states of CA cells was changed into the unclassified. So, only 1% CA cells stayed as classified. Such form of the goal was the initial configuration of CA to classification. After classification (reconstruction of goal) we obtained the finite CA state, and it was compared with the goal CA state; then the differences between both states (incorrect classified CA cells) and next ere calculated $Effectiveness$.

A. An analysis of the incorrect classifications for CA rules.

Classification in CA with the use of the Fawcett's rule, and new proposed probabilistic modification with von Neumann and Moore neighbourhood was realized in [8] for a linear goal during 1000 tests with above-presented conditions and assumptions. In [8] we can see that the effectiveness grows with the CA size, but it only depends on the fast growing area with the same class of data where the border with the different classes is increasing very slowly. The results showed that in general, the proposed modifications give better results in a classification for a linear goal than the original rule. For von Neumann neighbourhood, it could be observed for higher CA sizes (from 300 to 800) with both modifications in particular partially probabilistic one $n4\_V1\_nonstable\_PP$, where we can see that the effectiveness of new proposed modifications is better than for the original Fawcett's rule. Some kind anomaly one can see for CA size equal to 700×700 (see, Table 1 in [8]), where can be observed the best result of classification for the fully probabilistic classifier ($n4\_V1\_nonstable\_FP$), better than Fawcett's rule and much better than partially probabilistic one. For Moore neighbourhood both modification gives better results for each CA sizes except the size equal to 700×700 where Fawcett's rule classified effective (see, Table 2 in [8]).

In this paper is presented analysis mentioned above rules for sinusoidal goal (see, Fig. 1) with both von Neumann and Moore neighbourhood.

In the Tab. I one can see the results of classification for a sinusoidal goal in CA with the use of mentioned above three CA rules with Moore neighbourhood for 1000 tests. We can observe that the effectiveness of new proposed modifications is better than for the original Fawcett's rule for the sinusoidal goal. It could be observed for both modifications (marked in bold), in particular for fully probabilistic one ($n4\_V1\_nonstable\_FP$), except the tests for CA size equal to 400×400 and 600×600 (the underlined numbers mean the best results in general, from all analysed rules). We can also observe that effectiveness of classification with use of CA with Moore neighbourhood for a sinusoidal goal in much higher than for linear goal, it is easy to see in comparison the incorrect classification from Tab. I and Tab. 2 from [8].

TABLE I
CLASSIFICATION RESULTS OF GOAL SINUSOIDAL SET FOR CA RULES: $n4\_V1\_nonstable$, $n4\_V1\_nonstable\_PP$, $n4\_V1\_nonstable\_FP$ WITH MOORE NEIGHBOURHOOD. THE WORST EFFECTIVENESS AND (HIGHEST NUMBER OF INCORRECT CLASSIFIED CA CELLS) FROM 1000 TESTS.

CA size $N \times N$	**CA rule Fawcett's**	**CA rule partially probab.**	**CA rule fully probab.**
100×100	92,7% (730)	93,69% (**631**)	93,69% (**631**)
200×200	96,81% (1275)	97,1% (**1160**)	97,35% (**1062**)
300×300	98,21% (1613)	98,34% (**1493**)	98,4% (**1436**)
400×400	98,78% (1959)	98,82% (**1882**)	99,12% (1977)
500×500	99,04% (2388)	98,99% (2513)	99,12% (**2203**)
600×600	99,28% (**2606**)	99,22% (2817)	99,26% (2661)
700×700	99,37% (3076)	99,37% (3100)	99,4% (**2937**)
800×800	99,45% (3528)	99,47% (**3413**)	99,46% (**3465**)

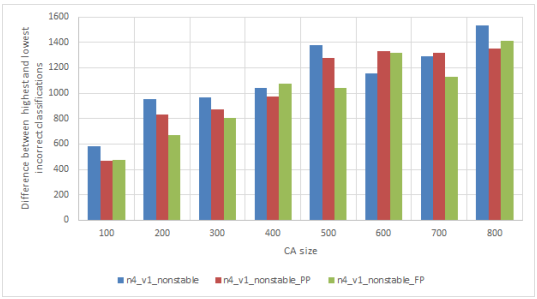
TABLE II
CLASSIFICATION RESULTS OF GOAL SINUSOIDAL SET FOR CA RULES: $n4\_V1\_nonstable$ (FAWCETT'S RULE), $n4\_V1\_nonstable\_PP$, $n4\_V1\_nonstable\_FP$ WITH VON NEUMANN NEIGHBOURHOOD. THE WORST EFFECTIVENESS AND (HIGHEST NUMBER OF INCORRECT CLASSIFIED CA CELLS) FROM 1000 TESTS.

CA size $N \times N$	**CA rule Fawcett's**	**CA rule partially probab.**	**CA rule fully probab.**
100×100	92,75% (725)	94,31% (**569**)	93,53% (**647**)
200×200	97,08% (1169)	97,43% (**1028**)	97,35% (**1061**)
300×300	98,44% (1403)	98,35% (1482)	98,44% (**1402**)
400×400	98,9% (1757)	98,92% (**1732**)	98,78% (1952)
500×500	99,13% (2184)	99,16% (**2102**)	99,08% (2310)
600×600	99,3% (**2507**)	99,28% (2588)	99,29% (2561)
700×700	99,41% (**2875**)	99,39% (2974)	99,41% (2913)
800×800	99,49% (3259)	99,49% (**3246**)	99,48% (3342)

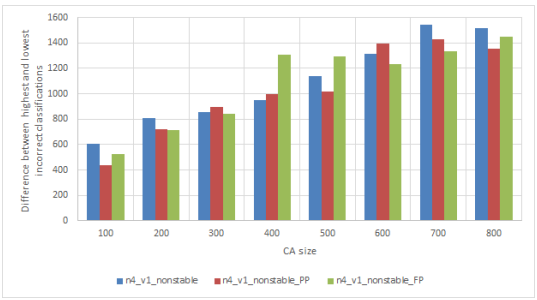
For the rule $n4\_V1\_nonstable\_FP$ the difference between number incorrect classification in linear and sinusoidal goal is equal to $\{210, 432, 436, 526, 726, 1008, 1171, 923\}$ for CA sizes $\{100, ..., 800\}$, and also for $n4\_V1\_nonstable\_PP$ differences are equal to $\{185, 167, 402, 564, 471, 617, 921, 1086\}$ respectively.

Similar results but not so high, are obtained for classification the sinusoidal goal with this three methods for CA with von Neumann neighbourhood. In the Tab. II one can see the results of classification for a sinusoidal goal in CA with the use of mentioned above three CA rules with von Neumann neighbourhood for 1000 tests. We can observe that the effectiveness of partially probabilistic modification ($n4\_V1\_nonstable\_PP$) is better than other rules for the sinusoidal goal (marked in bold and underlined). It can be observed for tests realised for most of analysed CA sizes (compare, Tab. 1 from [8] and Tab. II).

The observed highest effectiveness for modification of Fawcett's rule maybe is not so spectacular, but we should interpret it from the another point of view; it means the number of incorrectly classified CA cells should be analyzed. One can see that the modifications have in general the lowest number of incorrectly classified CA cells than the original rule (see, numbers in bold in Tab. II, Tab. I also Tab. 1 and Tab. 2 from [8]). For example, for the linear goal in the Tab. I for CA size 200×200, the fully probabilistic modi-



(a)



(b)

Fig. 3. Ranges of scattering for incorrect classifications for 1000 tests with a sinusoidal goal: **(a)** Moore neighbourhood, **(b)** von Neumann neighbourhood.

fication ($n4\_V1\_nonstable\_FP$) has 213 CA cells less than the original rule, and also partially probabilistic modification ($n4\_V1\_nonstable\_FP$) has 115 CA cells less.

So, the analysis of the worst effectiveness and highest number of incorrect classification for data presented above in Tables leads to the conclusion; if the worst results for classification with use of proposed modifications are better than for the original rule, then the new classifiers are more efficient because their the worst classifications are much better.

B. An analysis of the scattering ranges for incorrect classifications for CA rules.

The scattering range is the difference between the highest number of incorrect classifications and the lowest number of incorrect classification. The scattering ranges were calculated for each analysed CA rules for linear and sinusoidal goals with the use of both neighbourhoods von Neumann and Moore. The highest and lowest number of incorrect classifications were selected from 1000 tests for random initial configuration of CA.

We can observe in the Fig. 3 the scattering ranges for sinusoidal goal with Moore neighbourhood Fig. 3(a) and von-Neumann neighbourhood Fig. 3(b). One can see in Fig. 3(a) the scattering ranges for newly proposed modified CA rules are shorter in general than for original rule, in particular for fully probabilistic modification ($n4\_V1\_nonstable\_FP$) with the use of Moore neighbourhood. Moreover, remembering such rule has, in general, the lowest incorrect classifications we can conclude that fully probabilistic classifier shows up the more accurate and consistent with Moore neighbourhood for the sinusoidal goal.

Similarly, in Fig. 3(b) can be observed in general the shortest scattering ranges for proposed modification in particular for partially probabilistic modification ($n4\_V1\_nonstable\_FP$) of CA rule with the use of von Neumann neighbourhood.

For the linear goal, also we can observe the shortest scattering ranges in most cases of CA size, for the proposed new classifiers (see, [8] in particular the Moore neighbourhood).

V. Conclusions and Future Works

In the paper was presented problem of classification with use of three-state two-dimensional cellular automaton. Among classifiers were analysed the wide known Fawcett's rule and two proposed probabilistic modifications of such rule. The conducted experiments show the better effectiveness for classification applying a newly proposed classifiers (modifications) to reconstruction goals from state consisted of only 1% classified states. Moreover, the proposed modifications result in a much lower number of incorrectly classified CA cells.

Also, the analysis the data from Tab. I, Tab. II; Table 1 and Table 2 from [8] leads to the conclusion that seems to be a weak relationship between kind of modification and type of CA neighbourhood. For the von Neumann neighbourhood better classifications have obtained for partially probabilistic modification, and for Moore neighbourhood fully probabilistic modification are better.

Moreover, from Fig. 3 and Fig. 2 from [8] ensue in general the shortest scattering range for proposed modifications of Fawcett's rule than the original one. From that and above conclusions, we can understand that proposed probabilistic classifiers characterized by more accurate and consistent classification.

In the future works the newly proposed rules will also be examined with use of new testing goals like e.g.: parabolic, closed area (circular, square, concave boundary, ...), disjunctive and other. Also, will be analysed the effectiveness of classification depending on the number of unclassified states of CA cells initial configuration.

***Abstract*—We discuss several new methods for constructing approximate decision reducts from the rough set theory. We introduce generalized approximate majority decision reducts, which are an extension to standard approximate decision reducts known from literature but with improved calculation performance and complexity. We also discuss the relationship and differences of the new approximate decision reduct notion with so called decision bireducts – another type of approximate decision reducts.**

***Keywords*-Feature Subset Selection; Rough Sets; Approximate Decision Reducts; Decision Bireducts**

I. Introduction

ATTRIBUTE subset selection plays an important role in knowledge discovery [1]. It establishes the basis for more efficient classification, prediction and approximation models. It also provides the users with a better insight into data dependencies. In this paper, we concentrate on attribute subset selection methods originating from the theory of rough sets [2]. There are numerous rough-set-based algorithms aimed at searching for so called *reducts* – irreducible subsets of attributes that satisfy predefined criteria for keeping enough information about decisions. Those criteria are verified on the training data and, usually, they encode the risk of misclassification by if-then decision rules with their antecedents referring to the values of investigated attribute subsets and their consequents referring to decisions.

Original definition of a reduct is quite restrictive, requiring that it should determine decisions or, if data inconsistencies do not allow full determinism, provide the same level of information about decisions as the complete set of attributes. There are a number of approaches to formulate and search for approximate or inexact reducts, which *almost* preserve the decision information [3]. Approximate reducts are usually smaller than standard ones, providing the basis for learning more efficient classifiers [4], [5].

In our previous work [6] we compared approximate decision reducts based on feature subset quality functions [7], [8] with decision bireducts [9] – another extension to the rough set framework of decision reducts. In short, a decision bireduct is an irreducible feature subset which preserves the information about the decision but only on selected objects from the data set. The feature subset cannot be reduced as well as the object subset cannot be further expanded without violating the decision functional dependence.

In this article we show new methods for calculating approximate decision reducts based on generalized majority decision (GMD) function. The concept of GMD function might be considered as an modification to a very well known concept of generalized decision function known from the rough set theory. We also consider a few variations of decision rule-based classifiers induction from the discussed approximate decision reducts. We introduce the concept of *exception* decision rules which are created during the reduct calculation process. The use of *exceptions* can be helpful in case we need to construct simplified decision models [10] and preserve more information about the original data set. We also explain the relationship of the proposed methods to the notion of decision bireducts and propose a new algorithm for decision bireducts calculation based on GMD function.

The remainder of this paper is organized as follows. Section II briefly describes the concept of generalized decision function. In Section III we explain approximate decision reducts. In Sections IV and V we present a new definition of approximate decision reducts and show new algorithms in Section VI. In Section VII we introduce the concept of *exception* decision rules. In Section VIII we show relationship to the decision bireducts and a new way of decision bireduct calculation. Finally, we show experiment results in Section IX and conclude our work in Section X.

II. Decision Reducts and Generalized Decision

We use the standard notion of a decision system to represent data [2]. By a decision system we mean a tuple $\mathbb{A} = (U, A \cup \{d\})$, where U is a set of objects and A is a set of attributes and $d \notin A$ is a distinguished decision attribute. For simplicity, we refer to the elements of U using their ordinal numbers $i = 1, ..., |U|$, where $|U|$ denotes the cardinality of U. We treat attributes $a \in A$ as functions $a : U \rightarrow V_a$, V_a denoting a's value domain. The values $v_d \in V_d$ correspond to decision classes that we want to describe using the values of attributes in A. Each subset $B \subseteq A$ partitions the space U into *equivalence classes*. For such a division we get the partition space denoted as $U/B = \{E_1, \ldots, E_t\}$ where $E_t \subseteq U$. Each equivalence class is defined as $E_t = \{x \in U : B(x) = v_t\}$ where v_t is a vector of values on attributes B. We will further refer the set of objects with particular decision k as X_k.

Definition 1. *We say that $B \subseteq A$ is a decision reduct for $\mathbb{A} = (U, A \cup \{d\})$ if and only if it is an irreducible subset*

978-83-60810-90-3/$25.00

of features such that each pair $i, j \in U$ satisfying inequality $d(i) \neq d(j)$ is discerned by B.

Definition 1 works well in case of consistent decision tables, however in case of inconsistent data no attribute reduction is possible, in fact, even the whole attribute set A cannot be considered to be a decision reduct itself. There are many alternative definitions of decision reducts that could be applied to inconsistent decision tables, e.g., subsets of features that preserve the same positive region as the full set of attributes. Another example could be a decision reduct based on generalized decision function [2]:

Definition 2. *For a given decision table $\mathbb{A} = (U, A \cup \{d\})$, we say that a **generalized decision function** is a function $\partial_d : 2^U \to 2^{V_d}$ defined as follows:*

$$\partial_d(E) = \{k : X_k \cap E \neq \emptyset\} \tag{1}$$

The cardinality of a generalized decision may be used to express the level of inconsistency in describing decision attribute by subsets of features. In particular, if $|\partial_d([x]_A)| = 1$, for any $x \in U$, then the decision table $\mathbb{A} = (U, A \cup \{d\})$ is said to be *consistent*. Otherwise it is *inconsistent*. The example of a generalized decision is presented in Table I in column denoted as $\partial_d([x]_A)$.

Definition 3. *Let $\mathbb{A} = (U, A \cup \{d\})$ be given. We say that $B \subseteq A$ is a ∂-decision superreduct if and only if the following condition holds:*

$$\bigvee_{x \in U} \partial_d([x]_B) = \partial_d([x]_A) \tag{2}$$

We say that B is a ∂-decision reduct if and only if it is a ∂-superreduct and none of its proper subsets satisfy the above condition.

III. Foundations of Approximate Reducts

There are a variety of methods of searching for approximate decision reducts (e.g. [11], [12], [13]). The criteria usually include formulas for functions measuring degrees of decision information induced by subsets of features and thresholds for those functions' values specifying which subsets of attributes are *good enough*. The choice of functions may depend on the nature of particular data sets and methods of learning classifiers based on reduced sets of attributes. In order to follow the filter approach to feature subset selection, we need to design some measures that evaluate particular feature subsets in the selection process. From this point of view, the rough set literature may be regarded as a source of measures that draw correspondence between feature subsets and rule-based classifiers corresponding to those subsets, where each subset of attributes $B \subseteq A$ yields a set of decision rules based on all combinations of its values in U and the consecutive value is chosen according to some criteria.

Let us define a measure $F : P(A) \to \Re$ which evaluates the degree of influence $F(B)$ of subset $B \subseteq A$ in d. Then one can decide which features may be removed from A without significant loss of accuracy.

Definition 4. *Let $\mathbb{A} = (U, A \cup \{d\})$ and approximation threshold $\varepsilon \in [0, 1)$ be given. We say that $B \subseteq A$ is an (F, ε)-approximate decision reduct if and only if it satisfies the following condition:*

$$F(B) \geq (1 - \varepsilon)F(A) \tag{3}$$

and none of its proper subsets $C \subseteq B$ does it.

There are many examples how function F can be defined. Let us focus on two examples. The first is *Majority* measure (further denoted as M), proposed in [7]:

$$M(B) = \sum_{E \in U/B} \frac{|E|}{|U|} \max_{k \in V_d} \frac{|X_k \cap E|}{|E|} \tag{4}$$

The function M points to a decision value that appears the most frequently within a particular equivalence class E. It means that if we need to decide which decision should be attached to objects from a particular class, then we always choose the most frequent decision that was observed in the training data. Based on the measure M, one could generate decision rules for which the rules' right sides are the most frequent decisions for $E \in U/B$. Another example of F refers to a Bayesian extension of the classical rough set model, where rules induced by a given subset of attributes are pointing at the decision classes which become maximally frequent comparing to their overall occurrence in the data. This function called *Relative information gain* measure (further denoted as R) was proposed in [8].

$$R(B) = \frac{1}{|V_d|} \sum_{E \in U/B} \max_{k \in V_d} \frac{|X_k \cap E|}{|X_k|} \tag{5}$$

In our research the permutation based *REDORD* algorithm introduced in [14] is used as a baseline algorithm (see Algorithm 1).

Algorithm 1 Permutation-based (F, ε)-REDORD Algorithm

Input: $\mathbb{A} = (U, A \cup \{d\})$, $\varepsilon \in [0, 1)$,
$\sigma : \{1, ..., n\} \to \{1, ..., n\}$, $n = |A|$
Output: (F, ε) approximate decision reduct $B \subseteq A$

```
B ← A
for i = 1 → n do
    if F(B \ {a_σ(i)}) ≥ (1 − ε)F(A) then
        B ← B \ {a_σ(i)}
    end if
end for
return B
```

IV. Generalized Majority Decision Reducts

Approximate decision reducts calculation methods allow some level of interaction with users designing decision models. However, this interaction is only limited to a single parameter describing the degree of approximation that refers to the allowed overall misclassification rate of a decision model. What is more restricting is that the decision model based on

approximate decision reduct is always pointing to majority decision within particular equivalence classes. We would like to give the user the ability to decide about the decision classes distribution within each E. Based on the idea of generalized decision we formulate *generalized majority decision* (described in this section) and *generalized approximation majority decision* concepts. The approximate version is described in the next section.

Definition 5. *For a given decision table $\mathbb{A} = (U, A \cup \{d\})$, we say that a **generalized majority decision function** is a function $m_d : 2^U \rightarrow 2^{V_d}$ defined as follows:*

$$m_d(E) = \{k : |X_k \cap E| = \max_j(|X_j \cap E|)\} \tag{6}$$

Generalized majority decision function reflects the choice of most frequent decision classes within subsets $E \subseteq U$. In Table I we present an example of generalized decision and generalized majority decision attributes denoted $\partial_d([x]_A)$ and $m_d([x]_A)$ respectively.

Table I
DECISION TABLE AND GENERALIZED DECISION AND GENERALIZED MAJORITY DECISION ATTRIBUTES

Id	a_1	a_2	a_3	a_4	d	$\partial_d([x]_A)$	$m_d([x]_A)$
x_1	1	1	2	2	0	{0,1}	{0,1}
x_2	1	1	2	2	1	{0,1}	{0,1}
x_3	1	1	2	2	1	{0,1}	{0,1}
x_4	1	1	2	2	0	{0,1}	{0,1}
x_5	3	3	1	2	1	{0,1}	{0,1}
x_6	3	3	1	2	0	{0,1}	{0,1}
x_7	2	3	1	2	1	{1}	{1}
x_8	1	2	2	1	2	{0,1,2}	{1,2}
x_9	1	2	2	1	2	{0,1,2}	{1,2}
x_{10}	1	2	2	1	1	{0,1,2}	{1,2}
x_{11}	1	2	2	1	1	{0,1,2}	{1,2}
x_{12}	1	2	2	1	0	{0,1,2}	{1,2}
x_{13}	2	1	1	1	1	{1}	{1}
x_{14}	2	2	1	1	0	{0}	{0}

In case of consistent decision tables $|m_d([x]_A)| = 1$. In case of inconsistent decision tables the cardinality of $m_d([x]_A)$ will be greater than one only in a case of an equivalence class with more than one equally distributed decision values. However, let us notice that one could be interested in calculating $m_d([x]_B)$ for any subset of features $B \subseteq A$ containing the smaller number of attributes. In such a case the equivalence classes are relatively large, and equal frequencies of decision values are more common.

Definition 6. *Let $\mathbb{A} = (U, A \cup \{d\})$ be given. We say that $B \subseteq A$ is an $(m, =)$-decision superreduct if and only if the following condition holds:*

$$\bigwedge_{x \in U} m_d([x]_B) = m_d([x]_A) \tag{7}$$

We say that B is an $(m, =)$-decision reduct if and only if it is an $(m, =)$-superreduct and none of it proper subsets satisfy the above condition.

Proposition 1. *Let $\mathbb{A} = (U, A \cup \{d\})$ be given. If $B \subseteq A$ is an $(m, =)$-decision superreduct, then:*

$$\forall_{x,y \in U} m_d([x]_A) \neq m_d([y]_A) \Rightarrow \exists_{a \in B} a(x) \neq a(y) \tag{8}$$

Proof: First let us notice that we can transform the above equation to the following form:

$$\forall_{x,y}\Big(\forall_{a \in B} a(x) = a(y) \Rightarrow m_d([x]_A) = m_d([y]_A)\Big) \tag{9}$$

Let us consider any x, y such that $\bigwedge_{a \in B} a(x) = a(y)$. We need to show that $m_d([x]_A) = m_d([y]_A)$. Based on Definition (6) we know that $m_d([x]_A) = m_d([x]_B)$ and that $m_d([y]_A) = m_d([y]_B)$. Because $[x]_B = [y]_B$, then $m_d([x]_B) = m_d([y]_B)$, this also $m_d([x]_A) = m_d([y]_A)$. Let us take any $x \in U$. We need to show that $m_d([x]_B) = m_d([x]_A)$. Let us take any $v_k \in m_d([x]_A)$. We need to show that $v_k \in m_d([x]_B)$. If $v_k \in m_d([x]_A)$, then based on Equation (9) we have $v_k \in m_d([u]_A)$ for all $y \in [x]_B$. This means, that v_k has maximal frequency among all decision classes for all A-indiscernibility classes contained in $[x]_B$. This means that is also has maximum frequency in $[x]_B$. Thus:

$$m_d([x]_B) \subseteq m_d([x]_A) \tag{10}$$

always holds.
In Proposition (3) we will show that if the intersection of $m_d([y]_A)$ sets for all $y \in [x]_B$ for a given $x \in U$ is not empty, then the following holds:

$$m_d([x]_B) \subseteq m_d([x]_A) \tag{11}$$

Based on Equation (9) we know that this intersection is nonempty. Based on Equations (9) and (10) we have

$$m_d([x]_B) = m_d([x]_A) \tag{12}$$

■

Let us propose also another method of using the m_d function to define attribute reduction criteria, where we are not interested in the full discernibility with regard to the symbolic representation of generalized majority decision but we apply a weaker condition.

Definition 7. *Let $\mathbb{A} = (U, A \cup \{d\})$ be given. We say that $B \subseteq A$ is an $(m, \subseteq)$-decision superreduct if and only if the following condition holds:*

$$\bigwedge_{x \in U} m_d([x]_B) \subseteq m_d([x]_A) \tag{13}$$

We say that B is an $(m, \subseteq)$-decision reduct if and only if it is an $(m, \subseteq)$-superreduct and none of it proper subsets satisfy the above condition.

The following result emphasizes the importance of Definition 7.

Proposition 2. *Let $\mathbb{A} = (U, A \cup \{d\})$ be given. $B \subseteq A$ is $(m, \subseteq)$-decision superreduct if and only if the following condition holds:*

$$M(B) = M(A) \tag{14}$$

Let us further notice that Definition 7 is more flexible than Definition 6 and it usually allows more attribute reduction.

Proposition 3. *Let $\mathbb{A} = (U, A \cup \{d\})$ be given. $B \subseteq A$ is an $(m, \subseteq)$-decision superreduct if and only if:*

$$\bigwedge_{x \in U} \bigcap_{y \in [x]_B} m_d([y]_A) \neq \emptyset \tag{15}$$

Proof: Let us take any $x \in U$ and let us consider all objects $y \in [x]_B$. We know that:

$$\bigwedge_{y \in [x]_B} m_d([y]_B) \subseteq m_d([y]_A) \tag{16}$$

Because $y \in [x]_B$, then $[y]_B = [x]_B$. Thus:

$$\bigwedge_{y \in [x]_B} m_d([x]_B) \subseteq m_d([y]_B) \tag{17}$$

and therefore:

$$\bigwedge_{y \in [x]_B} m_d([x]_B) \subseteq \bigcap_{y \in [x]_B} m_d([y]_A) \tag{18}$$

Thus, $\bigcap_{y \in [x]_B} m_d([y]_A)$ cannot be empty.
Let us take any $x \in U$ and let us consider all objects $y \in [x]_B$. Because, we know that:

$$\bigcap_{y \in [x]_B} m_d([y]_A) \neq \emptyset \tag{19}$$

we also know that there exists such v that $v \in m_d([y]_A)$ for every $y \in [x]_B$. By Definition (5) we know that v must be one of the most frequent decision values on all equivalence classes $[y]_A$ such that $y \in [x]_B$. This is because $[x]_B$ is a sum of some disjoint blocks $E \in U/A$, which are represented by $[y]_A$ For that reason it must be also one of the most frequent values in the whole $[x]_B$ i.e. $v \in m_d([x]_B)$. For any other decision v' contained in $m_d([x]_B)$, it would have to be as frequent in $[x]_B$ as the decision value v. But if would require for v' to be as frequent as v in all blocks $E_A \in U/A, E_A \subseteq E_B$. Thus, it would be also $v' \in m_d(E_A)$ for all such blocks. In particular we would have:

$$m_d([x]_B) \subseteq m_d([x]_A) \tag{20}$$

■

Proposition 4. *Let $\mathbb{A} = (U, A \cup \{d\})$ be given. $B \subseteq A$ is an $(m, \subseteq)$-decision superreduct if and only if:*

$$\bigwedge_{x \in U} \bigcap_{y \in [x]_B} m_d([y]_A) = m_d([x]_B) \tag{21}$$

Let us illustrate the difference between $(m, \subseteq)$- and $(m, =)$-decision reducts. Let us consider a decision table presented in Table II. All three objects have exactly the same values on feature subset B but different values on attribute a. According to definition of $(m, =)$-decision reduct attribute a cannot be removed. $(m, =)$-decision reduct requires that generalized majority decision sets are exactly the same for merged equivalence classes. In case of $(m, \subseteq)$-decision reduct this attribute can be removed as it requires only set inclusion.

Table II
ATTRIBUTE REMOVAL IN $(m, \subseteq)$- AND $(m, =)$-*decision reducts*.

Id	B	a	$m_d([x]_{B \cup \{a\}})$
x_1		1	{0,1}
x_2	...	2	{0,1,2}
x_3		3	{0,2}

V. GENERALIZED APPROXIMATE MAJORITY DECISION

The generalized majority decision function points only to a single most frequent decision for a given equivalence class. Its drawback is that it does not keep any information about minority decision classes and there is no way to control the threshold how much information about the minority decision classes should be maintained. We propose to determine this threshold based on decision class distribution within equivalence classes and a level of approximation given by the user.

Let us introduce a definition of *generalized approximate majority decision* function. In comparison to Equation 1 we include not only the most frequent decision values but also those which are almost as frequent as the majority decision values. We express this statement by introducing a threshold parameter ε that controls the ratio between allowed decision values and the majority decision.

Definition 8. *For a given decision table $\mathbb{A} = (U, A \cup \{d\})$ and approximation threshold $\varepsilon \in [0, 1)$, we say that a **generalized approximate majority decision function** is a function $m_d^\varepsilon : 2^U \to 2^{V_d}$ defined as follows:*

$$m_d^\varepsilon(E) = \{k : |X_k \cap E| \geq (1 - \varepsilon) \max_j |X_j \cap E|\} \tag{22}$$

Proposition 5. *For $\varepsilon = 0$ and $\varepsilon \to 1^-$ we have:*

$$\bigwedge_E m_d^0(E) = m_d(E) \qquad \text{and} \qquad \bigwedge_E \lim_{\varepsilon \to 1^-} m_d^\varepsilon(E) = \partial_d(E)$$

Let us propose an alternative way of the attribute reduction based on the new concept of $(m^\varepsilon, \cap)$-decision reduct and generalized decision set intersections. Let us further notice that this approach is equivalent to the previous one for $\varepsilon = 0$.

Definition 9. *Let $\mathbb{A} = (U, A \cup \{d\})$ be given. We say that $B \subseteq A$ is an $(m^\varepsilon, \cap)$-decision superreduct if and only if:*

$$\bigwedge_{x \in U} \bigcap_{y \in [x]_B} m_d^\varepsilon([y]_A) \neq \emptyset \tag{23}$$

We say that B is an $(m^\varepsilon, \cap)$-decision reduct if and only if it is an $(m^\varepsilon, \cap)$-decision superreduct and none of it proper subsets satisfy the above condition.

Proposition 6. *Let $\mathbb{A} = (U, A \cup \{d\})$ be given. The following holds for every subset $B \subseteq A$:*

$$\bigwedge_{x \in U} \bigcap_{y \in [x]_B} m_d^\varepsilon([y]_A) \subseteq m_d^\varepsilon([x]_B) \tag{24}$$

Proposition 7. *If $B \subseteq A$ in an $(m^\varepsilon, \cap)$-decision superreduct then the following inequality holds:*

$$M(B) \geq (1 - \varepsilon) M(A) \tag{25}$$

Let us notice that in case of Proposition 2 we have the equivalence between of $B \subseteq A$ being an $(m, \subseteq)$-decision reduct and given the equality $M(B) = M(A)$, whereas in case of Proposition 7 and $(m^{\varepsilon}, \cap)$-decision reduct we have only the implication.

In the traditional decision rule induction approach one can use contents of a decision table and the set of attributes B to induce decision rules. Similarly, decision rules calculated with respect to the generalized majority decisions take such a form that the ascendants are based on values of B over objects $x \in U$ but consequents point at disjunctions of possible decisions belonging to $m_d^{\varepsilon}(E)$. For example, let us consider objects $\{x_8, x_9, x_{10}, x_{11}, x_{12}\}$ from Table I. Based on these objects we can produce the following decision rule:

$$a_1 = 1 \wedge a_2 = 1 \wedge a_3 = 2 \wedge a_4 = 1 \Rightarrow d = 1 \vee d = 2$$

It is important to note that such a rule could be rewritten as two separate rules, both having the same support and confidence:

$$a_1 = 1 \wedge a_2 = 2 \wedge a_3 = 2 \wedge a_4 = 1 \Rightarrow d = 1$$
$$a_1 = 1 \wedge a_2 = 2 \wedge a_3 = 2 \wedge a_4 = 1 \Rightarrow d = 2$$

In fact all decision values belonging to generalized approximate majority decision set are treated as equally distributed within a particular equivalence class. Moreover, all decision rules based on this equivalence class are considered to have equal quality support and confidence.

VI. Heuristic Search for Approximate Reducts

The above results could be utilized in a procedure for attribute reduction. First we calculate generalized majority decision for the whole attribute set A. Next we can remove the attribute a whenever the Equality 23 is satisfied. This means that if the intersection of all generalized decision of smaller equivalence classes induced by $B \cup \{a\}$ is nonempty we can remove attribute a without a significant loss of information. Algorithm 2 presents the procedure that utilizes *Reduce* function described in Algorithm 3. In Table III and Table IV we give brief examples of attribute removal tries, the unsuccessful and successful, respectively.

Table III
Impossible removal of attribute a_2

Id	a_1	a_3	a_4	$m_d^{\varepsilon}([x]_B)$	
$\{x_1, ..., x_4\}$	1	2	2	{0,1}	✓
$\{x_5, x_6\}$	3	1	2	{0,1}	✓
$\{x_7\}$	2	1	2	{1}	✓
$\{x_8 ... x_{12}\}$	1	2	1	{1,2}	✓
$\{x_{13} \cup x_{14}\}$	2	1	1	$\{1\} \cap \{0\} = \emptyset$	✗

Let us focus on decision rules that could be generated before and after removal of attribute a_1 based on objects $\{x_5, x_6, x_7\}$ Before removal of attribute a_1 that rules are as follow:

$$a_1 = 3 \wedge a_2 = 3 \wedge a_3 = 1 \wedge a_4 = 2 \Rightarrow d = 0 \vee d = 1$$
$$a_1 = 2 \wedge a_2 = 3 \wedge a_3 = 1 \wedge a_4 = 2 \Rightarrow d = 1$$

Algorithm 2 Generalized Majority Decision Reduct (GMDR2)

Input: $\mathbb{A} = (U, A \cup \{d\})$, $\varepsilon \in [0, 1)$, $\sigma : \{1, ..., n\} \to \{1, ..., n\}$, $n = |A|$,
$\mathbb{A}_{temp}$ - temporary decision table for storing equivalence classes)
Output: $B \subseteq A$

```
Calculate Generalized Majority Decision m_d^ε(E_A) for all objects in 𝔸
B ← A
E_B ← CreateEquivalenceClasses(A)
for i = 1 → n do
    E_C ← Reduce(E_B, B, a_σ(i))
    if E_C ≠ E_B then
        E_B = E_C
        B ← B \ {a_σ(i)}
    end if
end for
return B
```

Algorithm 3 Attribute reduction function

Input: Collection of equivalence classes $E_B \in U/B$,
Attribute subset $B \subseteq A$, Candidate attribute $a \in B$ for removal
Output: Collection of equivalence classes $E_C \in U/C$ where $C \subseteq B$ if attribute $a \in B$ was removed or $E_B \in U/C$ otherwise

```
function REDUCE(E_B, B, {a})
    C ← B \ {a}
    E_C ← ∅
    for all EquivalenceClasses e ∈ E_B do
        DEC ← ∅
        v_B ← GetInstance(e)
        v_C ← Remove(v_B, {a})
        e_tmp ← Find(E_C, v_C)
        if e_tmp ≠ NULL then
            DEC ← GetDec(e_tmp) ∩ GetDec(e)
            if |DEC| > 0 then
                SetDec(e_tmp, DEC)
            else
                return E_B
            end if
        else
            AddEquivalenceClass(E_C, e_tmp)
        end if
    end for
    return E_C
end function
```

After removal of attribute a_1:

$$a_2 = 3 \wedge a_3 = 1 \wedge a_4 = 2 \Rightarrow d = 1$$

From this perspective we can understand the described procedure as creating a lowe approximation of decision rules generated on the whole attribute set.

Table IV
SUCCESSFUL REMOVAL OF ATTRIBUTE a_1

Id	a_2	a_3	a_4	$m_d^{\varepsilon}([x]_B)$	
$\{x_1, ...x_4\}$	1	2	2	{0,1}	✓
$\{x_5, x_6\} \cup \{x_7\}$	3	1	2	$\{0,1\} \cap \{1\} = \{1\}$	✓
$\{x_8 ... x_{12}\}$	2	2	1	$\{1,2\}$	✓
$\{x_{13}\}$	1	1	1	$\{1\}$	✓
$\{x_{14}\}$	2	1	1	$\{0\}$	✓

VII. APPROXIMATE DECISION REDUCTS WITH EXCEPTIONS

Let us propose an another way of expressing levels of allowed inconsistency in the decision model. We introduce a new approximation threshold ϕ that relates to the maximal ratio of objects that can be misclassified. By analogy, we introduce a new definition of $(m^{\phi}, \cap)$-decision reduct which utilizes the generalized majority decision function.

Definition 10. *Let $\phi \in [0,1)$ and $\mathbb{A} = (U, A \cup \{d\})$ be given. Subset $B \subseteq A$ is an $(m^{\phi}, \cap)$-decision superreduct if and only if there exists subset $X \subseteq U$ satisfying inequality $|X| \geq (1-\phi)|U|$, such that the following condition holds:*

$$\bigvee_{x \in X} \bigcap_{y \in [x]_B \cap X} m_d([y]_A) \neq \emptyset \tag{26}$$

We say that B is an $(m^{\phi}, \cap)$-decision reduct if and only if it is an $(m^{\phi}, \cap)$-decision superreduct and none of its proper subsets satisfy the above conditions.

The idea behind $(m^{\phi}, \cap)$-decision reducts $B \subseteq A$ is to cover sufficiently the data set with decision rules constructed using attributes in B and provide a comparable level of information to decision rules constructed using all features from A. If $B \subseteq A$ is an $(m^{\phi}, \cap)$-decision superreduct, then there exists subset $X \subseteq U$ satisfying inequality $|X| \geq (1-\phi)|U|$ and condition (26) such that X is definable by A, which means that X is the set-theoretic sum of some equivalence classes of U/A. This explains in what sense subsets $X \subseteq U$ can be treated as set-theoretic sum of supports of premises of rules induced by A whose information is kept at comparable level after shortening them to more general decision rules induced by B. Thus, from now on, we will implicitly assume that all subsets $X \subseteq U$ discussed in context of $(m^{\phi}, \cap)$-decision reducts take a form of sums of some equivalence classes of U/A.

Proposition 8. *If $B \subseteq A$ is an $(m^{\phi}, \cap)$-decision superreduct, then the following inequality holds*

$$M(B) \geq M(A) - \phi \tag{27}$$

Let us notice that we could combine definitions of $(m^{\phi}, \cap)$-decision reduct with $(m^{\varepsilon}, \cap)$-decision reduct and formulate a combined definition of $(m^{\varepsilon,\phi}, \cap)$-decision reduct. For simplicity, we will further assume that $\varepsilon = 0$.

In Section IV we discussed an example showing that the attribute a_2 cannot be removed. This was due to the fact that objects x_{13} and x_{14} have an empty intersection of their generalized majority decision sets. In other words, there was only one object that was blocking the algorithm from reducing the number of features. If we removed either object x_{13} or object x_{14} from the discussed decision table the reduction would be possible but we would also lose some information. Exception rules allow us to reduce the number of features and at the same time to save additional information about lost objects. Let us focus on Tables V and VI where we again consider the same example but this time we can remove attribute a_2. We create the following exception rule (supported only by one object ($\{x_{14}\}$) but with confidence = 1.0)

$$a_1 = 2 \wedge a_2 = 1 \wedge a_3 = 1 \wedge a_4 = 1 \Rightarrow d = 0$$

In the next step we try to remove another attribute, again if some objects do not allow attribute removal we can remove them and save in form of exception rules, remembering that no more than $\phi \cdot |U|$ objects can be removed in total. This procedure is presented as Algorithm 4.

During the classification phase, the exception rules are always searched in the first place. If a proper exception rule is

Algorithm 4 Attribute reduction function with exceptions

Input: Collection of equivalence classes $E_B \in U/B$, Approximation degree $\phi \in [0,1)$; Attribute subset $B \subseteq A$, Candidate attribute $a \in B$ for removal

Output: Updated exception rules set R_{ex}, Collection of equivalence classes $E_C \in U/C$ where $C \subseteq B$ if attribute $a \in B$ was removed or $E_B \in U/B$ otherwise

```

found, we do not search any other rules related to this reduct, i.e., any shorter more general rule that had been created in the subsequent stages of the learning process.

VIII. BIREDUCTS AND GENERALIZED MAJORITY DECISION

The first formulation of decision bireducts occurred in [9], [6], where their Boolean characterization was described and a simple ordering algorithm aimed at their heuristic extraction from data was proposed by an analogy to classical decision reducts. The motivation to introduce decision bireducts was to allow for explicit analysis whether classifiers that use different selected subsets of attributes do not repeat classification mistakes on the same objects in the training data set. Experiments reported in [9] show that diversification of subsets of attributes with this respect may be important in practice.

Definition 11. *Let $\mathbb{A} = (U, A \cup \{d\})$ and subsets $B \subseteq A$, $\mathcal{X} \subseteq U$ be given. We say that B determines d within $\mathcal{X}$, further denoted as $B \Rrightarrow_{\mathcal{X}} d$, if and only if B discerns all pairs $u_i, u_j \in \mathcal{X}$ such that $d(u_i) \neq d(u_j)$. Further, we say that the pair $(\mathcal{X}, B)$ is a decision bireduct if and only if the following holds:*

1) *There is $B \Rrightarrow_{\mathcal{X}} d$,*
2) *There is no proper subset $B' \subsetneq B$ such that $B' \Rrightarrow_{\mathcal{X}} d$,*
3) *There is no proper superset $\mathcal{X}' \supsetneq \mathcal{X}$ such that $B \Rrightarrow_{\mathcal{X}'} d$.*

The original ordering algorithm to calculate a decision bireduct for a given data set is presented in Algorithm 5. It is recalled here as a reference point to a modified version of the algorithm (presented as Algorithm 6) that works with equivalence classes instead of single objects and with generalized majority decision intersections constraint instead of the original discernibility condition.

A major difference of the ordering algorithm for decision bireducts extraction, comparing to the ordering algorithms obtaining decision reducts (reduction on attributes only, e.g., Algorithm 2), can be observed in the main loop iterating on both the attributes and the objects at the same time. An appropriate action is taken, i.e., either removal of unnecessary attribute or addition of an object to the result, on base of a given condition for the generalized majority decisions intersections.

It is worth to notice that the reduct and bireduct versions of the generalized majority decision algorithms are not equivalent, i.e., there exist data sets for which certain results can be obtained only by one of the methods.

As an example, let us consider the following fragment of a decision table. All presented objects have the same values on feature subset B and the specified values on attributes a and

Algorithm 5 Original Ordering Decision Bireduct Algorithm

Input: a decision table $\mathbb{A} = (U, A \cup \{d\})$, σ – a permutation of a set $\{1, \ldots, |U| + |A|\}$
Output: a decision bireduct for $\mathbb{A}$

$\mathcal{X}_0 \leftarrow \emptyset, B_0 \leftarrow A$
for $i = 1 \rightarrow |U| + |A|$ **do**
  $B_i \leftarrow B_{i-1}$
  $\mathcal{X}_i \leftarrow \mathcal{X}_{i-1}$
  if $\sigma(i) \leq |U|$ **then**
    if $B_i \Rrightarrow_{\mathcal{X}_i \cup \{u_{\sigma(i)}\}} d$ **then**
      $\mathcal{X}_i \leftarrow \mathcal{X}_i \cup \{u_{\sigma(i)}\}$
    end if
  else
    if $B_i \setminus \{a_{\sigma(i)-|U|}\} \Rrightarrow_{\mathcal{X}_i} d$ **then**
      $B_i \leftarrow B_i \setminus \{a_{\sigma(i)-|U|}\}$
    end if
  end if
end for
return $(\mathcal{X}_{|U|+|A|}, B_{|U|+|A|})$

Algorithm 6 Ordering Generalized Majority Decision Bireduct Algorithm

Input: a decision table $\mathbb{A}^{m_d} = (U^{m_d}, A \cup \{m_d\})$ obtained from $\mathbb{A} = (U, A \cup \{d\})$, where equivalence classes induced by A are considered objects in $\mathbb{A}^{m_d}$, i.e., $U^{m_d} = U/A$ and where m_d is used to compute their decision values, σ – a permutation of a set $\{1, \ldots, |U^{m_d}| + |A|\}$
Output: a decision bireduct for $\mathbb{A}^{m_d}$

$\mathcal{X}_0 \leftarrow \emptyset, B_0 \leftarrow A$
for $i = 1 \rightarrow |U^{m_d}| + |A|$ **do**
  $B_i \leftarrow B_{i-1}$
  $\mathcal{X}_i \leftarrow \mathcal{X}_{i-1}$
  if $\sigma(i) \leq |U^{m_d}|$ **then**
    if $Test^{m_d}(\mathcal{X}_i \cup \{u^{m_d}_{\sigma(i)}\}, B_i)$ **then**
      $\mathcal{X}_i \leftarrow \mathcal{X}_i \cup \{u^{m_d}_{\sigma(i)}\}$
    end if
  else
    if $Test^{m_d}(\mathcal{X}_i, B_i \setminus \{a_{\sigma(i)-|U^{m_d}|}\})$ **then**
      $B_i \leftarrow B_i \setminus \{a_{\sigma(i)-|U^{m_d}|}\}$
    end if
  end if
end for
return $(\mathcal{X}_{|U^{m_d}|+|A|}, B_{|U^{m_d}|+|A|})$

Algorithm 7 Test function used by Algorithm 6.

```
1: function Test^{m_d}(X ⊆ U^{m_d}, B ⊆ A)
2:     X_Test ← ∅
3:     for all EquivalenceClasses e ∈ X do
4:         v ← Remove(GetInstance(e), A \ B)
5:         e_tmp ← Find(X_Test, v)
6:         if e_tmp ≠ NULL then
7:             DEC ← GetDec(e_tmp) ∩ GetDec(e)
8:             if |DEC| > 0 then
9:                 SetDec(e_tmp, DEC)
10:            else
11:                return false
12:            end if
13:        else
14:            AddEquivalenceClass(X_Test, e)
15:        end if
16:    end for
17:    return true
18: end function
```

b.

B	a	b	$m_d([x]_{B\cup\{a,b\}})$
$\cdots$	0	0	$\{0,1,2\}$
	0	1	$\{0,1,3\}$
	1	0	$\{0,2,3\}$
	1	1	$\{1,2,3\}$

Let as consider the generalized majority decision reduct computation flow. If we try to remove only one column a or b, respectively, we would get the following:

B	b	$m_d([x]_{B\cup\{b\}})$
$\cdots$	0	$\{0,2\}$
	1	$\{1,3\}$

B	a	$m_d([x]_{B\cup\{a\}})$
$\cdots$	0	$\{0,1\}$
	1	$\{2,3\}$

We can observe than in either case the second column cannot be removed because $\{0,2\}\cap\{1,3\}$ as well as $\{0,1\}\cap\{2,3\}$ are equal to $\emptyset$. Let us now consider a fragment of the input permutation $a,1,2,3,b,4$ to the generalized majority decision bireduct algorithm. We can remove the attribute a, add equivalence classes $1,2,3$ and remove the attribute b because the intersection of the appropriate decisions are equal to $\{0\}$:

B	$m_d([x]_B)$
$\cdots$	$\{0,1,2\}$
	$\{0,1,3\}$
	$\{0,2,3\}$
$\cdots$	$\{1,2,3\}$

The subsequent addition of the equivalence class 4 is not possible due to the fact that intersection of the decision $\{1,2,3\}$ with all other already added to the decision bireduct is equal to $\emptyset$. Therefore, we would finish with a decision bireduct consisting of the attribute subset B and the subset containing only the first three equivalence classes.

IX. Experiments

We conducted our experiments on a collection of benchmark data sets available from the University of California at Irvine (UCI) Repository [15]. We present our results based on two data sets (*DNA-splices* and *ZOO*) but similar results can be observed on other benchmark data. We compared different types of approximate decision reducts calculation: the approximate decision reducts (ADR) calculated according to Algorithm 1 and three variations on the generalized approximate majority decision reducts (GMDA) with exceptions rules (EXEP) and with exceptions pointing to unknown decision (GAPS) and without any exception rules (NONE) but with the same reduction criteria. We have also tested each algorithm based on M and R measures. In case of GMDA procedure, the indications M and R correspond to the way how generalized approximate majority decision set was constructed. In case of the R measure we considered the relative frequency of a decision class within each equivalence class prior to a decision frequency in the testing set.

The data sets that were not given with *a priori* split into training and testing data sets, have been tested using 5-fold cross validation. Every experiment was conducted at least 20 times. We followed the well known ensemble technique to construct a classifier consisting of 10 reducts, each yielding a single weak classifier with a set of decision rules (including exceptions) calculated according to a particular method. We calculated 200 decision reducts and selected reducts with the smallest number of features. In case of exception rules we also included exceptions in calculation of the average reduct size but we used weighted average, where number of recognized objects is understood as a weight of the reduct.

Like in any ensemble-based classifier, some combination technique of classifier outputs must be applied. We used voting based on decision rule confidence, but other rule measures can be also utilized – see our previous research [16] where we described and tested several methods for rule identification and voting mechanisms.

X. Conclusions

We have presented several new methods for calculating approximate decision reducts. All of presented methods are based on the generalized majority decision function and the concept of analyzing intersections between generalized majority decision sets. We consider new methods to be more flexible in expressing the user preferences to control the distribution of decision classes inside each equivalence class. The presented methods are also less computationally expensive in comparison to the standard methods for approximate decision reducts, as they allow, in most situations, a quicker test for attribute removal. We have also presented the idea of constructing a decision rule-based classifier that use a special type of rules referred as exceptions. These rules are produced during the decision model construction and allow constructing models with a reduced dimensionality but with information about original training data preserved. We have experimentally validated our propositions and algorithms. Results show that

Figure 1. Average accuracy on *DNA-splices* data set

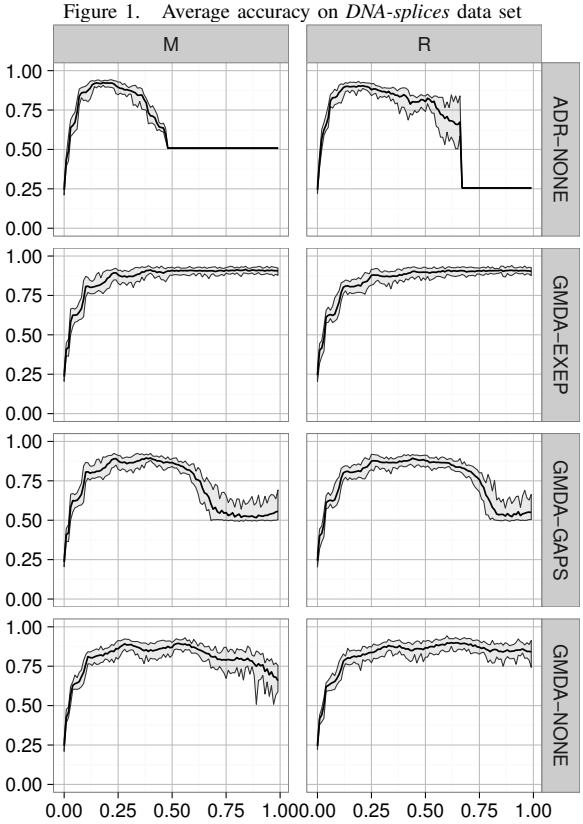

Figure 2. Average length of decision rules – *DNA-splices* data set

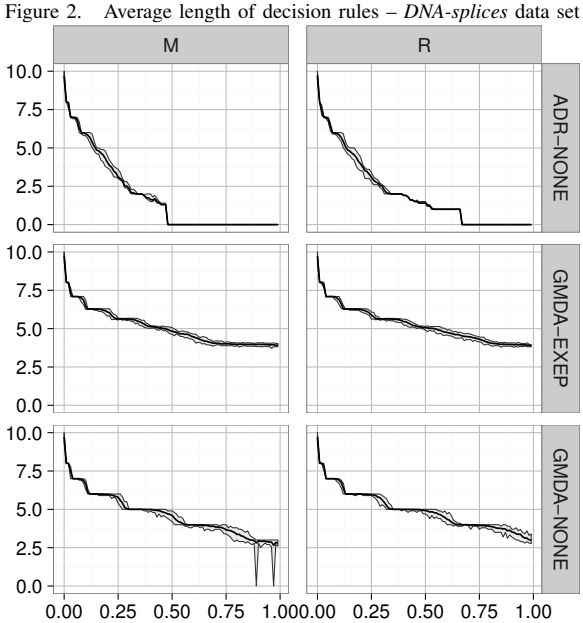

Figure 3. Average accuracy on *ZOO* data set

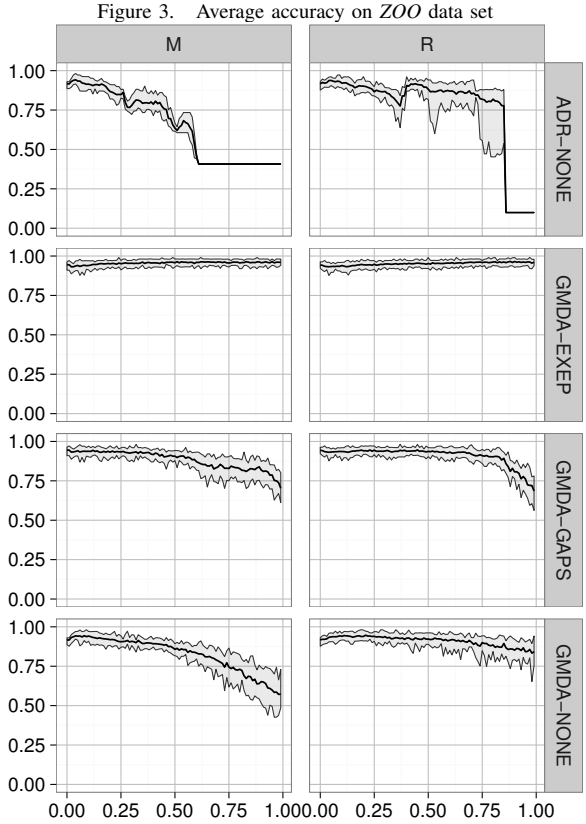

Figure 4. Average length of decision rules – *ZOO* data set

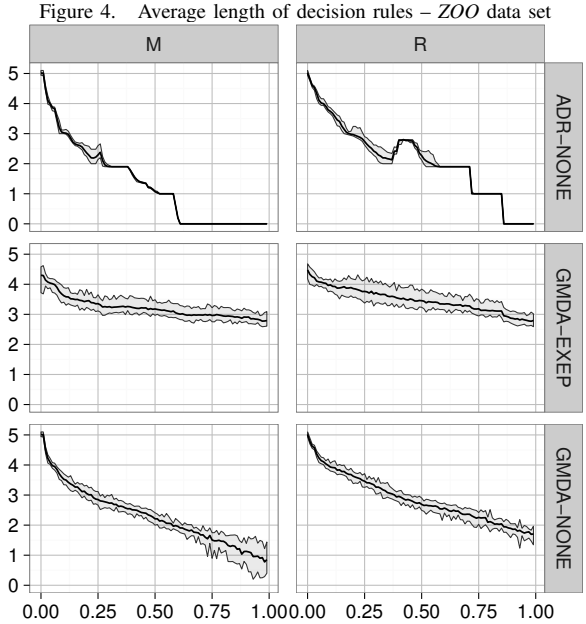

the new way of constructing approximation decision reducts have very comparable accuracy but is less computationally complex. Last but not least, we compared our method with bireduct framework and proposed new method for bireduct calculation based on the generalized majority decision set intersections. We plan to analyze the last method more deeply in the nearest future.

***Abstract*—Patent analysis is useful to understand the trends of technological problems and develop strategies for technologies. Here patent classification is a method to support the analysis. The purpose of this study is to propose a method for patent classification, with the use of hierarchical clustering based on the structural similarity of problems to be solved. The structural similarity can be calculated with case vectors based on predicate-argument structures of the contents of the patents. The interview survey indicated that this classification plays an essential role in analogical problem solving, by allowing visualization of similar technological problems.**

I. Introduction

IN COMPANIES, it is important to understand the trends of technological problems by analyzing patents. By this, they learn to improve strategies for the development of technologies. Classification symbols have been used for classifying patent documents in patent analysis. Patent examiners use them to search similar patent documents written in different technical words or languages. The classification symbols are updated manually by experts. For improving the efficiency, a method to classify patents automatically based on the semantic content is required.

A patent map, a model of patent visualization, is also a method of patent classification. Here patent information is collected for a specific purpose of use and depicted in a visual form of presentation such as a chart, matrix, graph, or table. Fig. 1 shows an example of a patent matrix map [1]. As can be seen from Fig. 1, a patent map is mainly produced to grasp its technology trends by gathering related patent information of target technology fields. However, it cannot be identified at a glance which patent documents are contained in each cluster. Also, the target technology fields have been specified manually by experts.

Analogy is the process toward understanding and solving the problem from the relation between the knowledge base (sometimes called the source) and the target problem. Finding the relationship between the base and the target can be useful for patent analysis. According to the structure mapping theory [2], there are two kinds of similarities: superficial similarity and structural similarity. Superficial similarity is characterized by elements contained in the target concept and the base concept. Structural similarity is characterized by the primary or higher-order relationships between elements included in them. MAC / FAC model has been proposed as a model to search common elements between the base and the target based on the superficial similarity, and to assess the validity of the reasoning by evaluating the structural similarity [3].

In this study, to support the creation of technical development strategy, we proposed a method for clustering to find a relationship between patent documents and classifying them, based on the structural similarity of texts expressing technological problems to be solved by invention. In addition, we proposed a method of visualization of patent documents to grasp technological problems of patent documents in each cluster at a glance.

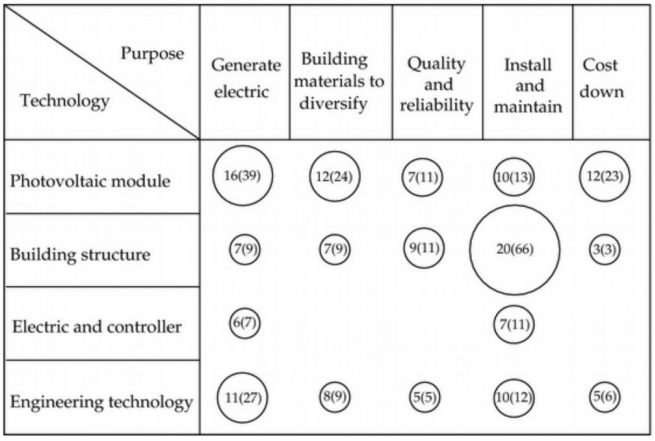

Fig. 1 example of a patent map: the size of each bubble correlates the number of registered patent publication (patent publication in parentheses.)[1]

II. Related Work

A. Extraction of Technological Problems by Clustering

A previous study proposed a method of extracting a topic by automatic classification of newspaper articles [4]. This method composes a document vector by using the frequency of each noun in the document as features and extracts the topic by performing hierarchical clustering. However, when the similarity between two documents is calculated by the frequency of each noun in the documents, a document including different words with the same structure can be regarded to be dissimilar. Therefore, using the frequency of each noun yields superficial similarity, not structural similarity. However, there is a possibility that a new topic of technological problems can be found by gathering technological problems with the same structure. Therefore, we considered both the superficial similarity and the structural similarity and represented the feature amount of patent document. This enables us to make clusters based on MAC / FAC Model, a human analogy model.

B. Conversion to a First-order Predicate Logic Formation

For supporting analogy, it is necessary to consider both structural and superficial similarities, not only for construction of sentence vectors but also for visualization. The previous study reports the usefulness of converting sentence to predicate-argument structures for the recognition of implicational relation and the analysis of dialogues [5]. This study applies the conversion result from a conversion system called Boxer [6, 7] to applied tasks of semantic analysis using analogy. However, the conversion system to predicate-argument structures has not been used for supporting idea creation. Furthermore, the conversion system from Japanese sentence has not been confirmed yet. Japanese grammar is different from English grammar and it is necessary to propose a method to convert into logical form particular in Japanese language.

Therefore, we proposed a method to support analogy with the use of predicate-argument structures. We expressed sentences of technological problems by combining important predicate-argument structures. Comparing technological problems written by predicate-argument structures with each other, patent researchers can find the structural similarity between the problems. With the use of predicate-argument structures, it enables the researchers to easily use analogy and to understand how each patent document approaches technological problems.

III. METHOD

The proposed method consists of six steps. Below let us describe details of each step.

Step.1 Summarization of Technological Problem

We extract important sentences about technological problems from patent documents by summarizing the content filled in the blank "problems to be solved by the invention." Here we use a basic model for summarizing text by selecting the important sentences [8]. The important sentences are selected based on the scores until the length limit is reached. The length of the summary is fixed as around 100 words to recognize at a glance. The score of each sentence, $score(s)$, is calculated by the amount of information included in the sentence s as shown in Eq. (1).

$$score(s) = \sum_i log\, freq(w_i, s) pos(w_i, s) / \|s\| \quad (1)$$

In a Bag-of-Words model, the probability of a word w in a sentence s can be measured by its frequency as $freq(w,s)/\|s\|$, where $freq(w,s)$ indicates the frequency of w in s and $\|s\|$ indicates the total number of words in s. w_i indicates the i th word in s. $pos(w, s)$ is the weight of the position of w in s. We take a geometric sequence as a calculate function of $pos(w, s)$ based on the position hypothesis that earlier appearances of a word are more informative. A geometric sequence is defined as $f(w, s, i)$ in Eq.(2), based on the assumption that the degree of every appearance of a word is the sum of the degree of all the following appearances of it.

$$f(w, s, i) = f(w, s, i+1) + f(w, s, i+2) + \ldots + f(w, s, n) \quad (2)$$

The content of "problems to be solved by the invention" represents the technological problem, starting from what previous methods could not solve, followed by details, concluding with the purpose of the invention, i.e. the target technological problems. Important words of technological problems tend to appear at the beginning and repeatedly appear in the content. Therefore, the scoring method is adequate to summarize the content.

Step.2 Extraction of Predicate-argument Structures

Next, the summary of a technological problem is expressed as the combination of predicate-argument structures. We use dependency parsing of the summary and extract predicate-argument structures. As a simple format of the technological problem, predicate-argument structures are composed of nouns, case-marking particles, and verbs. MeCab[9] is used for morphological analysis and CaboCha[10] is used for dependency parsing. Both of them are appropriate for Japanese language.

In this research, the research object is confined to predicate-argument structures with adnominal case particles "-ga" (means subjective case), "-wo" (means accusative case), and "-ni" (means objective case). These three factors construct the framework of a sentence, especially if the sentences expressing an aimed function of a subject interacting with things to be given as objects. That is, nouns are regarded as indications of subjects and objects in the sentence. If consecutive nouns including prefix or suffix are contained in the sentence, they are regarded as a whole word. Numbers, pronouns, and syncategorematic words are excluded from the extent of research object.

Categorematic verbs are extracted as predicates. When the verbal auxiliary, "-nai" (means adding negative) followed behind the verb, we mention it behind the verb. The noun related to the nominal verb, "suru" (means "do") are extracted together as one verb.

From the result of dependency parsing, each verb written in original form is defined as a predicate, and relevant nouns are defined as values of its variables. The verbs, which appear in over 90% of the datasets, are meaningless verbs and are excluded from technical problems.

Step.3 Representation of Case Vector

To consider both the superficial similarity and the structural similarity, we also focus on a predicate-argument structure, which consists of nouns, verbs, and their relations. The predicate-argument structure represents case form, which is defined by a form of generative grammar such as subjective and objective, based on the semantic relationship of noun phrases to verbs. As one sentence contains at least one predicate-argument structure, the structure of the sentence can be represented by case vectors.

In Japanese language, a semantic relationship between a verb and a noun is confirmed by a case-marking particle. Furthermore, a verb tends to have a relationship with certain nouns to express its meaning. For instance, the verb "boil" tends to have a relationship with the nouns such as "human being" as the subject and has the relationship with the nouns such as "meals" as the object. Therefore, we represent a verb vector based on the verb's semantic role by using frequency of the nouns, which have a relationship with the verb such as subjects or objects.

Additionally, a case relationship represents the influence of a verb to/from a related noun. That is, the case relationship is useful for a semantic vector representation of a verb. We represent a verb vector by using the appearance of the nouns, which are in the same case relationship. The same case relationship means that they have the same case-marking particle. We define a case vector as a verb vector of each case-marking particle. For example, verb "Iku" (meaning "goes") in sentence "Prime Minister Abe ga Russia ni Iku." in Japanese, meaning "Prime Minister Abe goes to Russia," is put into:

Iku: (subject: Prime Minister Abe, Object: Russia).

This will be then put into a case vector where numerical values are filled as elements corresponding to "subject: Prime Minister Abe", "Object: Russia".

The case vector is constructed by a Bag-of-Words model. This model is the simplest vector representation for a sentence or a document. Each dimension of the case vector is correlated with a noun. Let us take a subjective case vector as an example. The value of the dimension is calculated as 1 if there is a subjective noun for a verb in the document and otherwise calculated as 0. Furthermore, the vector for the *i*-th verb is weighted by the *j*-th noun, which is related to the verb in the sentence. When the verb *i* has a predicate-argument structure with *m* nouns in the corpus, the weight of the *j*-th noun is calculated in Eq. (3).

$$w_i = (w_{i1},\ w_{i2}, \dots, 2\ w_{ij}, \dots,\ w_{im}) \tag{3}$$

In this study, to identify patterns in the relationships between nouns and concepts of verbs, a method of Latent Semantic Indexing (LSI) is applied to nouns/verbs matrix. LSI is an indexing and retrieval method to identify patterns in the relationships between the terms and concepts contained in an unstructured collection of text [11]. Additionally, the computational complexity decreases and the accuracy of a clustering algorithm can be improved with the use of LSI. This study is different from the previous study in applying LSI to nouns/verbs matrix.

If *n* is the number of verbs and *m* is the number of unique nouns in the corpus, *A* is the matrix about verbs *V* (*V*=1, …, *n*) which are related to nouns *N* (*N*= 1 , …, *m*) in the sentence *s* as shown in Eq. (4).

$$A = \begin{array}{c} \\ N_1 \\ N_2 \\ N_m \end{array} \begin{array}{c} \begin{array}{ccc} V_1 & V_2 & V_n \end{array} \\ \begin{pmatrix} 0 & 2 & 0 \\ 2 & 0 & 0 \\ 0 & 0 & 4 \end{pmatrix} \end{array} \tag{4}$$

This matrix *A* is decomposed by Singular Value Decomposition (SVD). When the rank of *A* is *r*, *T* is an *m* by *r* noun-concept vector matrix. *S* is an *r* by *r* singular values matrix. *D* is an *n* by *r* concept-verb vector matrix. Then, the matrix *A* is compressed to *k* dimensional space by restructuring the matrix *A'* using top *k* amounts of large and primary factor shown in Eq. (5). Dimension *k* is defined from preliminary experiment (In this study, k=200).

$$A' = T_k S_k {D_k}^T \tag{5}$$

Step.4 Calculate Distance Between Patents

Next, hierarchical clustering by using average linkage is selected as a method of cluster analysis of technological problems of patents. The relationship of each cluster is visualized by hierarchical clustering. As the predicate-argument structure is the framework of the document, the distance between the documents can be treated as a total of the distance between the predicate-argument structures in the document. Therefore, we calculate a distance between two patent documents as the sum of distances between the case vectors in the documents. By this calculation, the distance between two documents can be determined according to their predicate-argument structures. For simplicity, in this study, we defined three kinds of case vectors: subjective case vector, accusative case vector, and objective case vector. Nouns, which prefer to relate to verbs are different on the type of case and the distance between case vectors should be calculated in the same type of case each other. Therefore, we calculate a distance of the same type of case vectors and add them together as shown in Eq. (6).

$$sdist = sdist_{sub} + sdist_{acc} + sdist_{obj} \quad (6)$$

$sdist$ means the distance between two documents, $sdist_{sub}$ means the distance between these documents in the subjective case.

The distance $cdist\ (V_1, V_2)$ between two case vectors, V_1 and V_2 is calculated by Euclidean distance divided by the

$$cdist\ (V_1, V_2) = \frac{1}{cdist_{MAX}} \sqrt{\sum_{k=1}^{n} (V_{1k} - V_{2k})^2} \quad (7)$$

maximum of all distances, as shown in Eq. (7).

V_{1k} and V_{2k} are values of V_1 and V_2 at a dimension k. Each distance takes a value within the range of $0 \leqq cdist \leqq 1$ so that the distance of each type of case should be treated as equivalent.

When the document p contains k subjective nouns and document q contains l subjective nouns, the distance $sdist_{sub}\ (p, q)$ between these documents in the subjective case is defined as Eq. (8).

$$sdist_{sub}\ (p, q) = \frac{1}{kl} \sum_{i \in k} \sum_{j \in l} cdist(V_i, V_j) \quad (8)$$

As shown in Eq. (8), the sum of distances of the subjective cases is divided by the number of the cases to consider the average of the distances as the distance of the case.

If one document contains one direct objective noun and the other does not, $sdist_{acc}$ cannot be calculated in Eq. (8). In this case, these two documents are completely different in accusative case and $dist_{acc}$ is regarded as the maximum $sdist_{acc}$, 1. Similarly, if two documents contain no indirect objective nouns, $dist_{obj}$ cannot be calculated in Eq. (8). In this case, these two documents are the same in objective case and $dist_{obj}$ is regarded as the minimum $sdist_{obj}$, 0.

To illustrate the above, there are two example sentences of calculating distances.

Example 1: Subject A / Verb B / Direct Object C

Example 2: Subject N / Verb O / Indirect Object P, Subject Q / Verb R / Direct Object S

There are two pairs of the subjective case (A-N and A-Q) and one pair of the accusative case (C-S). Therefore, $sdist_{sub}(s_1, s_2)$ is expressed to be $\frac{1}{2}\ (cdist(V_A, V_N) + cdist(V_A, V_Q))$ and $sdist_{acc}(s_1, s_2)$ is expressed to be $cdist(V_C, V_S)$. In addition, these two documents are completely different in objective case and $sdist_{obj}(s_1, s_2)$ is 1. In this example, the formula to calculate the distance $sdist(s_1, s_2)$ between Example 1 (s_1) and Example 2 (s_2) is shown in Eq. (9).

$$sdist(s_1, s_2) = \frac{1}{2}\ (cdist(V_A, V_N) + cdist(V_A, V_Q)) + cdist(V_C, V_S) + 1 \quad (9)$$

Step.5 Hierarchical Clustering of Patents

The hierarchical clustering method in the previous study[4] has a problem of fluctuating extracted topics because these topics subjected to the number of clusters and the number of clusters is decided in the hand. We here employed Upper Tail method [12, 13], clustering with an automatic decision of the number of clusters. This method is based on the stopping rule of Eq. (10).

$$\alpha_{j+1} > \alpha_{ave} + ks_\alpha \quad (10)$$

When the number of documents is n, the most appropriate number of clusters is j, and the number of clusters is n-j (j=0, 1,..., n-1), α_j is the minimum distance between two documents belonging to different clusters. α_{ave} is an average of a distribution of α_j. s_α is a square root of the unbiased estimate of variance. k is determined by the number of elements per cluster. We determine k=2, considering that the number of documents per cluster is estimated from 10 to 50. The previous study [13] shows normalizing α to be distributed by chi-square as shown in Eq. (11) achieved better accuracy and we perform the same procedures.

$$\alpha' = \Phi^{-1}(F_p(\alpha / s_\alpha \cdot p) \quad (11)$$

Φ^{-1} is the inverse function of the normal distribution. F_p is distribution function of chi-square when a degree of freedom is p (In this study, p=1).

Step.6 Visualization of Similar Technological Problems

In the end, we propose a method of visualization of technological problems. The format of output data is JSON, which is a lightweight data-interchange format. The embedded structure of the data is composed of the number of the cluster, technological problem solved by each patent document, and the patent number in sequence. In visualization, we use D3.js, which is a JavaScript library for visualizing data with JSON and HTML.

IV. Results and Discussion

A. Datasets

In this study, we used unexamined Japanese patent applications, which were published from 2013 to 2015 and contain the word "condiment" in the content of "problems to be solved by the invention" as datasets to make clusters and visualize. The number of documents was 348. The dictionary data for constructing the case vector was the content of "problems to be solved by the invention" of seventy thousand patent documents relating to "Foods" (theme code: 4H).

Fig. 2 Part of clusterization of patent documents in three conditions

First condition used the distance determined by the case vector, second condition used the distance by the sentence vector with the verbs as feature amount and third condition used the distance by the sentence vector with the nouns as feature amount.

B. Evaluation of Summarization of Technological Problem

324 summaries were created from the datasets in this study. The reason why some summaries could not be created is that the contents of "problems to be solved" of such patent documents were too short to summarize. In order to evaluate the validity of the summarization, randomly selected 100 summaries extracted by the method were compared to summaries determined by discussion among patent experts for the same documents. The rate of concordance in this comparison was 81% and it shows the method is adequate to summarize patent documents.

C. Evaluation of Cluster Analysis and Visualization

To evaluate the utility of the proposed method, we performed cluster analysis of patent documents, using three kinds of distances and compared the results with each other. The first distance was determined by the proposed method, the case vector. The second distance was determined by the sentence vector using frequency of verbs as the feature. The third distance was determined by the sentence vector using frequency of nouns as the feature. We used TF/IDF to weight the features in the second and the third distances. TF means the frequency of words in each sentence and IDF means logarithm of inverse number of the frequency of words used in total sentences of the summary of the technological problem. Fig. 2 shows part of the result of the cluster analysis in three conditions, corresponding to the three kinds of distances above. The number of clusters under each condition was determined as 44 (the first condition), 20 (the second condition), and 40 (the third condition).

We interviewed two patent experts engaged in the Intellectual Property Department of the food company for more than three years. We showed them the result of the cluster analysis in three conditions and asked two questions below.

Question 1. What kind of difference do you find by comparing the three types of clustering results? What similarities do you find in the technical problems in the same cluster?

Question 2. Can technological problems of patent document be grasped at the moment? Is there any use to develop technology strategy or intellectual property strategy?

The answers to Question 1 are shown below:

- At the first glance, each cluster in the first condition seems to lack in coherence. However, for example, the cluster No.9 seems to be aggregated by the same concept of verbs. The verbs such as "maintain", "take in" and "fill up" represent the concept of keeping and the verbs such as "sprinkle", "attach" and "add" represent the concept of adding.
- Each cluster at the second condition seems to be aggregated by the same verb roughly.
- As the cluster No.18 is aggregated by the same noun "extract" in the third condition, the same goes for others at the third condition.

These answers indicate that case vectors have a possibility to represent the concept of the verbs, which forms the

structural similarity of the sentences. On the other hand, as a result of the second and third condition, the sentence vector using frequency of words as the feature represents the superficial similarity based on the words. The third condition also indicates that the meaning of the sentence is more influenced by the meaning of nouns than that of verbs.

The answers to Question 2 are shown below:

- When technological problems are expressed by the predicate-argument structures, modifiers are removed. Therefore, removing terminology of confidential information with this method is useful for sharing confidential data with others. On the other hand, some technological problems are hard to read. For example, “advantage convenience+-ga+loses” is grammatically incorrect. The correct sentence is “advantage convenience is lost”.
- The words which indicate not only the material of condiment but also the method for processing were extracted as technological problems.
- Some technological problems were extracted with accuracy, while others with unnecessary words.

The first answer indicates that the proposed method of visualization is useful in not only patent documents but also confidential documents. The answer also indicates that sentences of technological problems including passive verbs are a little difficult to read. This is because an auxiliary verb that represents the passive voice was not considered in this study and excluded. The method of expressing a sentence with a passive verb as predicate-argument structures will be an issue to be addressed in the future.

The second answer indicates that technological problems extracted by the proposed method are useful to find a point of view in patent analysis, whereas existing patent classification is mainly divided by the material of a condiment.

The third answer suggests that the interviewee could find the structural similarity of some technological problems and the usefulness of this method. However, as the structural similarity is not based on the commonality of words, the interviewee had difficulty to find the structural similarity of others. Therefore, it is necessary to get an evaluation of this method to more interviewees. Another reason for this result is the structural similarity of two documents is not always directly represented by predicate-argument structures including in the documents. Therefore, it is necessary to consider the extraction method of the abstract predicate-argument structure in the documents.

V. Conclusion

In this study, we proposed a novel method of text clustering by using the distance of case vectors derived from predicate-argument structures of patent documents. A method for calculating the distance between documents based on predicate-argument structures has not been approached. This study suggested the possibility to capture not only superficial similarity based on nouns in sentences but also structural similarity based on the meaning of verbs in sentences. Furthermore, the interview survey indicated that the proposed visualization method of technical problems is useful to overview the problem, which patent researcher should search for. Therefore, this visualization method is thought to be effective to support to search patent documents relating to researcher's own technological problems.

In this research, we calculated the distance between patents as an average distance between case vectors included in the documents. However, as this method cannot consider the causal structures of documents, the similarity of documents could have been inaccurate. Therefore, an issue in the future is to evaluate the method for deriving similarity considering causal structures in documents.

***Abstract*—Public safety, especially the daily traffic accident is concerned by the public. Previous studies have already discussed accident reasons associated with accidents statistically. There is a method called Innovators Marketplace on Data Jackets created by Professor Ohsawa. This method is used to externalize the value of data via stakeholders' requirement communication. This paper applied the solution from an IMDJ workshop to research this topic creatively. This novel solution suggested to do analysis on the combination of urban data and traffic accident rate to find the impact factors to the traffic accident rate in the urban system. This paper used factor analysis, structure equation modeling and data mining to construct a theoretical frame for traffic accident rate analysis for urban data. Different accident indexes, such as total number of accident, fatality rate, injury rate, and casualty rate are combined to construct a traffic accident risk evaluation model. This paper chosen the urban data as the solution from IMDJ workshop, such as population structure information, vehicle information, road characters, public traffic system information, and the other kinds of data to explore factor meaning, and to identify relationships between different factors. It segmented these urban data based on their categories, and determined accident risk for each section. By doing analysis on not only the original data but also the changing rate of these data each year, the result analytical results showed that traffic accident rate on urban data could be described by the combination of population structure, road characters, public traffic system and public facilities. These four sections affects traffic accident rate significantly during the development of urban; however, the vehicle factor does not have influence on traffic accident rate. And it proves the solution from IMDJ workshop is not only novel but also practical strongly. Making some solution from IMDJ into reality, we will find another new way to affect the world.**

I. INTRODUCTION

In Beijing, the fatal accident rate was 39.56 per million populations in 2014, it decreased roughly 2.8% in comparison with 2013, even though the population of 2014 has increased 1.7%. Different losses caused by traffic accident in urban are considerable. Many previous researches on traffic safety tried to find methods for preventing traffic accidents. Among these researches, the analytical methods are used frequently, including Clustering Analysis (CA), Statement Statistic (SS), Regression Analysis (RA), evaluation of the correlation between independent variable sets and a dependent variable; but these models could not cover the causal relationship between these variables or combine different traffic accident indexes to identify accident risk. Even though all of the final purpose of them attempts to avoid traffic accident, they mostly used discriminate analysis or regression model in analyzing accident characteristics and identifying behaviors of drivers, weather condition or road sections prone to accidents, then constructed an accident prediction model by parametric approaches (i.e. on distribution model). However, these methods only analyzed accidents on drivers with different attributes and relevance, weather data or different road sections; they cannot define the causality between factors clearly enough. Some current studies have already utilized data mining, including non-parametric approaches where traditional models were not employed, to identify key accident related impact factors. However, data mining can just identify traffic accident risk indexes (i.e. number of traffic accident, of death, of injuries, or of casualties). But it is necessary to identify the latent correlations among the different factors which is suggested by solution from IMDJ, and find the correlations among the traffic accident rate and urban data-population structure, vehicles, road characters or some other cause-and-effect relationships. In this study, we focused on urban data, applied structural equation modeling to find impact factors associated with traffic accident. Important traffic accident factors were identified, population structure, vehicle information, road characters and other cause-and-effect relationship associated with traffic accident risk were discussed, and prediction model which describe the latent relationship between urban city and accident was constructed. This paper discussed six factor sets by constructing an accident risk causal framework based on urban data and the component factor sets of each feature and influence on traffic accident.

II. LITERATURE REVIEW

This paper builds a theoretical framework for traffic accident risk by the analysis on the latent relationship between different aspects of urban data and traffic accident to identify causal relationships. In the past, Etienn(2006) used logit regression analysis to discuss reasons that led to different degree of injury condition in the traffic accident. Gender, age, and protective gear were related to the condition of injury. By using bivariate and simple analysis, Wong and Chung(2007) applied a rough set approach for accident chains to analyzing the influence of traffic accident for different factors. They found that a single factor accident chain had poor quality and

978-83-60810-90-3/$25.00

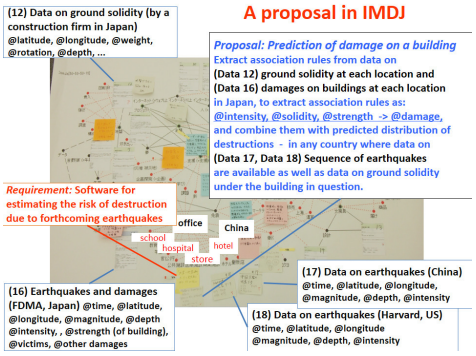

Fig. 1. A proposal in IMDJ

a multi-factor accident chain should be used when analyzing accidents. John(2007) has used mixed logit model to construct a prediction model for serious traffic accident. Variables related to daily traffic flow, such as average daily traffic flow, percentage of big vehicles, and number of access roads, and variables related to road features, such as curvature and road friction were significant variables impacting road accident risk. Niloofar(2015) utilized highly disaggregate spatial units for an analysis of area specific variables associated with urban traffic accident. These researches suggested that factors affecting traffic accident risk include drivers, road structure of city, public traffic system, which may affect each other. On the other hand, this paper applies the solution from IMDJ workshop to do factor analysis and structure equation modeling to analyze these features as well as the cause-and-effect relationships between urban factors and traffic accident rate. The main goal of this paper is necessary in order to have a clear enough structure of urban and traffic accident for improving safety which will be done with urban planning in the future.

III. MOTIVATION OF RESEARCH

The reason of doing this research comes from one solutions of IMDJ workshop. The IMDJ(Innovators Marketplace on Data Jackets) has been metioned about many times aboved. And this research is the application of a solution from IMDJ workshop, so I think it is necessary to introduce this amazing method. The purpose of IMDJ is making a social environment where analysits and decision makers in active businesses and science could be provided with data they need. During the workshop, each members could give requirements and provide solutions by checking or combining DataJackets on the Keygraph. And finally members can buy/sell their solutions in a reasonable condition. The Fig.1 shows a proposal in IMDJ workshop. DataJackets are small pieces of information containing the abstracts of data that exist but cannot be disclosed. And Keygraph created by Professor Ohsawa is the high-effective visualization method to show the relationship between different Datajackets by analyzing contents in Data jackets. Before an IMDJ workshop, the topic of the workshop should be determined by the organizer. During an IMDJ workshop which topic is ”Improving the quality of urban life”, a requirement about public safety has been asked. That requirement asked for a method to check the safety condition of objective people in an area. And another member supplied a solution of checking the safety index of the area by using combination of two Datajackets. One is the structure data of the city, and the other is the accident rate of the city. The research angle of this solution is totally different from the previous researches We selected the urban data just like the solution suggested to do this research. The society has paid lots of cost on traffic accidents significantly. And it is time to do the research to reveal the complex relationship between urban data and public saftery. The solution from IMDJ workshop gives a very novel and meaningful angle to do research on this problem.

IV. RESEARCH EXTENT AND METHODOLOGY

This study focused on urban data in Beijing City. Beijing is still in construction after Beijing Olympics 2008, and it is becoming bigger and advanced every year. Public facility and mass rapid public transit lines have been under construction in Beijing City. And also with some policy changed, the other social structures have been keeping changing every year, such as the different structure of population, the GDP of Beijing, the sales of different products and etc. These different structures have affected all of aspects in Beijing City. In respect of methodology, this paper used structure equation modeling with population, driver, vehicle, road characters, public transportation system, other urban data as independent variables, and accident rate as the dependent variable. All these data related to this urban were compiled into six categories. In addition to applying structure equation modeling, this paper used structure equation modeling method to explain the relationship between factors. To choose whether observation variables in each aspect are appropriate before model construction, each variable was subjected to factor analysis. It is necessary to exclude the unrelated factors in order to reduce the interference terms. After determining the variables, this paper analyzed the quantized the effect between these variable.

A. Data content

Urban data: We covered 30 factors, and clustered these factors into 6 sections according their categories. These 30 factors involving population, population in different age, number of truck, number of bus, gasoline consumption each year, number of hospital, number of police stations, road area, length of bus lane, green area in urban and some other aspects of urban. We assume, these data actually have the relationship among themselves and affect the traffic situation, it also includes the traffic accident naturally. Accident data: Accident rate was expressed by the sum of Fatality rate, Injury rate and Casualty rate multiplied by different weight.

$$Fatality\ rate = number\ of\ deaths/number\ of\ accident \quad (1)$$

$$Injury\ rate = number\ of\ injuries/number\ of\ accident \quad (2)$$

$$Casualty\ rate = number\ of\ casualties/number\ of\ accident \quad (3)$$

$$Accident\ rate = (1) * 3 + (2) * 2 + (3) * 1 \qquad (4)$$

Here, the above accident rate means the personal safety loss of the traffic accident.Theses different weights mean the degree of damage after accident based on the influence of traffic accident. The Fatal consequence is the most serious one, so I give the weight 3 to it; to the injury consequence, I give the weight 2 to evaluate it; to the casualty, because it prefers to refer to a range of affected people, I just use 1 to depict its weight. And the number of accident refers to the number of traffic accidents in that year. These traffic fatality, injury and casualty data were collected for the period 2010 to 2014 from the following sources: publications in the same period such as Beijing Statistics yearbook, official statistic site likes National Bureau of Statistics of China and official city traffic and accident reports.

B. Variables

We chose the data by which can be used to describe the urban objective situation in order to find the relationship between structure of urban, involving the structure of urban planning and social structure in urban, and accident rate. Then identified causality with the accident rate on the result. With the development of the urban and technology, the structure of urban is keeping changing every year. Doing analysis on the cause of the traffic accident to find the main reason by using statistical method or clustering method is common method. But we could not ignore the relationship between urban data and traffic accident rate. The changes in urban can affect every small aspects in our life, absolutely involving the accident. For example: alcohol drinking sales in urban may reflect the change of drunk driving rate in urban, and drunk driving is one of main reason of traffic accident, this chain shows the alcohol drinks sales has a tacit relationship with accident. And there must be other causes of the change in traffic accident from this kind of chain based on the urban system.

C. Model Framework

To build a traffic accident risk model on urban construction, different urban data were compiled. In this paper, we collected and compiled different data in an equal structure. This structure means that these urban data are on the same important position at the beginning of analysis. In this structure, the relationship does not only exist between the traffic accident rate and different urban factors, but also among these factors. It is more like a net of relationship. The model of analysis should be much more comprehensive, only in this way the result has persuasiveness, and intuitive. Fig.2 shows the framework in this research.

D. Analysis process

1) step1: Preprocessing the urban data: Using the raw data to do analysis is easily to ignore the influence of small change automatically during the analysis. It is necessary to preprocess the urban data. The purpose is to enlarge the influence of these factors and increase the efficiency of analysis.Also the final visualization will be clear enough to observe. Transforming the raw data into different ratio value, such as gender ratio, potential support ratio, vehicle type ratio, road light per meter, length ratio between road and total public traffic system, the ratio of green area, living space, and etc. Fig.3 shows the preprocess of urban data.

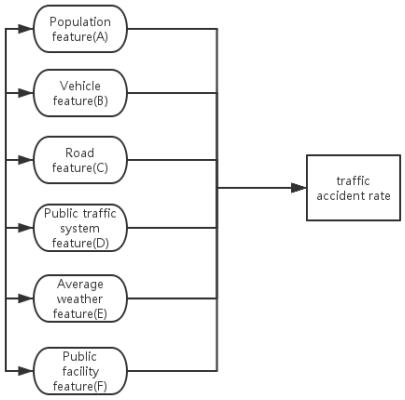

Fig. 2. model framework

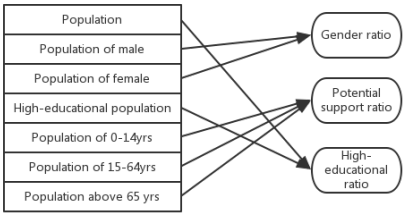

Fig. 3. Example of preprocessing

2) step2: Clustering latent factor sets: In order to distinguish the effects of different aspects in urban, before the analysis, it is necessary to define the preprocessed data into different sets. After the main components were analyzed, variables have been clustered in six features-population, vehicle,road characters, public traffic system, average weather data, public facility data. In this way, the result can give the structure and relationship between accident and variables, also among variables themselves. The TABLE I shows the result of clustering.

$$Population\ feature \longrightarrow A\ factor\ sets(A)$$
$$Vehicle\ feature \longrightarrow B\ factor\ sets(B)$$
$$Road\ feature \longrightarrow C\ factor\ sets(C)$$

TABLE I

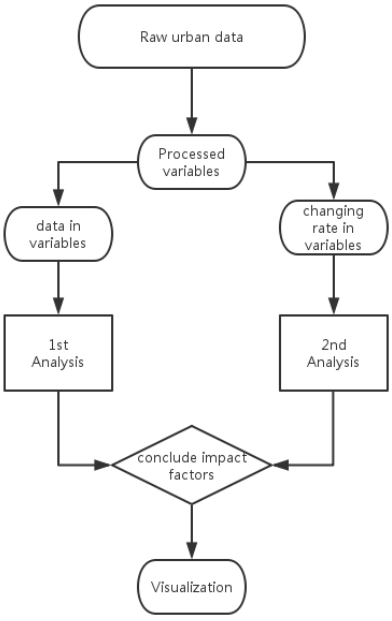

Fig. 4. Impact factors from result of analysis

3) step3: Calculating the changing rate. The whole process of analysis has been designed to do two times in order to confirm the effect of impact factors. The first used data in TABLE I directly, and the second used changing rate of factors in each year. The reason of second analysis on changing rate is to confirm the relationship between factors and the accident rate. I selected the factors which have strong relationship with accident rate by checking the P-value of analysis results. And two results can show overlap part of significant impact factors clearly, also it can confirm the influence of impact factors and quantize the influence of these impact factors.

4) step4: After getting results of these two analysis, factors which have no relationships with traffic accident are deleted. We used data of these impact factors to calculate the influence by numeric on urban traffic accident. Making a graph to visualize the relationship and degree of influence between these impact factors and traffic accident rate is necessary. With this graph, impact factors and their influence between each other can be observed clearly. The numbers marked on lines mean the degree of correlation between them. The positive number means the positive correlation, and the negative number means the negative correlation. The dotted line means the relationship is bidirectional relationship, and the solid line means the direction of relationship between sections is just one way. The Fig.4 aboved shows the whole process of analysis.

V. RESULT

The TABLE II showed results from analysis. Two columns showed impact factors and their quantized influence calculated by the assumed model.

After the first analysis, A5 factor(potential support ratio), D2 Factor(length of subway line), D3 Factor(subway station/urban area), F3 Factor(number of school) and F4 Factor(number of school) has been selected, they are from three different sections. The first result showed the potential support ratio, length of subway line, subway station/area, and number of school are the impact factors, among them the length of subway line showed the strongest relationship (0.938) with traffic accident rate. It gives some reasonable assumptions: the Beijing attracts more working population (due to the A5(potential support ratio)), and with the construction of subway line system, it is much more convenient, more and more people choose the public traffic system, and the traffic accident rate has been controlled. And with the number of hospital, the number of fatality in traffic accident has been affected. The number of school means, firstly the increasing working population takes more students, secondly the number of school has the relationship with public traffic system. The second analysis has used the changing rate in the same factors. The first result could be used to combine with it, then the combination of results could solve the problem comprehensively. After the second analysis, A2 factor(gender ratio), A3 Factor(high educational ratio), C1 Factor(length of road), D2 Factor(length of subway line) and F4 Factor(num of school) has been selected, from four different sections. The result of second analysis showed that gender ratio, high educational ratio, length of road, length of subway line and number of school are the impact factors. It showed the number of school has the strongest relationship with traffic accident rate.And it is apparently to find that the influence of F4 factor(number of school) has been improved. With considering the factor-High educational ratio, it showed some reasonable possibility: with the increasing of educational level, more people come to recognize the importance of traffic safety.And they know how to protect their safety,also it means in the traffic accident, the student accident has affected it strongly. With choosing the impact factors from these two analysis, we can visualize

First analysis	Second analysis
A5.Potential support ratio(0.55)	A2.Gender ratio(0.056)
D2.Length of subway line(0.938)	A3.High educational ratio(0.129)
D3.Subway station/city area(0.036)	C1.Length of road(0.028)
F3.Hospital(0.558)	D2.Length of subway line(0.004)
F4.Number of school(0.07)	F4.Number of school(0.867)

TABLE II

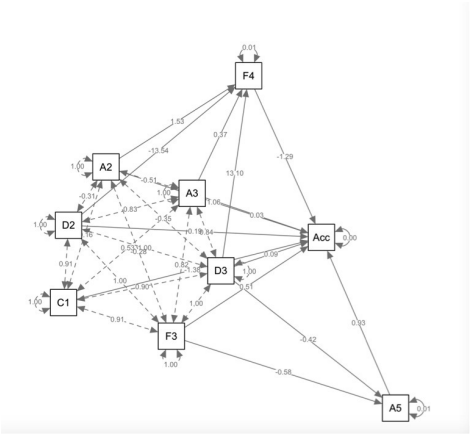

Fig. 5. Visualization of Impact Factors

the structure and the influence about them. Fig.5 showed the visualization of the result. The selected nine factors from these two analysis made this net diagram. As the interpretation of the diagram before, every impact factors showed the degree of influence, direction of the relationship and the combination of the relationship. For example, F3 (number of hospital) has affected the A5 (potential support ratio) by negative effect of 0.58, and the direction is just from F3 to A5. C1(Length of road) has the relationship with F3, they affected each other by the positive effect of 0.91. Generally, the traffic accident rate is affect by all of impact factors on this diagram. The A5(potential support ratio) has positive effect of 0.93 on traffic accident rate. The F4 (number of school) has negative effect of 1.29 on the traffic accident rate. The D2 (Length of subway line) has positive effect of 0.19 on the traffic accident. By gathering these coefficents, using these different factors as variables, we can define a model to describe the relationship between each factors and accident rate and the relationship among these different factors.

VI. DISCUSSION

"The more vehicles, the more accident.", it is a general consideration. But in this research, it showed there is no relationship with number of vehicles. Neither in the first analysis nor the second analysis, there is no result showing the accident rate has the relationship with vehicle factor. From the raw data, it showed even though the number of vehicle is increasing, the traffic accident rate has decreased, and by the result, it showed the vehicle data has no influence on the traffic accident data. On the other hand there is a strong relationship among the other urban data,such as-population structure, public traffic accident and traffic accident rate. Even though the traffic accident mainly about the vehicle caused accident on the road, the results here showed the other factors affected this rate obviously from the angle of urban structure data. And the other possibility exists, the changing data of vehicle variables has effects on the traffic accident rate, but the influence is too small, and the influence has been neutralized by other changed urban data. It still needs more and more data to make the model much more comprehensively, and make the correlation correctly.

VII. CONCLUSION

This paper constructed an assessment model for traffic accident risk which is novel in that we defined the relationship between urban data and traffic accident data. The four main sections-population structure, road characters, public traffic system and public facility had the significant impact on traffic accident rate, while the vehicle section was insignificant. A higher gender ratio (men/women) can reduce traffic accident risk, while a higher potential support increased the traffic accident risk. The longer length of road and public traffic lane can decrease the traffic accident rate.The results show that public traffic system and facilities are important factors to controlling the traffic accident rate. Traffic accident is mostly caused by people themselves, researchers can do many analysis on policy or reason analysis in order to reduce the traffic accident rate. However, from the new angle of IMDJ workshop, one should pay more attention to the significance from urban structure designing. This paper successfully made one traffic accident risk assessment model.Four sections-population structure, road characters, public traffic system and public facility are adequate for assessing traffic accident risk.It may require the deeper research in future, but this study was still restricted by its access to data. Although 30 variables were included,it was not enough. If the experiment add other kind of urban data, the model would be modified on causality and deduction. This paper was focus on the influence of urban data to traffic accident risk, it is suggestive to use this methodology to apply to other kind of public safe problem.

VIII. FUTURE WORK

Based on the conclusion of this paper, it showed that the relationship between urban data and accident could be quantized in number and described in a mathematical model. If there are other urban data, the model could be more perfect. So finding other urban data to construct the model more comprehensively. Trying to find what extent does this model match real sitiuation, and make it more comprehensive.
The requirement from that IMDJ workshop needs to check the safety condition of the objective people. So the model of traffic accident rate is not enough, because the public safety also covers the crime rate. From this solution of IMDJ, we prove the proposal which shows the traffic accident rate is related to the urban social data, so the crime rate of objective area could also be defined in that kind of mathematical model. And with combining these models, a synthesized prediction

model which can describe danger index of area based on urban data could be made. It could be used in checking the danger status of objective area. Also it could give reference to urban construction in the future. Because this interesting research angle was from IMDJ workshop, and this useful result was from the applicaiton of solution in IMDJ. I think the more results from IMDJ would make more exciting and useful things. The IMDJ workshop let members from different fields to externalize use value of data by combining their familiar data and other datas noveltly. It could help us to dig the deep value of the hidden datasets. Also it could help us to share the experience from professional people in different fields. I could not wait to hold a workshop with topic of public safety to find more new points in solving these kinds of problems.

ACKNOWLEDGMENT

This research was supported by Japan Science and Technology Agency (JST) and Core Research for Evolutionary Science and Technology (CREST).

FedCSIS'16 Plenary Panel on the Legacy of Professor Zdzisław Pawlak

Background

This is the year of the 90th anniversary of the birth and the 10th anniversary of the death of Professor Zdzisław Pawlak – a Polish mathematician and computer scientist known for his contribution to many branches of theory and applications, a full member of Polish Academy of Sciences, a recipient of Order of Polonia Restituta and many prestigious awards in Poland and abroad. The scientific work of Professor Pawlak is probably most recognized from the perspective of rough set theory that he founded in the early 80's. However, it is important to emphasize also some of his other achievements, e.g., designing the first Polish computer (GAM-1, 1950), introducing a new approach to random number generation (1953, the first international publication of a scientist from Poland in the area of computer science), introducing a positional numeral system with base -2, introducing a generalized class of reverse Polish notation languages, proposing a new formal model of digital machine, creating the first mathematical model of DNA (1965), or proposing a new, very-well received mathematical model of conflict analysis.

Topics and Format

The goal of this panel is to summarize the scientific journey of Professor Zdzisław Pawlak and discuss how to make further progress by following his great intuitions, emphasis on clarity of ideas, as well as willingness to work on interdisciplinary projects. Some of areas of Professor Pawlak's activities will be discussed by his friends and co-workers:

- **Stan Matwin –** Introduction: Professor Pawlak as a Scientist, a Teacher and a Mentor
- **Victor W. Marek –** Working with Zdzisław Pawlak: Excursions in Computer Science and Mathematics
- **Ewa Orłowska –** The Evolution of Rough Sets
- **James F. Peters, Sheela Ramanna –** Gentle Art of Zdzisław Pawlak's Paintings
- **Alicja Wakulicz-Deja, Małgorzata Przybyła-Kasperek –** Pawlak's Conflict Model: Directions of Development
- **Andrzej Skowron** – From Information Systems to Interactive Information Systems

FedCSIS'16 Plenary Panel will form a thematic block with one of FedCSIS'16 / AAIA'16 regular sessions focused on rough sets and approximate reasoning. Moreover, the panel's contents will be coordinated with the analogous event held at IJCRS'16 conference co-organized by International Rough Set Society (IRSS) in Santiago de Chile, October 7-11, 2016.

Working with Zdzisław Pawlak – Personal Reminiscences

Victor Marek
Department of Computer Science
University of Kentucky
Lexington, KY 40506, USA

***Abstract*—This paper accompanies panel contribution of the author to the session devoted to personal reminiscences of Professor Zdzisław Pawlak, a computer scientist and engineer. In particular we discuss some aspects of the work of Pawlak and researchers in his circle of collaborators in 1960ies, and especially, 1970ies. Given the lack of archival materials, the author bases this writing on personal recollections which may, at places, be imprecise.**

***Index Terms*—Zdzisław Pawlak, Information Storage and Retrieval Systems, Rough Sets**

I. How Did It Start

GIVEN that this text refers to personal recollections, I need to introduce myself to the reader. I finished High School in 1960, and started studies in Mathematics at Warsaw University. Soon, I met socially Andrzej Ehrenfeucht and he suggested attending a seminar that a group of scientists conducted at the Mathematical Institute of the Academy of Sciences. It was a series of meetings that can be characterized by a completely informal atmosphere and truly interdisciplinary subject of talks. Among the leaders of the groups were Robert Bartoszyński, Andrzej Ehrenfeucht, Zdzisław Pawlak and other future leaders of Computer Science in Warsaw. The atmosphere was very informal and the hierarchical relationship so often visible in the university education and research was, simply, absent. I was the youngest person attending the seminar. This informal atmosphere was very different from the seminars lead at Warsaw University by Professors Andrzej Mostowski (the head logician in Warsaw) and by Professor Helena Rasiowa. The main topics of these informal seminars were foundations and applications of computers. Of course, there were very few actual computers (but there were some) and the topics were an interesting mixture of entirely theoretical topics (for instance Turing Machines) and Hao Wang's experiments with proving theorems of "Principia Mathematicae" on IBM machines. There was strong presence of individuals interested in biomedical information (or, to be precise, what today is called such). This resulted from the research of Zdzisław Pawlak who, at the time, was interested in DNA as built by formal grammar. Eventually, Pawlak wrote a book (in Polish! [1]) devoted to this research. From my own perspective, the important aspect of the seminar was opening of a perspective – computers and their foundational issues.

In 1964 I completed my M.Sc. in Mathematics studies and joined Professor Mostowski group. This was Foundations of Mathematics group but also comprised of algebraists. Soon, Andrzej Ehrenfeucht emigrated to United States eventually settling in Boulder, CO (where he still teaches). Mostowski and his research group got involved in research on a new (and very exciting) topic called "forcing". This was, at the time completely mysterious, technique for independence proofs in Set Theory. In my case, I worked in this area for a number of years. But in 1970 I went for a post-doc appointment in Utrecht, Holland, in a group of Professor Dirk van Dalen. Their interests were different and were motivated by different aspects of Foundations. A strong influence on my thinking was exercised by Henk Barendregt and his research on λ-calculus. Even more importantly, as I was returning from Holland, I visited Arhus University in Denmark (where my colleague Dr. Janusz Onyszkiewicz was a post-doc) and noticed that logicians there were mainly interested in Computer Science considerations. This made me thinking that maybe it is time to look again at computers.

II. Changed Perspective

The year 1970 and the revolt of workers resulted in significant changes in Poland. From the point of view of Computer Science studies there were significant changes, too. Warsaw University reorganized its science programs. Mathematicians and physicists parted ways. The Mathematics and Physics faculty divided and Mathematics faculty became Mathematics, Mechanics and Computer Science. Computing Center of the Academy of Sciences evolved (first informally, then formally) into the Institute of Computer Science. Mathematicians in the Academy created a venue for Mathematical research called Banach Center. This place welcomed not only "pure" mathematicians but also computer scientists. Yet another important change was creation of "Technical Physics and Applied Mathematics" program at Warsaw Technical University. This program attracted students that were interested in applications, and became a premier program in Computer Science. The alumni of this program included Witold Lipski, Tomasz Imieliński, Mirosław Truszczyński and several other outstanding researchers. At the same time Professors Pawlak and Rasiowa created a publication venue; a journal *Fundamenta Informaticae*. This journal, associated with Polish Mathematical Society became, eventually one of premier places for the publication of Computer Science research. The very name of that journal (with the word *Fundamenta*) alluded to the great

978-83-60810-90-3/$25.00

traditions of foundational research, as done in Poland after WWI.

III. Information Storage and Retrieval Systems

So, after I came back from post doctoral stint in Holland, and seeing that many logicians started to do research in Computer Science, I was certainly open to look at the problems that were grounded in applications of computers. Given the academic system in Poland where one had to write *Habilitation* (a degree established in Germanic and other countries of Europe) took time, sometimes around 1973 I was ready to expand my interests into Computer Science. Then came a series of phone calls for Professor Pawlak (i.e. Zdzisław, recall the 1960ies seminar). After some time I understood the idea. It was a model of databases. Recall that since the work of E.F. Codd on the relational model of database, computer scientists investigated logical formalisms that would eliminate need for the fluency in data structures (such as double linked lists) to operate databases. Eventually several proposals for logic-based languages were proposed and SQL and many of its variations were adopted as a logic-based language for what is known as relational databases. But the Pawlak's proposal [2] differed from the Codd's proposal in several important details. The single table idea was closely related to so-called universal instance. In fact significant effort of a large group of researchers of relational model was spent on decomposing tables, since universal instances were too big to be effectively processed. This research and the enormous effort spent by the database community is at least partly forgotten now, as, with the increased processing capacity of computers, often one denormalizes databases. Other differences of Pawlak's proposal versus SQL-based databases was that SQL admitted null values (thus is, really, based on multivalued logic). But the real difference (and the one that was quietly incorporated into SQL-based systems) was the fact that Information Storage and Retrieval Systems (ISRs), from the very beginning admitted duplicate objects. In other words, different objects could have the same descriptions. This property of ISRs implied existence of (potentially nontrivial) equivalence relation on the set of objects, $\equiv$, namely: $o_1 \equiv o_2$ iff description of o_1 is the same as description of o_2.

The studies of ISRs were conducted by many researchers in Poland and other countries, and the reason for it was that the logicians were ready to investigate ISRs. Let me mention that the group of researchers in Warsaw alone consisted of over 10 individuals. Led mostly by Witold Lipski it included people in the Technical University, Warsaw University and the Academy of Sciences: Tomasz Imieliński, Paweł Traczyk, Michał Jeagermann, Cecylia Rauszer, Andrzej Jankowski, myself, and many others. Lipski and Imieliński tied ISR to the relational model and very soon we were aware of similarities and of differences with Relational Model.

The motivation of ISR came, not surprisingly, from the work of Pawlak with the physicians, more generally, biomedicine researchers. Once one thinks about it, it is clear that computerized medical records of patients may be quite similar or even (after elimination of personal identifiable information) identical. Since the idea in the background was to "mine" the information and find dependencies present in such data, the presence of duplicates was, actually, an interesting information.

IV. Rough Sets, Handling Different Description Languages

The ISRs were based on a first-order language; the objects possessed descriptions. But one observation (motivated by potential biomedical applications) was that there may be more than one language associated with a set of objects. To give one example let us look at a collection of patients. We may have a language associated with symptoms exhibited by the patients but there may be another language to describe the patients, one based on objective data such as various biochemical data (levels of enzymes, presence or absence of specific genes, etc.). The question asked by Pawlak, and one that lies behind the concept of rough sets [3] is this: do we need to specify the description language for the set of objects, or could we, instead, abstract from the specific language and consider equivalence relation "having the same description"? Once this fundamental question was asked, the concept of rough sets, and the associated "interior" and "closure" operations became very natural. Moreover, such approach opened, immediately, the need to look at numerical parameters associated with rough sets (for instance: measures of roughness such as various ratios (for instance of the boundary to the closure), and various characteristics of the equivalence relation (such as the discrepancy - the ratios of sizes of "large" equivalence classes to the small ones). The rest is history; rough sets were introduced, studied, and – most importantly – applied. Like many other fundamental concepts, they were specialized, generalized, investigated for relationship with other concepts (from logic, topology, universal algebra, and combinatorics). Contributions of many researchers, from many countries, and with many interests witness to importance of Pawlak's intuitions.

***Abstract*—The article provides an overview of different approaches to the methods of conflict analysis that are inspired by the model of Zdzisław Pawlak. In the first part of the paper, Pawlak's original model is described. In the second part, the model proposed by Skowron and Deja is discussed. In the third part, the model proposed by the authors is presented.**

I. Introduction

IN THE paper issues related to the problem of conflict analysis are considered. In 1984 Zdzisław Pawlak proposed a simple and intuitive model of conflict analysis. This model allows the relations between the units involved in the conflict to be defined and enables the conflict situation to be visualized and coalitions to be identified. In the model, the concept of agents was introduced and it is a multi-agent system, although it has nothing in common with the definition of the multi-agent systems that are known from the literature [9], [13], [37]. The first articles about this model were written by Pawlak and Skowron [18], [19], [20], [21], [22], [23], [24], [25], [38]. However, the intensive development of solutions to these problems occurred after Pawlak's death and was, in some sense, the realization of his intentions. The extensions of the model that were proposed allow for the analysis of conflicts in different situations as well as for numerous applications in real life situations. Some of these approaches stem from attempts to find solutions to real situations and the effects of different solutions to conflict. In this study, both the original conflict model of Pawlak as well as a review of the directions of its development are presented.

II. Pawlak's conflict model

Conflicts are inscribed in human nature and they have been with us since the dawn of history. Conflict analysis plays an important role in government, politics, business, lawsuits, disputes, negotiations, military operations, labor-management and others. In 1984, in the paper [18], a model to describe the complicated structure of conflict in a simple way was proposed by Zdzisław Pawlak. This issue was further developed by Pawlak in the papers [19], [20], [21], [22], [23], [24]. During the period in which Pawlak was interested in the issue of conflict, some other models of conflict situations were discussed in [1], [8], [10], [12], [15], [36]. Pawlak predicted that rough and fuzzy sets are the perfect candidates for modeling conflict situations in the presence of uncertainty, but at that time, not very much had been done in this area.

In the proposed model, the parties involved in the conflict are called agents. Depending on the type of conflict situation, that is considered, agents can be individuals, groups of individuals, institutions, companies, countries, etc. Each agent expresses his opinion about some discussed issue by assigning one of three values: -1 means, that an agent is against, 0 neutral toward the issue 1 means favorable. Knowledge about conflict situation is written in the form of table, in which rows are labeled by agents, and columns are labeled by discussed issues. The entries of the table are the values that were uniquely assigned to each agent and an issue. Each entry represents opinion of agent about issue. This type of table is an example of an information system $S = (U, A)$, that definition can be found in the literature [16], [17]. In the case of the Pawlak's conflict model elements of the universe U are agents, A is a set of issues, and the set of values of $a \in A$ is equal $V^a = \{-1, 0, 1\}$. The value $a(x)$, where $x \in U, a \in A$ is opinion of agent x about issue a. For each $a \in A$ function $\phi_a : U \times U \to \{-1, 0, 1\}$ is defined:

$$\phi_a(x,y) = \begin{cases} 1 & \text{if } a(x)a(y) = 1 \text{ or } x = y, \\ 0 & \text{if } a(x)a(y) = 0 \text{ and } x \neq y, \\ -1 & \text{if } a(x)a(y) = -1. \end{cases}$$

Then over $U \times U$ three relations are defined: R_a^+ alliance, R_a^0 neutrality, R_a^- conflict, that express the relations between agents:

$$\begin{array}{ll} R_a^+(x,y) & \text{if and only if } \phi_a(x,y) = 1, \\ R_a^0(x,y) & \text{if and only if } \phi_a(x,y) = 0, \\ R_a^-(x,y) & \text{if and only if } \phi_a(x,y) = -1. \end{array}$$

Directly from the definition indicates that the alliance relation is

- reflexive: $\forall_{x \in U} R_a^+(x,x)$,
- symmetric: $\forall_{x,y \in U} \big(R_a^+(x,y) \Rightarrow R_a^+(y,x)\big)$,
- transitive: $\forall_{x,y,z \in U} \big(R_a^+(x,y) \wedge R_a^+(y,z) \Rightarrow R_a^+(x,z)\big)$.

Relation R_a^+ is an equivalence relation. Each equivalence class of alliance relation R_a^+ is called coalition on a.

In order to evaluate views between agents x and y with respect to the set of issues $B \subseteq A$ a function of distance

between agents $\rho_B^* : U \times U \to [0,1]$ is defined

$$\rho_B^*(x,y) = \frac{\sum_{a \in B} \phi_a^*(x,y)}{card\{B\}},$$

where

$$\phi_a^*(x,y) = \frac{1 - \phi_a(x,y)}{2} =$$

$$= \begin{cases} 0 & \text{if } a(x)a(y) = 1 \text{ or } x = y, \\ 0.5 & \text{if } a(x)a(y) = 0 \text{ and } x \neq y, \\ 1 & \text{if } a(x)a(y) = -1. \end{cases}$$

In the definition of the function of distance between agents it is assumed that distance between agents that are in conflict is greater than distance between agents which are neutral. The function of distance between agents for the set of all issues $B = A$ is written in short as ρ.

Now we can in a more general way than before, without reference to specific issues, define the relations between agents. A pair $x, y \in U$ is said to be:

- allied $R^+(x,y)$, if $\rho(x,y) < 0.5$,
- in conflict $R^-(x,y)$, if $\rho(x,y) > 0.5$,
- neutral $R^0(x,y)$, if $\rho(x,y) = 0.5$.

Set $X \subseteq U$ is a coalition if for every $x, y \in X$, $R^+(x,y)$ and $x \neq y$. Coalitions defined in this way does not have to be pairwise disjoint, which was shown in Example 2.1.

Each agent has the strength, that is expressed in the form of non-negative real number $\mu : U \to [0, \infty)$. The strength $\mu(x)$ of agent x can represent economic or military power of a given agent. Each agent distributes his forces against his enemies according to a chosen strategy and knowledge of the situation. A strategy is defined as a function $\lambda : U \times U \to [0, \infty)$ that assigns a non-negative real number to each pair of agents x, y. This number expresses how much strength the agent x directed against the agent y. It is reasonable to assume that for every x, y:

$$\text{if } \rho(x,y) \leq 0.5 \text{ then } \lambda(x,y) = 0,$$

$$\sum_{y \in E_x} \lambda(x,y) \leq \mu(x),$$

where E_x is the set of all enemies of x, i.e., $E_x = \{y \in U : \rho(x,y) > 0.5\}$. The first condition indicates that the strength directed by x against agents who are allied with x or neutral to x is zero. The second condition ensures that the sum of all the forces led by the x against their enemies may not exceed the strength of agent x. Of course, the choice of strategy is essential in the case, which agents will win in a conflict situation, and which will lose.

Pawlak has defined a particularly important strategy, in which each agent has enough strength to destroy all of his enemies. A strategy of intimidation is a strategy λ that fulfills the conditions:

$$\forall_{x \in U} \quad \sum_{y \in E_x} \lambda(x,y) = \mu(x),$$
$$\forall_{x,y \in U} \quad \lambda(x,y) = \lambda(y,x).$$

The strategy of intimidation is unfavorable for all of the agents involved in the conflict, since its realization will cause that all agents will destroy each other.

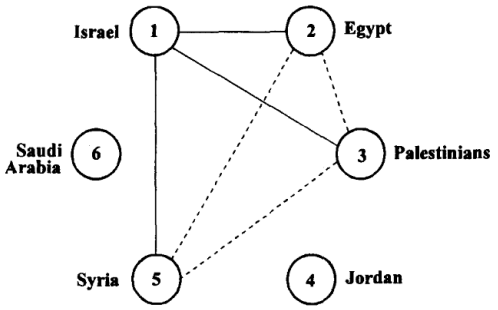

Fig. 1. A graphical representation of the Middle East conflict, issue a

Example 2.1: We consider an example named the Middle East conflict that is from the paper [22]. In the example there are six agents $U = \{1,2,3,4,5,6\}$

1 - Israel,
2 - Egypt,
3 - Palestinians,
4 - Jordan,
5 - Syria,
6 - Saudi Arabia

and five issues $A = \{a, b, c, d, e\}$

a - autonomous Palestinian state on the West Bank and Gaza,
b - Israeli military outpost along the Jordan River,
c - Israeli retains East Jerusalem,
d - Israeli military outposts on the Golan Heights,
e - Arab countries grant citizenship to Palestinians who choose to remain within their borders.

The relationship of each agent to a specific issue is presented in Table I.

As can be seen Egypt, Palestinian and Syria are allied on issue a, Jordan and Saudi Arabia are neutral to this issue whereas, Israel and Egypt, Israel and Palestinian, and Israel and Syria are in conflict about this issue. This can be easily illustrated by a graph. Figure 1 shows a graphical representation of the conflict situation. Agents are represented by circles in the figure. When a pair of agents is in conflict about the issue a, the circles representing the agents are linked. When agents are allied no this issue, the circles representing the agents are connected by dotted line.

The value of the function of the distance between agents is calculated for each pair of agents. These values are given in Table II. Now a graphical representation of a conflict situation, that takes into account all issues being considered by agents, is presented in Figure 2. As before when a pair of agents is in conflict, the circles representing the agents are linked. When agents are allied, the circles representing the agents are connected by dotted line. Neutral agents are not present in this conflict situation. In order to find coalitions, all cliques should be identified in the graph. So the subset of vertices such that every two vertices are connected by dotted line is determined. There are two coalitions in the Middle East conflict $\{1,6\}$ and $\{2,3,4,5\}$.

TABLE I
INFORMATION SYSTEM FOR THE MIDDLE EAST CONFLICT

U	a	b	c	d	e
1	-1	+1	+1	+1	+1
2	+1	0	-1	-1	-1
3	+1	-1	-1	-1	0
4	0	-1	-1	0	-1
5	+1	-1	-1	-1	-1
6	0	+1	-1	0	+1

TABLE II
VALUES OF THE DISTANCE FUNCTION BETWEEN AGENTS

	1	2	3	4	5	6
1						
2	0.9					
3	0.9	0.2				
4	0.8	0.3	0.3

6	0.4	0.5	0.5	0.4	0.6	

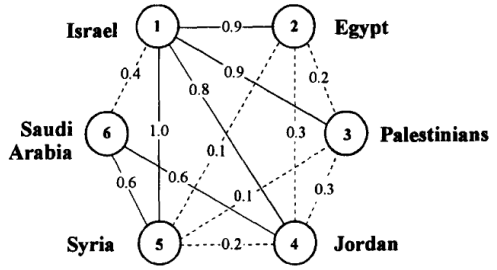

Fig. 2. A graphical representation of the Middle East conflict, distance between agents

The model of conflict analysis that was proposed by Pawlak allows to make advanced analysis of relations between agents and provides guidance that help to decide about strategy. Presented mathematical model is a simple way to illustrate the basic properties of conflicts.

The concepts described above were pursued by many authors [2], [3], [4], [5], [6], [7], [11], [14], [32], [33], [34], [35], [38], [39], [44], [45], [46], [47], [48], [49], [50], [51]. Some of these proposals are briefly described below.

III. CONFLICT MODEL PROPOSED BY SKOWRON AND DEJA

Around 1996, Skowron and Deja proposed conflict model [2], which is an enhancement of the Pawlak model. This concept is described in the papers [3], [4], [5], [6], [38], [7]. Motivation to propose a new model was that, as the authors noted, in the Pawlak model a set of the attribute's values may be too limited in many real situations. Moreover, the assumption that the issues the agents vote represent the issues each agent takes care of causing that the model can be applied in very few real situations. In addition, the reason for the conflict cannot be determined because views on the issues to vote are consequences of the decision taken, based on the local issues, the current state and some background knowledge that are the real cause of the conflict. The main aim of a new model is to define and analyse causes of conflict. It was assumed that the conflict between agents is the consequence of the limited resources which are available to agents in a situation. If the number of resources is insufficient to attain agents' goals it often comes into the conflicts. In the proposed model, the fact was taken into consideration that any agent is describing the situation in its own way. The manner of understanding the same world by each agent can be completely different. A reflection of this assumption in the mathematical model is that for each agent a separate information system is assigned. It was assumed that the sets of attributes of different agents are pairwise disjoint.

Let Ag be a set of agents involved in conflict. Knowledge about the views of agent $ag \in Ag$ on conflict situation is represented in an information system $S_{ag} = (U_{ag}, A_{ag})$, where U_{ag} - is a set of local states and A_{ag} - is a set of attributes. It was assumed that the sets of attributes of different agents are pairwise disjoint

$$\forall_{ag,ag' \in Ag;\, ag \neq ag'} \quad A_{ag} \cap A_{ag'} = \emptyset.$$

For each information system a target function $e_{ag} : U_{ag} \rightarrow [0, 1]$, that determines a subjective evaluation score to each state, is defined. The target function is used to determine the subset of local states, which are accepted by the agent with a fixed threshold value. A set of target states is $T_{ag} = \{s \in U_{ag} : e_{ag}(s) > \mu_{ag}\}$, where μ_{ag} is a level of acceptance, chosen subjectively by the agent ag. The set of target states in this model are presented in the form of Boolean formula.

Conflict is described by a situation and constraints. A situation S is any element of the Cartesian product $S_{Ag} = \prod_{ag \in Ag} U^*_{ag}$, where U^*_{ag} is a set of all possible local states of the agent ag. Constraints come from the bound on the number of resources and describe some dependencies among local states of agents. Constraints restrict the set of possible situations to admissible situations and are described by Boolean formulas.

The situations are evaluated. The score assigned to each situation can reflect the agents preferences (subjective states

evaluation) or the expert judgement - who takes into account the global good. In the second evaluation method, a quality function $q : S_{Ag} \rightarrow [0, 1]$ is defined. The set of situations satisfying a given level of quality t is defined by

$$Score_{Ag}(t) = \{S \in S_{Ag} : q(S) \geq t\}.$$

Boolean formula that describes the set $Score_{Ag}(t)$ is determined. Assessment of the situation expressed by preferences of the agents is defined by the global preference function $p : S_{Ag} \rightarrow R$, $p(S) = F\big(e_{ag_1}(s_1), \ldots, e_{ag_n}(s_n)\big)$, where $S = (s_1, \ldots, s_n)$ and $n = card\{Ag\}$. Aggregation function F may be chosen in many different ways. Boolean formula that describes the set of all preferred situations is also determined.

The multi-agent system, with local states for each agent defined and the global situations satisfying constraints, will be called the system with constraints and is denoted by M_{Ag}. In such systems, conflict can be defined on several levels. Three types of conflicts are distinguished

- local conflict - that arises from the low level of subjective evaluation of the current state,
- global conflict (based on an expert evaluation) - indicates the existence of a situation which is not preferable for the global good,
- global conflict (based on agents preferences) - indicates that the current situation is not preferred by most of the agents.

The concepts of conflict, that are defined above, are the basis for investigation of the most fundamental problem - the possibility to achieve the consensus. In this model, the solution of conflict is searched on various levels: local and global, subjective and objective. In all cases, this is accomplished by determining the conjunction of Boolean formulas that describe appropriate conditions.

IV. Conflict model proposed by Wakulicz-Deja and Przybyła-Kasperek

Around 2009, Wakulicz-Deja and Przybyła-Kasperek proposed conflict model, which is also an extension of the Pawlak model. This concept is described in the papers [26], [27], [28], [29], [30], [31], [40], [41], [42], [43]. Motivation to propose a new model was that, the authors wanted to use conflict model for making decisions based on dispersed knowledge that is stored in many local decision tables. These tables are given in advance and collected by different units for example in different medical centers. It is not assumed that the sets of conditional attributes or the universe of different local decision tables are disjoint or equal. In the situation that is described above the Pawlak model can not be directly applied, because we are dealing with a set of decision tables - not just one information system. The Skowron – Deja model can not be applied, because in order to resolve conflicts the Boolean reasoning is used there and the algorithm has exponential pessimistic execution time. The identification of constraints in the considered dispersed situation is not possible. In addition, the assumption that the sets of conditional attributes of all decision tables must be disjoint is not fulfilled.

The main assumptions that were adopted in the proposed model are that knowledge is stored in several decision tables. There are a set of resource agents, one agent has access to one decision table. The resource agents, that are similar, in some specified sense, are combined into a group. In the process of groups creating elements of conflict analysis and negotiation are used. System has a hierarchical structure. For each group of agents a superordinate agent is defined - a synthesis agent. The synthesis agent has access to knowledge that is the result of the process of inference that is carried out by the resource agents that belong to its subordinate group. Based on local decisions taken by synthesis agents, global decisions are generated using certain fusion methods and methods of conflict analysis.

Different approaches to creating a system's structure were proposed: from a very simple solution to a more complex method of creating groups of agents. Below, a brief overview of the proposed approaches was presented.

The first approach was proposed in the papers [40], [41], [42]. In these articles definitions of resource agents and synthesis agents are given, and the hierarchical structure of the system was established. We call ag in Ag a resource agent if it has access to the resources that are represented by a decision table $D_{ag} := (U_{ag}, A_{ag}, d_{ag})$, where U_{ag} is „the universe"; A_{ag} is a set of conditional attributes, and V^a_{ag} is a set of attribute a values that contain the special signs * and ?. The equation $a(x) = *$ for some $x \in U_{ag}$ means that for an object x, the value of attribute a has no influence on the value of the decision attribute, while the equation $a(x) =?$ means that the value of attribute a for object x is unknown; d_{ag} is referred to as a decision attribute and V^d_{ag} is called the value set of d_{ag}. The only condition that must be satisfied by decision tables of agents is the occurrence of the same decision attributes in all of the decision tables of the agents. In this first approach it was assumed that resource agents taking decisions on the basis of common conditional attributes form a group of agents called a cluster. For each cluster that contains at least two resource agents, a superordinate agent is defined, which is called a synthesis agent as. By a dispersed system we mean

$$WSD_{Ag} = \langle Ag, \{D_{ag} : ag \in Ag\}, As, \delta \rangle,$$

where Ag is a finite set of resource agents; $\{D_{ag} : ag \in Ag\}$ is a set of decision tables of resource agents; As is a finite set of synthesis agents, $\delta : As \rightarrow 2^{Ag}$ is a injective function which each synthesis agent assign a cluster. A significant problem that must be solved when making decisions based on dispersed knowledge has identified - inconsistencies of knowledge may occur within the clusters. This problem stems from the fact that there are no assumptions about the relation between the sets of the conditional attributes of different resource agents in the system. We understand an inconsistency of knowledge to be a situation in which conflicting decisions are made on the basis of two different decision tables that have common conditional attributes and for the same values for the common attributes using logical implications. The process of generating the common knowledge (an aggregated decision table) for each cluster was proposed that was named as the process for the elimina-

tion of inconsistencies in the knowledge. This method consists in constructing new objects that are based on the relevant objects from the decision tables of the resource agents that belong to one cluster. The aggregated objects are created by combining only those relevant objects for which the values of the decision attribute and common conditional attributes are equal. Based on the aggregated decision tables the values of decisions with the highest support of synthesis agents are selected. Global decisions are taken using the DBSCAN algorithm.

The second approach was proposed in the papers [26], [27], [43]. The same methods as in the first approach are used, however, additionally the decision tables of the resource agents are subjected to a certain transformation. In the paper [43], the method of editing and condensing were used on the decision tables of the resource agents. In the paper [26], based on the decision tables of the resource agents decision rules, using rough set theory, are generated. Then, in a single cluster, these rules are aggregated. In the article [27], from each decision tables of the resource agents unnecessary attributes are removed.

The third approach was proposed in the papers [28], [30]. The main modification, compared to the first approach, was conducted within the process of creating a system's structure. In the previous approaches a dispersed system has a static structure (created once, for all test objects), and this time a dynamic structure is used (created separately for each test object). The aim of this approach is to identify homogeneous groups of resource agents. The agents who agree on the classification into the decision classes for a test object will be combined in a group. The modified definitions of relations of friendship and conflict as well as the method for determining the intensity of the conflict, which were introduced by Pawlak, are used. Relations between agents are defined by their views for the classification of the test object to the decision classes. In the first step of the process of clusters creating for each resource agent ag_i a vector of probabilities that reflects the classification of the test object is generated. Then, based on this vector, the vector of ranks $[r_{i,1}(x), \ldots, r_{i,c}(x)]$, where $c = card\{V^d\}$ is generated. We define the function $\phi^x_{v_j}$ for the test object x and each value of the decision attribute $v_j \in V^d$; $\phi^x_{v_j} : Ag \times Ag \to \{0, 1\}$

$$\phi^x_{v_j}(ag_i, ag_k) = \begin{cases} 0 & \text{if } r_{i,j}(x) = r_{k,j}(x) \\ 1 & \text{if } r_{i,j}(x) \neq r_{k,j}(x) \end{cases}$$

where $ag_i, ag_k \in Ag$.

We also define the intensity of conflict between agents using a function of the distance between agents. We define the distance between agents ρ^x for the test object x: $\rho^x : Ag \times Ag \to [0, 1]$

$$\rho^x(ag_i, ag_k) = \frac{\sum_{v_j \in V^d} \phi^x_{v_j}(ag_i, ag_k)}{card\{V^d\}},$$

where $ag_i, ag_k \in Ag$.

We say that agents $ag_i, ag_k \in Ag$ are in a friendship relation due to the object x, which is written $R^+(ag_i, ag_k)$, if and only if $\rho^x(ag_i, ag_k) < 0.5$. Agents $ag_i, ag_k \in Ag$ are in a conflict relation due to the object x, which is written $R^-(ag_i, ag_k)$, if and only if $\rho^x(ag_i, ag_k) \geq 0.5$.

Then, the groups of agents who are in agreement about the classification to the decision classes of the test object are defined. Two different approaches to combining agents in the friendship relations into one cluster were considered.

In the paper [30] the approach is proposed in which disjoint clusters of resource agents remaining in the friendship relations are created. The process of clusters creating in this approach is very similar to the hierarchical agglomerate clustering method and proceeds as follows. Initially, each resource agent is treated as a separate cluster. These two steps are performed until the stop condition, which is given in the first step, is met.

1) One pair of different clusters is selected (in the very first step a pair of different resource agents) for which the distance reaches a minimum value. If the selected value of the distance is less than 0.5, then agents from the selected pair of clusters are combined into one new cluster. Otherwise, the clustering process is terminated.
2) After defining a new cluster, the value of the distance between the clusters are recalculated. The following method for recalculating the value of the distance is used. Let $\rho^x : 2^{Ag} \times 2^{Ag} \to [0, 1]$, let D_i be a cluster formed from the merger of two clusters $D_i = D_{i,1} \cup D_{i,2}$ and let it be given a cluster D_j then

$$\rho^x(D_i, D_j) = \begin{cases} \frac{\rho^x(D_{i,1}, D_j) + \rho^x(D_{i,2}, D_j)}{2}, & \text{if } \rho^x(D_{i,1}, D_j) < 0.5 \text{ and } \rho^x(D_{i,2}, D_j) < 0.5 \\ \max\{\rho^x(D_{i,1}, D_j), \rho^x(D_{i,2}, D_j)\}, & \text{if } \rho^x(D_{i,1}, D_j) \geq 0.5 \text{ or } \rho^x(D_{i,2}, D_j) \geq 0.5 \end{cases}$$

In the paper [28] the approach is proposed in which not disjoint clusters are created. The cluster due to the classification of object x is the maximum, due to the inclusion relation, subset of resource agents $X \subseteq Ag$ such that $\forall_{ag_i, ag_k \in X} \; R^+(ag_i, ag_k)$. Thus, the cluster is the maximum, due to inclusion relation, set of resource agents that remain in the friendship relation due to the object x.

In both approaches, the same definition of dispersed system is used. By a dispersed decision-making system with dynamically generated clusters, we mean

$$WSD^{dyn}_{Ag} = \big\langle Ag, \{D_{ag} : ag \in Ag\}, \{As_x : x \text{ is a classified object}\}, \{\delta_x : x \text{ is a classified object}\} \big\rangle$$

where Ag is a finite set of resource agents; $\{D_{ag} : ag \in Ag\}$ is a set of decision tables of the resource agents; As_x is a finite set of synthesis agents defined for the clusters that are dynamically generated for test object x, $\delta_x : As_x \to 2^{Ag}$ is an injective function that each synthesis agent assigns to the cluster that is generated due to classification of object x.

Also in both approaches the method of elimination of inconsistencies in the knowledge and the DBSCAN algorithm, that were proposed in the first approach, are used.

The fourth approach was proposed in the paper [29]. In this approach a dynamic structure is also used, but the process

of clusters creating is more extensive and as a consequence the clusters are more complex and better reconstructed and illustrate the views of the agents on the classification. The main differences between this approach and the previous approach are as follows. Now, three types of relations between agents are defined: friendship, neutrality and conflict (previously, only two types were used). The clustering process consists of two stages (previously, only one stage process was used). In the first step initial groups are created, it contains agents in friendship relation. In the second stage, a negotiation stage, agents which are in neutrality relation are attached to the existing groups. In order to define the intensity of conflict between agents two function are used: the distance function between agents (was used in the previous approach) and a generalized distance function. The process of clusters creating is as follows. At first the distance between agents ρ^x is defined. Definitions of the relations between agents are modeled on the definitions that were given by Pawlak. Let p be a real number that belongs to the interval $[0, 0.5)$. We say that agents $ag_i, ag_k \in Ag$ are in a friendship relation due to the object x, which is written $R^+(ag_i, ag_k)$, if and only if $\rho^x(ag_i, ag_k) < 0.5 - p$. Agents $ag_i, ag_k \in Ag$ are in a conflict relation due to the object x, which is written $R^-(ag_i, ag_k)$, if and only if $\rho^x(ag_i, ag_k) > 0.5 + p$. Agents $ag_i, ag_k \in Ag$ are in a neutrality relation due to the object x, which is written $R^0(ag_i, ag_k)$, if and only if $0.5 - p \leq \rho^x(ag_i, ag_k) \leq 0.5 + p$. The first step in the process of creating clusters is to define the initial cluster. The initial cluster due to the classification of object x is the maximum, due to the inclusion relation, subset of resource agents $X \subseteq Ag$ such that $\forall_{ag_i, ag_k \in X} \ R^+(ag_i, ag_k)$. After the first stage of clustering we obtain a set of initial clusters and a set of agents which are not included in any cluster. In this second group of agents there are agents which remained undecided. So those which are in neutrality relation with agents belonging to some initial clusters. In the second step, the negotiation stage, this agents play a key role. As it is known the goal of negotiation process is to reach a compromise by accepting some concessions by the parties involved in a conflict situation. In the negotiation process, the intensity of the conflict is determined by using the generalized distance function. This definition assumes that during the negotiation, agents put the greatest emphasis on compatibility of ranks assigned to the decisions with the highest ranks. That is the decisions that are most significant for the agent. Compatibility of ranks assigned to less meaningful decision is omitted. We define the function ϕ_G^x for test object x; $\phi_G^x : Ag \times Ag \to [0, \infty)$

$$\phi_G^x(ag_i, ag_j) = \frac{\sum_{v_l \in Sign_{i,j}} |r_{i,l}(x) - r_{j,l}(x)|}{card\{Sign_{i,j}\}}$$

where $ag_i, ag_j \in Ag$ and $Sign_{i,j} \subseteq V^d$ is the set of significant decision values for the pair of agents ag_i, ag_j. We also define the generalized distance between agents ρ_G^x for the test object x; $\rho_G^x : 2^{Ag} \times 2^{Ag} \to [0, \infty)$

$$\rho_G^x(X, Y) = \begin{cases} 0 & \text{if} \quad card\{X \cup Y\} \leq 1 \\ \dfrac{\sum\limits_{ag, ag' \in X \cup Y} \phi_G^x(ag, ag')}{card\{X \cup Y\} \cdot (card\{X \cup Y\} - 1)} & \text{else} \end{cases}$$

where $X, Y \subseteq Ag$. As can be easily seen, the value of the generalized distance function for two sets of agents X and Y is equal to the average value of the function ϕ_G^x for each pair of agents ag, ag' that belong to the set $X \cup Y$. For each agent which is not attached to any cluster we calculate the value of generalized distance function for this agent and every initial cluster. Then the agent is included to all initial clusters, for which the generalized distance does not exceed a certain threshold, which is set by the system's user. Also agents without coalition, for which the value does not exceed the threshold, are combined into a new cluster. We do not connect agents who are in conflict relation in one cluster. After completion of the second stage of the process of clustering we get the final form of clusters. Then the method of elimination of inconsistencies in the knowledge and the DBSCAN algorithm, that were proposed in the first approach, are used.

The fifth approach was proposed in the paper [31]. In this paper, a method of creating clusters is the same as in the previous approach but when the global decisions are taken the agents' weights are additionally calculated. Different methods of calculating the strength of a cluster was proposed:

- with respect to the number of component agents,
- with respect to the decisiveness of agents,
- with respect to the number of component agents and the decisiveness of agents,
- with respect to the decisiveness-based cluster strength.

Further work is carried out on the development of a dispersed system. The authors propose another approach in order to achieve a better efficiency of the system and always find inspiration in the work of Pawlak. The relations as well as the method for determining the intensity of a conflict between agents that were proposed by Pawlak are always the basis of the entire system.

V. Summary

In this article, the conflict analysis model that was proposed by Pawlak has been described. The aim of the study was to show the main extensions of this model that have been proposed in the literature. Pawlak's model is simple, intuitive and very useful in the analysis of the complex nature of conflicts. The model has many applications and is inspiration for developing new approaches.

***Abstract*—This paper is an application of Edelsbrunner-Harer (EH) nerves as approximating tools in discovering interesting perceptual clusters in Pawlak's painting of landscapes, thus giving us an insight into the style of the artist. A variation of EH nerves (collections of Voronoï regions called nucleus clusters) are used in this paper. The Rényi entropy is used to measure the information level of Voronoï regions. It is shown that the information levels (i.e., Rényi entropy) of maximal nucleus clusters in tesselled paintings are the highest compared with surrounding regions, thereby highlighting regions in the paintings with the greatest detail by the artist.**

I. Introduction

IN THIS paper, we are seeking to discover interesting clusters using the concept of nerves useful in visual arts. Visual art forms include paintings, ceramics, photography amongst others. Both spatial and descriptive forms of representation will be considered [1]. First, we start by considering a representative space for the visual information in paintings by Z. Pawlak. *Spatial representation* can be considered in two ways: i) one where a space is given and its characteristics are studied via geometry and topology ii) a space is approximated using some form of tool [2]. *Descriptive representation* starts with probe functions that map features of objects to numbers in $\mathbb{R}^n$ [1]. Probe values provide a description of an object. The problem of finding interesting clusters in an object space X is mapped to the problem of finding interesting clusters in a feature space $\Phi(X)$. The nearness of feature space clusters is studied in the context of proximity spaces.

Various forms of geometric nerves are usually collections known as simplicial complexes in a normed linear space (for details see, e.g. , [3], [1, §1.13]). A nerve $N(C)$ in a finite collection of sets C is a simplicial complex with vertices of sets in C and with simplices corresponding to all non-empty intersections among these sets.

In a descriptive representation, the simplicial complexes are a result of nerve constructions of observations (objects) in the feature space. To construct the simplicial complexes, we tessellate Pawlak Paintings with Voronoi diagram overlays. Then we compute nerves of sets of collections derived from these Voronoi regions [4]. A variation of Edelsbrunner-Harer nerves which are collections of Voronoï regions (called nucleus clusters) are used in this paper. Rényi entropy is used to measure the information level of Voronoï tessellation cells [5]. The focus here is on maximal nucleus clusters (MNCs) that are strongly proximal Edelsbrunner-Harer nerves. A proximity space setting for MNCs makes it possible to investigate the strong closeness of subsets in MNCs as well as the spatial and descriptive closeness of MNCs themselves.

Voronoi tessellation has great utility and has many applications such as geometric modelling in physics, astrophysics, chemistry and biology [6] and in the study of digital images [1], [7], [8]. The form of clustering introduced in this article has proved to be important in the analysis of brain tissue [9]. The contribution of this paper is an application of Edelsbrunner-Harer nerves as approximating tools in discovering interesting perceptual clusters in Pawlak's painting of landscapes, thus giving us an insight into the style of the artist.

II. Definitions Plus MNC Construction

Every Voronoï region of a site s is a convex polygon containing all points that are nearer s than another site in a Voronoï tessellation of a surface. Voronoï regions are *strongly near*, provided the regions have points in common. In Fig. 1, Voronoï region N in the tessellation, is the nucleus of a mesh cluster containing all of those polygons adjacent to N. This form of clustering leads to the introduction of what are known as nucleus-clusters.

A Voronoï *mesh nucleus* is any Voronoï region that is the center of a collection of Voronoï regions adjacent to the nucleus. A *maximal nucleus cluster* is a collection of a maximal number of Voronoï regions that are *strongly near* the mesh nucleus. Maximal nucleus clusters (MNCs) serve as indicators of high object concentration in a tessellated image.

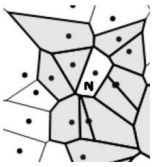

Fig. 1. Voronoï nucleus

Definition 1 (Voronoï region $V(s)$)**.** Let E be the Euclidean plane, $S \subset E$ (set of mesh generating points), $s \in S$.

$$V(s) = \{x \in E : \|x - s\| \leq \|x - q\|, \text{for all } q \in S\}.$$

Nonempty sets A, B in a topological space X equipped with the relation $\overset{\ast\ast}{\delta}$, are *strongly near* (i.e., strong proximity) (denoted $A \overset{\ast\ast}{\delta} B$), provided the sets have at least one point in common.

Definition 2. Nucleus Cluster (see, *e.g.*, Fig. 1). Let X be a collection of Voronoï regions containing N, endowed with the strong proximity $\overset{\ll}{\delta}$, $A \subset X, \mathrm{cl}A = \left\{x \in X : x \overset{\ll}{\delta} A\right\}$ (closure of A), and

$$\mathfrak{C}\, N = \left\{A \in X : \mathrm{cl}\ A \overset{\ll}{\delta} N\right\} \text{ (NC)} \qquad \blacksquare.$$

Let $A, B \subset X$ and let $\Phi(x)$ be a feature vector for $x \in X$, a nonempty set of non-abstract points such as picture points. $A\ \delta_\Phi\ B$ reads A is *descriptively near* B, provided $\Phi(x) = \Phi(y)$ for at least one pair of points, $x \in A, y \in B$ where $\Phi(A) = \{\Phi(x) \in \mathbb{R}^n : x \in A\}$ which are a set of feature vectors

The descriptive strong proximity $\overset{\ll}{\delta_\Phi}$ is the descriptive counterpart of $\overset{\ll}{\delta}$ defined in the feature space $\Phi(A)$. Let regions A, B be described by a feature vector of the form $(x, y, area, diameter)$. Then $A\ \overset{\ll}{\delta_\Phi}\ B$, provided A and B have matching descriptions. Formal proofs of the connection between relations and proximities are given in [1], [4].

Definition 3. Maximum Nuclear Cluster [4]. A nucleus cluster with nucleus N is *maximal*, provided N has the highest number of adjacent polygons in a tessellated surface denoted by $\max\mathfrak{C}N$. Similarly, a descriptive nucleus cluster is maximal, provided N has the highest number of polygons in a tessellated surface descriptively near N, (denoted by $\max\mathfrak{C}_\Phi N$). $\blacksquare$

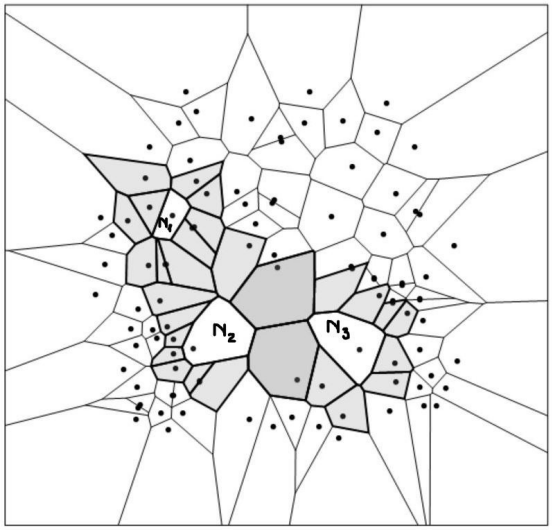

Fig. 2. $\mathfrak{C}\ N_1\ \overset{\ll}{\delta}\ \mathfrak{C}\ N_2$ and $\mathfrak{C}\ N_1\ \overset{\ll}{\delta_\Phi}\ \mathfrak{C}\ N_2$

Example 1. Let X be the collection of Voronoï regions in a tessellation of a subset of the Euclidean plane shown in Fig. 2 with nuclei $N_1, N_2, N_3 \in X$. In addition, let 2^X be the family of all subsets of Voronoï regions in X containing maximal nucleus clusters $\mathfrak{C}N_1, \mathfrak{C}N_2, \mathfrak{C}N_3 \in 2^X$ in the tessellation. Then, for example, $\mathrm{int}\mathfrak{C}N_2 \cap \mathrm{int}\mathfrak{C}N_3 \neq \emptyset$ where int is the interior of a set, since $\mathfrak{C}N_2, \mathfrak{C}N_3$ share Voronoï regions. Hence, $\mathfrak{C}N_2\ \overset{\ll}{\delta}\ \mathfrak{C}N_3 \neq \emptyset$ (for proof, see [4]). Similarly, $\mathfrak{C}N_1\ \overset{\ll}{\delta}\ \mathfrak{C}N_2$.

$\blacksquare$

Algorithm 1: Construct Maximal Nucleus Cluster

Input : Digital images img.
Output: MNCs on image img.

$img \longmapsto TitledImg$/*(Voronoï tessellation)*/;
Choose a Voronoï region in $TitledImg$: *;
$ngon \longleftarrow\!\shortmid TiledImg$;
$NoOfSides \longleftarrow\!\shortmid ngon$;
/* Count no. of sides in $ngon$ & remove it from $TitledImg$. */;
$TiledImg := TiledImg \setminus ngon$;
$ContinueSearch := True$;
while $(TiledImg \neq \emptyset$ *and* $ContinueSearch)$ **do**
  $ngonNew \longleftarrow\!\shortmid TiledImg$;
  $TiledImg := TiledImg \setminus ngonNew$;
  $NewNoOfSides \longleftarrow\!\shortmid ngonNew$;
  if $(NewNoOfSides > NoOfSides)$ **then**
    $ngon := ngonNew$;
  else
    /* Otherwise ignore $ngonNew$: */
  if $(TiledImg = \emptyset)$ **then**
    $ContinueSearch := False$;
    $max\mathfrak{C}N := ngon$;
    /* MNC found; Discontinue search */;

Let $\mathscr{F}$ be a finite collection of sets. An *Edelsbrunner-Harer nerve* (denoted by Nrv $\mathscr{F}$) consists of all nonempty subcollections of $\mathscr{F}$ that have a non-void common intersection, *i.e.*,

$$\mathrm{Nrv}\ \mathscr{F} = \left\{X \in \mathscr{F} : \bigcap X \neq \emptyset\right\}.$$

Lemma 1. [4] *Let $\mathscr{F}_{MNC}$ be a collection of polygons in a Voronoï MNC endowed with the strong proximity $\overset{\ll}{\delta}$. The structure $Nrv\mathscr{F}_{MNC}$ is an Edelsbrunner-Harer nerve.*

Theorem 1. [10, §III.2, p. 59] *Let $\mathscr{F}$ be a finite collection of closed, convex sets in Euclidean space. Then the nerve of $\mathscr{F}$ and the union of the sets in $\mathscr{F}$ have the same homotopy type.*

Theorem 2. [4] *Let the nucleus cluster $\mathfrak{C}N$ be a finite collection of closed, convex sets in a Voronoï mesh V in the Euclidean plane. The nerve $Nrv\mathscr{F}_{MNC}$ in $\mathfrak{C}N$ and the union of the sets in $\mathfrak{C}N$ have the same homotopy type.*

Theorem 3. [4] *Let X be a finite collection of MNC Edelsbrunner-Harer nerves $Nrv\mathscr{F}_{MNC}$ in a Voronoï mesh with nuclei N in the Euclidean plane and let X be equipped with the relator $\left\{\overset{\ll}{\delta}, \overset{\ll}{\delta_\Phi}\right\}$ with strongly close mesh nerves. Each nucleus N has a description $\Phi(N)$ = number of sides of N. Then $\bigcap_\Phi Nrv\mathscr{F}_{MNC} \neq \emptyset$.*

III. Experiments and Discussion

Let $p(x_1), \ldots, p(x_i), \ldots, p(x_n)$ be the probabilities of a sequence of events $x_1, \ldots, x_i, \ldots, x_n$ and let $\beta \geq 1$. Then the

Rényi entropy [11] $H_\beta(X)$ of a set of event X is defined by

$$H_\beta(X) = \frac{1}{1-\beta}\ln\sum_{i=1}^{n} p^\beta(x_i) \text{ (Rényi entropy).}$$

Rényi's entropy is based on the work by R.V.L. Hartley [12] and H. Nyquist [13] on the transmission of information. The information of order β contained in the observation of the event x_i with respect to the random variable X is defined by $H(X)$. Here, $H(X)$ is used to measure the information levels of maximal nucleus clusters in tesselled paintings by Z. Pawlak (places reflecting the greatest detail by the artist).

Fig. 3. 1954 Waterscape by Zdzisław Pawlak

Fig. 4. MNC in 1954 Waterscape by Zdzisław Pawlak

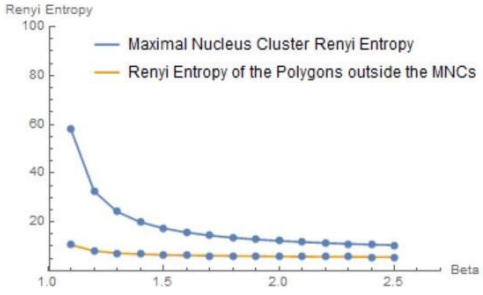

Fig. 5. MNC Rényi's entropy in 1954 Waterscape

The three sample paintings by Z. Pawlak, span 45 years, starting in 1954 and ending in 1999. In Z. Pawlak's paintings, places where the artist rendered with the greatest detail (splashes of colour, slanting brush strokes, clustering of paint

Fig. 6. 1999 Landscape by Zdzisław Pawlak

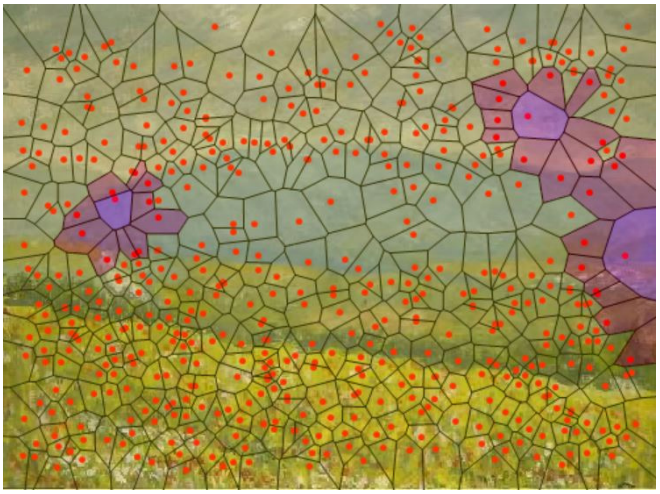

Fig. 7. MNC in 1999 Landscape by Zdzisław Pawlak

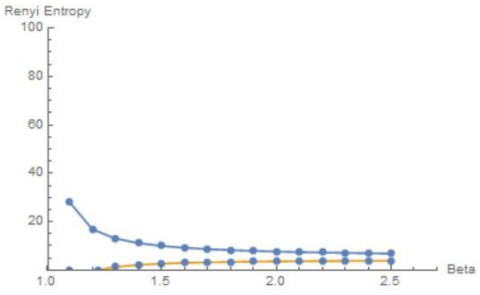

Fig. 8. MNC Rényi's entropy in 1999 Landscape

Fig. 9. 1999 Waterscape by Zdzisław Pawlak

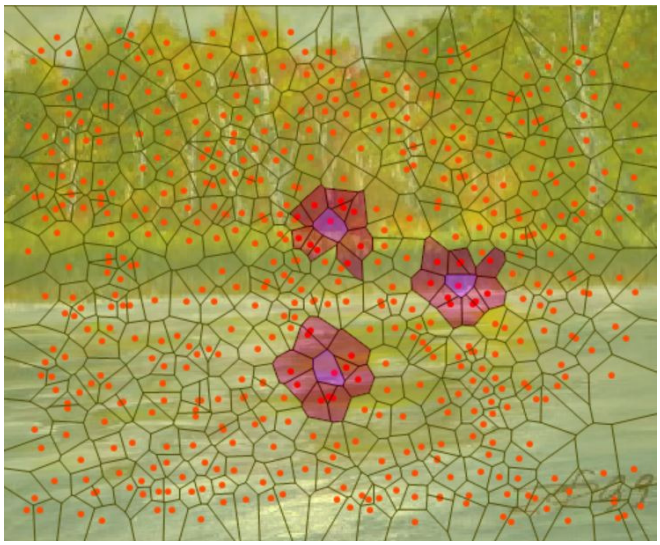

Fig. 10. MNC in 1999 Waterscape by Zdzisław Pawlak

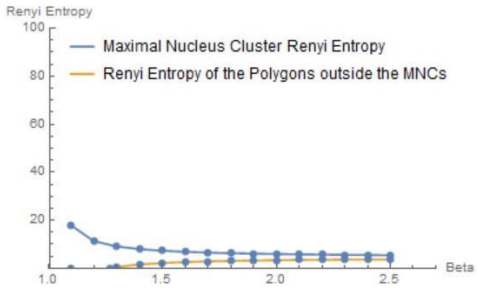

Fig. 11. MNC Rényi's entropy in 1999 Waterscape

patches) occurs where the Rényi's entropy is highest. In the examples, the entropy of the MNCs is consistently higher than the non-MNC areas in the paintings. Each of these paintings reflects a style very similar to the impressionist painting by Oscar-Claude Monet (1840-1926). The basic approach was to express one's perceptions of nature in which he created a record of the French countryside. Similarly, Pawlak's perceptions of Polish countryside are represented by dabs of paint to suggest things like buildings (see the red-roofed building in Fig. 3), long and short strokes of colour (see the trees in Fig. 9 and bits of white for distant roads and villages in Fig. 6). The MNCs in Z. Pawlak's paintings occur in those places in the paintings where the artist has expended his greatest efforts on the detailed woodland and waterscape structures he observed.

In conclusion, this paper presents a Voronoï diagram-based clustering which partitions a descriptive space represented by paintings into regions around a set of seed points. The clustering approach leads to the introduction of *maximal nucleus clusters* that are collections of a maximal number of Voronoï regions that are *strongly near* the mesh nucleus. It can also be observed that there can be several MNCs depending on the number of selected seed points. It is interesting to note that the Rényi's entropy shown in Figures 5,8,11 indicate the entropy of the MNC is higher than those of the surrounding polygons.

AAIA'16 Data Mining Competition: Predicting Dangerous Seismic Events in Active Coal Mines

AAIA'16 Data Mining Challenge is the third data mining competition associated with International Symposium on Advances in Artificial Intelligence and Applications (AAIA'16, https://fedcsis.org/2016/aaia) which is a part of FedCSIS conference series. This time, the task is related to the problem of predicting periods of increased seismic activity which may cause life-threatening accidents in underground coal mines. Prizes worth over 3,000 USD will be awarded to the most successful teams. The contest is sponsored by Research and Development Centre EMAG (http://ibemag.pl) with support from Polish Information Processing Society (http://www.pti.org.pl/).

Introduction

Providing safety of miners working underground is the fundamental requirement for the coal mining industry in Poland. Coal mining companies are obligated by the law to introduce many safety measures to secure proper working conditions of their underground personnel. However, expert knowledge-based safety monitoring systems sometimes fail to foresee dangerous seismic events which have disastrous consequences. In this data mining competition we would like to address this challenging problem. In particular, we want to ask participants to come up with reliable methods for predicting periods of increased seismic activity perceived in longwalls of a coal mine.

More details regarding the task and a description of the competition data can be found in Task Description section.

Special session at AAIA'16

A special session devoted to the competition will be held at the conference. We will invite authors of selected reports to extend them for publication in the conference proceedings (after reviews by Organizing Committee members) and presentation at the conference. The publications will be treated as short papers and will be indexed by IEEE Digital Library and Web of Science. The invited teams will be chosen based on their final rank, innovativeness of their approach and quality of the submitted report.

Awards

Authors of the top ranked solutions (based on the final evaluation scores) will be awarded with prizes funded by our sponsors:

- First Prize: 1000 USD + one free FedCSIS'16 conference registration,
- Second Prize: 500 USD + one free FedCSIS'16 conference registration,
- Third Prize: one free FedCSIS'16 conference registration.

The award ceremony will take place during the FedCSIS'16 conference (Sep 11-14, 2016, Gdańsk, Poland).

***Abstract*—This paper summarizes AAIA'16 Data Mining Challenge: Predicting Dangerous Seismic Events in Active Coal Mines which was held between October 5, 2015 and March 4, 2016 at the Knowledge Pit platform. It describes the scope and background of this competition and explains our research objectives which motivated the specific design of the competition rules. The paper also briefly overviews the results of this challenge, showing the way in which those results can help in solving practical problems related to the safety of miners working underground. In particular, our analysis focuses on applications of prediction models in order to facilitate the assessment of seismic hazards, in a situation when the exploration of a given working site has just started and there is very little historical data available.**

Keywords*—*data mining competition; multivariate time series data; attribute engineering; cold start problem; hazards assessment;

I. Introduction

THE COAL MINING is one of the most important industries which according to a report by *IBISWorld* employs worldwide over $3.5M$ people [1]. The exploration of coal often requires working in hazardous conditions. Miners in an underground coal mine can face many threats, such as, e.g. methane explosions, rock-burst or seismic tremors. To provide protection for people working underground, systems for active monitoring of the coal extraction processes are typically used. One of their fundamental applications is to screen the seismic activity in order to minimize the risk of severe mining incidents. To facilitate this task, data exploration and decision support tools can be employed, e.g. for predicting seismic activity in the nearest future.

From a data processing point of view, a decision support system which could aid in active monitoring of the coal mining process requires efficient methods for handling continuous streams of data [2]. Such methods have to be able to handle large volumes of data from multiple sensors. They also need to be robust with regard to missing or corrupted data. Moreover, a good decision support system should be easy to comprehend by the experts and end-users who need to have access not only to its outcomes, but also to arguments or causes that were taken into account. A few practical studies have been already conducted with this respect, relying on rule-based models for predicting the methane level [3]. However, the literature on this important subject is still very scarce.

One of very few research initiatives in that field is DISESOR – a Polish national R&D project aimed at creation of an integrated decision support system for monitoring of the mining process and early detection of viable threats to people and equipment working underground [4]. The system developed in the frame of DISESOR project integrates data from different monitoring tools. It contains an expert system module that can utilize specialized domain knowledge and an analytical module which can be applied to make a diagnosis of the mining processes. When combined, these modules are capable of reliable prediction of natural hazards, such as those related to increased seismic activity. The idea to popularize this topic among the data science community by organizing open data mining challenges originated within this project.

The competition described in this paper is the second one in the series. The first one – IJCRS'15 Data Challenge – was focused on the problem of active monitoring and prevention of dangerous methane outbreaks [5]. The task was to design an efficient classifier for multivariate time series data that is generated by various sensors placed in corridors of underground coal mines. The main difficulty in that task was related to the problem of, so called, concept drift [6] and the necessity of constructing robust representation of the available data [7]. This competition was hosted by the Knowledge Pit platform [8] which supports the organization of data mining competitions associated with data science-related conferences.

Following the success of our first competition, AAIA'16 Data Mining Challenge was also organized at Knowledge Pit. This time, however, the task was related to the problem of foreseeing periods of increased seismic activity, that may endanger miners working underground. The main motivation for organizing this challenge as an open on-line competition was the fact that such an approach allows to conveniently review and evaluate performance of the available state-of-the-art methods. It is also an objective way of verifying not only a viability of the predictive models but also whole analytic processes which include preprocessing, feature extraction, model construction and post processing of predictions (e.g. ensemble approaches). Additionally, a huge influence on the final shape of AAIA'16 Data Mining Challenge had our research interest in a severity of the cold start problem for prediction models. In the coal mining context, this problem appears in a situation when the exploration of a given working site has just started and there is very little historical data available that can be

978-83-60810-90-3/$25.00

utilized for a construction of the prediction model for the assessment of seismic hazards.

In the following Section II we reveal details regarding the organization of the data mining competition and then, in Section III, we describe its course and results, including a brief characteristic of the most interesting approaches among the submitted solutions. Next, in Section IV, we show how the competition results were used to conduct an analysis of the cold start problem in the prediction of seismic hazards. Finally, we conclude the paper in Section V by drawing our plans for a continuation of this study.

II. AAIA'16 Data Mining Challenge

AAIA'16 Data Mining Challenge: Predicting Dangerous Seismic Events in Active Coal Mines took place between October 5, 2015 and February 27, 2016. It was organized under auspices of 11^{th} International Symposium on Advances in Artificial Intelligence and Applications (AAIA'16, https://fedcsis.org/2016/aaia) which is a part of the FedCSIS conference series.

The task in this competition was related to the assessment of safety conditions in underground coal mines with regard to a seismic activity and early detection of seismic hazards. In particular, the data set provided to participants was composed of readings from sensors, such as geophones, that monitor the seismic activity perceived at longwalls of different coal mines and measure energy released by, so called, seismic bumps. Each case in the data was described by a series of hourly aggregated sensor readings from a 24 hour period. The provided data also contained information regarding the intensity of recent mining activities at the corresponding working site, coupled by the latest assessments of the safety conditions made by mining experts. Moreover, to further enrich the available data, for each working site that occur in the data set some additional meta-data were made available, such as an identifier of the mine, an identifier of a region where the working site is located or a working site's height.

Participants of the competition were asked to design a prediction model that would be able to accurately detect periods of increased seismic activity. In particular, the target attribute in the provided data (the decision) indicated cases for which the total energy of seismic bumps observed in a following 8 hour period exceeded a warning level of $5 * 10^4$ Joules (i.e. energy released in the period starting after the last hour of aggregated readings describing the case and ending 8 hours later).

In total, the provided data was described by 541 main attributes and 6 additional features related to particular working sites. The competition's data correspond to over 5 years of readings, which to best of our knowledge makes this research the most comprehensive study related to this domain, conducted anywhere in the world.

The data set was divided into a training part which was made available along with the corresponding decision labels and a test part. The labels for the test set were hidden from participants. The division of cases between the training and test sets was made based on a time stamps. In particular, the training data set corresponded to a period between May 5, 2010 and March 6, 2014. It consisted of a total of $133,151$ data rows, each corresponding to a different 24 hour period which were overlapping for consecutive cases. The test data covered the period between March 7, 2014 and June 24, 2015. Unlike for the training set, to facilitate an objective evaluation of solutions and prevent a common problem with, so called, data leakage [9], the test cases were not overlapping and provided in a random order. For this reason the test set used in the challenge was much smaller than the training data. It is important to notice, however, that even though it consisted of only $3,860$ cases, the test set covered a period of nearly 16 months.

Table I shows some basic characteristics of data from each working site that occurs in the competition data. It is worth noticing that not all working site that are present in training data also appear in the test set and there are a few working sites that are present in the test data but not in the training set. Such a situation reflects a real-life problem when the exploration of coal shifts to a new site for which there is no data available. A similar issue can also be identified within other domains, e.g. recommender systems, and is commonly referred to as *the cold start problem* [10]. Noticeable is also the fact that the distribution of cases with the *'warning'* decision label is quite uneven for different working sites.

TABLE I. Basic characteristics for data obtained from different working sites. The first column shows working sites ids, whereas the following columns present information regarding initial expert assessments of the working site's safety, number of data samples in the training and test sets, and the percentage of cases with the 'warning' decision label.

main working site ID	initial mining assessment	number of training cases	number of test cases	training warnings (percent)	test warnings (percent)

A. Evaluation of the uploaded solutions

Participants of the competition had to prepare their solutions in a form of predictions of a likelihood that a given record from the test set has the label 'warning' and send their solutions using the submission system of Knowledge Pit. Each of the competing teams could submit multiple solutions. Quality of the submissions was measured using Area Under the ROC Curve (AUC) [11], [12]. The submitted solutions were

evaluated on-line and the preliminary results were published on the competition Leaderboard. The preliminary score was computed on a subset of the test set, fixed for all participants. Size of this subset corresponded to approximately 25% of the test set and it was composed of data from four working sites with different characteristics. The final evaluation was conducted after completion of the competition using the remaining part of the test data.

Apart from submitting their predictions, each team was also obligated by competition rules to provide a brief report describing its approach. Only the final solutions from teams which sent a valid report could undergo the final evaluation and be published among the competition results. In this way we were able to collect a vast amount of information regarding the current state-of-the-art in predictive analysis of multivariate time series data and objectively verify different methods of preprocessing, feature extraction and post processing of the predictions (i.e. ensemble approaches [13]).

B. A course of a competition

Since one of the main objectives in organization of AAIA'16 Data Mining Challenge was to investigate the cold start problem in the domain of natural hazard detection, we designed this competition in an uncommon way. To gather comprehensive data about an impact of the size of available data on quality of predictions for a given working site, the training data set described above was divided into five separate parts and the course of the challenge was split into six phases. Table II shows some basic participation statistics related to each of the phase.

TABLE II. BASIC PARTICIPATION STATISTICS FOR EACH PHASE OF THE CHALLENGE. IN THE LAST PHASE ALL TRAINING DATA WAS MADE AVAILABLE TO ALL PARTICIPANTS, REGARDLESS OF THEIR ACTIVITY.

	training set size (cases)	number of submissions	best preliminary score	best final score
phase 1	79893	99	0.9296	0.9290
phase 2	93211	278	0.9412	0.9320
phase 3	106527	1377	0.9452	0.9405
phase 4	119839	363	0.9451	0.9375
phase 5	133151	513	0.9452	0.9379
phase 6	133151	505	0.9452	0.9439

After the start of the challenge only the first part of the training data was revealed to participants. The four consecutive parts were made available in approximately monthly intervals (each interval corresponded to a new competition phase), however, only active teams that submitted a required number of files with predictions could access the new data.

In the sixth phase, which lasted for the last two weeks of the competition, all training data parts were revealed to all participating teams regardless of their previous activity in the challenge. It was done to equalize winning chances for teams that decided to join the competition in its latest period.

III. OVERVIEW OF THE COMPETITION RESULTS

AAIA'16 Data Mining Challenge attracted many skilled data mining practitioners who managed to submit a variety of interesting solutions. In total, there were 203 registered teams with members from 31 different countries. The most of participating teams were from Poland (106), however, there were also many teams from countries such as India (14), United Kingdom (12), USA (12), Canada (9) and France (5).

Among the registered teams, 106 were active, i.e. submitted at least one solution to the Leaderboard. In total they submitted 3,236 solutions of which 3,135 were correctly formatted and successfully passed the evaluation procedure. Additionally, 50 teams provided a brief report describing their approach. These reports turned out to be a valuable source of knowledge regarding the state-of-the-art in the predictive analysis of time series data related to early detection of seismic hazards.

TABLE III. FINAL RESULTS AND NUMBER OF SUBMISSIONS FROM THE TOP RANKED TEAMS. THE LAST ROW SHOWS RESULTS OBTAINED SOLELY FROM ASSESSMENTS MADE BY MINING EXPERTS, WHICH WERE AVAILABLE IN THE DATA (ATTRIBUTES *latest_seismic_assessment* AND *latest_comprehensive_assessment*)

team name	rank	n of submission	final result
snm (organizers)	–	2	0.9396
tadeusz	1	31	0.9393
deepsense.io	2	111	0.9384
yata	3	54	0.9342
podludek	4	71	0.9336
jellyfish	5	1	0.9335
millcheck	6	80	0.9329
kkurach	7	32	0.9312
gabd	8	21	0.9299
basakesin	9	30	0.9297
rough	10	4	0.9269
...	...	...	...
experts	(18)	–	0.9196

Table III shows scores achieved by the top-ranked teams. It is worth to notice that the highest result in the final evaluation was obtained by a team involved in DISESOR project and organization of the challenge (team *snm*). Its solution was created using feature extraction methods developed for the purpose of the DISESOR system [7], combined with a rough set approach to reducing data dimensionality [14] and an ensemble learning approach. In order to construct their solution, authors were using only the data available to all participants, however, due to their organizational involvement, team *snm* was excluded from the final ranking. More details regarding this solution can be found in [15].

Among the ranked teams, the highest score was obtained by the team *tadeusz* which was also a subset of the second team in the ranking – *deepsense.io*. Their solution was also based on an ensemble technique. In their approach, authors carefully select a subset of the training data which they later use for constructing and validating the prediction models. Moreover, authors make a significant effort to develop a procedure for an unbiased performance evaluation for tuning parameters of their models and the resulting ensembles. The whole approach is comprehensively described in [16].

In general, the overview of the most successful approaches used by participants suggests that the key steps to achieving good results in this task were:

1) Extracting relevant features (computing a new data representation) that aggregate time series data and are robust with regard to a concept drift.
2) Designing an appropriate evaluation procedure for testing performance of used prediction models and tuning their parameters.
3) Using an ensemble learning techniques for blending predictions of simpler models.

Moreover, the results clearly showed that the proposed task proved to be a challenging one for the most of participants. From the 106 teams that submitted at least one solution only 18 were able to outperform in the final evaluation a simple scoring model that was based on safety assessments made by mining experts. These evaluations were available in the data as two attributes, namely *latest_seismic_assessment* and *latest_comprehensive_assessment*. Even though these features could take only four ordinal values ($a < b < c < d$), a simple logistic regression model that utilizes those two features achieves AUC score of 0.9196 on the final evaluation data (0.9028 on the preliminary test set).

The most likely reason for the weaker results of a large share of participants is over-tuning of their models to the preliminary evaluation set. In a case of many teams, preliminary results were much higher the final scores – the biggest difference was as high as 0.174 (over 17 percentage points). Noticeable is also the fact that in the preliminary evaluation 64 teams obtained a score which was higher than the score of the model based solely on the assessments of experts.

IV. Analysis of the cold start problem

The cold start problem is an important practical issue that is related to real-world applications of many decision support systems. In the case of coal mining, it typically appears when a system for monitoring natural hazards becomes operations for new, previously unexplored longwalls. One of our research objectives motivating the organization of AAIA'16 Data Mining Challenge was to investigate severity of this problem in the context of systems for early detection of periods of increased seismic activity.

For this reason the competition was divided into phases, as it was described in Section II (see Table II for details regarding availability of training data in consecutive phases). Since in each phase a new subset of training data was made available to active participants, we were able to verify the impact of this additional information by examining quality of solutions submitted in consecutive phases. Moreover, thanks to the competition rules that encouraged active participation, we received a large number of diverse solutions for analysis.

Figure 1 presents a distribution of evaluation scores obtained by submissions during the course of the competition. For this analysis we only used valid solutions with a reasonable quality (we disregarded 'random' submissions and those which obtained the preliminary score lower than 0.65). On that plot, black vertical lines denote dates on which additional parts of the training data set were released. Each solution on that plot is marked with a blue and red bar whose height corresponds to the obtained evaluation score. The level of red color in a bar indicates the final score, whereas the level of blue color marks the preliminary evaluation score.

A detailed analysis of the distribution of scores in time reveals some interesting observations. Firstly, in consecutive phases there is a quite conspicuous decrease in differences between the preliminary and final scores. In fact, in early phases of the competition preliminary scores tended to be much higher than the final ones, whereas in the last phase the trend was opposite. In order to confirm the statistical significance of this observation, we used a Wilcoxon rank sum test of preliminary and final scores in consecutive phases. The test confirmed that average differences in phases 1, 2 and 3 and significantly higher ($p-value << 0.01$) than for the phases 4, 5 and 6. Interestingly, in the last phase the differences become negative (final scores are usually higher than the preliminary ones). This phenomenon can be explained by the fact that in the last few days of every data mining competition participants tend to focus on maximizing their score by blending their previous solutions. For this reason we will exclude the last phase from our further analysis of the cold start problem. Table IV shows mean and standard deviation of evaluation scores for each of the competition phases.

TABLE IV. Mean and standard deviation of scores in each of the competition phases. Tha last column gives mean differences between the preliminary and final scores.

phase	prelim. mean	prelim. sd	final mean	final sd	mean diff.
phase 1	0.8590	0.0579	0.8251	0.0672	0.0339
phase 2	0.9059	0.0420	0.8851	0.0587	0.0207
phase 3	0.8683	0.0693	0.8307	0.1058	0.0376
phase 4	0.8868	0.0669	0.8772	0.0831	0.0096
phase 5	0.8943	0.0553	0.8857	0.0625	0.0086
phase 6	0.8820	0.0667	0.8942	0.0696	-0.0122

Another interesting observation related to analysis of the results shown on Figure 1 and displayed in Table IV is that the use of additional training data has a diminishing impact on performance of prediction models. For instance, if we compare average results from the second phase to results from the fourth or fifth phase, we see that the difference is minimal, even though in these phases we received a comparable number of submissions and the available training set data in, e.g. *phase 5*, was by nearly 43% larger than in *phase 2*. This was even less expected due to the fact that the data available in *phase 2* contained information about only 9 out of 21 main working sites present in the test data (these sites corresponded to $\approx 45\%$ of the test set), whereas in *phase 5* this number was much higher (13 out of 21 sites; $\approx 70\%$ of the test set).

To confirm the second observation, in each phase we analyzed the solutions with highest preliminary scores from teams that obtained scores higher than 0.85 – results of such teams better reflect performance of the state-of-the-art models. Figure 2 visualizes basic statistics (min,max,quantiles and mean values) for the preliminary and final evaluations of those submissions.

Conspicuous is the lack of significant differences in the best preliminary evaluation results in consecutive phases. The average final scores slightly increase from phase to phase, however, when we checked the statistical significance of the changes it turned out that a significant difference (p-value lower than 0.01) is only between results from the fifth and sixth phases. For other consecutive phases the p-value of Wilcoxon test was always higher than 0.175.

The above observations allow to formulate a hypothesis that having a sufficiently large data set it is possible to construct efficient prediction models for assessment of seismic hazards. The created models can outperform the currently used expert methods even for completely new working sites, as long as these sites have comparable geophysical properties and the same methodology is used for collecting new data. In order to verify this claim we decided to thoroughly investigate performance of top-ranked solutions submitted in each phase,

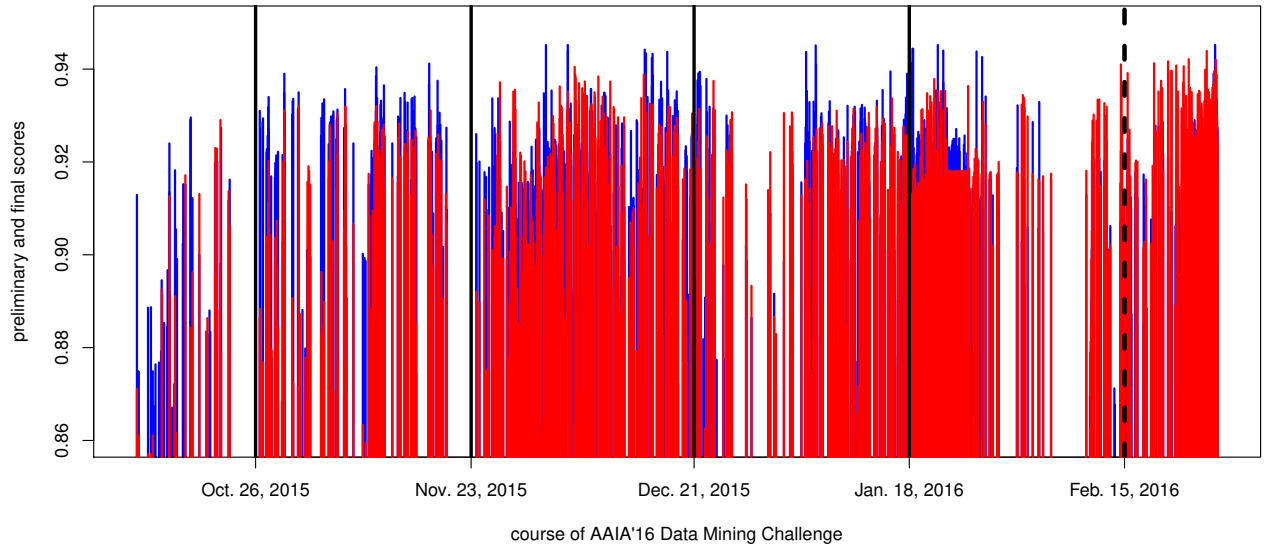

Fig. 1. Distribution of preliminary and final scores during the course of the competition. Blue bars show preliminary scores, wheras the corresponding red bars display final scores. The vertical black lines mark the dates which separate consecutive phases of the competition.

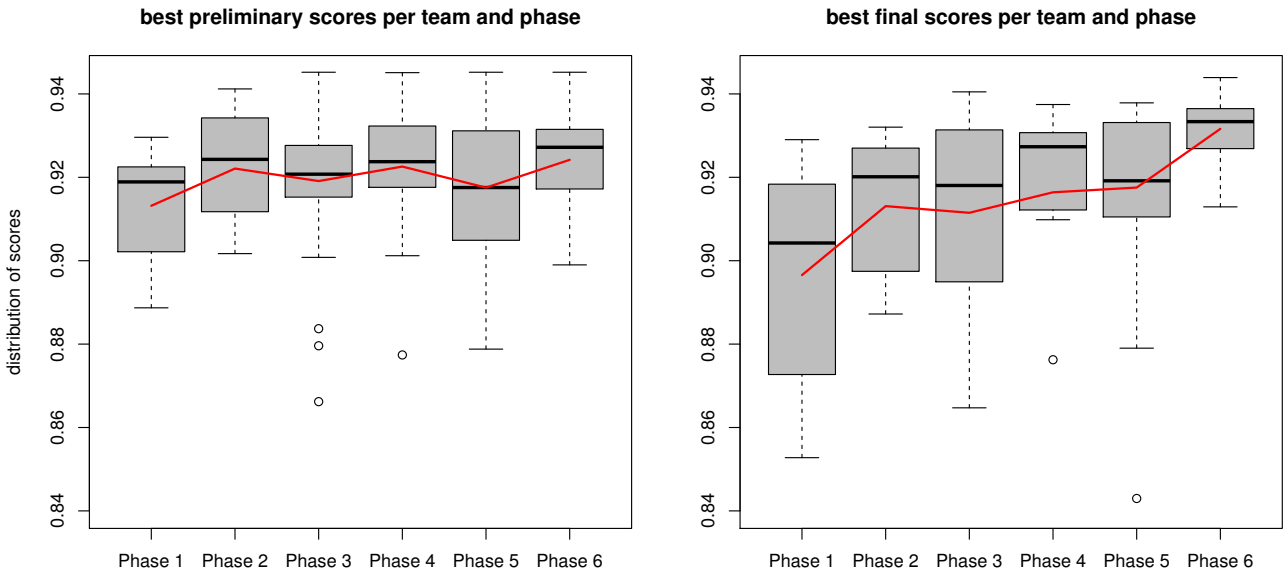

Fig. 2. Distribution of the best preliminary and final scores per team and competition phase. The red lines correspond to average values for given phases.

with regard to individual working sites.

For the purpose of this analysis we disregarded working sites for which there was no examples with the *'warning'* label in the test set. The reason for that was the inability to compute values of AUC on such data subsets. In this way, for the remaining part of our analysis there were 15 working sites left, which corresponded to $\approx 81.5\%$ of the test data.

From solutions submitted in each competition phase, we have chosen 6 with the scores in top 10% for a given phase. During the selection process we considered only solutions uploaded by teams actively participating in the competition, which fulfilled the criteria for obtaining all additional training data. Table V shows their average AUC values with respect to individual working sites. Additionally, the last two rows of the table give average values of AUC for working sites that are present in the training set and for those which are unavailable in the training data, respectively. Finally, the last column of Table V shows AUC values obtained for individual working sites using only the assessments made by experts.

For the most of working sites there is a statistically

TABLE V. AVERAGE SCORES OF TOP SOLUTIONS FOR INDIVIDUAL WORKING SITES, IN DIFFERENT PHASES OF THE COMPETITION. EVALUATIONS OF EXPERT ASSESSMENTS IS GIVEN FOR A COMPARISON IN THE LAST COLUMN. ADDITIONALLY, THE LAST TWO ROWS DISPLAY AGGREGATED VALUES (AVERAGES) FOR WORKING SITES WITH DATA IN THE TRAINING SET AND WITHOUT ANY AVAILABLE TRAINING DATA.

working site ID	phase 1	phase 2	phase 3	phase 4	phase 5	phase 6	expert assessments
149	0.8984	0.9056	0.8523	0.9062	0.8766	0.9005	0.9306

793	0.9499	0.9545	0.9585	0.9538	0.9361	0.9468	0.8868
avail. in training	0.8653	0.8915	0.8818	0.8852	0.8778	0.8912	0.8670
unavail. in training	0.9077	0.9433	0.9428	0.9374	0.9354	0.9486	0.9404

significant improvement (tested using t-test with a confidence level of 0.05) of results from the later competition phases in comparison to the first phase. However, in nearly all cases the improvement between the second and later phases becomes marginal (one exception is the working site with ID 599). Interestingly, there are event sites (e.g. 689, 777) for which there is a noticeable drop in average quality of solutions between the second phase and phases 3, 4 and 5. Interesting is also the fact that the top solutions obtained consistently higher scores for working sites that were not present in the training data. Explanation of this fact require further analysis.

A comparison of the selected solutions to predictions that were based solely on assessments made by experts revealed that more complex models were able to quickly attain significantly higher scores for working sites with available training data. In the case of the remaining working sites the advantage of complex prediction models was not that clear. The average results for selected models in phase 6 were only slightly higher, however, for a part of investigated solutions the difference was much more favorable than for others.

V. CONCLUSIONS

In this paper we summarized AAIA'16 Data Mining Challenge: Predicting Dangerous Seismic Events in Active Coal Mines which was held at Knowledge Pit platform in association with 11^{th} International Symposium on Advances in Artificial Intelligence and Applications (AAIA'16). We explained research goals that motivated us to organize this competition. We also explained the task in the challenge and briefly described its course. Finally, we showed a detailed analysis of competition's results with an emphasis on the cold start problem.

The conducted analysis revealed several interesting findings regarding the influence of additional training data on performance of prediction models for assessment of seismic hazards. It showed that in order to train prediction methods that aim to work well for a wide range of locations, it is sufficient to provide training data for only several different working sites. Adding more data may have a minimal impact on prediction quality but it definitely helps in computing more reliable estimations of expected prediction performance, as well as in avoiding over-fitting of models to the training data.

Moreover, our analysis confirmed usefulness of the expert methods for assessment of natural hazards. Not only these assessments were able to robustly predict the seismic activity (they outperformed solutions of more than 80% of teams participating in the competition), but also they could be successfully applied to completely new working sites, without a need for using additional training data and complex algorithms.

This observation allows to formulate a general strategy for dealing with the cold start problem: for new working sites start predicting seismic hazards using the expert methods and concurrently gather data for training a more sophisticated prediction algorithm. Initiate your model using data from other working sites and then adjust it using the newly obtained data. Periodically compare performance of your model to results of the expert assessments and switch to your predictions when they become more accurate.

There are still several unanswered questions and research problems that we plan to investigate in our future work. For instance, the competition setting does not allow to study performance of incremental learning methods which can be applied to this problem. We would also like to more thoroughly analyze severity of the concept drift problem which in this context can be related to temporal nature of the data, as well as to changes in characteristics of different working sites. Another important issue is related to a development of methods for identification of good data subsets for training a prediction model for a given working site. Such methods could be based, for instance, on a comparison of similarities between different sites and choosing the data from those with the most similar characteristics.

Finally, in order to guarantee practical applicability of models for the mining industry it is important that mining experts could easily interpret and explain their predictions. For this reason, interpretability of a prediction model may be as important as its performance. The development of efficient algorithms that yield interpretable results is also directly related to a problem of extracting informative, yet compact representation of the training data. These two issues indicate prominent research directions for our future work.

***Abstract*—This document describes an approach to the problem of predicting dangerous seismic events in active coal mines up to 8 hours in advance. It was developed as a part of the AAIA'16 Data Mining Challenge: Predicting Dangerous Seismic Events in Active Coal Mines. The solutions presented consist of ensembles of various predictive models trained on different sets of features. The best one achieved a winning score of 0.939 AUC.**

I. Introduction

IN 2015, the mining industry in Poland reported 2158 dangerous incidents with 19 casualties and 12 severe injuries [1]. Underground mining work poses a number of threats including fires, methane outbreaks or seismic tremors and bumps. Monitoring and decision support systems might play an essential role in limiting the number of incidents and their prevention. Such systems, often based on machine learning or data mining techniques, can be effectively applied to lessen the danger to employees and prevent potential losses arising from lost and damaged equipment, see, e.g., [2], [3], [4].

In this paper, we present a model for predicting dangerous seismic events in coal mines. Using different machine learning models, we address the classification problem of whether the total seismic energy in the upcoming few hours is going to reach a warning level. The model was developed for the *AAIA'16 Data Mining Challenge: Predicting Dangerous Seismic Events in Active Coal Mines* and proved to be the most successful approach among the 203 teams participating in the challenge [3].

The paper is structured as follows: the first section outlines the problem and describes the main challenges. Next, we describe our approach, focusing on feature engineering, model optimization and evaluation. Finally, in the last section we conclude the work.

II. The challenge

In this section we introduce the problem and describe the provided data. We also make some preliminary remarks about the data and its nature.

A. Problem statement

The given problem is a classification task. The goal is to develop a prediction model that, based on the recordings from a 24-hour long period, predicts whether an energy warning level is going to be reached in the upcoming 8 hours. The warning is reached when the total energy of seismic bumps exceeds 50 000 J = 50 kJ. The accuracy of a model is determined with respect to the Area Under ROC curve (AUC) metric. This accuracy measure is defined as follows. Let $(\mathbf{x}_i, y_i) \in \mathbf{X}$ denote an instance from the dataset $\mathbf{X}$, i.e., $\mathbf{x}_i$ stands for the feature vector associated with a single measurement and $y_i \in \{0, 1\}$ stands for its label. Let f be a model that maps each instance to probability that it belongs to class '1' (or, more generally, a real-valued risk score). Then AUC is derived as

$$AUC(f, \mathbf{X}) = \frac{\sum_{i:y_i=0} \sum_{j:y_j=1} \mathbb{1}(f(\mathbf{x}_i) < f(\mathbf{x}_j))}{|\{y_i : y_i = 0\}| \cdot |\{y_j : y_j = 1\}|} \quad (1)$$

where $\mathbb{1}(\cdot)$ denotes an indicator function that returns 1 if a given condition is satisfied or 0 otherwise, and $|S|$ denotes the cardinality of set S. This accuracy measure returns values in the range range $[0, 1]$, where 1 is achieved by a perfect predictor. A random predictor yields values around 0.5.

B. Data

Two sets of observations were provided: training dataset with accompanying labels and the test set without them. The former was provided so that the problem could be approached from a machine learning angle, the latter serves for evaluation purposes. The competitors were asked to submit the likelihood of the label 'warning' for each record in the test set.

In total, the training set consists of 133 151 observations. Each observation (instance) is described by a set of 541 numbers. Below, we briefly introduce the data provided. For a more thorough description of the dataset please refer to the competition website [5].

The instances are described by a set of 13 features of different type and 22 time series over last 24 hours prior to the forecasting period. The time series' names are followed by 1, 2, . . . , 24, indicating consecutive hours of measurements (with the most recent hour prior to forecasting period being 24). Possible suffixes `_e`ξ, $\xi \in \{2, 3, 4, 5, 6\texttt{plus}\}$ refer to orders of magnitude of a given time series in a certain range, e.g. `sum_e3.5` stands for sum of energies within range $(10^2, 10^3]$ in the 5th hour of the time series. The series are listed below:

- `count_e2`, ..., `count_e6plus` - number of registered seismic bumps;
- `sum_e2`, ..., `sum_e6plus` - sum of energy of registered seismic bumps;
- `total_number_of_bumps`;
- `number_of_rock_bursts`;

978-83-60810-90-3/$25.00

- number_of_destressing_blasts;
- highest_bump_energy.

Additionally, for the most active geophones, the following series are provided:

- max_gactivity;
- max_genergy;
- avg_gactivity;
- avg_genergy;
- max_difference_in_gactivity;
- max_difference_in_genergy;
- avg_difference_in_gactivity;
- avg_difference_in_genergy.

There are also 4 *assessments* provided by experts. They are provided as categorical variables with four levels ranging from 'a' (the lowest risk) to 'd' (the highest risk):

- latest_seismic_assessment;
- latest_seismoacoustic_assessment;
- latest_comprehensive_assessment;
- latest_hazards_assessment.

Finally, several features which we will refer to as *general* are provided:

- total_bumps_energy;
- total_tremors_energy;
- total_destressing_blasts_energy;
- total_seismic_energy;
- latest_progress_estimation_l;
- latest_progress_estimation_r;
- latest_maximum_yield;
- latest_maximum_meter.

Metadata: For each observation we are given its location, i.e., a *longwall* in a particular coal mine that the measurement comes from. Each location is accompanied with additional information (metadata included in a separate file):

- main_working_id - ID of the main working site (at a longwall);
- main_working_name - name of the main working site;
- region_name - name of region where the main working site is located;
- bed_name - name of coal bed;
- main_working_type - type of the main working site;
- main_working_height - height of the main working site;
- geological_assessment - geological assessment of the main working site made by experts before the beginning of exploration (ordered categorical variable ranging from 'a' (lower risk) to 'c' (higher risk)).

Most of metadata were unique to the working sites, therefore were discarded early due to the reasons discussed later. The only information of potential use were main_working_height and geological_assessment, however they still had to be treated with caution:

- geological_assessment: A closer insight revealed that there is none mine assessed as 'd' and only one marked as 'c'. It was replaced by 'b'. Moreover, the proportion of 'a' assessments for longwalls in the training and test dataset varied significantly, 25% to 48%, respectively.
- main_working_height: many working sites had unique working heights - this posed a danger that the feature would be used by a model as a proxy for particular location rather than a potentially valuable information about the height. One solution, discussed later, could be to add extra noise, to diminish the relations between the mines and their heights.

The test set consists of 3 860 unlabeled observations. Approximately 25% of them were used for evaluation on the preliminary leaderboard, which was updated throughout the contest when participants submitted their solutions. The remaining observations were used for selection of the best solutions at the end of the competition.

We should also note that the observations in the test set were randomly selected events rather than time series as provided within the training set. More precisely, given a series consecutive observations, samples were uniformly drawn from them to form a test set. If two samples collected laid within the same window of 32 hours (for 24-hour long time series describing seismic activity plus 8 hour window for prediction), one of them was dropped so as to assure that the samples were approximately independent. This procedure removes a significant amount of observations hence the size of the competition test set was relatively modest in comparison to the amount of training data available. This resulted in a very unreliable leaderboard evaluation during the competition that was based on ca. 1 000 observations. Therefore, we put great emphasis and efforts to develop reliable evaluation methods given the available training data as discussed in the next section.

C. Initial remarks

When we approached the problem we quickly realized that the main challenge was to develop a prediction model that generalizes well to new locations. Table I presents the warning frequencies per location in the dataset. We observe that first of all, different locations vary considerably in terms of the frequency of warnings. Secondly, the sets of locations differ between the training and test dataset. Additionally, the test set in the competition originated from future recordings with respect to the training data available. This is the root of the problem. Hence a proposed model should be both location and time independent in the sense that it yields unbiased predictions for instances with no regard to their origin and time they are collected. We also see that the number of instances originating from different locations varies considerably. These preliminary observations should be carefully considered during model building and evaluation steps. We elaborate on this in the next section.

III. The solution

In this section we describe in detail our solution to the given problem. We discuss different sets of features that were proposed, various evaluation methods, models and their set up.

A. Feature engineering

In our experiments we created several feature sets for model training. For the sake of simplicity and completeness, we describe them under consecutive headers and denote as $\mathbf{FS_n}$ which stands for the n-th *feature set* we proposed. These feature sets were developed independently by members of our team. Inevitably, there are significant overlaps between them.

$\mathbf{FS_1}$: The processing of the data focused mainly on aggregation, aiming to reduce the number of the hourly measurements as the majority of them were just zeros (for the training set, about 66% of all numbers were 0). The feature extraction step ended up with 133 features, over 4 times less than the original set. From the original features we kept:

- all *general* features;
- all seismic assessments converted to consecutive integers and their average;
- number of bumps (`count_e*`) and their energies (`sum_e*`) summed over all 24 hours, together with mean energies resulting from division (if `count_e*` was 0, then we were substituting the result by 0);
- number of bursts and the highest bump energies were just summed.

We also aggregated the remaining time series related to most active geophones (8 time series), however this time we introduced some aggregations over subsets of hourly measures based on their relative importance. The process is described below.

In order to assess the impact of features we used a functionality provided by the implementation of Gradient Boosting Trees available in the **XGBoost** [6] package. The library allows building a tree classifier and assessing the importance of particular features by providing the number of times the feature was used in a split. The more often a feature is used, the more separation gain it offers and therefore the more important it is. We used an XGBoost classifier with 150 trees (other parameters were default). Fig. 1 presents an example of such feature importance analysis for `avg_genergy`. It seems that features are gaining importance towards the end of the time-series - it agrees with the intuition that the measurements closer to the forecasting period are more informative. Therefore in this case, apart from the entire time-series statistics, we are also interested in statistics based on the last five hours (they stand out from the preceding hours). Also, we keep the measurements from the very last hour as a separate feature. Having applied analogous analysis to the above feature groups, we selectively compute statistics such as:

- average and average over absolute values;
- standard deviation;
- max and max over absolute values;

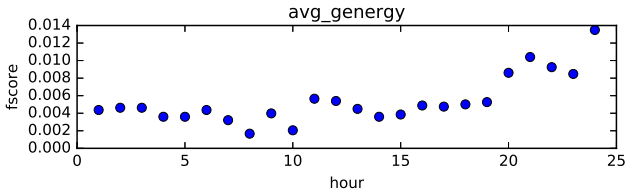

Fig. 1. Importance of hourly measurements of `avg_genergy`.

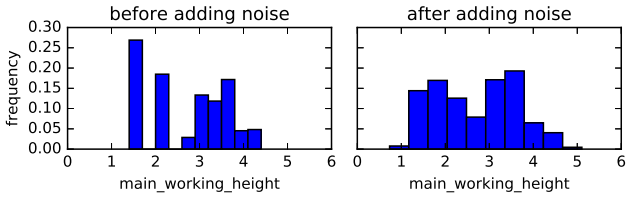

Fig. 2. Distribution of `main_working_height`, before and after adding noise.

- average over last γ hours (were γ varies from 1 to 6);
- standard deviation over last γ hours;
- slope of a linear regression over last 5 hours with respect to time.

As mentioned above, competitors were also provided with the metadata describing specific mine sites. Most of them were discarded. The only metadata used here were the *main working height*, but only after adding Gaussian noise ($\sigma = 0.2$) resulting in more even distribution, see Fig. 2. This step was performed to prevent a model from recognizing a particular location by its height.

In addition to the above features, we produced a vast set of more than 6 000 interactions between them, i.e., pairwise products of features. This is obviously an exhaustive number and we were not planning to use all of them. However, some interactions proved to be valuable. We applied an iterative process of selecting the most promising subsets of features and their interactions. We will come back to them when describing the final model (Section III-C Model$_1$).

$\mathbf{FS_2}$: In constructing this set, at first we decided to drop time series describing maximum statistics (`max*`) since they were highly correlated with corresponding average records. For the series `count_e*`, `sum_e*`, `number_of_rock_bursts`, `number_of_destressing_blasts`, `avg_gactivity`, `avg_genergy` we extracted the following features:

- minimum,
- maximum,
- standard deviation,
- indicator variable, if there is a non-zero value in the series,
- hours elapsed from the last non-zero observation.

Moreover, these statistics were derived over the window of the last 2, 4, 8 and 24 hours prior to the forecasting period in order to describe the most recent data in greater

detail. These features were appended to data with the original time series that they were computed for. Additionally, for series `avg_difference_in_gactivity` and `avg_difference_in_genergy` maximal absolute value was derived over the last 2 and 24 hours. Finally, the categorical variables were converted to binary features using one-hot encoding, i.e., for each possible value of a categorical a separate column was created which indicates that a given observation has this particular category. These operations produced a feature set with a total number of 700 features.

FS_3: In this set of features, we first derived several new series based on the original ones

1) `log_max_avg_diff_genergy` which was derived as difference in `max_genergy` and `avg_genergy`, with application of logarithm hereafter. Analogous operation was performed for other series `avg` and `max_difference_in_genergy` and a corresponding series for `gactivity`
2) `log_ave_energy` series was produced by computing average energy based on `sum` and `count` series.

In addition to features enumerated for **FS_2**, we derived the following statistics:

- 0.25, 0.5 and 0.75-quantiles,
- number of times a series increased in comparison to the previous hour's recording,
- number of positive values in a series,
- indicator variable, if there is a non-zero value in the series.

The statistics were computed on 4, 8 and 24 hours window. Furthermore, we computed the coefficient, intercept and R^2 statistic for a fit of linear model of series `avg_difference_in_gactivity`, `avg_gactivity`, `log_ave_energy` to an independent hourly temporal variable (1, 2, . . . , 24). Finally, we computed correlations between `avg_difference_in_gactivity` and `avg_difference_in_genergy` as well as `avg_gactivity` with `avg_genergy`. After extracting features, constant features were dropped from the feature set. Also, if there were features that were correlated over 0.99 (according to Pearson correlation coefficient), one of them was removed. For categorical variables, they were one-hot encoded for logistic regression model or converted to integers (with higher risk categories being assigned a higher integer) for tree-based models.

These steps produced a training set of 426 features (for the integer encoding of categorical features).

FS_4: The feature set that was created with the goal of being simple and as such leaving little room for overfitting. Out of the basic (not time-based) features, `main_working_id` was dropped. Out of the metadata, only `geological_assessment` was used. The time-based features were ran through maximum and standard deviation functions on 8-hour time periods with 4 hour increments, only the features concerning quantities and maximums were used (features listing averages and sums were left out).

B. Evaluation procedures

Evaluation methodology is a crucial part of creating a successful application of a model. Below we list different validation techniques that we employed to assess the accuracy of a model. Here, the issue of overfitting a model to particular locations and time-frames of samples is considered in detail.

k-fold cross validation (k-CV): This is one of the basic validation procedures. It is performed by assigning each example in the training set randomly to one of k folds (in our application we used $k = 10$ or 20). Note that due to temporal alignment of instances in the training data, this evaluation procedure tends to produce overly optimistic evaluation scores (we observed that during the contest by, e.g., large discrepancy in local evaluation and leaderboard scores). This is because consecutive instances are likely to share the same label. If some of them pertain to a training fold and the others to test fold, then a classifier has a relatively easy task to assign this instance to the proper label.

Leave one location out (LOLO): This evaluation method was chosen to estimate the model's performance on mining sites not included in the training data (see Table I). It was supposed to promote models that overfit less and filter out those whose good performance was actually based on data leaks. We have decided to not use the three largest locations (with IDs 264, 373 and 437) for testing. These three locations constitute to a large portion of the total training data (48%) and were not appearing in the test set. Locations that had no 'warning' labels were also not used as validation data, as AUC could not be computed for them. This approach resulted in a 8-fold cross-validation that gave much lower scores than the other ones (not even the best models could exceed 0.9 AUC), and the scores varied between folds (from as low as 0.6 to as high as 0.999) but it should not be percieved as a flaw — it was intended behavior.

Train and test split #1 ($TrTs_1$): This evaluation methodology was devised to reflect the way the leaderboard was constructed. It is based on multiple train and test splits of the data. It proceeds in two steps:

1) 5 series are chosen at random and included in the validation set,
2) among series that have not been selected in 1) we include the first 70% observations in the training sample and the other 30% in the validation set.

Moreover, in each of those 70%-30% splits, 32 observations between the split point were removed to assert approximate independence between the training and validation set (by introducing a gap of 32 hours between them). Again, data from locations with IDs 264, 373, 437 where included only in the training set.

In order to arrive at a reliable error estimate, this evaluation was repeated 25 times and consecutive measurements were

averaged. With that many iterations we arrived at stable results for mean AUC value.

Train and test split #2 ($\mathbf{TrTs_2}$): The evaluation was based on multiple train and test splits (20 in the final model) with some restrictions. By comparing the `total_seismic_energy` (TSE) of mines (which turned out to be linearly correlated with the frequency of appearances of warnings) we tried to make the split, so the TSE in the inferred test sets resembled the level of energies in the private test set.

TABLE I
NUMBER OF INSTANCES ORIGINATING FROM DIFFERENT LOCATIONS IN THE TRAINING AND TEST SET ALONG WITH AVERAGED TOTAL SEISMIC ENERGIES (TSE) AND FREQUENCY OF WARNINGS (NOT AVAILABLE FOR TEST SET CASES).

Mine ID	Train set			Test set	
	Instances	Mean TSE [J]	Warnings Frequency	Instances	Mean TSE [J]
373	31236	81002	1.1%	-	-
264	20533	7563	0.4%	-	-
725	14777	190232	9.4%	330	106741

437	11682	4727	0.4%	-	-
541	6429	9397	0.9%	5	324
146	5591	678	0.1%	98	1
575	4891	9775	0.5%	253	7503
765	4578	136	0.0%	329	51265
149	4248	48357	7.3%	98	72749
155	3839	322021	17.2%	98	527229
583	3552	2595	0.2%	215	73302
479	2488	5548	0.0%	35	102
793	2346	0	0.0%	330	11547
607	2328	6027	0.0%	209	9470
599	1196	29932	1.9%	363	39962
171	-	-	-	49	33
470	-	-	-	258	10701
490	-	-	-	160	13698
508	-	-	-	58	32183
641	-	-	-	97	10672
689	-	-	-	83	63889
703	-	-	-	145	44031
799	-	-	-	317	8

Table I presents averaged TSE for each mine grouped over train and test datasets, together with the frequencies of warnings in the training dataset. It is worth to point out significant discrepancies between the activity levels of mines in both sets. For mine 765, the activity in the training set is mere 136 J, with no warnings. In the test set, the average activity is above 50 kJ, so there must have been several warnings emitted. A closer look reveals that there are some abnormalities in the training set. Fig. 3 presents the TSE of mines 155 and 765. While the activity of the former looks realistic, 765 is mute for majority of the time, only to exhibit a few spikes towards the end of the time series. On the other hand, its activity in the test set greatly increased. Some mines do not exhibit any activity in the training set, i.e. TSE equals zero (mines 777, 793). This is one of the reasons we have to avoid producing models that would be able to recognize the mines, the classifiers should generalize correctly from the activity records, regardless any behavior specific to certain mines. Also, it poses a problem - whether to consider the suspicious

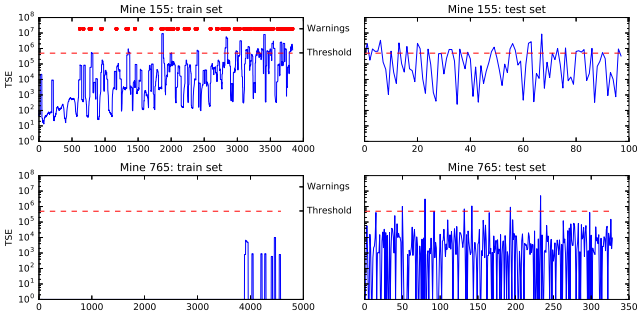

Fig. 3. Total seismic energy over time.

mines during the training or not. It is rather unusual for a mine to have a zero seismic activity and supposedly the data in these periods might be corrupted.

The final train and test splits were based on the above TSE analysis and were produced in the following way:

1) mines 777, 793 were excluded due to their suspicious lack of any activity in the training set (although they represented a significant amount of data);
2) in every split, five randomly selected mines were left only for testing (to evaluate the generalization properties of classifiers);
3) from the remaining sites we were taking 20% of samples for testing. For mines 146 and 599 samples were drawn from the beginning (due to corresponding energy levels in the test set), for the remaining - from the end;
4) in some cases (mines 373, 437) only samples where TSE were nonzero were taken into account.

The process was repeated several times to obtain multiple train/test splits. The final evaluation was based on the average score over 20 splits.

C. Model training and optimization

There are several models that we employed in creating the final solution to the problem. We used the implementation of models available in Python's **scikit-learn** package for machine learning (ver. 0.17.1) [7], [8] and **XGBoost** package for tree boosting models (ver. 0.4) [6]. Throughout the paper, for brevity, we use the following abbreviations for the model names: Linear Discriminant Analysis - LDA, Logistic Regression - LR, Extra Trees Classifier - ETC (all from **scikit-learn** library) and Extreme Gradient Boosting Classifier - XGB (from **XGBoost** library).

$\mathbf{Model_1}$: The fist model was built using $\mathbf{FS_1}$ and $\mathrm{TrTs_2}$ evaluation method. Several models were considered, apart from XGB and ETC, also logistic regressions and neural networks, finally only the first two were used in the final blend. They were performing particularly well in spite of rather large number of features.

First, we ran learning on all the features and interactions we produced. Based on the importance scores provided by XGB (described in Section III-A $\mathbf{FS_1}$) we kept the first 982

interactions and all *individual* features. Then, a grid search returned sets of parameters scoring the highest:

The optimal parameters for XGB model were (otherwise default):

- `n_estimators = 100`
- `max_depth = 2`
- `learning_rate = 0.08`

The optimal parameters for ETC were (otherwise default):

- `n_estimators = 1000`
- `max_depth = 7`
- `criterion = entropy`

It is worth to note, that trees, by their design, are relatively powerful in discovering interactions between features. However, in their case the interactions are not discovered concurrently, but rather in a multilevel manner, between consecutive splits. By explicitly using interactions as features, they can be made use of directly.

Having obtained well performing hyperparameters, we ran a randomized search for best features' subsets. In each iteration we were randomly selecting from 20 to 40 individual features (out of 133) and additionally up to 10 interactions (out of 982). We ran several thousands evaluations on XGB and several hundreds on ETC, tracking their validation scores.

The idea was to produce many models built only on subsets of features and to take advantage of assembling them which reduces variance of predictions and minimize the risk of overfitting to anomalies in particular features. This is a powerful method for increasing the performance of the model [9].

The final blend was composed of:

- single ETC of 10 000 trees using all 133 features and 20 best interactions;
- single XGB using the same features;
- a blend of 20 ETCs built on 20 best subsets of features;
- a blend of 20 XGBs built on 20 best subsets of features;

The final submission scored 0.9199 on the public leaderboard. The score in the final evaluation reached 0.9393 and turned out to be the best in the competition.

Model$_\mathbf{2}$: The second model involved the following classifiers: two linear models (LDA and LR) as well as the tree-based ETC model.

The first part of the solution was the LDA model trained on **FS$_\mathbf{2}$** using k-CV evaluation procedure. The regularization shrinkage parameter selection was done in an automated way (i.e., the parameter `shrinkage` set to "`auto`") in **scikit-learn**'s LDA implementation. The other models were LR and ETC trained on **FS$_\mathbf{3}$** using TrTs$_1$ evaluation method. The parameter values were set using grid search. The optimal values for LR model were:

- `penalty = l1`
- `C = 0.003`

The optimal parameters for ETC were:

- `n_estimators = 1000` (number of trees)
- `max_depth = 3`
- `max_features = 200`
- `min_samples_split = 3`
- `class_weight = 10` (for label '1').

The three models were blended by averaging their predictions with equal weights to produce a solution. Prior to averaging, the model predictions were standardised so that their standard deviations would equal 1. This step aims to convert the probabilities yielded by individual models to the same scale. Note that the mean values of predictions are irrelevant since AUC is invariant to monotonic transformations of output, see Equation 1. On the competition test set, the model yielded 0.9385 and 0.9340 of preliminary and final evaluation score, respectively.

Model$_\mathbf{3}$: This model used only **FS$_\mathbf{4}$** and was meant to be more universal than the other models and thus was tuned on LOLO validation. The algorithms used were ETC, XGB and logistic regression. For each algorithm, many sets of predictions were generated (using the top results from a grid search). This model achieved 0.928 and 0.933 on preliminary and final evaluations, respectively.

Below we list the best parameters found for each algorithm:
ETC

- `min_samples_leaf = 5`
- `n_estimators = 40 000`

XGB

- `subsample = 1.0`
- `num_round = 200`
- `max_depth = 10`
- `objective = binary:logistic`
- `base_score = 0.05`
- `eta = 0.04`
- `colsample_bytree = 0.8`

LTR

- `solver = sag` (Stochastic Average Gradient, just for speed)
- `C = 1.0`

D. Model ensemble

We have decided to use sorted order position averaging (as the AUC assessment method considers only the rank of predicted likelihoods and not the values) of the three presented models' predictions with the final weights being 1, 3 and 2 for models 1, 2 and 3 respectively. The averaging was employed in order to leverage various approaches and come up with yet a better predictor for the given task. The weights for the ensemble were chosen basing on individual model's scores on the preliminary leaderboard. The ensemble produced a model scoring 0.933 and 0.938 on preliminary and final leaderboard, respectively. All in all, it turned out that model 1 outperformed the full ensemble by a small margin (0.939 to 0.938). However, it might be caused by the relatively small test set size.

E. Things we tried that did not work

Throughout the process of creating the most successful model we tested a couple of ideas that turned out not to

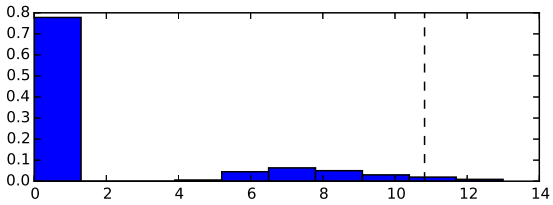

Fig. 4. Histogram of the total energy within 8 next hours (after with application of $\log(x+1)$ transformation). The dashed line indicates the warning level of $\log(5 \cdot 10^4 + 1)$ J.

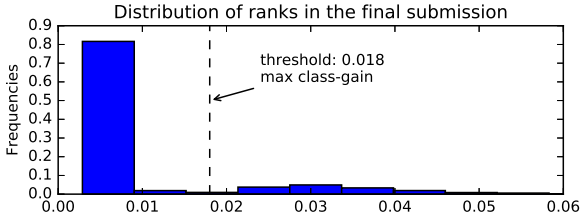

Fig. 5. Histogram of likelihoods returned by the winning model.

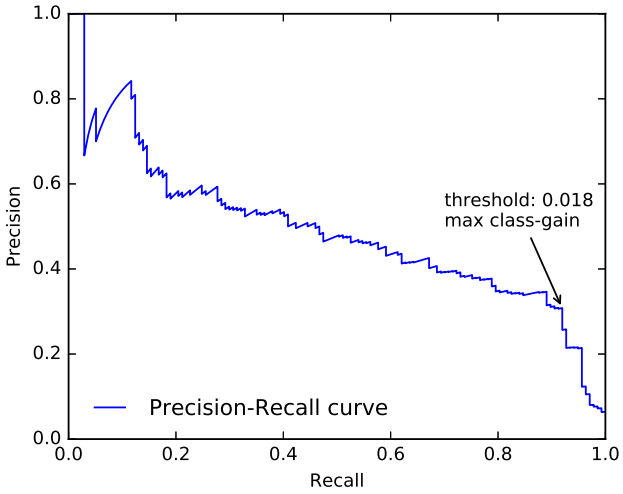

Fig. 6. Precision-recall curve.

improve our results. First of all, we framed the problem given in the competition as a regression task. Because the observations in the training data were given as time series, it was possible to retrieve the energy level for the next hours, see Fig. 4. This allowed us to forecast energy levels within the target window of 8 hours. Note that predictions from a regression model may be directly evaluated using AUC accuracy measure as it can be considered as a *risk scoring* model for high values of energy. For the original classification problem, we tried to modify the energy levels and train the models on an enriched set of labels, e.g., we assumed 30 kJ (and a couple of other values) as the warning level and estimate the model.

We also experimented with undersampling of training instances pertaining to class 0 so that the proportion of '1' in the training data increases. We also tried to reduce samples from locations 264, 373 and 437 in the training set by undersampling or assigning them a lower sample weight (in, e.g., LR model).

However, in this particular application, our efforts were not successful as the performance of the models (in terms of evaluation scores) was not improving.

F. Model performance on the final test set

After the competition we were provided with the true labels used during the final evaluation. We were able to compute different metrics than AUC. The winning model's predictions had a strongly skewed distribution (Fig. 5), corresponding to total energies seen in Fig. 4. The distribution has two modes, however of a much lower mode related to predicted warnings - this is due to imbalance of classes. Depending on the threshold beyond which we consider predictions as warnings we can derive the confusion matrix:

		True warning	
		1	0
Predicted warning	1	$TP = 126$	$FP = 284$
	0	$FN = 11$	$TN = 2390$

Based on the matrix we can compute several useful accuracy measures of the model:

$$\texttt{precision} = \texttt{TP} / (\texttt{TP} + \texttt{FP}) \tag{2}$$

$$\texttt{sensitivity (recall)} = \texttt{TP} / (\texttt{TP} + \texttt{FN}) \tag{3}$$

$$\texttt{specificity} = \texttt{TN} / (\texttt{TN} + \texttt{FP}) \tag{4}$$

$$\texttt{F1} = 2 \cdot \frac{\texttt{precision} \cdot \texttt{recall}}{\texttt{precision} + \texttt{recall}} \tag{5}$$

$$\texttt{Class-gain} = \texttt{specificity} + \texttt{recall} - 1 \tag{6}$$

The threshold maximizing the class-gain score is 0.018 (see Fig. 5) and yields the following accuracy on the final test set:

precision	recall	specificity	F1	class-gain
0.31	0.92	0.89	0.46	0.81

The entire precision-recall curve can be seen in Fig. 6.

In order to assess our results we looked for research addressing similar problems as the one considered here. In [4] we found an approach to solve the same problem, however the results are not directly comparable since they are based on different datasets. Our results prove to outperform results reported there for all presented classifiers (the highest class-gain reported is 0.75). Also, in the cited paper there was no inter-coal-mine validation, while the models described in our work were cross-validated on separate coal mines. Therefore, the models proposed are designed to generalize well and should be applicable also to working sites with no historical data available.

IV. Summary

Given that the dataset originates from working mine sites, with the entire measurement infrastructure already installed,

we hope that the approach presented in this paper could be implemented and serve as a valuable tool for alerting about dangerous seismic events early. This hopefully should result in preventing possible accidents which pose a threat to employees and generate losses from damaged coal mine infrastructure and machinery.

Even though the models presented here have outperformed the other models in the competition, we recommend they be ensembled with other high-scoring models, because properly combined efforts of multiple participants are expected to yield better results than individual solutions.

Lastly, we would like to thank the organizers for the opportunity to solve a real-life problem and the contestants for creating such a competitive environment.

***Abstract*—We describe our submission to the AAIA'16 Data Mining Competition, where the objective is to devise a reliable prediction model for detecting periods of increased seismic activity in coal mines. Our solution exploits a selective naive Bayes classifier, with optimal preprocessing, variable selection and model averaging, together with an automatic variable construction method that builds many variables from time series records. One challenging part of the competition is that the input variables are not independent and identically distributed (i.i.d.) between the train and test datasets, since the train data and test data rely on different coal mines and different times periods. We apply a drift-aware methodology to alleviate this problem, that enabled to get a final score of 0.9246 (team marcb), less than 0.015 from the challenge winner.**

I. Introduction

The AAIA'16 Data Mining Competition[1] is related to a problem of prediction of dangerous seismic events in coal mines. Coal mines are equipped with seismic sensors that register bumps and energy. Sensor readings are available as times series of 24 records, with hourly statistic summaries (such as number of bumps, sum, mean or max of energy...). Train data consists of 79,893 samples from a first period, whereas the test data contains 3,860 samples coming from a second period. In the test data, the time periods do not overlap and are in random order, which is not the case in the train data. In this competition, active participants are rewarded by up to four additional train datasets, provided that they make enough submissions. Altogether, the most active participants can obtain up to a total of 133,151 train samples. The objective is to predict if the total seismic energy perceived with 8 hours after the period covered by a data sample exceeds a warning threshold, and the evaluation criterion is the Area Under the ROC Curve (AUC).

In this paper, we present our submission to the challenge. It exploits a Selective Naive Bayes classifier together with an automatic variable construction method (Section II). A good classifier trained on the train data obtains a disastrous leaderboard score. This is not caused by over-fitting, but by a severe distribution drift between train and test data. We suggest in Section III a methodology to alleviate this problem, and apply it in Section IV to elaborate our submissions to the challenge. Finally, Section V summarizes the paper.

[1]https://knowledgepit.fedcsis.org/contest/view.php?id=112

II. Supervised Classification Framework

We summarize the Selective Naive Bayes (SNB) classifier[2] introduced in [1]. It extends the Naive Bayes classifier owing to an optimal estimation of the class conditional probabilities, a Bayesian variable selection and a Compression-based Model Averaging. We also describe the automatic variable construction framework presented in [2], used to get a tabular representation from times series.

A. Optimal preprocessing

Numerical variables are preprocessed using supervised discretization [3] to evaluate the class conditional probabilities. In the MODL approach [4], the discretization is turned into a model selection problem and solved in a Bayesian way. Using a hierarchical prior distribution on the discretization parameters, the Bayes formula is applicable to derive an exact analytical criterion to evaluate the posterior probability of a discretization model. A 0-1 normalized version of this criterion provides a univariate informativeness evaluation of each input variable. Similarly, categorical variables are preprocessed using supervised value grouping [5].

B. Bayesian Approach for Variable Selection

The naive independence assumption can harm the performance when violated. In [1], the Selective Naive Bayes (SNB) classifier [6] is trained using a Bayesian model selection approach to select the best subset of variables [7]. Efficient search heuristics with super-linear computation time are proposed, on the basis of greedy forward addition and backward elimination of variables.

C. Compression-Based Model Averaging

Instead of taking the best subset of variables, the method introduced in [1] averages all the classifiers resulting from different subsets of variable, using a logarithmic smoothing of the posterior distribution of the trained classifiers. The weighting scheme on the models reduces to a weighting scheme on the variables, and finally results in a single Naive Bayes classifier with weights per variable.

D. Automatic Variable Construction for Multi-Table

Variable construction [8] has been less studied than variable selection in the literature. It is all the more necessary in the case of relational data to obtain a flat input data table with tabular representation. It implies a large amount of work for the data analyst and heavily relies on domain knowledge to construct new potentially informative variables. Learning from relational data has recently received an increasing attention in the literature, since the introduction of Multi-Relational Data Mining (MRDM) in [9], [10]. In this paper, we exploit the automatic variable construction framework presented in [2]. It relies on a formal description of the data structure, with a root table and several secondary tables in 0 to 1 or 0 to n relationship and a set of construction rules (*Count*, *CountDistinct*, *Mode*, *Min*, *Max*, *Mean*, *Median*, *StdDev*, *Sum*, *Selection*). The space of variables that can be constructed is virtually infinite, which raises both combinatorial and over-fitting problems. These problems are solved by introducing a prior distribution over all the constructed variables, as well as an effective algorithm to draw samples of constructed variables from this distribution.

III. A Methodology to Reduce the Drift Problem

Statistical learning relies on identically and independently distributed (i.i.d.) data. Given this assumption, models trained from a train dataset can be deployed on a test dataset, with some guarantees of performance. This i.i.d. assumption does not hold in many real world cases, for example in case of time series data, in the marketing field where a model (churn, fraud, cross-selling...) is trained on a past period and deployed on a future period, ergonomics where a model is trained from a panel of few volunteers... In these cases of *drift* between the train and deployment datasets, as the data are not i.i.d, obtaining good classification performance on the train data does not guarantee good performance on the test data.

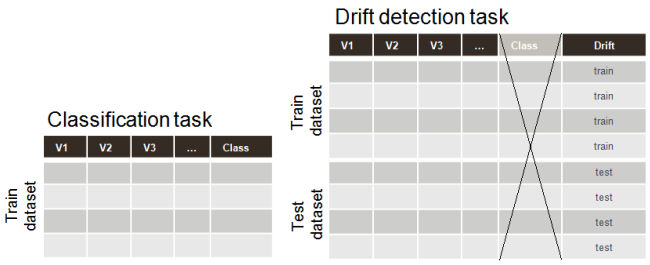

Fig. 1. Classification and drift detection tasks

In [11], [12], we have investigated this issue and proposed a methodology to reduce the drift problem. Let us assume that we have a classification task, a train dataset with class labels and a test dataset that potentially comes from a different distribution. The objective is to train a classifier and to predict the test class labels as accurately as possible whatever be the drift. Let us then consider two tasks: classification and detection of the drift. The drift detection task can be turned into a classification task as in [13], by merging the train and test datasets and using the dataset label ('train' or 'test') as the target variable (see Figure 1).

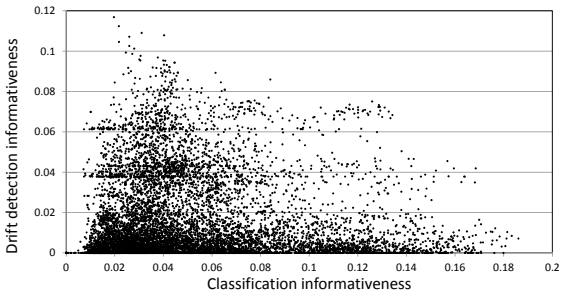

Fig. 2. Informativeness of 10,000 input variables

The initial representation is then evaluated using the pre-processing method summarized in Section II-A, both for the classification and the drift detection tasks. Intuitively, if we are able to select an input representation with good classification performance on the train data but poor drift detection, we expect that our classifier will be less sensitive to drift and its performance drop on the test dataset will be reduced.

The objective is then to explore varying input representations and select the one with the best classification performance together with the poorest drift detection. To illustrate this, we represent in Figure 2 the informativeness of 10,000 input variables for the classification and drift detection tasks (borrowed from the AAIA'2015 challenge [11]). The results show that there are variables with large drift informativeness and small classification informativeness (top-left of the figure), or on the contrary variables with small drift informativeness and large classification informativeness (bottom-right). The interesting variables are those on the right and close to the X axis, with small drift informativeness. Using these information, we can select interesting variables, either automatically (as in the AAIA'2015 challenge [11]) or manually with a focus on interpretability (as in the IJCRS'2015 challenge [12]). With interesting variables only, the classification performance may slightly decrease in the train dataset (because only part of the available variables are exploited), but the performance is likely to be more resilient to drift, with a better performance on the test dataset.

IV. Challenge Submissions

A. Applying the Framework for the Challenge

Coal mines are represented using a multi-table schema:

- root table that contains the identifier of the main working site (coal mine) and 12 other characteristics related to the whole period of 24 hours,
- secondary table (0-n) for the time series of 24 hourly summarized seismic sensor readings,
- secondary table (0-1) that contains some meta-data per working site.

Using the data structure presented in Figure 3 and the construction rules introduced in Section II-D, one can for

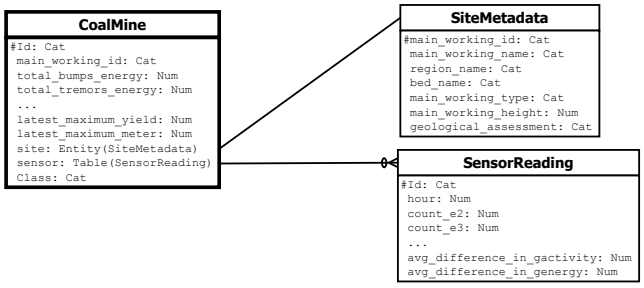

Fig. 3. Multi-table representation for the data of the AAIA'16 challenge

example construct the following variables ("name": comment) to enrich the description of a *CoalMine*:

- "Mean(sensor.sum_e2)": mean of the sensor sum_e2 readings,
- "Count(sensor) where sum_e2 $>$ 0.5": number of sensor readings where the sum_e2 value is greater than 0.5,
- "Max(sensor.sum_e2) where highest_bump_energy $>$ 50": max of the sum_e2 value from sensor readings where highest_bump_energy is greater than 50.

The number of variables to construct is the only user parameter. An input flat data table representation is then obtained from the set of all automatically constructed variables. All these variables are then preprocessed using the optimal discretization method (cf. Section II-A) to assess their informativeness and evaluate their class conditional probabilities, before training the SNB classifier.

For each experiment, 1000 variables are built using the automatic variable construction framework summarized in Section II-D.

B. Preliminary experiments

We first perform some explanatory analysis to better understand the data, without any submission on the leaderboard.

1) Evaluation of the expected performance: Using a 70%-30% train-test split of the train dataset, we obtain a train AUC of 0.99 and a test AUC of 0.97. The performance are both accurate and reliable. However, prediction of increased seismic activity should not be so easy, and we suspect that the good performance might be caused by some bias in the dataset.

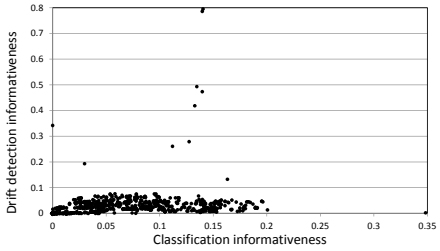

Fig. 4. Informativeness of 1000 input variables for the AAIA'2016 challenge

2) Evaluation of the drift: To evaluate whether the train and test dataset are i.i.d, we apply the drift detection methodology described in Section III. This drift detection task achieves an almost perfect performance with an AUC of 0.995, meaning that the train and test data can be well separated. The most informative variables for the drift detection task are the identifier of the main working site, as well as all the meta-data variables per working site. These drift informative variables are far above most other input variables in Figure 4. As the data are not i.i.d, obtaining good classification performance on the train data does not guarantee good performance on the test data.

3) Distribution of coal mines in train and test datasets: To further investigate on the observed drift, we collect the identifiers of the coal mines in the train and test datasets. Overall, 24 coal mines are used: 7 in the initial train dataset, 16 with all the additional train datasets and 21 in the test dataset. The distribution of the coal mines is heavily unbalanced in the train dataset, whereas is is more balanced in the test dataset.

4) Distribution of the target labels: The target class is heavily unbalanced, with 1171 *warning* (around 1.5%) and the rest as *normal*. Furthermore, 2 among the 7 initial train coal mines are never labeled as *warning*.

According to the challenge organizers, the time periods in the test data do not overlap and are in random order. We then assume that in the train data, the time periods overlap and are in sequential order. This overlapping causes an additional problem of non i.i.d data, with the train data being over-sampled compared to the test data.

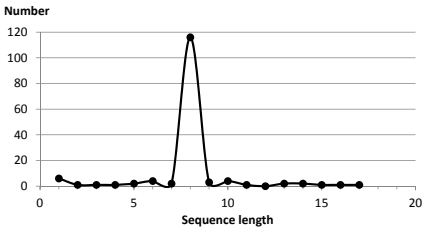

Fig. 5. Number of sequences of train warnings per sequence size

To evaluate the over-sampling factor we collect the sequences of consecutive *warning* in the train dataset. The results, displayed in Figure 5, show that most sequences are of length 8.

C. First submission

The preliminary explanatory analysis summarized in Section IV-B shows that there is a severe drift between the train and test datasets, caused by different mines, different time periods and different sampling rates. To reduce this drift problem, we apply the following protocol:

- remove any variable that identifies the coal mines (*main_working_id* plus the additional meta-data variables per working site),
- re-sample the train mines by keeping at most 5% of instance per mine, so as to get a more balanced distribution as in the test dataset (21 test mines, thus $1/21 \approx 5\%$),
- sub-sample the remaining train instances by a factor of $1/8 \approx 12\%$), so as to get approximatively the same sampling factor as in the test dataset.

This first trial, submitted one day after entering the challenge, obtains a leaderboard AUC of 0.9239, which is very competitive ($\approx 1\%$ from the leader at the submission time).

D. Second and final submission

Although the first obtained results are quite good, they exploit only a small subset of the train instances (around 3% after applying the sampling strategies). To better exploit all the available train data, we repeat the train protocol described previously 100 times (based on different random samples) and average the predictions. This second trial (our final one) obtains almost the same leaderboard AUC (0.9243), but we expect the averaging strategy may lead to more reliable predictions (the leaderboard AUC is evaluated on only 25% of the test data).

Furthermore, this averaging over 100 train samples provides additional insights w.r.t. the variance of the results, which amounts to around 1%. We expect that the variance of leaderboard AUC is still higher and that the best participant submissions (over potentially hundred of submissions) are likely to over-estimate the true test AUC. Thus getting a leaderboard AUC within the variance of the leader leaves few room for further improvement.

E. Additional experiments

First, as a sanity check, we submitted the first prediction obtained using all the available train data (all variables and instances: see Section IV-B). As expected, the drift effect is disastrous, and our 0.97 train AUC dropped down to a 0.60 leaderboard AUC.

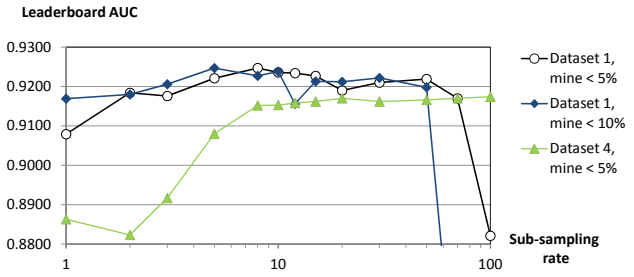

Fig. 6. Leaderboard AUC per sampling rate for three scenarios

We also performed sensitivity analysis, with varying the train mine re-sampling rate, sub-sampling rate, averaging strategy and number of constructed variables. We also experimented with using the additional train datasets, with some manual or automatic feature selection as well as finer anti-drift approaches (see [12]). For example, Figure 6 displays the leaderboard AUC using 1 or all 4 additional train datasets, with train mine resampling rate of at most 5% or 10%, and sub-sampling rate varying from 1% to 100%. This shows that the initial train mine re-sampling rate (5%) looks stable in a wider range (than 10%), that the initial sub-sampling rate (12%) is in a plateau of good performance (between 8% and 20% looks fine). Finally, using all the 4 additional train datasets, the performance was slightly less accurate, but as this is within the expected variance, this is not significant.

Overall, the obtained leaderboard results showed that the preliminary chosen protocol parameters (see Sections IV-B, IV-D) were quite stable, and the results dropped down only for significant changes in the re-sampling and sub-sampling rates (worse performance for at least half or twice the initial value of the parameters). The additional data did not provide any further improvement, but there was not much room for such improvement. In the end, we choose to keep our second submission, that went from a 0.9243 leaderboard AUC to a 0.9246 final AUC.

V. Conclusion

In the AAIA'16 Data Mining Competition, the train and test data are not i.i.d, which causes a dramatic drop of the test performance, even for accurate and reliable trained classifiers. After preliminary explanatory analysis, we identified several causes of drift between the train and test data: different distributions of coal mines, different sampling rate and different period. To be more robust to drift, we proposed a methodology based on removing variables too sensitive to drift, re-sampling to get a more balanced distribution of the train mines and sub-sampling to achieve approximately the same sampling rate. Applying this methodology, 100 classifiers were trained, each exploiting sub-samples of only 3% of the trained instances, and the averaged predictions obtained a 0.9246 final AUC.

Massively Parallel Feature Extraction Framework Application in Predicting Dangerous Seismic Events

Marek Grzegorowski
Faculty of Mathematics, Informatics and Mechanics, University of Warsaw,
Banacha 2, 02-097 Warsaw, Poland, Email: M.Grzegorowski@mimuw.edu.pl

***Abstract*—In this paper we introduce an automated mechanism for knowledge discovery from data streams. As a part of this work, we also present a new approach to the creation of classifiers ensemble based on a wide variety of models. Furthermore, we describe an innovative, highly scalable feature extraction and selection framework designed to work with the MapReduce programming model and the application of designed framework to build an ensemble of classifiers which takes into account both the quality and the diversity of individual models. The effectiveness of the solution has been verified through a participation in an open data mining competition which concerned the problem of predicting periods of increased seismic activity causing life-threatening accidents in coal mines. The submitted solution obtained the highest AUC score of all the solutions uploaded by 106 participating research teams.**

I. Introduction

FOR SOME time, we can observe a massive shift in technology that makes sensors are more and more available and common. On the other hand, we can notice a significant grow in popularity of stream analytics as well as a decline in prices of data storage. One of the main beneficiaries of the aforementioned changes are monitoring, threats detecting and decision supporting systems. An exemplary application of which could be active monitoring of coal extraction [21] to provide protection for people underground or supporting fire commanders in decision making [14].

Nowadays, an increasing number of business technology objectives is related with comprehensive data analytics. Meanwhile, many researchers recognize feature engineering [8] as a major step in the process of knowledge discovery, necessary to obtain good results of the analysis. In this paper we propose an innovative approach to data analysis that, in order to provide high quality assessment, implies creation of an ensemble [3] of classifiers using a wide variety of models based on various subsets of attributes, in this way, resulting not only in enhancement of the quality of indications, but also minimizing the impact of concept drift on the final evaluation of results.

The continuous collection and analysis of multiple reading streams from a large network of sensors located underground raises a problem of long lasting and usually very complex preparation of data. Therefore, in order to simplify and speed up the feature extraction we introduced a novel framework designed to process streams of numerical readings from multiple sensors. The developed framework is ready to operate in production environments and, hence, is tailored for incremental processing of the emerging data based on the sliding window technique and the concept of parallelization presented in [5].

In the following sections we present the extension of our former solution [6], [7] with additional features and describe modification of the architecture allowing the work both with incremental data as well as with highly-scalable batch computations via MapReduce [2] programming model. The assessment of the solution was carried out on the basis of real life problems related to the streaming data [22].

The effectiveness of the framework has been confirmed in the analysis of several significantly different problems within the data analysis competitions. The first, concerned the recognition of the activity and posture of firefighter based on readings from multiple motion and vital sensors as a part of AAIA'15 Data Mining Competition: Tagging Firefighter Activities at the Fire Scene[17]. The second concerned the prediction of dangerous concentration of methane in the atmosphere of the mine sidewalks as a part of IJCRS'15 Data Challenge: Mining Data from Coal Mines[10]. The third concerned the prediction of increased seismic activity in mines as a part of AAIA'16 Data Mining Challenge: Predicting Dangerous Seismic Events in Active Coal Mines [9]. In all competitions, the results were very promising. It is worth noting that in the case of the seismic activity analysis, the solution based on the elaborated framework received the highest score in terms of Area Under ROC Curve (AUC) measure, equal to 93.96%, while in the methane concentration level analysis it achieved the second highest result with AUC equal to 94.73%.

The paper is organized as follows. In Section II we present the description of the data challenge problem. In Section III and IV we provide detailed information about the elaborated feature engineering framework, including insights of feature extraction and selection. Next, in Section V, we describe the conduct of the experiments and resulted ensemble model. Finally, in Section VI we summarize the work.

II. AAIA'16 Data Challenge Problem Description

Providing safety of miners working underground is the fundamental requirement for the coal mining industry in Poland. Coal mining companies are obligated by the law to introduce many safety measures to secure proper working conditions of their underground personnel. The task in the competition was to devise a reliable prediction model for detecting periods of increased seismic activity that could endanger miners.

More precisely, the tasks of the data challenge was to predict likelihood of the 'warning' label for the records from the test

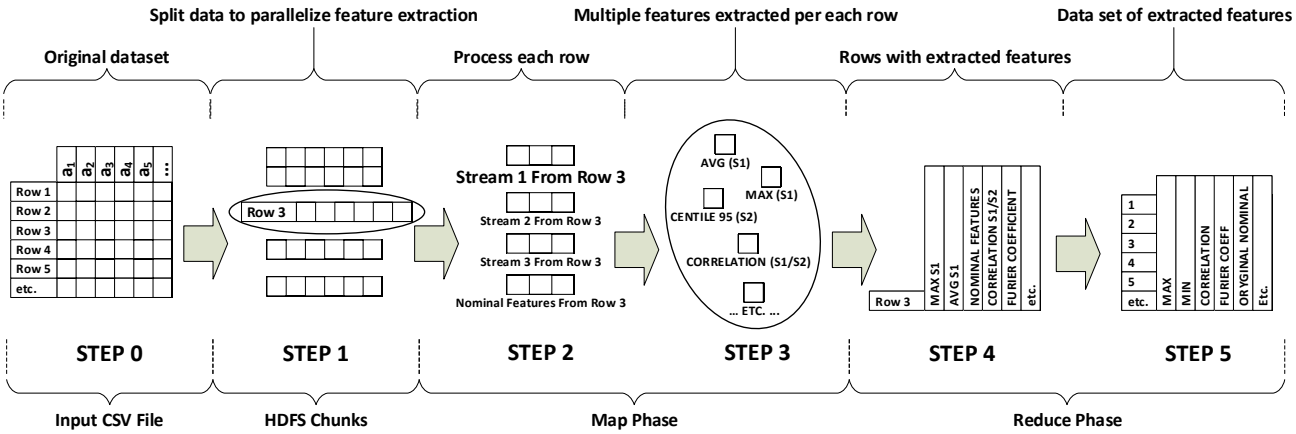

Figure 1. This diagram presents the high level overview of the feature extraction process broken down into individual steps. The curly braces at the top of the diagram indicate goals achieved in each processing step. The curly braces at the bottom of the diagram show how the individual processing steps were implemented. The 'original dataset' in STEP 0 corresponds to dataset provided by organizers of AAIA'16 Data Mining Challenge: Predicting Dangerous Seismic Events in Active Coal Mines. Features $a_1, a_2, a_3, ..$ correspond to attributes presented in Table I. STEP 1 was designed to partition of the original dataset into individual rows in order to parallelize calculations - this step was implemented by internal mechanisms of the MapReduce framework. STEP 2 was to split each row into nominal and stream data.In STEP 3 the feature extraction framework was applied to each data stream (e.g. time series containing 24 values corresponding to the average energy of the most active geophone - see Table I) and all features described in Tables II and III were created. In STEPs 4 and 5 all features, the nominal attributes as well as attributes newly extracted from streams, were put together.

set. The real number corresponding to the predicted likelihood was not expected to be in any particular range, however, higher numerical value should have indicated a higher chance of the 'warning' label. The final assessment of solutions were calculated using the Area Under the ROC Curve (AUC).

The data set, which was provided by Research and Development Centre EMAG, consisted of hourly aggregated readings from seismic sensors that count the number of seismic bumps perceived at longwalls and measure their total energy. Data records were composed of 24 consecutive hours of such readings coupled with the most recent assessments of the conditions at longwalls made by mining experts. All the attributes of the data set are described in Table I. The data sets were well prepared, cleaned of malformed and erroneous values, without missing attributes.

Table I
THE TABLE PRESENTS ATTRIBUTES OF THE MAIN DATA FILES.

no.	feature description
1	id of the main working site where the measurements were taken
2	total energy of: seismic bumps, major seismic bumps, destressing blasts and all types of bumps registered in the last 24h
3	latest progress in the mining from, both, left and right side
4	latest seismic, comprehensive and seismoacoustic (standard and alternative method) hazard assessments made by experts (a/b/c/d): a - no hazard; b - moderate hazard; c - high hazard; d - dangerous
5	maximum yield from the last meter of the small-diameter drilling
6	depth at which the maximum yield was registered
7	five time series containing 24 values (one per hour 1..24) each corresponding to a number of seismic bumps with energy in the following ranges: $(0, 10^2]$, $(10^2, 10^3]$, $(10^3, 10^4]$, $(10^4, 10^5]$ and $(10^5, Inf)$ aggregated per hour (1..24)
8	five time series containing 24 values (one per hour 1..24) each corresponding to sum of energy of registered seismic bumps with energy in the following ranges: $(0, 10^2]$, $(10^2, 10^3]$, $(10^3, 10^4]$, $(10^4, 10^5]$ and $(10^5, Inf)$ aggregated per hour (1..24)
9	four time series, each containing 24 values (one per hour 1..24) corresponding to the number of: seismic bumps, rock bursts, destressing blasts and to energy of the strongest seismic bump
10	four time series, each containing 24 values (one per hour 1..24) corresponding to maximum activity, maximum energy, average activity and average energy of the most active geophone
11	four time series, each containing 24 values (one per hour 1..24) ccorresponding to the maximum difference and average difference in, both, activity and energy registered by the most active geophone

In total, the training file contained 133150 records provided in a tabular format with 541 columns. The label indicates whether a total seismic energy perceived during 8 hours after the period covered by a data record exceeded the warning threshold of $5 * 10^4$ Joules. There were 2963 examples labeled as 'warning' and 130187 'normal' cases in the training set.

III. FEATURE EXTRACTION

In the course of feature extraction we generated a large number [26] of potentially relevant characteristics [16], [23] and applied the feature selection in the next step. The feature extraction was based on the sliding window [24] method and was configured to accept on its input a data set containing readings from multiple streams [5]. According to the submitted configuration each stream, stored in a row of the csv file (training and test set), was divided into three non-overlapping frames. During the process of moving a sliding window through the time series a number of aggregating functions were applied. The Table II presents features extracted form a single time series.

The statistics indicated in Table II were supplemented by Kendall's correlation between each pair of data streams for every row in csv. Furthermore, because there were more than one window generated for each time series we extracted inter-window statistics, that is, a set of values that express

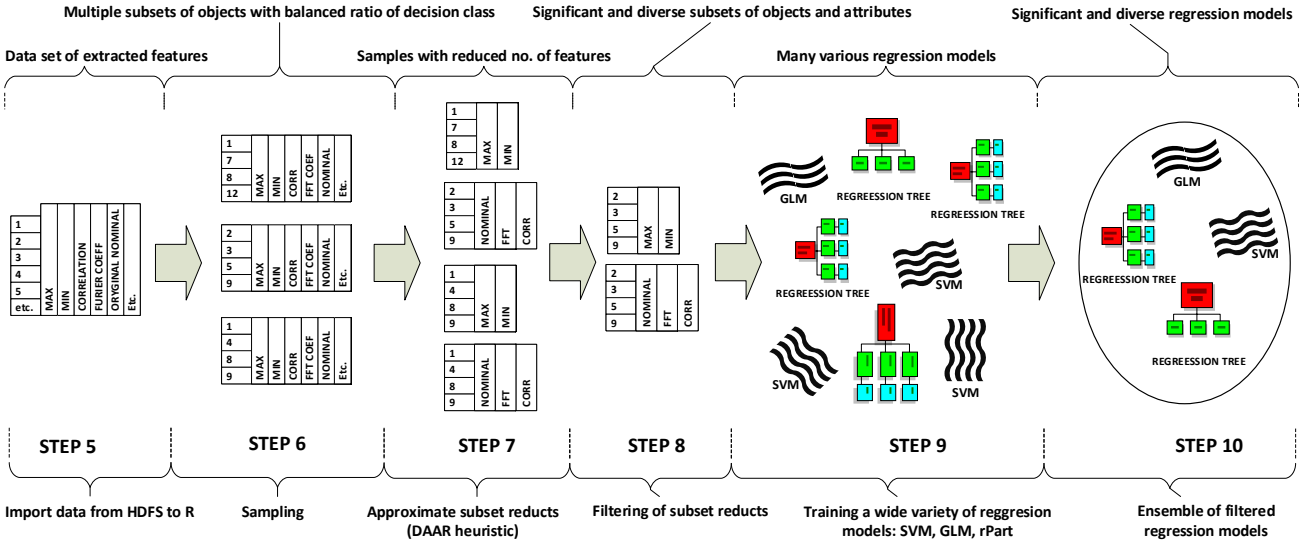

Figure 2. This diagram presents the course of feature selection, regression models training and construction of the final ensemble of regression models broken down into individual steps. The curly braces at the top of the diagram indicate goals achieved in processing steps. The curly braces at the bottom of the diagram show how each processing step was implemented. All the processing steps from 6 to 10 were implemented in R environment for statistical computing. Consecutive processing steps were designed to: STEP 6 - was to drew a number of random samples of objects with balanced decision classes. In STEP 7 the reduced attribute subsets were calculated - this step was implemented basing on the concept of approximate decision reducts derived from the theory of rough sets. In STEP 8, a number of attribute subsets were obtained. Each subset was derived by merging 2 or 3 reducts, however, only significantly different subsets were maintained for the purpose of model training in the following phase of processing. In STEP 9 previously obtained subsets of objects and attributes were used to train regression models based on selected algorithms: rPart, SVM, GLM. Lastly, in STEP 10 the most important models were used to form an ensemble. In the process of models selection for the purpose of ensemble construction we took into consideration, both the quality of the reggresion model as well as the degree of diversity in relation to already selected models. The course of steps 9 and 10 has been described as Algorithm 1.

the changes between pairs of same statistics in consecutive sliding windows. The inter-window stats are presented in Table III.

In order to optimize time-effectiveness of the experimentation process the framework implementation was modified so that it could be run in several modes, including: incremental stream processing[5], single-threaded mode and the map-reduce mode. In order to allow multi-mode framework operation, the feature extraction mechanism was isolated as a separate tool with respect to the runtime environment.

The solution for the competition was calculated in batch mode and launched on a cluster of Docker[2] containers with installed Hadoop[3] software library as an implementation of MapReduce protocol. The scheme of the whole feature extrction process is depicted in Figure 1. In the "Map" phase (compare steps 2 and 3 in Figure 1) every data row was divided into: sub-streams of numerical readings from various sensors, set of nominal and aggregated features and, in case of the training set, also label. Labels, nominal and aggregated attributes were transferred to the "Reduce" phase unchanged while the numerical streams were subjected to an additional feature extraction described above. In the "Reduce" phase

Table II
THE TABLE PRESENTS FEATURES WHICH ARE CALCULATED TO REPRESENT THE TIME SERIES IN A SLIDING WINDOW.

feature	description
max	a maximum value of the readings in the window
min	a minimum value of the readings in the window
maxMinDiff	a difference between the max and min
mean	a mean value of readings in the window
percentileX	a Xth percentiles for the readings, where: $X \in \{2,5,10,15,20,25,30,50,70,75,80,85,90,95,98\}$
percentiles5Diff	a subtraction of the percentiles 95% and 5%
stdDev	a standard deviation of the readings
variance	a variance deviation of the readings
fftCoeffSet	a set containing first 5 Fourier transform coefficients
kurtosis	a Kurtosis measure [1]
skewness	a measure of the asymmetry

Table III
INTER-WINDOW STATISTICS THAT EXPRESS THE CHANGES BETWEEN A PAIR OF EQUIVALENT FEATURES IN CONSECUTIVE WINDOWS.

feature	description
maxDiff	a difference between *max* stats in the consecutive sliding windows
meanDiff	a difference between *mean* stats in the consecutive sliding windows
minDiff	a difference between *min* statistics in the consecutive sliding windows
percentileXDiff	a difference between *Xth* percentile statistics in the consecutive sliding windows, where: $X \in \{5,25,50,75,95\}$

(steps: 4 and 5 in Figure 1) all the attributes obtained for each row were combined back together.

IV. Feature Selection

The experimentation was significantly affected by the fact that the training data set was very unbalanced, rows labeled as 'warning' represented only 2,3% of all objects. Therefore, in the first step we drew a number of random samples that contained between 10 000 and 20 000 objects out of 133 150 all objects of the training set. Created samples differed in the number of objects of "warning" class (minority class), each contained a minimum of 1000 and a maximum of 2000 objects of this class. Objects within a particular sample were unique, however they could be repeated between different samples.

The generated data samples were randomly divided into two disjoint groups: group A - containing object subsets for the purpose of the feature selection, group B containing samples for the purpose of training of regression models. It should be noted that in order to use the chosen feature selection algorithms, before generating the 'A' samples the training set was subjected to discretization of a numerical attributes using local (univariate) version of the algorithm described in [18].

The selection of attributes [12] was carried out on the basis of a filter method derived from the theory of rough set[19]. Using the R[4] language and environment for statistical computing with installed RoughSets [20] package we calculated approximate decision reducts[13] with DAAR [11] heuristic. Approximate decision reducts are relatively small, thus, we decided to merge few as a single attribute subset. As a result of feature selection process (depicted in Figure 2) we prepared a number of significantly different attribute subsets.

V. Models Training and Ensambling

The task of maximizing AUC measure, posed by the organizers of the competition, prompted us to apply regression algorithms to identify the probability of the 'warning' label. The final solution is based on the concept of building an ensemble of diverse regression models which interpret 'warning' label as 1, while 'normal' label as 0. To provide a diversity of models we trained them on various subsets of attributes, what was important in order to provide a variety of regression models because the analyzed data set had few very dominant attributes. An additional effect of using different features for different models was to protect the ensemble against significant concept drift [1] on the part of the attributes between the training and test sets. This approach was also expected to protect the model against over-fitting [15] and, hence, against the significant decrease in the quality of prediction on the test set.

The machine learning were conducted on pre-prepared samples of objects with reduced number of attributes. The ultimate ensemble consisted of 8 significantly different regression models which were calculated with three various algorithms, including: regression trees (calculated by the algorithm from the rPart[5] package), SVM regressor (computed using the algorithm from the e1071[6] package) and the glm[7] function from R language to fit a generalized linear model. The following list presents models included in the final ensemble:

- Five simple regression tree models calculated with rPart.
- Two SVM models with different kernel functions
  - SVM_1 - regression, kernel: linear, cost: 1, gamma: 0.1, eps: 0.1 , Number of Support Vectors: 2968
  - SVM_2 - regression, kernel: radial, cost: 1, gamma: 0.07143, eps: 0.1, Number of Support Vectors: 7171
- One generalized linear model

Algorithm 1: The construction of regressors ensemble.

Data:
- *attSubsets* - pre-calculated subsets of attributes - approximate reducts
- *objectSamples* - pre-calculated object samples
- *testSet* - test set
- *regressionAlgorithms*, default: { rPart, SVM, glm }
- *allowedAttempts*, default: 3
- *minimalQualityTreshold* - minimal quality treshold

Result:
- *ensemble of regression models*

```
/* Initialization of variables                    */
ensemble ← ∅;  weakAttempts ← 0
alg ← regressionAlgorithms.removeFirst
while TRUE do
    a1, a2 ← attSubsets.drawAndRemoveTwo
    b1, b2 ← objectSamples.drawAndRemoveTwo
    /* Every model is trained and
       validated on various samples               */
    model ← alg.trainAndEvaluate(a1, b1, a2, b2)
    score ← model.score(testSet)
    /* The ensemble is expanded if the
       model meets the quality threshold
       and there is no similar model              */
    if model.evaluation > minimalQualityTreshold ∧
     ¬ensemble.containsSimilar(model, score) then
        ensamble ← ensamble ⋃ {model ⊕ score}
    else
        weakAttempts ← weakAttempts + 1
        if weakAttempts < allowedAttempts then
            continue;
        if regressionAlgorithms ≠ ∅ then
            alg ← regressionAlgorithms.removeFirst
              weakAttempts ← 0
        else end of experimentation
            break;
return ∑_{s∈ensemble.scores} s;
```

[7]See https://stat.ethz.ch/R-manual/R-patched/library/stats/html/glm.html

The whole phase of machine learning were carried out in the R statistical environment. The ensemble was successively extended with new models based on one of three designated algorithms, starting from the the rPart algorithm which in the initial assessment achieved the most promising results. In each step of the experiment: a sample of objects from those available in group 'B' and a subset of the attributes form those obtained in the phase of feature selection were drawn. The prepared subset of the training set was used to train a single regression model which was added to the ensemble under two conditions. First, the evaluation of the results had to exceed the satisfactory quality threshold. Second, the results of the regression for the test set had to be significantly different from any of the models already added to the ensemble. A detailed description of the experiment is presented in the Algorithm 1.

VI. Summary

The paper introduces an automated framework of extraction and selection of attributes designed to work with big data using MapReduce programming model. The article presents the proof of concept application of the framework to build an ensemble of classifiers based on a simple heuristic indicating the extension of the ensemble which takes into account both the quality and the diversity of the ultimate solution. The effectiveness of the developed solution has been verified by the participation in an open knowledge discovery competition in which it obtained the highest score in terms of AUC (93.96%) of all solutions submitted by 106 participating research teams.

***Abstract*—Identification of seismic activity levels in coal mines is important to avoid accidents such as rockburst. Creating an early warning system that can save lives requires an automated way of predicting. This study proposes a prediction algorithm for the AAIA′16 Data Mining Challenge: Predicting Dangerous Seismic Events in Active Coal Mines that is based on transient activity features along with average indicators evaluated by a Fisher's linear discriminant analysis. Performance evaluation experiments on the training datasets revealed an accuracy level of around 0.9438 while the performance on the test dataset was at a level of 0.9297. These results suggest that the proposed approach achieves high accuracy in predicting danger seismic events while maintaining low complexity.**

I. Introduction

ONE OF the most important subjects in coal mining is to detect specific gas emissions and seismic activity rates. The miners can suddenly find themselves in dangerous situations due to methane explosions or rockburst [1]. The most common accident cause in coal mines are cave-ins (roof, rock and coal) which account for 70.6 of all injuries [2]. Safety of miners' lives substantially depends on an early warning mechanism that can potentially be constructed using specific alert measurements for seismic activities as well as physical conditions of the mine. In order to create such an early warning mechanism, warning signals can be triggered if the measured values or energy levels, taken measurement from reference points of the mine, exceed a preset hazard threshold. However, seismic activity datasets that are observed from coal mines are very high dimensional and hard to process due to the fact that they are measured from a wide range of points and for a long duration. Since the dataset is very complex and high dimensional, expert knowledge-based systems can fail for foresight of the dangerous activities. The automation of early warning systems in coal mines has vital importance to prevent interpretation differences between mining experts and make analysis more rapid.

In the literature, there are several automated methods that have been proposed to recognize hazardous seismic activity patterns. Neural networks are the most popular method for prediction of seismic events in coal mines [3]. Identification of neural network parameters and layer numbers, however, is complicated, and entails substantial cost because of its "black-box" structure [4]. As a simpler and practical alternative, we propose a hazardous seismic ebent activity prediction method based on Fisher′s Linear Discriminant Analysis [5] that operates on an encoding of transient seismic activity are on 24 hour period along with average seismic activity parameters and conventional risk assessment methods. Performance evaluation of the method on the AAIA′16 Data Mining Challenge Dataset suggest that the approach offers accurate prediction of hazardous seismic activity around %92.97 levels.

In the next section, we provide a detailed description of the dataset and explain the proposed approach. In the third section, we present performance evaluation results of our method on both initial training dataset as well as the additional training datasets. At the conclusion section, we summarize our algorithm and discuss the results.

II. Material and Methods

The dataset used in this study was provided by Research and Development Centre EMAG for AAIA′16 Data Mining Challenge: Predicting Dangerous Seismic Events in Coal Mines. The dataset consists of total energy measurements for 24 hour period from different sensors and the counts for seismic bumps perceived at longwalls. In addition, the dataset contains hourly readings for 24 consecutive hours that are related with the most recent assessments of the conditions determined by mining experts. In the dataset each sample has one ID of the main working site where the measurements were taken and 540 features which contains 12 average risk parameters and 528 risk assessments measures. Finally, the respective labels ("normal" or "warning") are provided for each individual sample to assist on the training.

We propose a method that evaluates the average risk parameters along with the risk assessment measures separately from the hourly measurements of the provided parameters over a 24-hour period for the prediction task at hand. To this end, we extracted the hourly measurements of the 22 different parameters provided in the training dataset

978-83-60810-90-3/$25.00

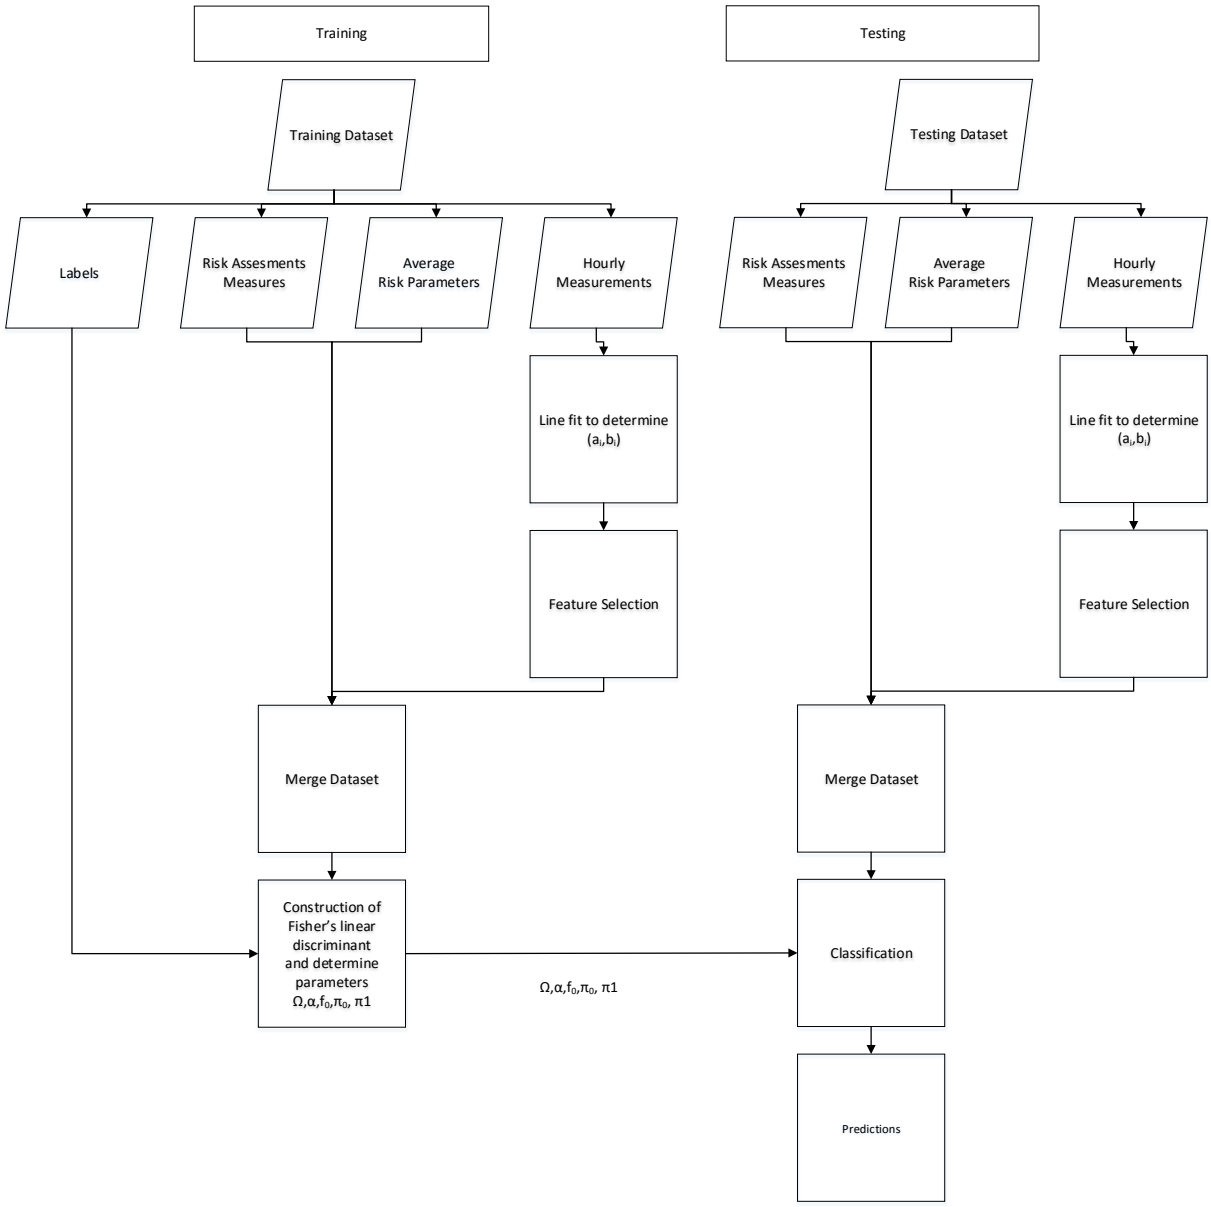

Fig. 1. Block Diagram of the Proposed Method

in indices from 14 through 541 and performed a line fit to determine the parameters (a_i, b_i) such that the fit error

$$\frac{1}{2}\sum_{h=1}^{24}(p_{i,h}-(a_i h+b_i))^2 \tag{1}$$

is minimal for each parameter p_i with hourly measurements $p_{i,h}$, for $i = 1,2,\ldots,22$. This resulted in a time evolution dataset with 44 features. To further refine this dataset, we have calculated the Kolmogorov-Smirnov statistic [6] between the empirical cumulative probability distributions of the two groups over each of the 44 time evolution parameters (a_i, b_i) for $i = 1,2,\ldots,22$, and ranked the parameters in the order of decreasing statistic value, with the understanding that the larger values of the statistic indicate more pronounced separation between the groups. Next, we have carried out Fisher′s linear discriminant analysis [7] on the top ranked $1,2,\ldots,44$ time evolution parameters, and calculated the area under the resulting receiver operating characteristics curve obtained on the original training dataset and the associated labels. This analysis identified 39 time evolution parameters with the greatest Kolmogorov-Smirnov statistic providing the highest area under the curve on the original training dataset, that were then collected to form the

calculated time evolution dataset containing the transient features.

The final prediction was obtained by merging the average risk parameters and the risk assessment measures provided in indices 2 through 13 in the training dataset with the calculated time evolution dataset, and constructing a Fisher's linear discriminant over the merged dataset. This entailed calculating the average vectors and covariance matrices

$$\mu_0 = \frac{1}{\ell_0} \sum_{j \in J_0} x_j \tag{2}$$

$$\mu_1 = \frac{1}{\ell_1} \sum_{j \in J_1} x_j \tag{3}$$

$$\Sigma_0 = \frac{1}{\ell_0 - 1} \sum_{j \in J_0} (x_j - \mu_0)(x_j - \mu_0)^T \tag{4}$$

$$\Sigma_1 = \frac{1}{\ell_1 - 1} \sum_{j \in J_1} (x_j - \mu_1)(x_j - \mu_1)^T \tag{5}$$

over the parameter vectors of the merged dataset $\{x_j\}$ with respect to the index sets J_0 and J_1 defined by

$$J_0 = \{j | y_j = 0\} \tag{6}$$

and

$$J_1 = \{j | y_j = 1\} \tag{7}$$

in terms of the training labels $\{y_j\}$ with $\ell_0 = |J_0|$ and $\ell_1 = |J_1|$. This allowed expressing the discriminant function $f(x)$ for a new parameter vector x through

$$f(x) = w^T x \tag{8}$$

with

$$w = (\Sigma_0 + \Sigma_1)^{-1}(\mu_1 - \mu_0). \tag{9}$$

As the final step of the analysis, we have identified the parameters α and f_0 to convert the values of the discriminant function into an empirical log-likelihood ratio for the two groups via the expression

$$L(x) = \alpha(f(x) - f_0) \tag{10}$$

so that the collection of values $\{L(x_j)\}$ over the merged training dataset $\{x_j, y_j\}$ achieved the smallest average training errors on the two groups with respect to a threshold of 0, or the average of the Type I and Type II training error rates, and the corresponding empirical posterior probabilities given by

$$P_1(x_j) = \frac{\pi_1}{\pi_0 e^{-L(x_j)} + \pi_1} \tag{11}$$

satisfied

$$\frac{1}{\ell_0 + \ell_1} \sum_{j=1}^{\ell_0 + \ell_1} P_1(x_j) = \pi_1 \tag{12}$$

with π_0 and π_1 denoting the prior probabilities of the respective groups in the training dataset. This was carried out by finding the f_0 value that achieved the equality above for a specific value of α for $\alpha = 2^{-5}, 2^{-4.5}, 2^{-4}, \ldots, 2^5$. Calculating the errors over the resulting (α, f_0) pairs identified the best values for α and f_0 for the smallest training error while maintaining the required prior probabilities.

In the next section, we present the results that we have obtained on different training and test dataset combinations.

III. Results

We have been tested our proposed method using the five different dataset and respective warning level labels that were provided by AAIA′16 Challenge committee. These datasets were named as: `training dataset`, `additional training dataset 1`,`additional training dataset 2`, `additional training dataset 3` and `additional training dataset 4`. Different combinations of these datasets were used to train the algorithm and the others were used for testing its performance.

Firstly, we used the original training dataset and we estimated the posterior probabilities for both additional training datasets as well as the original training dataset. The receiver operating characteristic (ROC) curves for this trial is shown in Figure 2.

The greatest AUC was obtained on the additional train dataset 1 at 0.9619 followed by at 0.9422 and at 0.9345 and at 0.9088 and at 8943. Next, we merged each additional

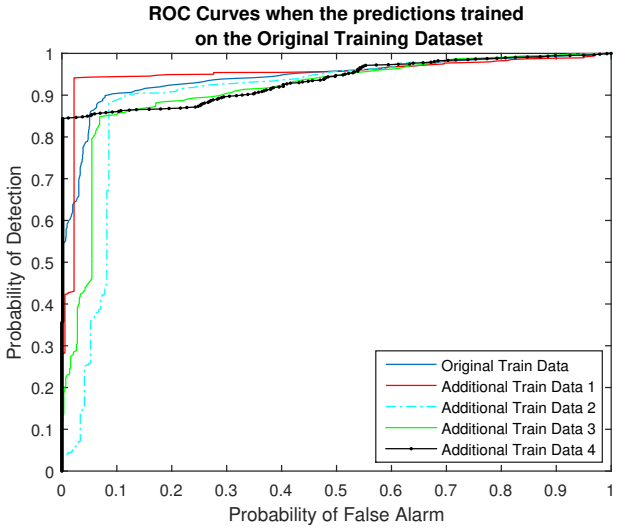

Fig. 2. The ROC curves when the algorithm trained by original training dataset. Best prediction is performed on additional training dataset 1

training dataset with the original training dataset and used the combined data to train the algorithm, and tested the resulting prediction on all datasets. The average area under curve (AUC) values are shown in Table I.

The area under the receiver operating characteristics curve obtained on the test dataset was 0.9297 as reported by the evaluation committee of the AAIA'16 Challenge when the training data was combination of the original training data and additional training data 1. The ROC curves are shown in Figure 3 for each dataset.

IV. CONCLUSION

In this paper, we have proposed a prediction algorithm for dangerous seismic events in coal mines using a combination of existing risk assessment parameters, average seismic energy measurements as well as hourly seismic activity measurements and Fisher's linear discriminant analysis. The method fits a line to capture the seismic activity information provided by hourly measurements and uses the two line-fit parameters as features for the ensuing prediction subjected to feature selection using Kolmogorov-Smirnov statistics and area under the curve measures on the training data. In order to produce the final predictions, we have applied a mathematical conversion on the outputs of the discriminant function to produce empirical posterior probabilities that ranged between 0 and 1, indicating the likelihood of a future seismic event. At an additional level of complexity, we have also evaluated the performance of the predictions subject to different training datasets, as training datasets themselves vary in the level at which they represent the actual prediction problem. In the performance comparison tests over the training data, we observed varying accuracy levels for the different training datasets used, and submitted the best performing configuration to the AAIA'16 challenge, that achieved an area under the curve level of 0.9297 on the test data that was withheld from the challenge participants. The strengths of our proposed method lie first in the manner with which the hourly seismic activity measurements are evaluated and merged with the average measurements as well as existing risk assessment parameters. In addition, the simplicity of the Fisher's linear discriminant function offers a greater potential for generalizability of the demonstrated high performance to other seismic activity prediction cases as it minimizes the risk for overtraining. Finally, the conversion of the prediction results into posterior probabilities allows processing the results in conjunction with other probabilistic insights that one may have on the prediction problem at hand such as site-specific conditions and associated risks no reflected in the measurements. This also reflect the weakness of the method proposed here as it does no take into account any site-specific information, though this can be remedied in future applications.

***Abstract*—This paper presents an application of a Gaussian Mixture Model-based voting mechanism for an ensemble of Support Vector Machines (SVMs) to the problem of predicting dangerous seismic events in active coal mines. The author proposes a method of preparing an ensemble of SVMs with different parameters and using the "wisdom of the crowd" for a classification problem. Experiments performed during the research showed an improvement in the quality of the classification after the mixture of Gaussian distributions was applied as votes distribution. The author also proposes a method of data selection for long sequences of measurement arranged chronologically with highly unbalanced occurrence of the positive class in the two-class classification problem. Finally, using the proposed model to solve the problem defined by the organizers of AAIA'16 DM showed an increase in the stability of the ensemble classifier and an improvement in the quality of the classification problem solution.**

I. Introduction

THE AIM of this paper is to present a solution to the problem introduced in AAIA'16 Data Mining Challenge: Predicting Dangerous Seismic Events in Active Coal Mines [1]. The task was related to the issue of predicting periods of increased seismic activity that may cause life-threatening accidents in underground coal mines. The task was divided into a classification problem of risk states with low hazard called "normal" and the state with high hazard called "warning". Application of hybrid methods of machine learning for a similar problem was presented in [2], but instead of a two-class problem, the authors of the experiments proposed a tripartite division: "normal", "warning" and "hazard", and focused on the medium-term (several minutes) forecasting of the maximum methane concentration at the wall end area. They also pointed out that "mathematical models correlating methane emission with methane content of a seam, ventilation method and geological features of mine workings facilitate overall prediction of average methane concentrations during exploitation of a working, nevertheless they cannot be applied for a direct short- or medium-term prediction of methane concentration" [2]. The problem discussed at AAIA'16 Data Mining Challenge focused on a different scope of time. Granulation of data is adjusted to one-hour windows. During this time, various kinds of information are accumulated, i.e. the number of registered seismic bumps of a specific energy level, or the average activity of the most active geophone. This problem does not allow to use information on the dynamics of changes within the hour during which signals were collected, and forces the participants of the challenge to process coarse-grained information about general characteristics of the signals.

Another solution for a similar problem with regression rule learning was described in [3]. The main objective of research presented in [4] was to reduce the number of forecasting errors during monitoring natural hazards and machinery in coal mines, achieved by the application of the regression rule induction, the k-nearest neighbors method, and the time series ARIMA forecasting.

A. Proposed solution

I propose a solution based on an ensemble of Support Vector Machines (SVM) of the kind described in [5][6], and on a voting mechanism based on the Gaussian Mixture Model described in [7]. Common approach based on ensemble of classifiers like boosting and bagging focus on preparing different training data set for each member of ensemble [8][9]. Instead of that my solution focus on receiving different information by changing parameters of SVMs in ensemble. Each SVM was trained on the same data. The GMM voting-based mechanism allows to extract correlation between SVMs outputs and evaluate likelihood of class occurrence. Process of preparing solution is illustrated in Fig. 1

The solution ranked 4th in AAIA'16 Data Minning Challenge with a final result 0.934. The final results were evaluated in accordance with Area under Curve values on a specially curated testing set. Finding parameters of model was mostly leaded by data driven strategy. Preparing solution focused on achieving balance between quality of solution scored by AUC value evaluated in cross-validation procedure and computation complexity.

II. Preparing data

The data set included 133 151 records, each corresponding to a 24-hour measurement. Vectors had 541 columns. Values stored in a single record can be divided into two separate parts. The first part consists of an identifier of the main working site and 12 other characteristics related to the whole period of 24 hours described by the record. The second part is composed of

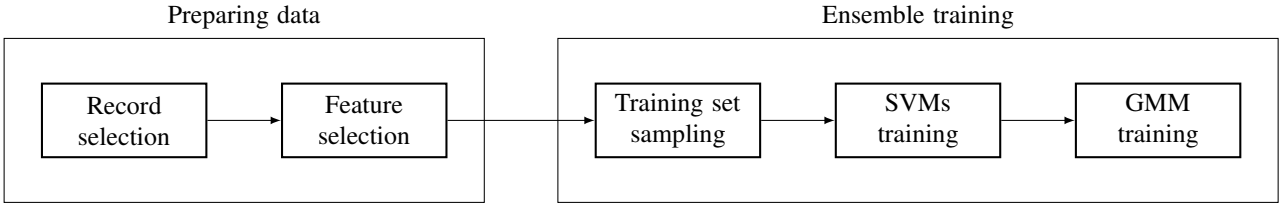

Fig. 1. Procedure of preparing data and training GMM-SVM classifier. Ensemble training was repeated 300 times and the best classifier was chosen based on cross-validation results.

hourly aggregated measurements, thus for each characteristic it includes 24 consecutive values associated with readings of geophones [1].

Measurement was labelled as "normal" or "warning" which indicate whether a total seismic energy perceived with 8 hours after the period covered by a data record exceeds the warning threshold, in correspondence with the classes prepared for solving the classification task. The distribution of classes was highly unbalanced. The "normal" class covered 130 187 of all records, while the "warning" class only corresponded to 2 962 "warning" measurements. Records were sorted chronologically, which highlighted the tendency of "warning" states to occur in short sequences. The testing set provided by AAIA'16 Data Mining Challenge consisted of 3 860 records.

A. Record selection

Before any operations on the data, the set vectors were linearly normalized to $[-1; 1]$. The first step towards the proposed solution was to choose the data vectors that would provide the most discriminative information. I assumed that this information was kept in boundary periods of an occurrence of "warning" measurement. Because of that, "normal" records were limited to the period corresponding to six hours before and to six hours after the "warning" sequence occurred. This approach permits focusing on the most important records and to solving the problem of highly unbalanced classes occurrence in the training set. In the next part of this paper all references to the training set are corresponding to the set prepared in this way.

B. Preparing base model

The next step was to prepare a base classification model which allows future data analysis. Since the problem is a high-dimensional one, it required a model with high resistance to high dimensionality of data. Another criterion of choosing the model was the fact that almost all attributes in a vector was represented by floating or integers values and represented measurements of signal sensors which suggested that data could be naturally represented in a Hilbert space. The chosen model was SVM. The procedure of adjusting parameters of hyperplane splitting space into areas corresponding to two classes is not highly sensitive to high dimensionality of space. Moreover, expanding dimensionality of space with a constant number of data records could enable the SVM to simplify finding optimal hyperplane splitting space into two subspaces problem [8]. The SVM was also designed to solve the problem of classification of two classes. Finally, proven high effectiveness of SVM for a classification problem [10] [11] made it a natural candidate to being the base classification model for this problem. Radial Basis Function (RBF) was chosen as kernel function, for it allows SVM to map a non-linear relationship between attributes and outputs. This ability is not approachable for the linear kernel. In [12], it has been shown that the linear kernel is a special case of the RBF kernel.

Before proceeding further, the SVM was trained on a set with all attributes. Parameters of the SVM were adjusted based on the grid search procedure. In the end, the base SVM took parameters $\gamma = 0.015625$ and $C = 2$.

C. Feature selection

Firstly, record attribute corresponding to the record ID was excluded from the training set. 529 attributes of training set records was grouped in a sequence of 24 elements corresponding to values in 24-hour period of measurement. A backward elimination was performed to drop out some of these sequences. The evaluation was based on 2-fold cross-validation method. The influence of removing the whole 24-hours sequence was investigated on each step. The procedure showed that removing 12 sequences significantly increased the accuracy of the base classificator and limited vector to 252 attributes. Four attributes corresponding to the latest available hazard assessment prepared by experts took on ordinal values, which represented the level of hazard were transformed to choose only from two values "no hazard" or "hazard".

III. Classification model

After preparing the data, a classifier based on the generated ensemble of SVMs classifier was proposed. Creation of this ensemble could be divided into two steps: choosing appropriate SVMs classifiers and preparing the voting mechanism.

A. Choosing SVMs

At this step, a grid search was performed and the best result it yielded was collected. I decided to use the base SVM described in the previous section of this paper and two additional SVM classifiers.

Since the high value of C allows the SVM to select more vectors as support vectors, the method could overfit. Thus, I took the first additional SVM $\gamma = 0.015625$ and $C = 1$. A second additional SVM was selected by getting a smaller value of γ, because a high value γ parameter could prevent the

SVM from finding the boundaries which allow to generalize the "shape" of the area covered by class. Based on the cross-validation results, I have chosen the SVM with parameters $\gamma = 1.22 \times 10^{(-4)}$ and $C = 1024$. Because procedure of training ensemble was repeated 300 times to avoid underfitting problem number of additionally SVMs was limited for computation time reduction.

Choosing base SVM and two additional SVMs for ensemble allow to achieve balance between computation complexity and quality of classification.

B. Voting mechanism

Instead of a simple voting mechanism, the GMM was used to represent a distribution of voting for each class. Since the testing set contains only 3 860 records, it was extremely probable that the sample would not have the same a priori distribution as the training set. It limits the possibility of a correct application of Bayes theorem in the classification model based on the estimated priori distribution. The priori likelihood of occurrence for all classes was assumed as equal in the testing data. In order to make the data represent the priori, I have limited the training set of the "normal" class for GMM to four hours before and four hours after the "warning" sequence occurs. The experiments showed that the results of the model has improved, since the data information about working wall, where measurement had been collected, was added to the vector. The working walls could be correctly identified by their IDs, but IDs do not fit well into the normal distribution âĂ¿ the base of the GMM. Hence, the ID was replaced with the height of a working wall.

The m parameter, representing the number of Gaussian components in the GMM for each class, was estimated on the basis of choosing the best results of the cross-validation procedure. If we describe parameters of a distribution as θ, a density function of the mixture distribution of features is described by:

$$f(x) = \sum_{i=1}^{m} w_i p(x \mid \theta), \tag{1}$$

where $p(x \mid \theta) = \mathcal{N}(x \mid \mu_i, \Sigma_i)$ corresponds to normal distribution that:

$$p(x \mid \theta) = \frac{1}{2\pi^{\frac{d}{2}}\sqrt{|\Sigma_i|}} \exp\left(-\frac{1}{2}(x-\mu_i)^T \Sigma_i^{-1}(x-\mu_i)\right). \tag{2}$$

Σ_i, μ_i and w_i are covariance matrix, mean vector and w_i represent the weight of the ith component in the mixture and d is a number of dimension in the modeled space. Parameters were estimated in EM procedure [13]. If y is assumed to be an unobserved data, then EM method takes the form of:

E-step: calculate the expectation of the unobserved data $E_{f(y|x,\theta^{(t)})}\left[\log f(x, y \mid \theta^{(t)})\right]$

M-step: find $\theta^{(t+1)}$ such that:
$\theta^{(t+1)} = \underset{\theta}{\operatorname{argmax}} E_{f(y|x,\theta^{(t)})}\left[\log f(x, y \mid \theta)\right]$

For n elements in the training set and an unobserved variable y_i^j takes:

$$y_i^j = \begin{cases} 1, & \text{if } i\text{th element was generated by } j\text{th component,} \\ 0, & \text{otherwise.} \end{cases} \tag{3}$$

To estimate parameters of the jth Gaussian component estimators take the form of:

$$w_j^{(t+1)} = \frac{1}{n}\sum_{i=1}^{n} E(y_i^j \mid x_i, \theta^{(t)});$$

$$\mu_j^{(t+1)} = \frac{\sum_{i=1}^{n}\left(E(y_i^j \mid x_i, \theta^{(t)}) x_i\right)}{\sum_{i=1}^{n} E(y_i^j \mid x_i, \theta^{(t)})}; \tag{4}$$

$$\Sigma_j^{(t+1)} = \frac{\sum_{i=1}^{n}\left(E(y_i^j \mid x_i, \theta^{(t)})(x_i - \mu_j^{(t+1)})(x_i - \mu_j^{(t+1)})^T\right)}{\sum_{i=1}^{n} E(y_i^j \mid x_i, \theta^{(t)})}.$$

The mixture of Gaussian components was prepared as a distribution of feature occurrences under the condition of class occurrence. Finally, the likelihood of the "warning" class was predicted on the basis of a posterior likelihood, which was evaluated basing on the Bayes theorem [14].

As Table I shows, the GMM with only one Gaussian component obtained the best results. It suggests that the SVMs' results tend to evaluate likelihood unanimously, which reduced the GMM-based voting mechanism to a single Gaussian component discriminant analysis.

C. Learning classifier

The training set for the ensemble of SVMs was different than for the GMM. Ensemble of SVMs was trained on a random sample of 30 percent of the training data. The objective of this mechanism was to avoid the overfitting problem.

Since the ensemble of SVMs was trained only on 30 percent of the training data, the risk of underfitting increased considerably. In order to solve this problem, the procedure of learning classifier GMM-SVMs was repeated. The model was learnt 300 times and the best train set for SVMs was chosen basing on the cross-validation results.

IV. Experimental results

Application of the SVM to the proposed solution was based on a LIBSVM implementation [15]. The organizers of AAIA Data Mining Challenge provided the training set in two steps. Initially, only half of the training data was available for participants. The rest of the training data was divided into four parts and supplied after some conditions, associated with the number of submissions, were met. My experiments focused on the quality of the classification performed by different approaches and the variance of results of SVM ensembles. For research variance of different strategy of voting I had collected results of an average voting, which corresponds to the voting based on simple mean of generated outputs of each SVM in

the ensemble and a GMM-based voting mechanism times 50 and then estimated the mean and standard deviation of the results.

The experiments concerned with data preparation were performed on the training set provided in the first stage. The quality of solution was described by AUC and evaluated in cross-validation procedure. Other experiments, concerning the classifier quality, covered the whole training data. All cross-validation procedures were performed with fold = 2. As shown in the Table I, GMM-SVM provided the best results. I compared the average voting strategy with the GMM voting mechanism. SVM ensemble based on a simple average voting achieved worse results, but still better than a single SVM classifier.

As shown in Table II, the results of an average voting are not stable. One reason may be that all SVMs lacked the ability to cope with underfitting, which resulted in higher standard deviation of the AUC results. Since the GMM learning method calculates parameters to fit the best maximum likelihood of the prediction based on the training set, it has the ability to obtain information on the errors of each SVM and the correlation between their outputs. This allows for the use of information about the areas in space that were problematic for some of the ensemble classifiers.

TABLE I
EXPERIMENTAL RESULTS - CLASSIFICATION QUALITY

Data set	Experiment	AUC %
First part of training data	Raw data	69.098
	After backward elimination	71.923
Whole training data	SVM	71.346

GMM-SVM m = 2	72.963	0.831

V. SUMMARY

This paper presents an application of the GMM-based voting mechanism for an ensemble of SVMs for the problem of predicting dangerous seismic events in active coal mines. The problem defined by the organizers of AAIA Data Mining Challenge allows for the successful use of GMM-SVM model of classification. My experiments showed that using the GMM voting instead of the average of outputs allows to decrease model variance. The GMM also makes obtaining information about classifier errors in the ensemble possible.

***Abstract*—In this paper we present a solution to the AAIA'16 Data Mining Challenge. The goal of the challenge was to predict, from multivariate time series data, periods of increased seismic activity which may cause life-threatening accidents in underground coal mines. Our solution is based on Recurrent Neural Network with Long Short-Term Memory cells. It requires almost no feature engineering, which makes it easily applicable to other domains with multivariate time series data. The method achieved the 5th place in the AAIA'16 competition, out of 203 teams.**

I. Introduction

UNDERGROUND coal mine workers are exposed to a life-threatening danger in a form of seismic events. To improve workers' safety, it is crucial to predict those phenomena in advance. However, knowledge-based safety monitoring systems that are currently deployed in coal mines sometimes fail to forecast such occurrences early enough. The goal of the AAIA'16 Data Mining Challenge: Predicting Dangerous Seismic Events in Active Coal Mines competition [12] was to design methods that could improve reliability of seismic activity prediction.

The task is an instance of a classification problem with unbalanced data provided in a form of multivariate, non-stationary time series. We present a solution based on Recurrent Neural Network with Long Short-Term Memory cells. The proposed model is generic and does not rely on the domain knowledge. It requires only minimal feature preprocessing and no feature engineering or feature selection steps. The solution achieved a competitive 5th place in the AAIA'16 competition.

The rest of the paper is organized as follows. In Section II we give an overview of the related work. The details of the AAIA'16 challenge are described in Section III. Section IV gives a brief introduction to Recurrent Neural Networks and Long Short-Term Memory cells. In Section V we describe the details of our architecture, training and model selection. Finally, Section VI summarizes the paper.

II. Related Work

Seismic hazard and rock bursts pose a threat to miners' lives and overall safety of the coal mining operation. One of the techniques for addressing this problem is to monitor the sensor readings' with automated algorithms. Originally, natural earthquake seismology approaches have been used to deal with the problem [3]. Mine-induced seismicity can be assessed using mechanisms of mine tremors, such as magnitude, moment, stress drop and seismic efficiency [16] or using seismic tomography [10]. More recently, typical machine learning approaches have been used – such as Random Forests [4] and other nonlinear methods [5], including Support Vector Machines or Naive Bayes Classifier.

The recent IJCRS 2015 Data Challenge competition [13] provided an opportunity to compare different approaches on the data set coming from coal mining. Although the goal was a bit different (to predict dangerous levels of methane concentration), the data shared similar characteristics – being an example of a time series, multivariate prediction problem with concept drift. Most of the top solutions relied heavily on feature engineering, either manual or automatic, such as: automatic variable construction [1], window-based feature engineering [8], hand-crafted features [15] or thousands of automatically generated features [21][22].

III. Challenge description

A. Data

The aim of the AAIA'16 competition was to predict relative likelihood of seismic events in coal mines based on the recorded measurements. It is an instance of supervised learning classification task, with most of the data given in a form of non-stationary multivariate time series. The data is split into 5 training sets and a single test set. All the training sets together contain $133,151$ records, while the test set contains $3,860$ records. Each record describes a period of 24 hours and consists of:

- an identifier of the main working site and 12 characteristics related to the whole period of 24 hours, such as total energy of seismic bumps registered in the last 24 hours,
- 22 times series with 24 numeric per-hour aggregated measurements, such as energy of the strongest seismic bump within a given hour.

Thus, in total each record contains 541 values. As mentioned previously, the records are grouped into 5 training sets and a single test set. The subsequent training sets correspond to later periods, adjacent records in them overlap by 1 hour and are given in a chronological order. The test set contains records that come from period later than the last training set, its records are non-overlapping and given in random order.

A label is given for each record in the training set while for the test set such label is missing – it is the goal of the

978-83-60810-90-3/$25.00

competition to forecast those values. The label is a categorical variable that can be either *normal* or *warning*. Value *warning* indicates that a total seismic energy measured within 8-hour period after the time covered by the record exceeded the warning threshold of $50,000$ Joules. For each record in the test set, the numeric predictions are to be made about those (hidden) values.

Additionally, there is an extra „meta-data" set that describes main working sites included in the training and test sets. It contains information such as the height of the main working site or the latest geological assessment. We note that the training and test sets are highly unbalanced, with respect to both the *main working site* attribute (Figure 1) and the labels (Table I).

B. Evaluation

The competition score is defined as an *area under the ROC curve*. It is calculated based on predictions of label values, made for all $3,860$ test set records. Each prediction is a number, where a higher value denotes that the true label value is more likely to be *warning*.

The contestants submit their predictions during the competition. However, before the competition is concluded, the contestants know only the score computed over *preliminary test set* – a part of the whole test set that contains approximately 25% of the data. This subset is chosen randomly by the organizers and is the same for all the contestants. It is not revealed to the participants which of the test records belong to it. The contestants can select a single final solution, possibly guided by the scores obtained on the preliminary test set. The final score, however, is computed over the *final test set*, which consists of the remaining approximately 75% of the test data. This score is shown only after the end of the contest and is used to compute the final standings – the highest-scoring team is declared the winner.

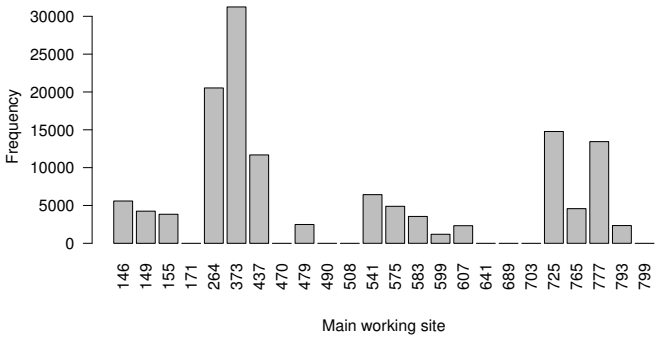

Fig. 1. The frequencies of different main working sites in the training sets. Some sites appear only in the test set.

TABLE I
DISTRIBUTION OF LABELS ACROSS THE TRAINING SETS

	tr. set 1	tr. set 2	tr. set 3	tr. set 4	tr. set 5
normal	78722	13137	13047	12744	12538
warning	1171	181	269	568	774

IV. Deep Recurrent Neural Network

A. Recurrent Neural Networks

Recurrent Neural Network (RNN) is a type of artificial neural network in which dependencies between nodes form a directed cycle. This allows the network to preserve a state between subsequent time steps. We focus on a simple RNN with a single, self-connected hidden layer.

RNNs process all elements from a sequence one-by-one, and the output at every time step depends on all previous inputs. This is a fundamental difference from feedforward networks, where the network's output depend only on the current element. It has an important theoretical implication: RNNs are capable of approximating arbitrary well any measurable sequence-to-sequence mapping [9].

Since RNNs contain loops, the standard backpropagation algorithm does not work. Instead, a *backpropagation through time* algorithm is used [20]. The idea behind this method is to unroll the network over N time steps, and copy the parameters N times. The RNN parameters are shared across all time steps, which makes them trainable and allows generalization.

Since the number of unrolled steps can be arbitrary, RNNs are particularly suited for modeling sequential data, where the length of the input is not fixed or can be very long. Recurrent nets have shown impressive results in many NLP tasks. One particularly successful variant of RNN is a recurrent network with LSTM cells, which we describe below.

B. Long Short-Term Memory

One important problem with training RNNs is the *vanishing gradient*, which can occur when values smaller than 1.0 are multiplied at each time step during the backpropagation through time. For some activation functions, the maximal value of the derivative is small. For example, the derivative of commonly used sigmoid function is never bigger than 0.25. As a result, after N time steps the gradient is multiplied by a value less than or equal to 0.25^N, which quickly becomes very small as N increases. While using some activation functions (eg. ReLU [17]) can reduce the likelihood of vanishing gradients, there is a special architecture designed to address this problem: Long Short-Term Memory (LSTM).

The LSTM is better at storing and accessing information than standard RNN [11]. The LSTM block consists of a self-connected memory cell and 3 gates named: input, output and forget. The gates control the access to the cell and can be interpreted as "read", "write" and "reset" operations in the standard computer's memory. The network learns to control the gates and decides to update and/or use the value at any given time step. Since all the components are built from

differentiable functions, the gradients can be computed for the whole system and it is possible to train it end-to-end using backpropagation. There are several variants of LSTM that slightly differ in connectivity structure and activation functions. Below we describe the definitions of the input, output and forget gates that we used.

Let $h_t \in \mathbb{R}^n$ be a hidden state, $c_t \in \mathbb{R}^n$ be a vector of memory cells of the network and let x_t be the input at the time step t. Let W_i, W_f, W_u, W_o be matrices and b_i, b_f, b_u, b_o the respective bias terms. We define LSTM as a transformation that takes 3 inputs $(h_{t-1},\ c_{t-1}, x_t)$ and produces 2 outputs (h_t and c_t). In all equations below $\odot$ is element-wise multiplication. We assume also that $\oplus$ is an operation that aggregates h_{t-1} and x_t. We used plain sum, but concatenation of vectors is also commonly used.

The *forget gate* which decides how much of the information should be removed from the cell is defined as:

$$f_t = \text{sigm}(W_f * [h_{t-1} \oplus x_t] + b_f) \tag{1}$$

The *input modulation* gate value i_t and the cell update u_t are defined as:

$$\begin{aligned} i_t &= \text{sigm}(W_i * [h_{t-1} \oplus x_t] + b_i) \\ u_t &= \tanh(W_u * [h_{t-1} \oplus x_t] + b_u) \end{aligned} \tag{2}$$

Intuitively, input modulation decides how much of the u_t should be added to the memory at step t. For example, if x_t can be ignored, i_t will be close to 0. Knowing the values above, the new cell value c_t is computed as:

$$c_t = f_t \odot c_{t-1} + i_t \odot g_t \tag{3}$$

The last step is to compute h_t, the output passed to the next LSTM's time step. It is controlled by the *output gate* o_t:

$$\begin{aligned} o_t &= \text{sigm}(W_o * [h_{t-1} \oplus x_t] + b_o) \\ h_t &= o_t \odot \tanh(c_t) \end{aligned} \tag{4}$$

The LSTM networks have been successfully applied to real-world problems, including language modeling [18], handwriting [7] or speech [6] recognition, and machine translation [19].

V. Model

A. Preprocessing

Recall from Section II that most of the solutions to the previous challenge depend heavily on feature engineering. Such approach, while effective in practice, makes the model less generalizable as the feature engineering steps depend on the problem at hand. Our goal was to create a model that learns everything from the raw data and does not rely on the domain knowledge. To this end, we limit our preprocessing only to the following two operations:

- **Data normalization**, in regards to *mean* and *standard deviation*. This is a standard Machine Learning procedure, and as such it should be applicable to almost any problem. The normalization makes easier both optimization of the loss function and the regularization, because all feature values are at the same scale.
- **Upsampling positive examples**. As presented in Table I, the ratio of positive to negative examples is highly skewed. To make it more balanced, we sample with repetition from the set of positive examples and add them to the training set. We experimented with different upsampling ratios and achieved best results for increasing the number of positives by $10 - 20$ times.

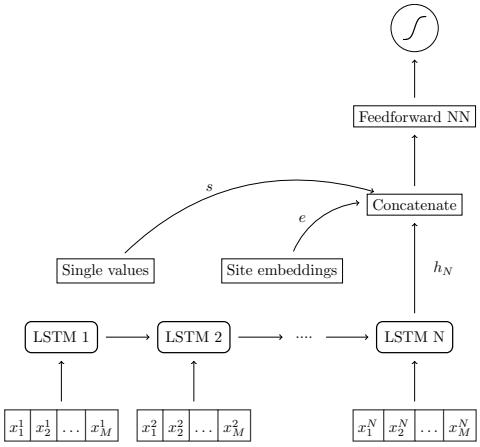

Fig. 2. Overview of the architecture. A core component is a single-layer LSTM unrolled for $N = 24$ time steps that processes $M = 22$ per-hour measurements. The ith per-hour measurement is marked as x^i. After processing N time steps, the last hidden state $h_N \in \mathbb{R}^{50}$ of the LSTM encodes information about all per-hour measurements. Then, h_N is concatenated with vector $s \in \mathbb{R}^{12}$ of per-record characteristics and the vector $e \in \mathbb{R}^{10}$ representing the working site id embedding.

B. Architecture

The overview of the architecture is presented in Fig. 2. We use a single-layer LSTM model that is processing 24 hourly aggregated measurements. At every time step, the hidden state of the LSTM ($h_i \in \mathbb{R}^{50}$) is connected to the previous state h_{i-1} and the normalized measurement values from the ith hour (x^i in the picture). After processing the whole sequence, the network's final hidden state h_N encodes all measurements in the order in which they appeared.

The vector h_N is concatenated with 2 other vectors: s and e. The vector s contains 12 per-record characteristics described in Section III-A. The vector e is an 10-dimensional embedding of the working site id. The values of the embedding vectors are initialized randomly and learned from the training data.

On top of the concatenation layer we build a standard supervised classifier (2-layer feedforward network in this case). We apply sigmoid on the network's output to ensure the predicted value is in the range $[0, 1]$ and can be interpreted as the probability of the *warning* label. The Binary Cross Entropy loss is used as the cost function.

TABLE II
WORKING SITES CHARACTERISTICS

site id	region name	bed name	assessment	mapped to
146	Partia F	416	a	N/A
149	Partia F	418	b	N/A
155	Partia H	502	b	N/A

470	Z	405/2	c	264
..	.....	....	.....	....
777	9	504	b	N/A
793	0	405	b	N/A
799	9	504	a	777

C. Training

We initialize all model's parameters by sampling uniformly from $[-0.1, 0.1]$. The optimization of the loss function is done using Adam algorithm [14] with a learning rate of 0.0005 and ε parameter equal to 10^{-10}. The training is run for 5 full passes (epochs) over the training data. After each epoch, the learning rate is multiplied by 0.63 and the training set is randomly shuffled.

We apply standard l_2 regularization of the weights with $\lambda = 0.01$. To avoid *exploding gradient* problem, the gradients are clipped globally to the value of 1. The model was implemented in Torch [2] and trained using a single GPU.

D. Model selection

Model selection was a significant challenge in the AAIA'16 competition. Recall from Section III-A that the time periods in the training data are overlapping. As a result, the standard cross-validation on a random split of the data tends to be over-optimistic. Also, there is a significant concept drift between the 5 provided training sets. The k-th training set was collected in a time period right after the set $(k-1)$th. We also know that the last training set was collected before the test set.

To address the problem of overlapping periods and to make the local evaluation as close to the final one as we can, we decided to use 5-fold cross-validation, with one training file being one fold. The average of the AUC scores was the final score we assigned to the model. We completely ignored the leaderboard score, as it proved to be very misleading in the past for this type of data [13].

E. Dealing with unknown sites

As described in Section V-B, our architecture computes embedding vectors for every working site id. However, recall from Fig. 1 that some of those identifiers exist only in the test data and not in the training data. We used the following method to fix this problem: we looked at the working site metadata and manually mapped 8 missing ids to existing ids that share similar characteristics. An example is presented in Table II which contains a subset of the metadata file. The id 171 is mapped to 146 because the region name and geological assessment is the same for those two sites. Similarly, id 799 is mapped to 777 because of the same region and bed names.

The above approach can be automated by joining (in SQL sense) the training data with the metadata on working site id attribute and then embedding different categorical variables (region/bed name, etc). This would remove the need of manual mapping of the missing ids and potentially improve the quality as well. However, we did not manage to try this approach during the competition.

F. Ensembling

From the begin of the competition, our main design decision was to create a competitive solution that consist of only one model trained from the raw data. However, the practice of machine learning competitions shows that ensembling of many different models is an easy way of improving the final score. We decided to do a simple rank average ensembling with a logistic regression model. More precisely, we use two models: RNN (described in section V) and LR (logistic regression) to evaluate records from the test set in the following way.

Let $\mathrm{rank}_X(\mathrm{record})$ denote the rank of the prediction given to the record by model X, among all predictions by model X on the test set. Then, the final prediction is computed as follows:

$$pred(record) = \frac{rank_{RNN}(record) + rank_{LR}(record)}{2}$$

By employing this technique we moved our solution one place up on the leaderboard.

VI. CONCLUSION

In this paper we presented a solution to AAIA'16 data mining challenge based on a Recurrent Neural Network with LSTM cells. It achieved a competitive score of 0.934 and the 5th place in the competition.

Compared to other methods (see Section II), our solution does not rely heavily on many hand-crafted features. Instead, it learns feature representation from the raw sensor data with a minimal feature engineering. It is a similar method to the one that we used in the previous IJCRS'15 competition, where our model achieved the 6th place. Top performance in both competitions suggests that our approach is versatile and can be successfully applied to different multivariate time series problems.

***Abstract*—In this paper we present our submission to the AAIA'16 Data Mining Challenge, where the objective was to predict dangerous seismic events based on hourly aggregated readings from different sensor and recent mining expert assessment of the conditions in the mine. During the course of the competition we have exploited a framework for automatic feature extraction from time series data that did not require any manual tuning. Furthermore, we have analyzed the impact of overlapping of input data on model robustness. We argue that training an ensemble of classifiers with distinct (i.e. non-overlapping) chronological data rather than one classifier with all available data can produce more reliable and robust prediction models. By doing that, we were able to avoid overfitting and obtain the same score performance on the evaluation and test datasets, despite the significant data drift in the datasets.**

I. Introduction

The task in the AAIA'16 Data Mining Competition [1] is to devise a reliable prediction model for detecting periods of increased seismic activity that endangers miners working underground in coal mines. The data set consists of hourly aggregated readings from seismic sensors that count the number of seismic bumps perceived at longwalls and measure their total energy. Data records are composed of 24 consecutive hours of such readings coupled with the most recent assessments of the conditions at the longwalls made by mining experts. The target attribute in the data corresponds to information whether in a following period of 8 hours the total energy of seismic bumps exceeds a warning level. The full training dataset contains 133151 records with 541 columns, each corresponding to 24 hours of measurements. The evaluation metric of the competition was Area Under the ROC Curve (AUC).

The challenges of the competition were versatile: quite different distribution of working sites in the training and tests dataset that indicated of potential distribution drift in the data; the training class distribution was imbalanced; the final training set was 40 times larger than the test set; and the class distribution in the test set was unknown. After the competition ended it was disclosed that 2% of the records in the training and 5% in the test set were warnings. These challenges required very robust features and prediction models that would prevent over-fitting to the training set. In this paper we describe how our submission to the challenge addressed these challenges.

II. Cross-validation for model selection

In order to evaluate the models and feature sets locally, a way that will take into consideration the distribution of working sites, classes and train/test dataset size is required. To address this challenge, we developed a strategy that splits the training set keeping in mind the following parameters: general class distribution in the training set; class distribution per working site in the training set; and ratio of unknown versus known working sites in the test set.

Using these parameters, we tried to replicate a split of the train set into two sets, one for training and one for local testing, that would resemble the relation between the real training and test sets. When splitting the training set, we iteratively choose whether to add the working site to the train or test split based on its working class distribution, the current and desired class distribution in the splits, and the known vs unknown ratio in the test split. Using this approach, we were able to get a more realistic estimate of the feature set performance than the cross-validation schemes. We considered cross-validation scores to be more realistic if they resembled the leaderboard score, and thus were lower than the ones obtained with regular cross-validation. However, even with different feature subsets it was always 6% greater than the leaderboard score (always over 0.98).

Even though it was promising approach, we did not have time to develop a stratified or leave-one-subject-out cross-validation strategy based on it, so we have eventually abandoned it and relied for performance estimation based on the leaderboard score. In addition, this strategy based on the assumption that the training and test sets have similar class distribution, which was not specified in the task description. After the competition ended and the test labels were disclosed, it turned out that this assumption did not hold indeed.

III. Feature Engineering Framework

This competition coincided with our work on a framework for automated feature extraction from time series data. Therefore, it presented a good opportunity to test an early prototype of the framework on this dataset.

A. Feature generators

Using a systematic approach, the system is able to generate a variety of features that can robustly describe the dataset. A recent data mining competition for posture recognition of firefighters [2] inspired different feature engineering approaches

that are very effective [3, 4, 5]. Using the proposed approaches there, from each series of readings the system generates the following types of features: basic statistics (minimum, maximum, range, arithmetic mean, harmonic mean, geometric mean, median, mode, standard deviation, variance, skewness, kurtosis, signal-to-noise ratio, energy, etc.); curve fitting parameters [4]; equal-width histogram features [5]; percentile based features (first quartile, median, third quartile, inter-quartile range, amplitude, etc.) [3]; auto-correlation of the signal with several types of correlations (signal processing auto-correlation and Pearson, Spearman and Kendall correlation) [4]; and inter-correlations between each pair of raw time series values using the aforementioned types of correlation coefficients.

B. Time series generators

The feature extraction framework is able to generate new time series and then based on them to extract new sets of features, just like from an original time series. Authors of [3, 4, 5] demonstrated that this approach can further enhance the predictive performance of the system. Therefore, the framework uses the following time series generators (TSG): first derivatives of the original series [5]; amplitudes, frequencies and magnitudes obtained with fast Fourier transformation [3]; delta series (the deviations of the original values from the mean of the particular block of the time series), which can remove the seasonality in the data; sliding window time series [6]; and combining two time series by multiplying, subtracting or dividing their values [4].

C. Learning algorithms

For estimating the informativeness of individual features and the predictiveness of the whole problem the framework uses Random Forest (RF) [7] and Extremely Randomized Trees (ERT) [8] with high number of trees. They are used with the default parameters, as we have noticed that tuning them does not improve the performance dramatically (unlike with SVMs, for example). ERT models are very similar to RF in terms of predictive performance, but quite faster. We have noticed that when using the same number of trees ERT is significantly faster (over 50%) than RF, especially when the number of features is large (over 500).

D. Feature extraction and selection heuristics

Applying all possible feature transformations would generate very large number of features and would make learning based on them practically impossible. To mitigate this, the feature engineering and selection processes are interleaved, so generation of new time series and features is heuristically guided.

The algorithm for feature extraction and selection is shown in Figure 1. After the initialization and configuration of which features should be computed, the processing starts, one dataset instance (record) at a time. When the features are extracted from the whole dataset, it estimates the predictive performance and calculates feature importances in order to prepare a baseline for the feature selection loop that follows.

To improve the performance of the model under data drift, the framework performs greedy wrapper feature selection, inspired by the idea proposed in [9]. First it merges the training and validation or test dataset and generates an artificial "drift" class, denoting whether the instance is from the training or the test dataset. Then it estimates the importance of each feature when predicting the regular class (normal/warning) and the drift class (train/test). Afterwards, it calculates a set of feature importance thresholds for the regular class and the drift class. Next, in a loop it evaluates the performance different sets of features based on whether they fall within these importance thresholds.

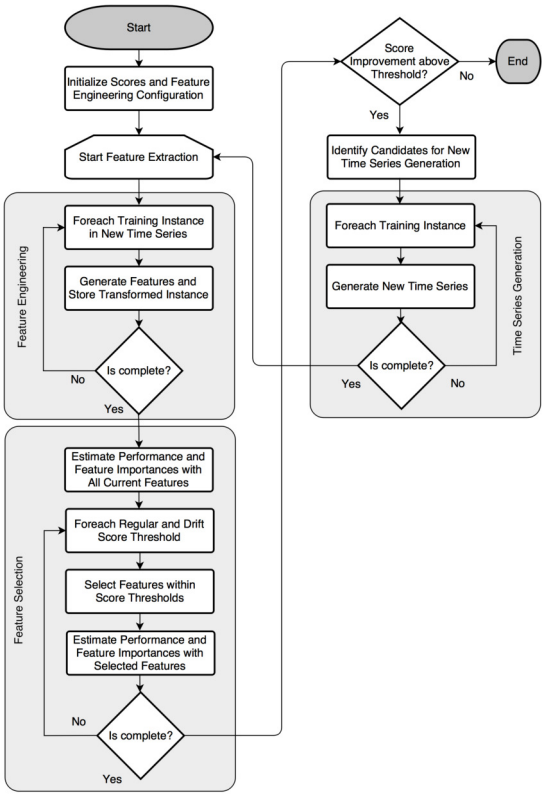

Fig. 1. Algorithm for feature extraction and selection

Next, by averaging the regular informativeness of the retained features for a particular time series the framework estimates which time series are informative for prediction of the target class. Additionally, it calculates correlations between different time series. Based on these heuristics, it identifies candidates for new which new series should be generated. After the new series are generated, the algorithm returns to the feature engineering phase. The second time it only generates features with only those transformations that resulted in retained features in the initial run. Afterwards, it merges the new feature set with the selected features in the previous iteration. The feature engineering and selection loop ends when generating new features does not improve the best performance by a considerable margin. For this competition, the we have only used the initial and one additional loop of generation of features.

Given that we were not able to replicate the training/test split for performing local evaluations, we decided to use the leaderboard scores for selecting the feature importance thresholds. By default, the framework uses cross-validation.

IV. The Feature Engineering Framework in Practice

The framework implementation it is still not publicly available. It has been implemented in Python on top of the scikit-learn Library [10]. In order to use the framework, we only need to specify the data set information: number and indexes of nominal features and numeric features, the number of time series and samples per series, the CSV files containing the description of columns and series. Then the framework takes over. It starts by calculating the basic statistics, inter-correlations, autocorrelations, histograms and quantiles. Based on them it evaluates which time series are informative. In this case, it discovered that the time series can be ranked as shown in Table I (columns IRI and IR - initial relative importance and initial rank, respectively).

This drift detection mechanism turned out to be very helpful for feature reduction. Namely, depending on the particular feature set size, removing the features that are good drift predictors improved our leaderboard score by 1-3 %. In our final solution the threshold 30 for both scores turned out to give good results thus removing almost 60% of the generated features. After their removal, the relative importance of different time series changed dramatically compared to the initial ranking, as can seen in Table I (columns IR and FR - initial and final rank, respectively).

A. Importance of time series

Some of the time series were significantly less informative than others, so they were discarded, keeping only the top 16 series. When evaluating the performance locally without the leaderboard, the system was able very quickly to find a feature set with AUC ROC score over 0.99 with stratified and regular cross-validation. When submitting those predictions to the public leaderboard we were able to get to a score of about 0.91. This dramatic drop of performance was a clear evidence of drift in the training and test datasets, which was somewhat expected due to the different mining sites.

TABLE I. Time series importance before and after importance evaluations. IRI=Initial Relative Importance, IR=Initial Rank, FRI=Final Relative Importance, FR=Final Rank

Time Series Name	IRI	IR	FRI	FR
max_gactivity	1.000	1	1.000	1
avg_difference_in_gactivity	0.998	2	0.788	9
max_difference_in_gactivity	0.962	3	0.786	10
avg_difference_in_genergy	0.954	4	0.771	11
max_difference_in_genergy	0.938	5	0.766	12
avg_genergy	0.916	6	0.886	4
max_genergy	0.889	7	0.902	3
avg_gactivity	0.885	8	0.909	2
highest_bump_energy	0.663	9	0.861	6
sum_e2	0.410	10	0.742	15
sum_e3	0.345	11	0.874	5
total_number_of_bumps	0.310	12	0.793	8
sum_e4	0.192	13	0.766	13
count_e2	0.175	14	0.646	16
count_e3	0.140	15	0.744	14
count_e4	0.116	16	0.811	7
sum_e5	0.040	17		
count_e5	0.022	18		
sum_e6plus	0.017	19		
count_e6plus	0.013	20		
number_of_distressing_blasts	0.004	21		
number_of_rock_bursts	0.000	22		

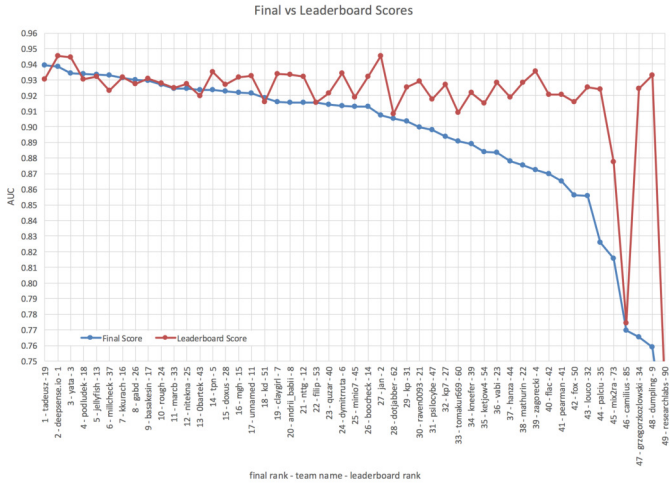

Fig. 2. Final vs. Leaderboard scores of the competitors.

As described earlier, the cross-validation scores were significantly different the leaderboard scores. On the other hand, different feature subsets performed similarly to each other with cross-validation and on the leaderboard. Because of those two reasons and the limited time we had for spending on this competition we decided to use only the features of the original time series and disable generation of new time series.

B. Oversampling in datasets

The fact that the size of the training set was significantly larger than the test set, pointed out that there must be some over-sampling in the training instances. To investigate this, we have analyzed the training dataset comparing consecutive rows that are for the same working site. We have discovered that in most cases the consecutive rows are shifted by 1 hour, thus overlapping for 23 hours. However, the test instances do not have any overlapping (or at least it can not be discovered). This mean that the training and test dataset are not identically and independently distributed. That combined with the over-sampling posed significant risk of over-fitting. In order to alleviate that, we have split the training set into 24 folds of instances that do not overlap. In particular, if we have consecutive overlapping instances (1 shift, 23 hours overlap) numbered with $1..n$ from the same working site, in the i-th fold the following instances would be assigned: $i, i+s, i+2\times s, ...$, where $s = 24$ is the number of folds. Likewise, we have tested with 12, 8, 6, 4 and 2 folds. Then, having s folds we train a separate classifier on each fold and then average the predictions of all s classifiers. Regardless of the feature subset and used classifier, when using 24 folds gave best results, about 1-3% more than training one classifier on the complete training set (i.e. only one fold). This was very peculiar discovery that should be considered when creating batches from continuous streams of data. A similar effect of over-sampling in datasets was discovered and explained in [11].

C. Final submission

The predictions based on different feature subsets and different training data subsets scored similarly on the public leaderboard. In order to diversify the predictions and aiming

to achieve more robust prediction models, we aggregated the results from 5 different predictions: 4 ERT models trained with various feature subsets that had 200-900 features (various basic statistics, histograms, percentiles, linear and quadratic fit coefficients, correlations, etc. obtained from the 16 retained time series listed in Table I) and 1 logistic regression model trained with only 21 features (reduced from the larger feature set with Correlation-based Feature Selection). This improved our leaderboard score to 0.9276, about 1.5% better than any the individual classifiers that were used in the ensemble. Some classifiers (e.g. logistic regression) made predictions close to 0 while all others were predicting exactly 0 (the probability of warning). To leverage these properties, we decided to determine whether the prediction is 0 or not with simple majority vote. If not then the individual predictions are averaged. Instead of averaging the predictions in such cases, predicting 0 improved the leaderboard score by 0.5%.

As it can be seen from Figure 2, many of the teams had dramatically over-fitted their models to the training and leaderboard datasets, thus their performance of the final dataset dramatically dropped. Only few teams were able to produce the same or better score on the final dataset as on the leaderboard.

V. Conclusion

This competition provided an interesting and interactive opportunity to tackle various challenges encountered in real-world data analysis. Our initial goal was to test if automatic feature extraction and selection from time series data would be feasible for such problem. We were able to discover and understand interesting patterns in the data, such as the ranking of importance of time series or other important features like expert seismic assessments. Additionally, we discovered the importance of overlapping in the training dataset in relation to over-fitting. Another interesting realization was that even simple classifiers like logistic regression with very simple features can give leaderboard score of about 0.92. Our best leaderboard score was average of predictions of several different classifiers and/or different feature sets and it was about 0.928.

It is important to point out that the process of automatically generating features did not require manual tuning. Furthermore, the framework was able to generate and recognize informative features and time series, as well as to retain only features that are robust to drift in the data. The only manual work that we performed was related to the cross-validation experiments and for submitting solutions to the competition system. We consider that the obtained performance is significant due to the automatically generated features. We acknowledge that the framework still requires work to be done in relation to more efficient searching of redundant features and more optimal iterative generation of new features. Our experiments with other datasets confirms that it is able to match the best published performance, or in some cases to even improve them.

***Abstract*—Underground coal mining is a branch of an industry which safety of operation is very dependent on the natural hazards. A proper seismic event prediction is a significant aspect of building classification models from the real data, which can affect the coal mining safety increase. In this paper four models, built in a well known data mining environments, are presented. The obtained models, depending on a given implementation of popular methods, occurred comparable to the best results from the competition.**

I. Introduction

THOUGH the production of energy from renewable resources has been increasing recently, the mining is still an important part of the industry. There are many countries — even in Europe — which produce most (e.g., 83% in 2012, Poland) or almost half (e.g., 45% in 2012, Germany) of its energy from coal. This means that problems of coal mining — especially the underground coal mining — still have a global meaning.

One of the aspects of safe and efficient coal mining is prediction of seismic hazards. Safety refers to saving workers from the accidents and injuries while efficiency refers to unplanned stops of longwall systems. Analysis and proper prognosis of potentially dangerous methane concentration [1, 2, 3] and seismic events [4, 5, 6] should improve the safety and reduce the costs of underground coal mining.

This paper presents several solutions of a problem of predicting dangerous seismic events in hard coal mines. This classification problem was a goal of a AAIA'16 competition for data scientists. The paper is organized as follows: it starts from a short description of a competition, data provided to the competitors and the evaluation method that was applied to submitted models. Then, the four models and the way of their development are described. The paper ends with a comparison of the result quality delivered by both the presented approaches and the contest winner followed by a final conclusions.

This work was partially supported by Polish National Centre for Research and Development (NCBiR) grant PBS2/B9/20/2013 within Applied Research Programmes. The infrastructure was supported by "PL-LAB2020" project, contract POIG.02.03.01-00-104/13-00.

II. Competition Task

This paper describes solutions submitted to the AAIA'16 data mining competition which summary is presented in [7]. Data for this edition of the competition came from the hard coal mining industry and was provided by Research and Development Centre EMAG. The main goal of the analysis was a prediction of dangerous seismic events in coal mines. The following part of the paper presents more detailed description of the data provided for the contest and a method of model evaluation. More detailed information about the competition can be found in [8].

The objective of each competitor was to devise a reliable prediction model able to detect periods of increased seismic activity that endangers miners working underground in coal mines.

A. Data

The competition training file contained 79,893 records, each corresponding to 24 hours of measurements. Values stored in a single record could be divided into two parts. The first one consisted of an identifier of the main working site and 12 other characteristics related to the whole period of 24 hours described by the record. The second part consisted of hourly aggregated measurements that count the number of seismic bumps perceived at longwalls and measure their total energy, thus, for each characteristic it included 24 consecutive values.

There was a total number of 541 columns in the data (including the main working site id). There was also available a separate file with additional information about all main working sites included in the data (in the training and test parts).

Labels in the data indicated whether a total seismic energy perceived within 8 hours after the period covered by a data record exceeded the warning threshold (i.e. $5 \cdot 10^4$ Joules). The labels of the test series were hidden from participants. It is important to note that time periods in the test data did not overlap and they were given in a random order.

An additional impediment for competitors and their models was the fact that the data was unbalanced. 78,722 records belonged to a "normal" class while the rest of them (only 1,171) was labelled as "warning".

The goal for the competition participants was to predict likelihood of the label "warning" for the records from the test set. For the consecutive objects exactly one real number corresponding to the predicted likelihood should be placed. The values did not have to be in a particular range, however, higher numerical values should indicate a higher chance of the label "warning".

B. Evaluation

The submitted solutions were evaluated on-line and the preliminary results were published on the competition leaderboard. The preliminary score was computed on a subset of the test set, fixed for all participants. It corresponded to approximately 25% of the test data. The final evaluation was done after completion of the competition using the remaining part of the test data. Those results were also published on-line. The assessment of solutions was done using the Area Under the ROC Curve (AUC) measure.

III. Overview of Solutions

The presented solutions were developed by students at the Institute of Informatics, Silesian University of Technology. Participation in the competition was an additional and optional activity for the students of the Computational Intelligence and Data Analysis course. The best achievements in the competition was promoted by the exemption from the final exam.

During the university course the students learn, among others, R [9] and RapidMiner [10] environments. Therefore, these two environments were applied by them to solve the competition task. Among the solutions presented in this paper one was developed in RapidMiner and the other three were developed in R environment. Besides, two solutions implemented the Artificial Neural Network (ANN) model and the other two implemented Boosted Trees model. The details of the data preprocessing and the model parameters are presented in the following paragraphs.

A. Solutions based on the Artificial Neural Network model

The presented solution was defined in the RapidMiner environment, where the process was based on the *Neural Net* operator. The whole process is presented in the Fig. 1. The usage of a *Nominal to Numerical* operator in the process was planned as a constant mapping of the consecutive (increasing) levels of threats a, b, c, d to the increasing integer values $1, 2, 3, 4$. In this approach the set of independent variables was reduced and therefore, the following variables were taken into consideration:

- latest_seismic_assessment,
- latest_comprehensive_assessment,
- max_gactivity.24,
- max_genergy.24,
- total_number_of_bumps.24.

These variables were determined by trial and error, starting from the attributes that are highly correlated with the predicted variable.

The final model of the network had 8 neurons in a hidden layer and the following set of initial parameters of the *Neural Net* operator was chosen:

- training cycles: 700,
- learning rate 0.05,
- momentum: 0.2,
- decay: False,
- shuffle: True,
- normalize: True,
- error epsilon: 1.0E-5,
- use local random seed: True,
- local random seed: 1337

The final prediction quality of this model — submitted by Krzysztof Kozłowski as *unnamed* to the Knowledge Pit platform — expressed by means of AUC criterion was calculated as 0.9215.

The second solution based on the ANN model was developed in R environment. The H2O platform [11] which can be used in R environment was chosen as an implementation of neural network engine. One of the reasons of this implementation selection was the fact that it is very well documented and many helpful remarks on neural network parameter tuning are available [12].

Due to the data structure where 24 hour measurements were contained in each record, it was required to aggregate information from 24 columns representing consecutive hours of a day into a single one. The other attributes were selected on the basis of their correlation. From the results of experiments it occurred that due to normalization of the data the quality of results decreased. Thus, this processing method was abandoned.

The following set of initial parameters of artificial neural network was chosen:

- neuron activation function: $\tanh$ with dropout,
- number of neurons in a hidden layer: 5,
- input neurons droput: 0.1,
- hidden neurons droput: 0.3,
- classes balancing: turned off,
- maximal number of epochs: 300,

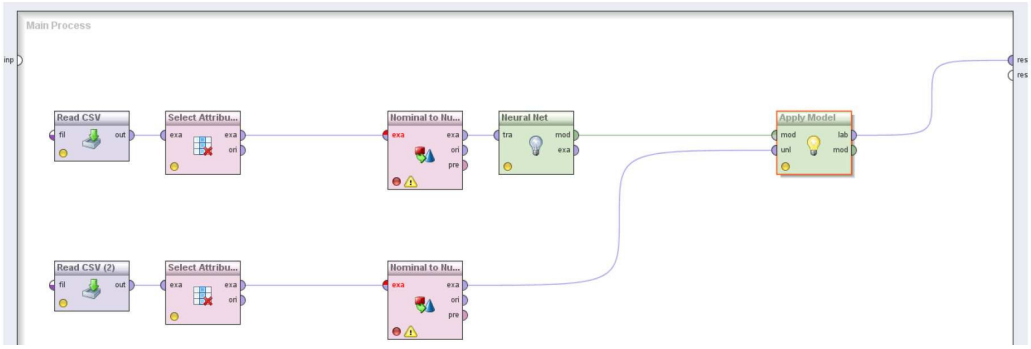

Fig. 1. Process of building the prediction model in RapidMiner.

The rest of the parameters was set to default values. The obtained neural network gave the following result expressed by means of AUC criterion: 0.9101.

Next, further tuning of parameters was performed what resulted in the following parameter values:

- neuron activation function: rectifier with dropout,
- number of neurons in a hidden layer: 4,
- input neurons droput: 0.2,
- hidden neurons droput: 0.3,
- classes balancing: turned off,
- maximal number of epochs: 250,
- $L1$ regularization: 10^{-5},
- adaptive speed of learning: turned off,
- number of training objects per iteration: 1000,
- number of testing objects: 80,
- maximum duty cycle fraction for scoring: 0.

This solution submitted by Dominik Korda and identified as *doxus* at the Knowledge Pit platform achieved the final prediction quality (AUC) value equal to 0.9225.

B. Solutions based on the Boosted Trees model

There are two approaches based on the Boosted Trees method presented in this section. Both of them were developed in R environment and both of them utilised a *caret* package [13]. The approaches differ due to the data processing stage.

Within the first approach the Kibana tool [14] was applied to visual analysis of the attributes. It enabled to notice an important association between the attribute *latest_seismic_assessment* and the decision attribute. Therefore, this attribute was included into the model in the first order.

Another important observation was connected with the *total_destressing_blasts_energy* attribute: for all objects that have a *warning* value of a decision, *total_destressing_blasts_energy* equals 0. Therefore, it was decided to introduce a new derived variable named *tdbeGTzero* (total destressing blasts energy greater than zero) defined in the following way:

$$\text{IF } total\_destressing\_blasts\_energy > 0$$

$$\text{THEN } tdbeGTzero = true$$

$$\text{ELSE } tdbeGTzero = false$$

The final set of the selected independent variables was as follows:

- sum_e3,
- sum_e4,
- sum_e5,
- sum_e6plus,
- highest_bump_energy,
- max_genergy,
- avg_genergy,
- tdbeGTzero,
- latest_seismic_assesment.

This solution, submitted by Bartłomiej Szwej and identified as *0bartek* at the competition platform, achieved the final prediction quality (AUC) value equal to 0.9238.

The set of independent attributes of the second approach was selected arbitrarily and it contained:

- latest_seismic_assessment,
- latest_seismoacoustic_assessment,
- latest_comprehensive_assessment,
- latest_hazards_assessment.

These attributes categorize the seismic activity into four levels (a, b, c, d), and a proper value is set by a domain expert working in a coal mine.

This solution, submitted by Katarzyna Dusza and identified as *kd* at the competition platform, achieved the final prediction quality (AUC) value equal to 0.9185.

IV. Results and Conclusions

Over one hundred (106) competitors accessed the challenge and 49 of them submitted their results. The quality of the top ten approaches and the solutions presented above are listed in Table I.

If we take into consideration all 49 results it can be stated that students' models placed higher than the median of all of them (25^{th} result was 0.91304342). This enables a positive assessment of these students' involvement to the contest. It is also worth to be noticed that some of them did not limit themselves only to tuning the method parameters but also tried to select and derive explainable attributes for the model.

TABLE I
SELECTED RESULTS FROM THE FINAL BOARD OF AAIA'16 DATA MINING CHALLENGE.

rank	participant	AUC
1	tadeusz	0.9393
2	deepsense.io	0.9384
3	yata	0.9342
4	podludek	0.9336
5	jellyfish	0.9336
6	millcheck	0.9329
7	kkurach	0.9312
8	gabd	0.9300
9	basakesin	0.9297
10	rough	0.9269
13	**0bartek**	0.9238
15	**doxus**	0.9225
17	**unnamed**	0.9215
18	**kd**	0.9185
49	researchlabs	0.6998

Additionally, it can be noticed that all the presented solutions were developed in a well known data mining environments. Therefore, these approaches are more general at the level of model creation, where only parameter tuning was performed. Besides, the presented solutions focused on a proper data pre-processing in order to select and derive the right independent variables.

Tuning of the parameters was performed in case of ANN-based approaches and the results presented in Tab. I show its positive impact. However, in case of the approaches based on the Boosted Trees model, where the parameters were identical and the results (see Tab. I) were significantly different, it is visible how important is the data processing phase of analysis.

Finally, from the university course leader perspective the involvement of the students into such data analysis competition is very promising. The students have the opportunity to operate on a real-life data and to compare the quality of their results with the other competitors. Therefore, it can be twofold interesting for them and hopefully it will increase their motivation to further studies.

***Abstract*—A face occlusion detection scheme which is based on both skin color ratio (SCR) and Local Binary Pattern (LBP) feature, is proposed. The proposed method mainly consists of four steps: foreground extraction, head detection, feature extraction, and occlusion detection. First, foreground is extracted by codebook background subtraction algorithm. Then, the head region is located using HOG head detector. After that, the skin-color ratio and LBP feature are extracted. Finally, SVM is trained based on LBP feature. The recognition result of SVM and the result of skin-color ratio feature are merged by weighted voting strategy, and then occluded faces are classified as three categories: concealed, partially concealed, and visible. Experimental results show that the proposed detection system can achieve desirable results in intelligent video surveillance systems.**

I. Introduction

Nowadays, intelligent video surveillance system has been a very active research field, and has many practical applications, such as face identification, behavior recognition, abnormal event detection, and so on. It greatly reduced the manual inspection and verification to improve the effectiveness. Face occlusion detection is an essential component of intelligent video surveillance system. This is necessary for the prevention of suspicious behavior in security zones, such as bank, government, and other sensitive areas. With the increasing requirements for security, face occlusion detection has become a hot research topic in pattern recognition and image processing. If the surveillance system can automatically detect a person with concealed face, it would be helpful for making more secure society. For example, the system can be widely used for automated teller machine (ATM) security.

Concealed face detection is a very challenging task in image understanding field due to the complexity of environment condition, such as low resolution, illumination changes, and object movement, etc. Under complex conditions, there is no guarantee of image quality, so face occlusion detection becomes extraordinary difficult. Furthermore, the designed system requests reduced computation and high reliability, so that it can be able to realize the real-time processing requirement. Although various methods have been proposed to detect occluded face, but most of them are for ATM, this fact leads to a problem that these methods cannot be used directly for video surveillance systems.

In order to solve the above-mentioned problems, we proposed an efficient approach that combines skin color ratio feature and texture feature for concealed face detection. The method consists of the main four steps: (1) Extraction of moving foreground by using codebook model which is a real-time segmentation algorithm, (2) Head detection based on HOG head detector, which only focus on the foreground moving region, (3) Skin color feature and LBP feature are extracted, (4) The two assessment methods are fused by weighted voting and the final recognition result is obtained.

The main contributions of this work can be stated as follows: (1) A novel framework of face occlusion detection in the application of the real-world video surveillance environment is proposed, (2) The skin color feature and texture feature with LBP operator are merged by weighted voting strategy in order to improve detection performance.

The rest of this paper is organized as follows: Section 2 introduces the related works on face occlusion detection. Section 3 describes the details of the proposed method. Section 4 presents the experimental results and analysis. Section 5 draws a conclusion with the future plan.

II. Related Works

Generally, SCR-based methods [1]–[4] adopt various skin models, extract color information, and then calculate skin ratio. Lin *et al.* proposed a method based on the combination of ellipse fitting and skin area ratio to determine whether the face is concealed or not [1]. Kim *et al.* presented a face occlusion verification method that combines a shape-based face detection and skin color [2]. Zhang *et al.* used Adaboost to combine skin color detection and face templates matching to produce the strong classifier for occlusion detection [3]. Charoenpong *et al.* proposed a face occlusion detection method from a viewpoint of face by skin color ratio of two parts of head re-

gion [4]. These methods present an effective detection system for bank ATM application. However, it can only handle the detection problem in which the target is close to the camera. Therefore, these methods cannot be directly used in intelligent video surveillance environments.

On the other hand, learning-based methods [5]–[9] require feature extraction to train the classification model, and then achieve classifying recognition. Yoon *et al.* proposed a method based on principal component analysis (PCA) and support vector machine (SVM). By applying PCA and SVM to extract the feature points and classify that the feature points are near the normal or concealed face [5]. Min *et al.* presented a novel learning based method for scarf detection. The method exploits Gabor wavelet feature and SVM classifier to distinguish the normal and scarf faces [6]. Priya *et al.* proposed a Mean Based Weight Matrix (MBWM) algorithm, which is an improved form of LBP, and the SVM classifier to detect face occlusion [7]. Bianco *et al.* designed a recognizability of concealed face system, in which Adaboost algorithm is taken to build the facial feature detectors [8]. Kim *et al.* also proposed a face occlusion detection method based on gradient map and SVM, used especially for the partially concealed face [9]. Although good results are reported in these methods, the robustness cannot be guaranteed under complex conditions. In particular, surveillance systems cannot always produce high quality images. Therefore, the proposed method should handle both high quality and low quality images to meet the result of robustness.

In addition, component-based methods [10], [11] use facial component regions to detect face occlusion. Suhr *et al.* proposed a face occlusion detection system, which combine the eye-mouth combinations and geometric constraints [10]. Eum *et al.* presented a face recognizability evaluation to use facial components and the exceptional occlusion handling (EOH) [11]. This method is insensitive to illumination condition and achieves the robustness against facial postures, but it needs a high computational cost.

Nowadays, deep learning is a hot topic in machine learning, and CNN is one of deep learning methods, which can learn hierarchical features from low-level data [12]. Xia *et al.* proposed a robust and effective facial occlusion detection method based on CNN and multi-task learning [13]. The trained CNN model is applied in extracting facial features and predicting face occlusion. However, the disadvantages are complex structure, and it requires large-scale and complete training data.

III. FACE OCCLUSION DETECTION SCHEME USING SKIN COLOR RATIO AND LOCAL BINARY PATTERN

This section mainly introduces the details of our proposed method. The processing procedure includes the following steps: foreground extraction, head detection, feature extraction, and occlusion detection. The proposed system architecture is shown in Fig. 1.

A. Foreground extraction

Extracting foreground accurately is the first step for face occlusion analysis. By foreground extraction, the moving foreground is segmented in the video sequence. There are many ways for foreground segmentation, such as Gaussian Mixture Model (GMM) and background subtraction. Compared with the above methods, the codebook model can detect foreground more accurately and efficiently, and handle scenes containing moving backgrounds or illumination variations [14]. It is a kind of adaptive background subtraction algorithm by building a codebook for each pixel. So the information of the foreground areas in current frame is obtained with codebook model. Some examples of foreground segmentation using codebook model are shown in Fig. 2.

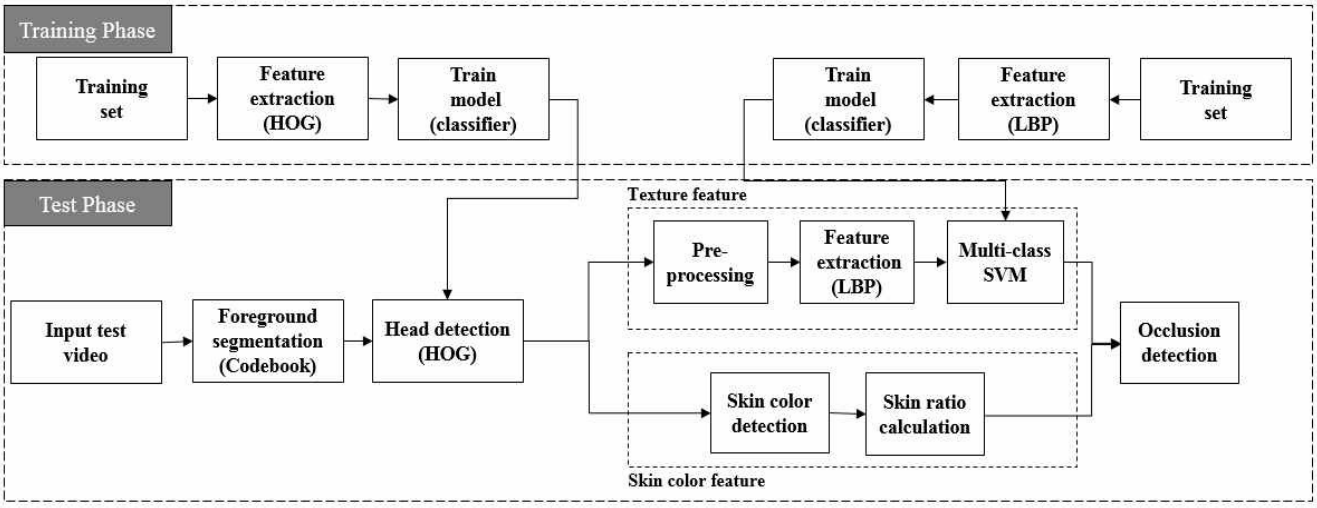

Fig 1. The framework of face occlusion detection system

(a) (b)

Fig 2. Foreground extraction results: (a) original (b) Codebook

B. Head detection

In our method, head detection is accomplished by combining HOG and SVM method proposed by Dalal and Triggs [15] and the part-based models proposed by Felzenszwalb *et al.* [16]. HOG can well describe the edge or local shape information, so it is suitable to depict characteristics of head. Meanwhile, this method is capable of handling head detection with challenging illumination conditions and low resolution.

While the HOG is one of the popular descriptors in image processing, it needs a high computational cost. To address the problem, GPU technique is used to accelerate process by using a parallel implementation of the HOG algorithm. Comparing CPU implementation, GPU based on parallel architecture has a better computational performance [17], [18]. The result of head detection demonstrates that our implementation using GPU can achieve a speedup of over 5 times, which allows for real-time detection. Moreover, the scanning area only focuses on the moving foreground region, and the probability of false and failure detections is significantly reduced. Examples of head detection are shown in Fig. 3.

Fig 3. Some results of head detection

C. Feature extraction

The analysis of skin color is adopted to discriminate skin and non-skin pixels. An unconcealed face includes a large number of skin color pixels. The whole process of skin color detection consists of two steps: color space transform and skin ratio calculation.

1) Color Space Transform: RGB is a basic color model. Because of the sensitivity to illumination variations, it is hardly separated from chrominance and luminance information [19]. Compared with RGB, YCbCr has a clear distinction between chrominance and luminance components. Thus the first step is to convert color space from RGB to YCbCr representation. Using (1), we transform RGB to YCbCr color space.

$$\begin{bmatrix} Y \\ C_b \\ C_r \end{bmatrix} = \begin{bmatrix} 65.481 & 128.533 & 24.966 \\ -37.797 & -74.203 & 112.0 \\ 112.0 & -93.786 & -18.241 \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix} + \begin{bmatrix} 16 \\ 128 \\ 128 \end{bmatrix} \quad (1)$$

2) Skin ratio calculation: In chromatic space, the skin color mainly focuses on a narrow range. Obviously, we can determine the skin pixel by judging whether the YCbCr value is in a certain range. As shown in (2), the skin ratio is defined as the skin pixels of the head region.

$$S = \frac{number\ of\ skin\ pixels}{total\ \ number\ of\ head\ region\ \ pixels} \quad (2)$$

Where, S is the skin ratio. Because it is hard to ensure the detection result with only one frame, we can utilize multiple frames to ensure high accuracy. Consequently, the calculation of the ratio comes out from the combination of multi-frames.

For the reason that the camera will be a certain distance from the people in real scenes, it makes the face appear smaller and vaguer. However, with the movement of the body, the size of head region is also varying constantly. To assess the impact, scoring method is used for the evaluation process. Large size can obtain a higher score than head image of small size, but the performance is going to reach a specific limitation [20]. Given a specific value μ, it is suitable for the width and height. Using (3), we represent the score related to the size.

$$Q = min\left\{1, \frac{width}{\mu} \times \frac{height}{\mu}\right\} \quad (3)$$

Therefore, this method, which applies the head size as criterion, is used to realize multi-frame selection. When the head size is larger than a preset threshold, these frames are selected in video sequence. Let N be the number of frames, and we obtain the final ratio to integrate the scores. It can be expressed as

$$R = \frac{\sum_{i=0}^{N} S_i Q_i}{\sum_{i=0}^{N} Q_i} \quad (4)$$

where, S_i is the skin ratio of i-th frame, and Q_i is the score of i-th frame.

Based on fusion strategy, we need to know the classification result for the detected N frames. Thus we introduce two ratio threshold parameters τ_1 and τ_2, which will be discussed in the following section. For every frame, the

occlusion result can be determined by comparison of two parameters. Let X_i be the number of detection result for each class in all frames, *i= {1,2,3}*, which denote concealed, partially concealed, and visible, respectively. Assume p_i is the likelihood for every class, it is calculated by using (5).

$$p_i = \frac{X_i}{N} \tag{5}$$

In practice, the above skin color method is sensitive to light condition. And when face covers by objects of colors similar to the skin color, its effect is not ideal. To overcome this problem, we extract texture feature with LBP operator [21]. As a popular texture descriptor, it describes well the image texture information. Therefore, we can effectively distinguish them by the texture. The operator labels the pixels of an image by thresholding the neighborhood of each pixel with the center value and forming the result of binary pattern. Then, a pattern code is computed as follow

$$LBP_{(P,R)} = \sum_{n=0}^{P-1} s(g_n - g_c)2^n \tag{6}$$

$$\mathrm{s(x)} = \begin{cases} 1, & x \geq 0 \\ 0, otherwise & \end{cases} \tag{7}$$

where, g_c corresponds to the gray level of the center pixel, g_n to the grey values of the neighbor pixels. The notation (*P*, *R*) indicates *P* sampling points on a circle of *R* radius. This paper uses the uniform LBP, and the selection of *P* and *R* will be discussed in the next section.

The feature extraction process includes the following steps. The first step is pre-procession, such as normalization and histogram equalization. Second, we divide the image into several sub-blocks, and the feature histogram is extracted from each sub-block. Then, all the local histograms are concatenated into a feature vector. The more the block number is, the higher the computational complexity is. Therefore, a suitable block number should be selected. And this issue is explored future in the next section. Fig. 4 shows the process of feature extraction.

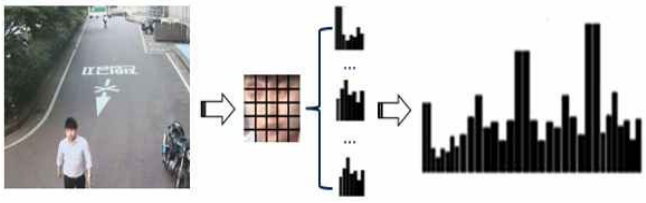

Fig 4. LBP feature extraction

In this paper, the detection of concealed faces can be considered as a multi-class problem: concealed, partially concealed, visible. Therefore, we use a multi-class SVM to fulfill the concealed face classification. Furthermore, assume X_i is the number of detection result for each class in all frames, which represent concealed, partially concealed, visible respectively, *i={1,2,3}*. Let p_i' is the likelihood for each class and it is calculated by using (8).

$$p_i' = \frac{X_i}{N} \tag{8}$$

D. Occlusion detection

The system uses the idea of decision level fusion to improve performance. On the phase of decision fusion, the weighted voting strategy is used to fuse the result for all levels to get target detection output. First, we determine whether it is the concealed face by skin color ratio in the skin color method, and whether it is the concealed face based on LBP. Then we assign different weight according to the contribution of various assessment methods. Using (9), we calculate the weighted vote result.

$$W_i = p_i w_1 + p_i' w_2 \tag{9}$$

where W_i is the weighted results, *i={1,2,3}*, W_i denote the weighted result in three classes: concealed, partially concealed, visible, respectively. p_i and p_i' can be obtained by using equation (5) and (8). w_1 and w_2 are the weights of *i*-th method, respectively, and they are measured by

$$w_x = \frac{n_x}{\sum_{x=1}^{k} n_x} \tag{10}$$

where k is the number of methods. Because the system has two methods, namely, k=2. n_x is the recognition rate based on various assessments on test video set, $x = \{1,2\}$. The idea of weight distribution comes from [22]. Eventually, the largest W_i will be chosen to determine the concealed face classification.

IV. EXPERIMENTS

To evaluate the system performance, experiment inputs are taken on a dataset with 138 video samples, which are collected from indoor or outdoor surveillance cameras. The video set includes three classes: concealed, partially concealed, visible. We chose 60 video samples as the training set, and the rest is used as test set. The video sequence has a resolution of 720×576 at 15 frames per second. The face covers by some objects such as hat, mask, sunglasses, book, etc. The sample set contains the different times of the day. The experiment is carried out with an Intel(R) Core(TM) i5-3230M CPU @2.6GHz and NVIDIA GeForce 710M. Fig. 5 illustrates some examples of face occlusion in surveillance cameras.

Fig 5. Examples from surveillance camera for the concealed face

A. Head detection

In order to evaluate the head detection accuracy and acceleration effect based on GPU implementation, experiments are taken. In experiments, head samples are collected from surveillance cameras, and then the head detector is trained on manually annotated data. The data set has approximately 5,000 head images as positives training samples and randomly chosen windows that do not contain any head area as negative training samples from surveillance videos. The size will vary depending on the distance between the people and camera, and is normalized to 64×64 pixels.

The algorithm is tested on video samples with different resolutions. Table I shows the processing time with the GPU and CPU implementations. It can be concluded that GPU implementation speeds up more than 5 times for the processing time over CPU implementation. And the GPU implementation shows more significant effect of acceleration for higher resolution image. On the other hand, to evaluate the accuracy of head detection, we carried out the experiments on several video clips. The experimental results are summarized in Table II. Hit rate can be calculated as the number of detected heads divided by total number of heads, while the false alarm rate is the number of false heads divided by total number of heads [23]. The results show that our approach has high detection rate and can reduce the false alarm rate effectively.

TABLE I.
THE COMPARISON OF PROCESSING TIMES FOR DIFFERENT RESOLUTION

Resolution	CPU Time(ms)	GPU Time(ms)	Overall Speedup
320*240	126.10	24.63	5.12
720*576	653.59	97.08	6.73
1280*1024	2083.33	299.40	6.94

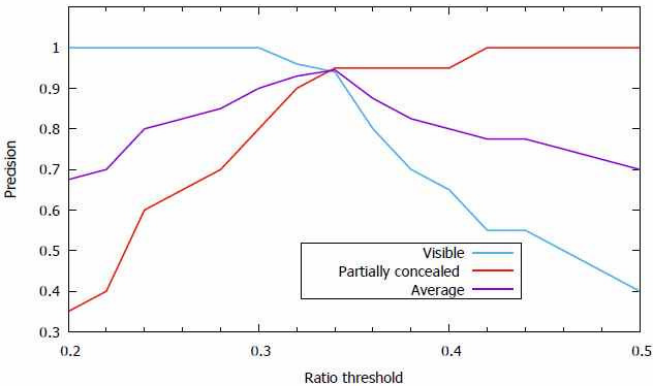
TABLE II.
ANALYSIS OF HIT RATE AND FALSE ALARM RATE

Total frames	1462
Total number of heads	1512
Number of detected heads	1373
Number of false heads	16
Hit rate(HR)	90.8%
False alarm rate(FAR)	1.0%

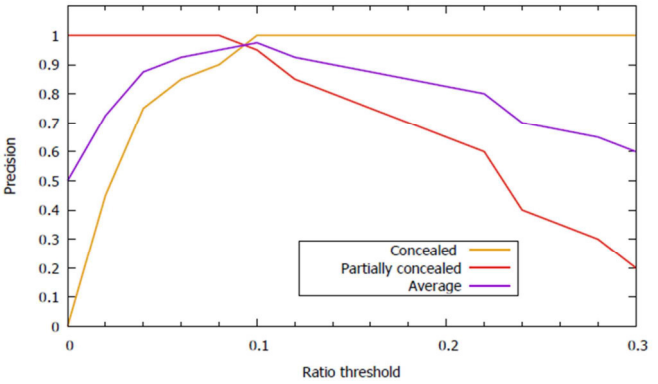
B. Threshold determination in skin color ratio

The skin ratio threshold is important factor that directly affects the accuracy of face occlusion detection. In order to achieve higher results, the optimal threshold should be determined. In our experiment, we use training video set to decide the optimal threshold. The result is illustrated in Fig 6. As seen in the Fig 6(a), it shows that along with the increasement of skin color ratio, the recognition rate of visible face is declining gradually, and partially concealed face is increasing at the same time. There is a peak value of average recognition rate at 0.34. On the other hand, a conclusion can be drawn from Fig. 6(b), which is similar to the above conclusion, and the peak point appears at 0.10. Then, let τ_1 and τ_2 denote two thresholds respectively, that is, the ratio thresholds are set to be τ_1= 0.34 and τ_2 = 0.10.

If the ratio is more than τ_1, this case is called visible. If the ratio is less than τ_2, it's called concealed. In addition to this, all other cases belong to partially concealed. Finally, we have tested its performance on the test video set. The average accuracy can reach to 87 %.



(a)



(b)

Fig 6. Precision of various ratio threshold on training video set.

C. Parameter determination for LBP

In order to analyzing the influences of some parameters, a series of experiments is carried out. In our experiment, we manually crop concealed & unconcealed face images from the training video set. All these concealed faces are normalized to 90×90 pixels. Then multi-class SVM is trained to detect the concealed face. In testing phase, we use the trained classifier to detect whether the face is concealed or not in every frame.

Taking into account the feature dimension, we choose uniform patterns of LBP operator. We adopt cross validation to determine some parameters. Let *N*N* and *R* denote the number of blocks and sample radius. In the experiment, the parameters are set to *N={1,2,3,5,6,9}*, *R={1,2}*. Fig. 7 gives the comparison with the recognition rate of different parameters. From this figure, it indicated that the recognition rate increased with the incensement of block number. But the feature dimension has doubled and redoubled when the number of blocks increased. Therefore, we select *N=5, R=1* as the best choice, which can both maintain a relatively high precision and lower dimension. The trained classifier can be used to classify the unknown face samples. Similarly, we have tested it on test video set. The average accuracy can reach to 70%.

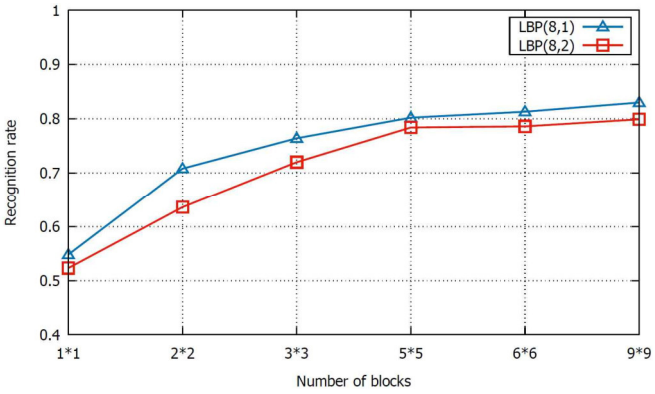


Fig 7. Comparison with the recognition rate of different parameter

D. Fusion strategy

For the purpose of comparing these two methods, the fusion experiment is carried out. In the fusion strategy, the average accuracy is above 95% by combining the above two methods in the test video set. Fig. 8 summarizes the confusion matrix. As can be seen from the chart below, our fusion strategy can improve the recognition rate obviously. In SCR approach, the concealed face was often classified as partially concealed face, primarily because of the individual difference of human beings, such as short and thin hair, which largely affects the skin color ratio. In LBP method, the partially concealed face has the poor accuracy of recognition, and this is due to the diversity of partially concealed face. Therefore, the fusion strategy verifies its effectiveness.

V. CONCLUSIONS

This paper proposed a novel scheme to detect concealed face for intelligent video surveillance systems. It combines texture feature & skin color feature to detect concealed face. To ensure the accuracy, we have studied a multi-frame detection algorithm. There are two parts in this method. First, we introduced and analyzed the codebook foreground segmentation model, and the head region is located by using HOG with GPU implementation. Then the decision fusion is used to validate concealed face by combining LBP and skin color. In the future work, we are planning to improve overall system performance through robust method for feature extraction, and solve head pose estimation problem.

***Abstract*—The paper presents a method of splitting patent drawings into subimages. For the image based patent retrieval and automatic document understanding it is required to use the individual subimages that are referenced in the text of a patent document. Our method utilizes the fact that subimages have their individual captions inscribed into the compound image. To find the approximate positions of subimages, first the specific captions are localized. Then subimages are found using the empirical rules concerning the relative positions of connected components to the subimage captions. These rules are based on the common sense observation that distances between connected components belonging to the same subimage are smaller than distances between connected components belonging to various subimages and that captions are located close to the corresponding subimages. Alternatively, the image segmentation can be defined as a specific optimization problem, that is aimed on maximizing the gaps between hypothetical subimages while preserving their relations to corresponding captions. The proposed segmentation method can be treated as the approximate solution of this problem.**

I. Introduction

BEFORE inventors prepare a patent application they should spend some hours doing a good search for patents that are related to their idea. Usually, searching for patents, they prepare phrases that in the best way describe the core concept. However, the list of results often contains hundreds or even thousands of patents depending on the popularity of the term or phrase selected. It also happens that one thing is described with different names and labels. Therefore, the results obtained are not always relevant.

Many specific tools exist that support patent databases searching ([4]), but in most cases they are mainly based on textual analysis. It is worth noticing however, that patent drawing is almost always required to illustrate the invention. Frequently, patents include numerous drawings showing a variety of views. Therefore, it seems that patent search results would be much more relevant, and it would be much easier to access the patent if a query considered illustrations included in patent documents. This observation leads the concept of content-based patent image search ([12], [13]). When applying content-based search paradigm, patent searchers are browsing thousands of patents looking only on images contained in drawings section. This task can be accelerated by using patent image search engines, which can retrieve images, based on their visual content. The importance of images in patent search can be further emphasized by the fact that images are both language independent and independent of the scientific terminology that may evolve over the years. They are also important in attempts to understand a patent.

Usually, a patent includes several figures or drawings showing how an invention looks. Drawings in patents can contain reference numerals that are used in the detailed description to identify parts of the drawings and to draw reader's attention, but they introduce difficulties in the case of image segmentation.

It happens that the invention is compound, and the patent document shows drawings of one or more parts. The drawings in patents are specific and differ much from other illustration in other types of documents.

A variety of styles can be encountered in patent images, e.g., surface shading, plots, pattern area fills, broken lines and varying line thickness. However, in most cases, patents include some views prepared as black-and-white line art. The drawings can be made using different techniques. Sometimes, CAD tools are used, but there are also numerous old patents with drawings prepared manually with ink. In many cases, component subimages are not separated by distinct wide areas of background, so naive approach based merely on the segmentation by wide background bands fails. The example of a compound patent image consisting of many subimages is presented in Fig.1.

Thus, to develop an image content based patent search engine, it is necessary to employ techniques to identify the number and the position of the figures on the page to isolate them. To this end, an efficient segmentation of the page in its figures is required. Its accuracy will determine to a large degree the performance of image patent search process. Our research is focused on drawings segmentation from patent documents.

All these mentioned above features cause that images and subimages segmentation in patents is a challenging task and methods developed in other areas, e.g. for segmentation of color or gray shade images included in journals are not appropriate in the application are being considered here.

The paper is organized as follows. Section II contains a short review of other works related to compound image segmentation into parts. In the next two sections, the segmentation

This work was supported by the statutory funds of the Department of Computational Intelligence, Faculty of Computer Science and Managament, Wroclaw University of Science and Technology and partially by EC under FP7, Coordination and Support Action, Grant Agreement Number 316097, ENGINE European Research Centre of Network Intelligence for Innovation Enhancement (http://engine.pwr.edu.pl/). All computer experiments were carried out using computer equipment sponsored by ENGINE project.

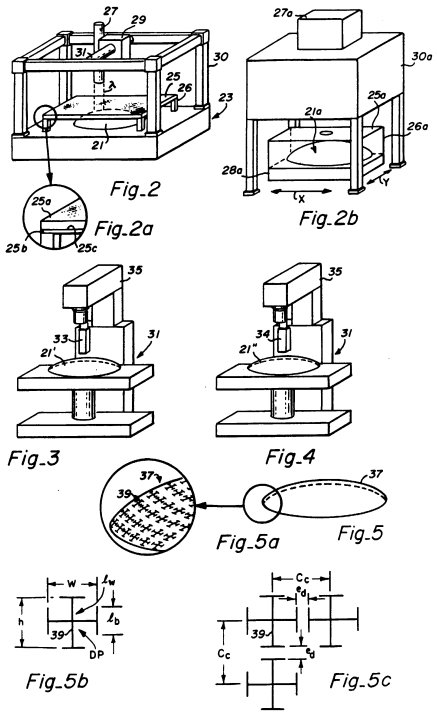

Fig. 1. Example of patent image consisting of many captioned subimages

problem is defined, first intuitively and then more formally. Sections V-A and V-B describe two possible algorithms of segmentation that we tested. In Section VI the specific method that can be applied to simple grid-layout images segmentation is presented. The method of caption detection used here, based on text extraction with OCR support is shortly described in Section VII. The method of automatic evaluation of human-defined and automatic segmentation consistency is explained in Section VIII. Experimental results obtained with proposed segmentation methods on a patent images benchmark database are presented in Section IX. Finally, some conclusions and suggestions for further works are formulated in Section X.

II. Related Work

The idea of searching documents on the basis of figures included in documents is not new. For instance, Lu et al. in [7] proposes to utilize the content of figures in searching scientific literature in digital libraries. The work described in this paper is only focused on the categorization of figures included in scientific documents. Authors developed a machine learning based method for document image categorization. A figure is categorized as a photograph or a non-photograph. A non-photograph is then further classified as plot, diagram, or another graph. The aim of a method presented in [6] is similar - image classification using machine learning methods. The authors also propose numerical data extraction from pictures.

Although the idea of figure content based document retrieval exists since many years, there are still many challenging tasks to implement. The problems attract the attention of researchers. It is important to detect figures in documents and separate them from a text. The exemplary approaches can be found in [9], [3], [1], [10]. Some of the figures are composed of subfigures. Their separation is also a challenge [2]. The next problem is a classification of figures to the defined groups. Research devoted to image content understanding is a rapidly developing area.

Considering the area of our research in this short survey, we have particularly focused on image and subimage extraction (segmentation). The paper [2] presents a technique of compound image separation. It is based on systematic detection and analysis of uniform space gaps. The method assumes the separation of subimages by thin horizontal or vertical uniform space that separate compound figures from a major part of compound figure images.

The paper [5] describes a solution to the similar problem but located in biomedical literature. Articles in this area are often composed of multiple subfigures and may illustrate diverse methodologies or results. This solution is similar to our approach in that it also is based on capture recognition. Their method first analyzes figure captions to identify the label style used to mark panels, then determines the panel layout, and finally, each figure partition into panels is performed. To identify the number of panels, authors developed three stage procedure. First, a simple lexical analysis is made to determine the potential panel labels in the captions. Then, the list of potential panel labels is analyzed in order to identify and remove false positive ones. Finally, the segmentation of captions according to the set of identified panels is carried out. In the next step, the image processing is executed. First, the optimum threshold value for segmenting the figure is computed. The text embedded in images is also detected in order to find panel labels. Next, the number of panels in the figure is determined. Then panels are partitioned it into a set of panel-subcaption pairs, on the basis of the set of subcaptions, panel labels, and connected components. To partition the figure, they first create a node for each recovered panel label and then create an edge connecting each node to its closest horizontal and vertical neighbors. It means that the method assumes the specific horizontal or vertical relative position of subimages.

Another method of figure classification and subimage extraction is that described in [14]. It also refers to the biomedical area. The method of subimage extraction retrieves subimages using reconstruction from Hough peaks.

Comparing to the presented methods, in the case of patent documents, subdrawings rarely have easy to detect vertical or horizontal separating spaces. Therefore it is a much challenging task.

III. Problem formulation

Let us consider a binary black and white image. Black pixels are assumed to represent drawn lines, captions and inscribed text (foreground), while white pixels constitute background. The image consists of subimages, where each subimage is associated with its individual text caption. We assume that

captions can be reliably detected in earlier stages of the image segmentation procedure. The applied method of caption detection is described shortly in section VII. So, at the current stage, we know the number of subimages, which is equal to the number of detected captions. If no caption is detected, then it can be assumed that the whole image constitutes the single component, unless there are sufficiently wide background areas separating clouds of foreground pixels. In the later case, one of segmentation methods based merely on separation by background (described in the previous section) can be applied. We will not deal with such cases in this paper.

We are considering here only such images where the set of detected captions is not empty. Our aim is to subdivide the set of all foreground pixels into disjoint subsets constituting subimages associated with captions in such a way, that it corresponds to the image author intent and to the intuition of a human observing and interpreting the image.

Unfortunately, in practice, there are no strict rules followed when drawing compound images, so depending on the degree of the image complexity, shape of components and the logical (semantic) relation between them, the subimages may be arranged on the image plane quite freely. For this reason, it is hardly possible to define the formal segmentation principle, so that it always corresponds to the intent of the image creator. Nevertheless, usually, some basic principles are applied when arranging the layout of the compound image. The intuitive rules typically used are as follows:

- subimages are separated by relatively wide areas of background,
- in most cases, subimages are not connected by foreground elements; if it is not the case, only few simple lines connect subimages (the example can be a single line connection between subimages captioned *"Fig.2"* and *"Fig.2a"* or *"Fig.5"* and *"Fig.5a"* in the drawing in Fig.1,
- each subimage contains at least one "dominant" element consisting of foreground pixel which size is comparable or greater than the size of the caption,
- captions are close to elements of the subimage associated with them,
- in certain cases, the subimages are regularly arranged in a grid-like manner, where subimages are clearly separated by horizontal and vertical bands of foreground pixels, which often include subimage captions (an example of such layout is presented in Fig.2.

Images complying the latter principle can be segmented very easily and also such a regular layout is easily distinguishable. The method proposed here first tries to detect whether or not the image being analyzed a case of a regular layout. Regular images are segmented with a specific (easy) method and excluded from further considerations. For other images, we apply the segmentation procedures based on remaining intuitive rules.

In the approach described in this paper, we follow these informal rules to build the clustering method, which groups foreground elements of the image into subsets associated with individual captions. The method of image segmentation

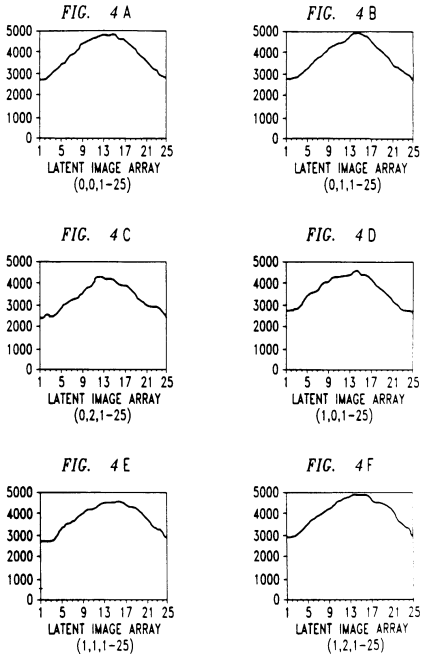

Fig. 2. Example of the regular grid-like layout of subimages

described here; clusters connected components of foreground pixels into sets representing captioned subimages. It means that, in most cases, each subimage consists of entire connected components. The only exception from this rule is where there exists a substantial evidence that some subimages share commonly connected components. In such situation, some connected components are split. We will start with defining the notion of connected components more formally, and then some proposals of connected components clustering will be described.

IV. Finding Subimages by Connected Components Clustering

Let us define the connected component (*CC*) of the image as the set of foreground pixels that are linked by other foreground pixels belonging to the same CC. A pixel p will be here represented by the pair of its coordinates:

$$p_i = (x_i, y_i), x_i \in \{0, ..., x_{res}-1\}, y_i \in \{0, ..., y_{res}-1\}, \quad (1)$$

where x_{res}, y_{res} denote the image horizontal and vertical resolution. Let $\mathcal{F}$ denotes here the set of all foreground pixels in the image being segmented. We divide the set $\mathcal{F}$ into the set of disjoint CCs:

$$C = \{c_1, ..., c_M\}, c_i \subseteq \mathcal{F}, c_i \cap c_j = \emptyset, \bigcup_{i=1}^{M} c_i = \mathcal{F}. \quad (2)$$

The connected component c is the set of pixels such that if two pixels $p_a, p_b \in c$ then there exists the sequence of pixels $(p_a = p_1, p_2, ..., p_k = p_b)$, all of them belonging to c that

for each pair of pixels $p_i, p_{i+1}, i = 1, ..., k-1$, pixels p_i and p_{i+1} are direct neighbors. We consider two pixels to be direct neighbors if they are *8-connected*, i.e. they have common edge or corner. A CC is maximal if no more foreground pixels can be attached to it. Further on, we will be considering *maximal CCs* only. We define the distance $d(c_i, c_j)$between two CCs c_i and c_j as:

$$d(c_i, c_j) = \underset{p_l \in c_i, p_k \in c_j}{min}(\quad e(p_l, p_k) \quad), \tag{3}$$

where $e(p_l, p_k)$ denotes Euclidean distance between pixels in 2D. Similarly, we can define the distance between two sets (clusters) s_i, s_j of CCs:

$$d(s_i, s_j) = \underset{c_l \in s_i, c_k \in s_j}{min}(\quad d(c_l, c_k) \quad). \tag{4}$$

Our aim is to split the whole binary image into a set of subimages S_A, where each subimage $s_i \in S_A$ is the set of CCs (we will call it *cluster*), $s_i \subseteq C$. We also assume that clusters are disjoint and they all sum up to the whole image, i.e. each foreground pixel from $\mathcal{F}$ belongs to exactly one cluster (or in other words - subimage). The partitioning of the image into clusters should be as close as possible to the intent of the image creator. Initially, we make the assumption that each CC belongs entirely to a single subimage, which may be not true in some cases (as shown in Fig.1). We will deal with such cases later and will propose a method of connected component splitting. By taking into account the set of intuitive rules given in the previous subsection we assume that: a) subimages consist of graphical elements (corresponding to CCs) that are located close each to other within the single subimage and b) disjoint subimages are separated with relatively large bands of background (white) pixels. Additionally, we assume that each subimage is associated with its individual caption. We assume that captions are reliably detected in earlier stages of the image segmentation procedure. So, at the current stage we know the number of subimages, which is equal to the number of detected captions. It seems also reasonable to make assumption, that caption areas are located close to the corresponding subimage. The problem is therefore how to split connected components set into disjoint subsets such that the obtained partitioning corresponds to subimages, as a human perceives it.

Formally, the presented intuitive assumptions correspond to finding such clustering of connected components, where the number of clusters is fixed (and is equal to the number of detected captions k) and the minimal distance between clusters of CCs is maximized. The graphical elements constituting captions (characters and their graphical elements) are being considered here as ordinary foreground image elements. We assume that each caption (as a graphical element) is entirely included in a single cluster and each cluster includes exactly one caption. The elements of a caption are being considered as a single indivisible CC (even though actually a caption consists of many "true" CCs). Let Γ denotes the set of all possible partitionings of the set C into k clusters $\{s_1, s_2, ..., s_k\}, s_i \subseteq C$, which satisfy the above restriction. By s we denote here the cluster of CCs. We need to find such "optimal" clustering $\gamma^* \in \Gamma$ that:

$$\gamma^* = \arg\max_{\gamma \in \Gamma}(\underset{s_i, s_j \in \gamma}{min} d(s_i, s_j)), \tag{5}$$

where $d(s_i, s_j)$ is the distance between clusters defined in equation 4. Because the number of possible partitioning in Γ is very big if the number of CCs is high (equal to the Stirling number of the second kind that determines the number of possible partitioning of n-element set into k nonempty subsets) the problem is computationally hard and a suboptimal solution must be applied.

A. Connected component splitting

In certain subimages, the single large CC may span many subimages as shown in Fig. 1, where subimages 2 and 2a or 5 and 5a share a common CC. Any method based on complete CCs clustering cannot retrieve the correct segmentation in cases like this. The selected CCs need to be split into smaller ones, so that the principle of composing subimages from complete CCs can be still used. The method applied there consist of: first, carying out the segmentation procedure using the original CCs set, detecting CCs that possibly need to be split, splitting them into smaller CCs and executing the clustering procedure again. In the second clustering, the new set of CCs is used, where original large ones are replaced by their parts.

1) Detection of CCs that need to be split: The CCs that are "suspect" of spanning between adjacent subimages are detected by examining the position of sufficiently large CCs, with relation to the nearest captions. The detection is performed after initial clustering with original CCs. In this way we can consider only these captions that are close enough to obtained clusters. If two captions are close to a large CC then, instead of having only one cluster containing this large CC, we should split the large CC and allocate its parts to two smaller clusters labeled by captions close to "suspect" large CC. CC splitting seems especially adequate if two candidate captions are closer to this CC than to other clusters.

Let $l(C)$ denotes the caption l assigned to the cluster C. By L_C we denote the set of captions being candidates for captions assigned to subimages obtained by possible split of the cluster C into smaller ones. The set L_C consists of: a) the caption $l(C)$ assigned to C by the primary clustering carried out using the original CCs found in the image and b) other captions, which distance to C is comparable to the distance between $C \backslash \{l(C)\}$ and $l(C)$. Only these captions are included in L_C which are not "strongly bound" to other clusters. We assume here that $l(C')$ is strongly bound to C' if its distance to C' is much lower than the distance of any other caption to C'. The threshold of distances used for classifying the caption as "strongly bound" can be determined experimentally using the set of validation images.

The captions collected in L_C are then used to detect sufficiently large CCs $c \in C$ that possibly span many actual subimages. For simplicity, let us consider the pair of captions

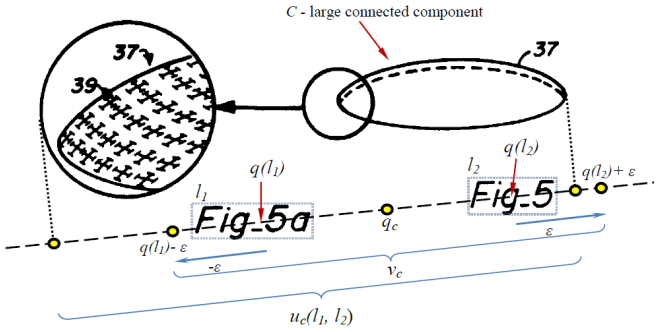

Fig. 3. Evaluation of a CC as a candidate for split with respect to two captions

$l_1, l_2 \in L(C)$. They define the line containing the centroids of captions $q(l_1), q(l_2)$ and the line segment with end points at $q(l_1)$ and $q(l_2)$. Each CC $c \in C$ can be projected onto the line $(q(l_1), q(l_2))$. Because, by definition, each CC is compact then its projection onto the line also constitutes the compact line segment $u_c(l_1, l_2)$. We consider the CC $c \in C$ to be a candidate for split if $u_c(l_1, l_2)$ covers the center of the line segment $q_c = (q(l_1), q(l_2))$ and it is sufficiently long. In our experiment we assumed the minimal length of $u_c(l_1, l_2)$ to be at least $0.75 * \|q(l_1) - q(l_2)\|$. In this way, for a pair of captions in L_C we can selected some CCs in C that are candidates for splitting. If there are more than two elements in L_C then they can be ordered into the sequence $(l_1, l_2, ..., l_m)$ so that the path $(q(l_1), q(l_2), ..., q(l_m))$ is the shortest. Hence we obtain pairs of captions that are close each to another and possibly are assigned to adjacent subimages. Then for each pair of captions $(l_i, l_{i+1}), i = 1, ..., m-1$ adjacent in the ordered sequence, the described above procedure is carried out resulting is some CCs as candidates for splitting. The idea of finding CCs for splitting in presented in Fig. 3.

2) Finding CC split point: The next element of the proposed procedure is finding the split point for a CC that has been selected as a candidate for split with respect to two captions l_1 and l_2. We want to split it into two parts which are close to captions l_1, l_2 and so that the minimal number of connections between resultant components exists. The later assumption follows from the observation that in cases where the large CC needs to be split, it consists of fragments connected by a few lines, most often - by just a single one. We applied the method where the boundary between components of a CC is the straight line which satisfies the following conditions:

- it is perpendicular to the line defined by $(q(l_1), q(l_2))$,
- it crosses the extended line segment $v_c = (q(l_1) - \epsilon, q(l_2) - \epsilon)$, where $\epsilon = (q(l_2) - q(l_1))/4$,
- it minimizes the number of split lines of the skeletonized image of the CC being considered; if there is more than one position of the split line where this minimum is reached then the position closest to the center of the line segment $(q(l_1), q(l_2))$ is selected.

If the described above CC splitting procedure creates at least one subdivided CC then clustering is being carried out again using the set of modified CCs.

V. Image Segmentation by Connected Components Clustering

We propose two methods to find suboptimal solution of the problem defined in eq. 5. The first one is based on human intuition that binds subimage elements to the close captions and initially focuses attention on big graphical elements. The second method is typical k-means algorithm application to the set of CCs. The only introduced constraint is that the components corresponding to captions cannot be assigned to the same cluster.

A. CCs clustering by human perception imitation

In this method we follow the human way of reasoning when dividing the image into subimages. Later on, we will call it *intuitive segmentation*. Although precise way of human reasoning is unknown, it seems that when splitting an image into subimages, humans proceed as follows. Initially, we seek for big graphical components that are located close to captions. They become cores of further activities. If a smaller element is completely surrounded by closed shapes of big components already associated with a caption, a human tends to assign it to the same caption. All remaining smaller elements are assigned to these already constituted subimages to which the distance is smallest. The detailed procedure that can be applied is defined as Algorithm 1.

B. CCs clustering by k-means

k-means algorithm is a widely known and successfully applied method of clustering, so we will not describe it here in details. Its primary description can be found in [8]. In order to apply it to our problem, we need to specify how the initial clustering is obtained and how centers of clusters are determined. Initial clustering is obtained creating k clusters that initially contain CCs representing captions. Remaining CCs are assigned to initial clusters so that the including cluster corresponds to the caption closest to a CC. We mean here the distance computed as in equation 3 where in place of c_j the single pixel is used that is the center of the caption bounding box. The core of k-means algorithm is the computation of cluster means and computing the distance of elements being clustered to cluster means. Here we are clustering CCs (not individual foreground pixels). Therefore two methods of cluster center positions computing can be proposed:

- a cluster center is the centroid of all equally weighted foreground pixels belonging to CCs in the cluster,
- a cluster center is the weighted mean of bounding box centers that enclose CCs belonging to the cluster, the component weights can be based either on the size (maximal length along x and y, or the bounding box area) or on the number of pixels belonging to a CC.

Both variants were evaluated experimentally and the better one is finally recommended. Details are presented in Sec.IX.

Algorithm 1 "Intuitive" CC clustering

Require: C - set of all connected components; L - set of captions; ($L \subseteq C$)

sort CCs by size in decreased order;
create the family G of initially empty sets of CCs assigned to captions;
while empty sets in G exist **and** there exist unassigned CCs **do**
  get the first biggest CC that is not assigned to any caption;
  assign it to the set in G corresponding to the closest caption;
end while
if there exist empty sets in G **then**
  for all captions with no CCs assigned **do**
    find CC c closest to unassigned caption which is not the only element of the family in G that contains it;
    remove c from the set in G that currently contains it;
    assign c to the current caption;
  end for
end if

/* Now we have big CCs assigned to captions */

make initial clusters of CCs assigned to labels so far;
while not all CCs are assigned to clusters **do**
  get the next unassigned CC;
  find the cluster closest to it;
  assign CC to the closest cluster;
end while

return (G) - the family of CC sets assigned to individual labels

Algorithm 2 "CC clustering with modified k-means"

Require: C - set of all connected components; L - set of captions; ($L \subseteq C$)

$G \leftarrow$ the family k initial clusters containing individual captions from L;
compute the centroid position for each cluster in G;
assign all CCs in $(C \setminus L)$ to clusters in G using minimal distance to the centroid as a criterion;
$G' \leftarrow G$;
repeat
  $G \leftarrow G'$;
  compute the centroid position for complete clusters in G;
  $G' \leftarrow \{g_i : i = 1, ..., k; g_i = \emptyset\}$;
  for all $c \in C \setminus L$ **do**
    $g^* \leftarrow \underset{g \in G}{argmin}(X(g), c)$;
    $I(g^*|G, G') \leftarrow I(g^*|G, G') \cup \{c\}$;
  end for

/* Now we have all non-caption components initially clustered */

sort clusters in G' in descending order of their sizes;
$L' = L$;
for all $g \in G$ in decreasing order of size **do**
  $l^* \leftarrow \underset{l \in L'}{argmin}(d(g, l))$;
  $g \leftarrow g \cup l^*$;
  $L' \leftarrow L' \setminus \{l^*\}$;
end for
until $G' \leftarrow G$ - no change in clustering
return (G') - the family of CC sets assigned to individual labels

In order to preserve the restriction that each cluster contains exactly one CC representing a caption, the typical k-means algorithm must be modified. In the initial partitioning, this restriction is obviously satisfied, provided that it is established according to the recipe described above. In the k-means algorithm phase, where cluster centroids are computed, all CCs assigned to a cluster in the previous iteration are taken into account. However, when the new clusters are being build in the next iteration only CCs not being elements of captions are a subject to be moved to the cluster with nearest centroid. In this way, new clusters are constituted, which do not contain CCs representing clusters. The caption CCs are then uniquely assigned to these clusters. The assignment is achieved by considering created clusters in decreasing order of its size (biggest first) and assigning such already unassigned cluster to the current cluster for which the distance to a cluster is minimal. Finally, centroids of new clusters that include captions are computed and the next k-means iteration starts. The modified algorithm is presented in Algorithm 2. In the algorithm the following symbols are used: $d(\alpha, \beta)$ is the distance between elements α and β, L is the set of CCs that are graphical elements constituting captions (each caption is treated as a single CC), $X(g)$ is the centroid of the cluster g. Let G and G' denote two families of CC sets, such that in both G and G, each caption $l \in L$ belongs exactly to a single set in G and G'. $I(g|G, G'), g \in G$ denotes the element from G' that contains the same caption $l \in L$ as g.

VI. Segmentation of grid-like composed images

In certain cases subimages are located in a compound image, so that they create grid-like layout as presented in Fig. 2. Correct segmentation is quite easy in such cases and it can be carried out using a simplified method. Sometimes, general methods described in preceding sections fail in grid-like layouts, so it seems reasonable to apply specific method to this class of images which very often leads to the segmentation consistent with an image creator intent.

By grid-layout of subimages we mean here such a placement of subimages where

- captions can be enclosed by narrow horizontal bands spanning from left to right edge of the image, which do not contain significant elements of subimages and all CCs located in caption strips can be separated by the path consisting only of background pixels that connects left and right edge of the image;
- the subimages are consistently located either under or above their captions - it means that there are no significant CCs either below the lowest caption band or above the highest caption band. In result, horizontal areas between caption bands can be uniquely assigned to their caption bands;
- if there are more than one captions in a caption band then all CCs in the corresponding image band can be separated into as many clusters as the number of captions in the caption band. The separation areas are vertical areas consisting only of background pixels.

The above conditions can be easily tested programmatically. The testing procedure immediately provides the segmentation of the image, which appears to be very reliable. In our approach, each image being segmented is subject to grid layout test before other segmentation methods are tried. If the test passes then final segmentation is a byproduct of the grid layout testing procedure. If the grid layout test fails then the image is passed to general segmentation procedure based on concepts presented in preceding sections.

VII. Caption localization

Text extraction methods are used in order to find subimage captions. In this work we used the method described in [11]. The procedure consists of two phases. In the first phase, some rectangular areas are detected which are likely to contain (any) text inscribed to the image. In the second phase, areas recognized as containing text are tested for occurrence of specific text patterns being the actual captions.

1) Detection of text areas in the image: The first phase consists in turn of three stages. In the first stage, the procedure finds candidate areas that possibly contain texts, by grouping small CCs into rectangular areas of shapes and sizes typical for areas including individual words of text inscribed into the image. In the next stage, candidate areas are passed through the classification procedure which classifies them as "text" or "non-text" using the set of features related to distribution of foreground pixels and line segments within the candidate area. Areas recognized as "text" are passed to OCR module running in no-dictionary mode. Finally, only such candidate areas are considered to be text areas, for which the results of OCR recognition satisfy an empirical criterion related to the ratio of untypical characters occurrence in the recognized textual string.

Initially, connected components (CCs) that possibly enclose individual characters or their sequences are found. The series of criteria were experimentally elaborated that must be satisfied in order to reject CCs that are not likely to contain text characters. All used criteria are discussed in [11]. One of the most important criteria appeared to be the ratio $f_i^{(hv)} = h_i/v_i$ of the height of the shape contained in CC h_i to the average line width v_i in the i-th CC. If the ratio value is out of the interval covering the range typical for text areas in images, the test fails and the area is not further considered as a candidate area. The acceptance interval is determined by considering text areas appearing in the validation set of patent images, for which "true" text areas were manually annotated. By analyzing the set of manually confirmed text areas in the validation set, the histogram of $f_i^{(hv)}$ has been created. As the acceptable range of $f_i^{(hv)}$ we assumed the interval covering 98% of values encountered in the validation set, leaving aside 1% of very small and 1%of very high text areas as outliers. Other parameters of criteria used in candidate text areas selection were established in the similar way.

The candidate areas that passed two first stages of text extraction are finally subject to OCR that runs in no-dictionary mode. The result of OCR recognition is first used as the data for the last stage of text area detection. It has been observed that in the case of "false" candidates that contain no text, the string created by OCR includes many punctuation characters (like . , ; : -). The final criterion of a candidate area acceptance as the text area (no necessarily the area of caption) is the ratio of punctuation characters occurrence in the whole recognized string. Details are described in [11].

2) Selection of text areas containing caption patterns: If the OCR module were absolutely accurate then caption detection would be a trivial problem. It would be possible to simply compare the OCR results to one of predefined text strings that can be a caption. However, in patent images, inscribed textual elements are hard to recognize. In most cases, the main reason is that images are hand-drawn, so is the included text. While OCR works well with machine printed text, its performance seriously deteriorates when it is presented with handwriting or hand-printed text. Therefore, it seems reasonable to consider as captions not only areas where OCR produced exact caption patterns, but also to accept such ones, where the recognized sequence is in some sense similar to one of acceptable caption patterns.

The idea of recognizing the text area as a caption is based on finding in the sequence recognized by the OCR module, the subsequence that is similar to one of *caption patterns*: "FIG" "fig" "Fig". The visual similarity of characters in the recognized subsequence to the corresponding characters in these patters is taken into account. It may happen that the recognized sequence is a correct word containing the pattern as a subsequence (e.g. "conFIGuration", "FIGhter"). In order to exclude such texts from considerations, first the result of recognition is compared with the list of correct words containing the pattern as a subsequence. Only words longer that 4 characters are used. If the length of the sequence recognized by OCR module is longer than 4 characters, then the minimal edit distance to words in the dictionary is found with Levenshtein algorithm. If the edit distance is less than one fourth of the number of characters in the closest word, then the label is rejected as rather being the part of ordinary

word appearing in the image.

If the OCR recognition result was not rejected by the dictionary test then the similarity to caption patterns is computed. The procedure finds a three-character substring in the recognized sequence that is most similar to patterns. When computing the similarity, we multiply similarity factors for the individual characters in a pattern. The similarity measures should be specific to properties of used OCR module and used fonts. The similarity factors can be computed as a relative frequency of errors consisting in replacing the actual character c_a by another erroneous character c_r: $n(c_r|c_a)/n(c_a)$. $n(c_r|c_a)$ is the count of errors consisting in replacing c_a by c_r and $n(c_a)$ is the number of c_a occurrences. In our experiments we however used similarity factors based on visual intuitive similarity of various character shapes. We assumed than nonzero similarities are given only to the following sets of characters recognized by OCR:

- for F : F E f P
- for I : I l i 1 J L T
- for G : G C 6 c
- for f : f t
- for i : i j 1 l
- for g : g 9

For remaining characters we assume that the similarity is equal 0.0.

Let us consider the character sequence $(c_1, c_2, ..., c_m)$ returned by OCR module running in no-dictionary mode. For each subsequence consisting of three consecutive characters $s^{(3)}(j) = (c_j, c_{j+1}, c_{j+2})$, the similarity to the three-characters pattern sequence f is defined as:

$$\Delta(s, f) = \prod_{i=1}^{3} \delta(s_i, f_i), \tag{6}$$

where s_i, f_i is the i-th character in the sequence, $\delta(a, b)$ is the similarity between characters a and b. Here we assume that $0.0 \leq \delta(a, b) \leq 1.0$ and $\delta(a, a) > \delta(a, b)$ for all $a, b; a \neq b$.

The final likelihood that the sequence s represents a caption is computed as:

$$Q(s) = \max_{j=1,...,m-2} \max_{f \in \Phi} \left(\Delta(s^{(3)}(j), f)\right), \tag{7}$$

where $\Phi = \{"fig", "Fig", "FIG"\}$ is the set of caption patterns. In order to make the final decision whether or not the text area passed to OCR is the caption, the computed similarity is compared to a threshold. The lower is the threshold value, the more actual captions are recognized but also the likelihood to accept "false" captions increases. On the other hand - the higher it is, the higher is the likelihood that an actual caption will be omitted. The threshold value is determined as a metaparameter. The threshold should be set depending on he losses following form two types of caption recognition errors (i.e. rejection of true caption and false acceptance of non-caption text as a caption). The threshold value was fixed using the validation set in images containing captions and non-caption texts. Details are described in Section IX.

VIII. Automatic segmentation evaluation

In order to evaluate the accuracy of the automatic segmentation, the results obtained automatically need to be compared with "ground truth". By ground truth we mean here the results of manual segmentation of images in the test set, done by humans We assume that each manually defined segment has at most one automatically created counterpart that most closely matches it. Each automatic segment can be then used at most once as a counterpart of a certain manual segment. Some automatic segments may remain unassigned to any manual segment, as well as some manual segments may have no corresponding automatic segments. More formally, let us denote the set of manual and automatic segments by S_M and S_A. At the first stage, we define the function $f(s) : S_M \rightarrow S_A + \{\phi\}$, where ϕ denotes here "no automatic segment matches the segment s". The function $f(s)$ can be constructed in such way that maximizes the matching measure between elements of S_M and S_A. In the case of small number of elements in these sets, the exhaustive search that tries all possible mappings can be applied. In other cases, suboptimal procedures of $f(s)$ construction must be applied.

Having f function defined, we can evaluate the matching between manual and automatic segmentation by evaluating the matching defined by $f(s)$ for each segment $s \in S_M$. Popular $F1$ measure is used to evaluate the matching. Let for some $s \in S_M$ we have $a \in S_A \cup \{\phi\}$. We treat here s and a as sets of foreground pixels. If $a = \phi$ then a is assumed to be the empty set. The pixels in s are "relevant" elements, while the pixels in a are "retrieved" elements. The precision and recall can be then computed as

$$prec = \frac{\mid s \cap a \mid}{\mid a \mid} \tag{8}$$

$$rec = \frac{\mid s \cap a \mid}{\mid s \mid} \tag{9}$$

$$F1 = 2\frac{prec * rec}{prec + rec} \tag{10}$$

In the case when $\mid a \mid = 0$ (no automatic subimage is assigned to the manual one) we assume that $F1 = 0$. The $F1(s)$ score is computed for each $s \in S_M$. The overall automatic segmentation accuracy for the whole image is calculated as:

$$F1_T = \frac{\sum_{s \in S_M} \mid s \mid * F1(s)}{\sum_{s \in S_M} \mid s \mid}. \tag{11}$$

Thus, bigger subimages are assigned higher weights than smaller ones in the overall evaluation. In order to compute the assessment for the collection of images, the measures $F1_T$ computed for individual images are averaged.

IX. Experimental results

For the sake of drawings segmentation testing we used the subset of images collected in *PATExpert* project conducted by ITI CERTH institute and available at http://mklab.iti.gr/project/patentbase web page. The image set is described in [13]. Images in the database are scanned images of manually

created drawings. Only a few of them seem to be created with drawing software. Also in these cases they were printed and the image was finally acquired by scanning. Near-duplicates (i.e. identical or almost identical images) included in the original database were excluded.

For experiment purposes, 1461 images containing at least one caption were selected from *PATExpert* database. Each selected image was manually segmented into subimages and caption areas were marked. In such a way, we obtained "ground truth" information about the actual segmentation and localization of captions. The set of images was divided into two parts: a) the subset of images containing exactly one caption (1135 images) and b) the set of images containing multiple captions (296 images). 600 images from the part a) were assigned to the validation set. It was used for caption detection metaparatemers tuning. Remaining images from the set a) and images from the set b) were used as the testing set.

The experiment carried out consists of two phases. In the first phase we evaluated the accuracy of caption area recognition. The second phase was aimed on the assessment of the automatic segmentation consistency with the manual segmentation.

A. Evaluation of caption recognition accuracy

The aim of this experiment was to set the metaparameters used in the caption detection algorithm and then to estimate the performance of the proposed method. Tesseract OCR module with its default character set for English was used for extracted text recognition.

The validation set consisting of 600 images from the part a) was used for tuning the text area detection algorithm as described in [11]. It was also used to set the likelihood threshold $Q(s)$ defined by equation 7. The threshold value was set as the maximal value that accepts 98% of all true captions appearing in text areas in the validation set.

The test set for caption detection consisted of 535 remaining images from the part a) and all 296 images from the part b). They included total 1322 subimages with captions.

The caption recognition errors occurred in 168 of 1322 caption occurrences, so the caption detection error rate was 12.71%. The error caused by insertion of false captions occurred only in 5 images. In two cases, captions were erroneously recognized where actually they were parts of longer words inscribed in the image. Only three false captions were recognized in text candidate field that in fact contained graphic elements. 163 errors out of the whole number 168 were caption omissions. The reasons of all observed caption errors are summarized in the Table I.

It is evident that the most frequent reason of caption omissions is related to handwriting and unusual fonts. In future, some of this errors can be avoided by providing OCR module with samples of character shapes used in patent images. Validation set can be used for this purpose. Another possibility is to use OCR recognizer aimed more on handwriting. Tesseract program used in our experiments is trained on machine fonts, so it performs poorly in case of handprinted texts.

B. Automatic segmentation assessment

For the sake of automatic segmentation, only these elements of the test set were used, for which all captions were recognized correctly. 267 images from the part b) passed caption detection test successfully and they were used as the test set in the next experiment.

First, the images of grid-like structure were selected using the procedure described in Section VI. The procedure is purely technical and very accurately selects grid-like layout. The method detected 152 grid-like subimages. The segmentation defined by caption bands corresponded exactly to the actual segmentation in 150 images from this group. Only in two images, small and probably well-tolerated inaccuracies occurred. They were caused by existence of subcaptions appearing on the opposite side of the caption than the side including the related subimage. The proposed procedure for grid-like layouts detection and segmentation based on grids can be therefore assessed as very accurate and useful in many cases.

Remaining 115 images from the test set were segmented by intuitive segmentation described and by the modified k-means algorithm described in Sections V-A and V-B. For methods evaluation we used F1-score as explained in Section VIII. We observed that the F1-measure computed in this way is related to the degree of inaccuracy of "true" and automatic subimage matching. The intervals of F1 values roughly correspond to the following inaccuracy levels:

- $F1 \in (0.99, 1.0 >$ - subimages match almost perfectly, the differences are not meaningful and concern only individual pixels and dot-like graphical elements;
- $F1 \in (0.97, 0.99 >$ - differences in matching images concern usually misplaced very small graphical elements, in most cases of minor importance for image understanding;
- $F1 \in (0.95, 0.97 >$ - small elements like individual characters or digits appearing in descriptions, pointing arrows, distant and not graphically connected elements are displaced; usually it does not impair the concept presented in a image;
- $F1 \in (0.85, 0.95 >$ - relatively big elements of subimages are misplaced, but the presented concept is usually still readable;
- $F1 \leq 0.85$ - major elements of subimages are misplaced or missing (i.e. - they remain unassigned to subimage), the presented concept is not readable.

TABLE I
CAPTION DETECTION ERROR REASONS

Error reason	Number of occurrences
Strange but repeatable font	35
Handwritten captions	66
Oversegmentation of text fields	43
Caption patterns in ordinary words	2
Untypically rotated image	7
Falsely inserted captions	3
Unexplained	12
TOTAL	**168**

TABLE II
$F1$ SCORE DISTRIBUTION FOR TWO PROPOSED SEGMENTATION PROCEDURES

$F1$ **interval**	**Fraction of subimages**	
	intuitive segmentation	k-means segmentation
$F1 \in (0.99, 1.0>$	72.65	66.85
$F1 \in (0.97, 0.99>$	11.87	10.22
$F1 \in (0.95, 0.97>$	3.59	4.14
$F1 \in (0.85, 0.95>$	5.52	6.91
$F1 \leq 0.85$	6.35	11.88

Taking the above observations into account, we can assume that the segmentation fails if for at least one of subimages in the image, its $F1$ score is less than 0.95.

In order to evaluate the accuracy of automatic segmentation procedures and to compare them, $F1$ scores were evaluated for all automatically created subimages assigned to their "true" counterparts. Table II shows fractions of all tested subimages falling into $F1$ score intervals described above.

Overall performance of k-means segmentation is lower than the performance of intuitive segmentation. In the test, intuitive segmentation provided usable results for 88.13% of images, while k-means segmentation gave good results only in 81.20%. The main weakness of k-means based segmentation lies in its tendency to create unbalanced subimages, where one automatically determined subimage contains numerous big CCs, while others consist only of small components. In many cases it leads to segments that contain CCs actually belonging to various subimages. One of reasons of such situations is frequent appearance of empty clusters created in the course of the algorithm execution. The correction consists of forced assignment of some CCs to the empty cluster. The implemented cure consists in selection of the CC which is closest to the caption not assigned to any nonempty cluster. Sometimes it is a small CC, what can lead to the phenomena of unbalanced clusters.

The results of k-means segmentation is usually close to the human intent in the case of images containing many small, almost equally sized CCs. In such images, k-means often outperforms the intuitive segmentation. However, the k-means segmentation accuracy decreases significantly in images consisting of a few large CCs located close to each other.

X. CONCLUSIONS AND FURTHER WORKS

In this paper we presented the complete procedure of patent image segmentation supported by caption detections. In both phases of the procedure (detecting captions and segmenting) we obtained the correctness at the level of about 90%. This result seems to be practically acceptable and makes it possible to recommend it for practical application in patent document processing.

In the future research we plan to introduce the third approach to clustering problem which is most closely related to the formal definition of the problem in equation 5. We are going to apply the simulated annealing method which seems well suited to our discrete optimization problem with a huge search space. . Caption detection method should be also improved to avoid some segmentation errors induced by true caption omission. Promising direction seems to apply 2D Fourier spectrum analysis in order to raise text area detection accuracy.

***Abstract*—This paper focuses on analyzing a Spatial Pooler (SP) of Hierarchical Temporal Memory (HTM) ability for facilitating object classification in noisy video streams. In particular, we seek to determine whether employing SP as a component of the video system increases overall robustness to noise. We have implemented our own version of HTM and applied it to object recognition tasks under various testing conditions. The system is composed of a video preprocessing block, a dimensionality reduction section which contains SP, a histograms collecting module and SVM classifier.**

Our experiments involve assessing performance of two different system setups (i.e. a version featuring SP and one without it) under various noise conditions with 32–frame video files. In order to make tests fair and repeatable the videos of several 3–D geometric shapes were artificially generated. Subsequently, Gaussian noise of a different intensity was introduced to the videos making them more indistinct. Such an approach mimics real–life scenarios where the system is taught ideal objects and then faces in its normal working conditions the challenge of detecting noisy ones.

The results of the experiments reveal the superiority of the solution featuring Spatial Pooler over the one without it. Furthermore, the system with SP performed better also in the experiment without a noise component introduced and achieved a mean F1–score of 0.91 in ten trials.

I. Introduction

DESPITE the huge technological growth witnessed nowadays, there are still no autonomous machines available which would be capable of operating in the real world. Such machines would take over most of our tedious everyday duties and clear the way for a breakthrough in Artificial Intelligence. However, such robots need to be able to process inputs in real time, learn, generalize and react to events. This requires building an appropriate processing system which has human–like capabilities [1] [2].

A mammalian brain is an example of such a system which evolved over millions of years. Despite its apparent complexity there is only one algorithm [3] within the brain which governs the body functions. This allows for scalability of the solutions based on the algorithm since more complex systems may be built on a top of the simpler ones just by duplication of the basic structure.

The human brain as a whole has not been completely explored yet, making its artificial implementation and verification a very hard task. However, there are initiatives [4] which have taken up the challenge of simulating and modeling a brain as we know it today. Rather than model the brain, the authors of this paper have adopted a slightly different approach of gradually introducing selected components of HTM to the video processing system with the intention of enhancing its performance. By doing so we aim to develop a complete system working on the principles of the human brain as they were presented in [3][5] with our modifications making the algorithm suitable for hardware implementation.

Consequently, this paper attempts to take a step forward in examining the feasibility of using HTM for classifying objects in noisy video streams. The authors state the following hypothesis: employing Spatial Pooler in the video processing flow will improve the object classification ratio due to its beneficial reduction property of mapping to Sparse Distributed Representation (SDR). It is verified through a series of experiments.

The rest of the paper is organized as follows. Sections I-A and I-B provide the background and related work of object classification in video streams and Hierarchical Temporal Memory, respectively. The custom designed system used for the experiments is presented in Section II. Section III provides the results of the experiments. Finally, the conclusions of our research are presented in Section IV.

A. Object classification in video streams

Most state–of–the–art information extraction systems consist of the following sections: preprocessing, feature extraction, dimensionality reduction and classifier or ensemble of classifiers (Fig. 1). Their construction requires expertise knowledge as well as familiarity with the data that will be processed [6][7].

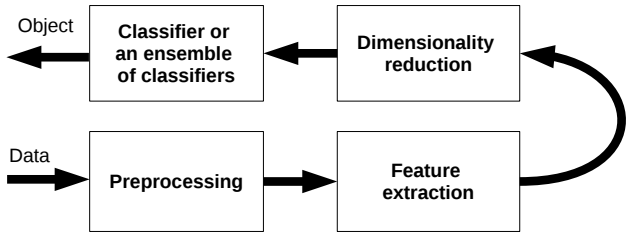

Fig. 1. Architecture of a video processing system

Usually, systems for object classification in video streams are also designed according this scheme. Consequently, the proper choice of the operations which constitute all the mentioned stages of the system is important and decides about the classification result [8]. One of the most challenging stages is feature extraction, which substantially affects the overall performance of the system.

There are also systems which take advantage of the spatial–temporal [5] profile of the data [1][9]. They are closer to the concept of the solution presented in this paper, which may be considered a hybrid approach since it features components of both schemes.

B. Hierarchical Temporal Memory

Hierarchical Temporal Memory (HTM) replicates the structural and algorithmic properties of the neocortex. It can be regarded as a memory system which is not programmed, but trained through exposing it to data flow. The process of training is similar to the way humans learn which, in its essence, is about finding latent causes in the acquired content. At the beginning, the HTM has no knowledge of the data stream causes it examines, but through a learning process it explores the causes and captures them in its structure. The training is considered completed when all the latent causes of data are captured and stable. The detailed presentation of HTM is provided in [5][10][11].

HTM is composed of two main parts, namely Spatial and Temporal Pooler. This paper focuses on Spatial Pooler (SP), aka Pattern Memory, which is employed in the processing flow of the system. Is contains columns with synapses connected to the input data [5]. The main role of SP in HTM is finding spatial patterns in the input data. It may be decomposed into three stages:

- Overlap calculation,
- Inhibition,
- Learning

The first two stages are very computationally demanding but can be parallelized, therefore the authors decided to implement them on GPU in OpenCL. The learning stage is implemented on CPU in Python. The detailed description of algorithms is provided in [5].

The overlap section computes *col.overlap* for every column in SP structure i.e. a number of active and connected synapses.

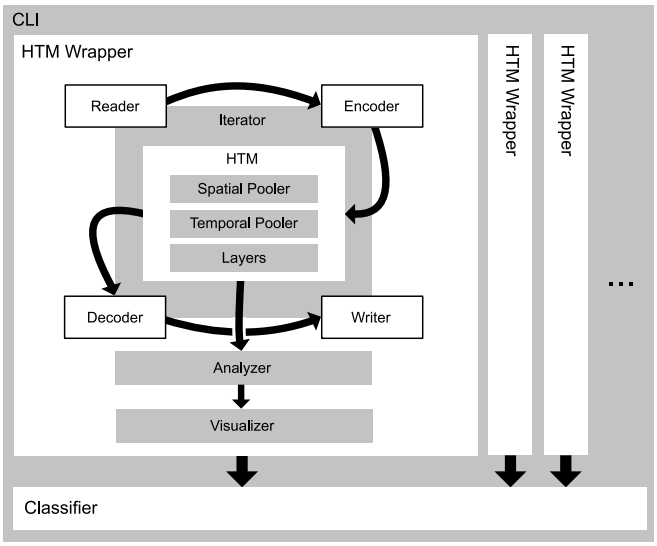

Fig. 2. Architecture of the implemented system

If the number is larger than *col.min_overlap* then it is boosted and passed on to the inhibition section.

The inhibition stage implements a winner–takes–all procedure where for each column a decision is made as to whether it belongs to a range of n columns of the highest values.

II. System description

The implemented HTM version [12] follows description from [5], with the exception of synapses bias implementation being replaced with random connections. Its main purpose however is to emphasize the algorithm parallelism and to allow progressively replace parts of it with GPU–accelerated (and in the future FPGA–accelerated) fragments written in OpenCL. The system (Fig. 2) is highly configurable, with numerous parameters responsible for the core HTM's structure, the encoder behavior, statistics rendering, etc. The configuration is stored in a file written in JSON format, which allows it to maintain its readability while providing clear structure. In addition to the core module, a set of supporting modules has been developed. Most of them are used for feeding video data to the core module, and receiving and analyzing the results.

The complete processing flow of the system is presented in Fig. 3. The data is fed into the system in a frame–by–frame manner. In the first step the original frame is reduced and binarized using OpenCV procedures. During the encoding process, the original video frame is converted to a smaller binary image. Preliminary tests showed that reducing a 960x540 image by a factor of 16 (producing 60x33 images) has a low impact on the end results while significantly shortening the processing time (Fig. 4). After reduction, the color image is converted to grayscale, which later is turned into a binary one using adaptive thresholding (using a potentially different threshold value for each small image region).

Those operations constitute the encoding which allows the generation of input data for the SP processing stage. There-

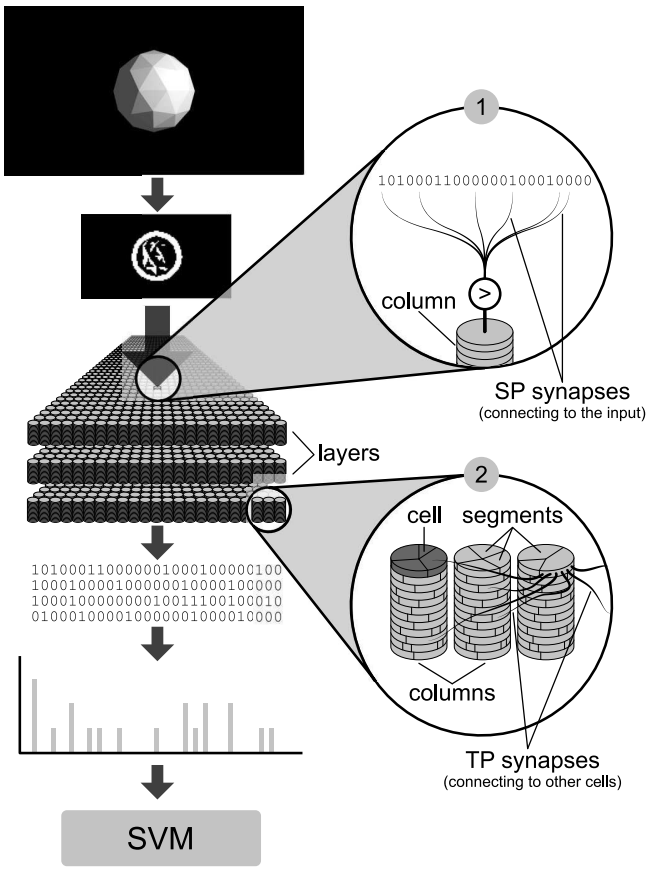

Fig. 3. Block diagram of the proposed approach

after, the data is mapped to SDR with SP and may be passed on to TP. Since our current work focuses on finding the optimal SP parameters values we do not use TP in this particular application, but the system in general has such capability. In the next step, histograms of consecutive processed frames are built on a per–video basis. The histograms are used as the input data for the SVM classifier which comes next.

There are two different working modes of the system, namely learning and testing modes. The system is trained in the learning mode with 80% of available data and then it is tested with the remaining 20% of the data in the testing mode.

III. Experiments and the discussion

A series of experiments (details of which are provided in Tab. I and Tab. II) was conducted to validate the hypothesis stated in the introduction of the paper. They allow a comparison of the performance of the system featuring Spatial Pooler in the processing flow with the one lacking it.

The challenging part involved generation of sample videos for testing (available from [13]. The videos had to meet a series of requirements such as object location, camera location and object–camera distance. Consequently, a dedicated application was used to generate the videos (i.e. Blender [14]). Blender provides Python API, which was used to automate and randomize the video generation. Each video contains a single, centered shape and a randomly positioned light source which brightness is picked from predefined range. During the course of a video the camera randomly changes position. Since noise addition at the runtime proved to be a very time consuming process, a separate script introducing noise to a large set of generated videos was created. Embedding noise also ensures equal conditions for all the experiments and test setups.

TABLE I
VIDEO PARAMETERS

Parameter		Value
Size of a single video frame		960x540
Reduction level		16
Frame size after reduction		60x33
No. of frames in a single video		32
Object classes		cone, cube, cylinder, monkey, sphere, torus
No. of classes		6
Total no. of videos	all	6000
	training	4800
	testing	1200
Videos per class	all	1000
	training	800
	testing	200
Videos per trial	all	100
	training	80
	testing	20

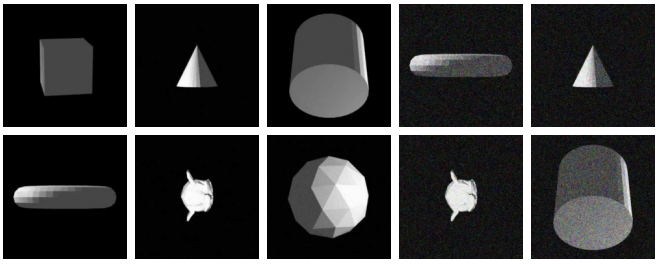

Fig. 4. Sample frames of different shapes and noise levels

The F1–score is used as a quality evaluation of the experiments' results presented in this paper.

Experiments conducted for higher noise levels than presented in Tab. III resulted in an unacceptably low F1–score (below 0.75). Therefore, the authors decided not to include the results of those experiments in the table.

It is worth noting there there was a huge difference in the calculation time of a single experiment across setups, see Tab. IV. This is the result of an HTM algorithm complexity,

TABLE II
SP PARAMETERS

Parameter	Value
No. of columns	2048
No. of synapses per column	64
Perm value increment	0.1
Perm value decrement	0.1
Min overlap	8
Winners set size	40
Initial perm value	0.21
Initial inhibition radius	80

TABLE III
EXPERIMENTS RESULTS FOR DIFFERENT NOISE LEVELS

Noise level (σ)	F1–score : mean and variance (10 repetitions)	
	SVM	SVM + SP
0	0.82 (0.001)	0.91 (0.001)
4.25	0.81 (0.001)	0.89 (0.001)
8.5	0.78 (0.001)	0.88 (0.003)

TABLE IV
EXECUTION TIME OF A SINGLE EXPERIMENT FOR DIFFERENT SETUPS

Setup	Time [hours]
SVM	0.23
SVM + SP	28.5

object–oriented programming approach and high level scripting language used in implementation. Code optimization and introducing more hardware–accelerated fragments should improve execution time. The tests were run on Intel(R) Core(TM) i5–4210M CPU @ 2.60GHz, and Nvidia GeForce GT 730M (selected sections of SP). Each experiment consisted of 10 trials.

According to the authors knowledge it is hard to find papers which directly correspond to the research conducted in this work (i.e. video classification in noisy video streams). Nevertheless, we examined the following papers : [15], [16], [17] which presents results of video classification using UCF-101 dataset. The best systems presented in those papers are based on various architectures of Convolutional Neural Networks (CNNs) and achieve accuracy of 80% and more. It is worth emphasising that despite similar performance in terms of the quality results our test setup is different mostly in a process of the video generation.

IV. CONCLUSIONS AND FUTURE WORK

This paper presents the preliminary experimental results of using an HTM–based system for object classification in video streams. The authors showed that using SP in the video processing flow improves the object classification ratio by approx. 10%. In future work, the authors are going to modify the preprocessing stage of the video processing flow and introduce TP. The authors are going to implement the most computationally–exhaustive routines in OpenCL and deploy the system on platforms equipped with GPU– or FPGA–based acceleration. This will enable conduction of experiments with video of a lower image reduction ratio.

TABLE V
EXAMPLE CONFUSION MATRIX FOR SVM–ONLY SETUP AND GAUSSIAN NOISE WITH $\sigma = 8.5$

	Predicted classes					
	cone	cube	cylinder	monkey	sphere	torus
cone	19	0	0	0	0	1
cube	0	10	8	0	2	0
cylinder	0	3	16	0	1	0
monkey	0	1	2	14	2	1
sphere	0	3	3	0	13	1
torus	0	1	0	0	0	19

ACKNOWLEDGMENT

I would like to thank my wife Urszula Wielgosz for her huge contribution to the preparation of the paper.

6th International Workshop on Artificial Intelligence in Medical Applications

THE workshop on Artificial Intelligence in Medical Applications – AIMA'2016—provides an interdisciplinary forum for researchers and developers to present and discuss latest advances in research work as well as prototyped or fielded systems of applications of Artificial Intelligence in the wide and heterogenious field of medicine, health care and surgery. The workshop covers the whole range of theoretical and practical aspects, technologies and systems based on Artificial Intelligence in the medical domain and aims to bring together specialists for exchanging ideas and promote fruitful discussions.

TOPICS

- Artificial Intelligence Techniques in Health Sciences
- Knowledge Management of Medical Data
- Data Mining and Knowledge Discovery in Medicine
- Health Care Information Systems
- Clinical Information Systems
- Agent Oriented Techniques in Medicine
- Medical Image Processing and Techniques
- Medical Expert Systems
- Diagnoses and Therapy Support Systems
- Biomedical Applications
- Applications of AI in Health Care and Surgery Systems
- Machine Learning-based Medical Systems
- Medical Data- and Knowledge Bases
- Neural Networks in Medicine
- Ontology and Medical Information
- Social Aspects of AI in Medicine
- Medical Signal and Image Processing and Techniques
- Ambient Intelligence and Pervasive Computing in Medicine and Health Care

***Abstract*—Making life easier for the elderly represents a new challenge for the ICT sector. This paper presents a new web-based system designed and implemented with the aim to support the social inclusion and to improve the daily routine of the elderly people within basic information and communication features. The system provides some advanced functionalities to utilise the information value of the data collected within the presented system, e.g. the recommendations based on similar hobbies or health problems; a simple medical diagnostics; a creation of a knowledge base containing experiences and best practices, etc. We designed the system in accordance with local conditions in Slovakia, so its full functioning relies on the progress in e-Health legislation. Presented version is a preliminary result that will be further improved and tested within a real practice.**

I. Introduction

PROGRESSIVE ageing of the population represents a big challenge for various European politics and societies. The European Union has created some initiatives such as Digital Competence or Lifelong Learning Programme (LLP) to support these activities on the national and European level too [7]. Improving the lives of elderly people within suitable ICT solutions in combination with existing social or medical services represents a big challenge for not only public but also the private sector. Successful adaptation of these solutions requires cooperation between all involved organisations, governments, stakeholders and providers. Of course, various local conditions affect the whole implementation process in line with the common EU principles and create the barriers that need to be passed.

Acquired experiences and knowledge from two international EU funded projects OLDES and SPES motivated us to propose a new solution that will meet the identified requirements, will respect existing standards and will be customised for the Slovak local conditions. The project OLDES (Older People's e-services at home) aimed to develop a very low cost and easy to use entertainment and health care platform, designed to ease the life of the elderly in their homes. The implemented platform was tested at two different locations and countries: Prague in the Czech Republic and Bologna in Italy. The SPES project (Support Patients through E-services Solutions) aims at transferring the original approach and results achieved in implementing the OLDES focusing on new target problem domains: dementia, mobility-challenged persons, respiratory problems, and social exclusion [14]. The new tele-health and entertainment platform was tested in four different conditions: Ferrara (Italy), Vienna (Austria), Brno (Czech Republic) and Košice (Slovakia.)

The paper is organised as follows: the introduction with a brief overview of the selected similar approaches or initiatives to identify possible gap for a new solution. The second one describes the proposed solution with emphasis to meet the identified requirements and existing best practices in this domain. Next section presents the current prototype with the results of the testing. The last one concludes the paper and outlines some directions for our future work.

A. State of the Art

This section presents some selected initiatives and research works with the aim to identify possible gaps or research problems. As we mentioned before, the OLDES project resulted in the solution developed in accordance to the specific needs of the two pilots [13], [15]. The core of this solution is a low-cost PC creating a hub for other connected devices as TV set and the medical devices communicated via Bluetooth. The TV display information provided by the platform and users can access it through a simple remote control. In addition, users can actively participate in discussion groups through adapted handset connected the PC. In the case of medical devices, users tested e.g. a glucometer, scale, adapted version of a sphygmomanometer, etc. After testing partners identified following directions for future improvement: access through the remote controller, prefer medical devices commonly available on the market, the overall architecture of the platform.

The follow-up project SPES aimed to solve these issues and to support four target groups suffered by respiratory problems, dementia, handicapped people and social exclusion. It resulted in an information and communication technology platform connected to the different medical devices and installed in a patients' home [14], [21]. The main advantages of this solution are continuous monitoring of the elderly with the respiratory problems; the presence of various entertainment oriented application that supports orientation and practising memory and a set of services to support the social inclusion of the elderly through virtual communication, information sharing and a personal social network creation. Despite some improvements over the OLDES platform, still, some open issues and gaps existed,

e.g. SPES platform was available only as a desktop application and this approach required a two-layer transfer of the collected measurements from the medical devices, to the local and main database. From the users point of view, a possibility to create an own personal network was missing, e.g. based on similar hobbies or health problems. In addition, the GUI needed to be refined based on existing trends and best practices. Whereas the currently valid legislation in Slovakia does not allow sharing the medical information between patients and the doctor in the electronic form, some type of decision support system for common health problems can be a very interesting part of the supporting ICT (Information and communication technologies) solution for the elderly.

Decision support systems (DSS) in medicine have a long history that started within a system called Mycin [3]. The actual trend includes a creation of the sufficient quality and broad knowledge base further used for diagnostics of various diseases within suitable analytical methods [16], [12], [11], [6]. These works specifically focus on selected diseases so this factor strongly limits their generality and usability in a wider range. A separate group contains applications called symptom checkers. Typically, they are available as web-based applications and patients have a possibility to start the diagnostics process with an initial description of their symptoms. According to a recent study realised by the Harvard Medical School, most of these sites and applications provide inconsistent and unclear information and patients should not focus on this diagnosis and results [19].

Early diagnosis of the typical civilisation diseases represents one of the main challenges for the cooperation between artificial intelligence represented by analytical methods and medical data obtained through various medical tests or devices [8], [10], [22]. Equally important is a selection of the appropriate attributes for an effective diagnostics [17], [4], [5]. Authors in [1] used data collected in a family practice from Croatia to extract the patient's characteristics necessary for the positive diagnosis of the Metabolic Syndrome. The data include patients in retirement. Authors generated a set of decision tree models within CART or C4.5 algorithms. In addition, authors investigated the optimal cut-off values for the identified key biomarkers.

In summary, we concluded that still some gaps and potential for a new system to support the daily life and health status exist. In close cooperation with a possible target group, based on our previous experiences and actual existing approaches, we identified some features creating the core of a new web-based system. For example a possibility to create an own network of friends without a need to store personal data such as existing social network, a possibility to find a new friend based on similar hobbies or health problems, a possibility to use a simple decision support system to evaluate the discovered symptoms.

II. Web-based System

A. Functional Requirements

We specified following requirements based on the provided state of the art analysis, experiences obtained from the SPES project and in communication with a participated group of elderly from the Košice City. Users can use the system on the various devices, i.e. the system will be responsible. Users have a possibility to create their own profile containing information such as a nickname, hobbies, health problems, personal general practitioners or specialist, etc. In additional, users can create their own social network including people recommended based on the similar hobbies or health problems. Through this network, users have a possibility to share various multimedia or news, to use simple on-line chat or to invite their friends to the public or private event. From a medical point of view, users can manage their planned medical examinations, import and visualise the collected measurements from the supported medical devices or use the continuously constructed knowledge base to support the basic medical diagnosis. Last, but not least, the system informs the users about relevant information within simple notifications, current weather forecast or published newspaper articles from selected RSS (Rich Site Summary) source.

B. GUI Proposal

We designed the graphical user interface (GUI) in accordance to the current relevant W3C standard [22] and verified recommendations [9], i.e. we use a sans serif typeface, 12pt or 14pt type size for body text, medium or bold face type. The optimal option for a text alignment is the left. We present the body text in upper and lowercase letters; we use the capital letters and italics in headlines only. We reserve underlining only for the web links. We avoid using a combination of yellow, blue and green colour in a close proximity, because some elderly have problems to discriminate these colours. We used the graphics against a light background. We ensure that users can resize the content without assistive technology up to 200 percent without loss of content or functionality. We provide the labels when content requires a user input. The headings and labels describe topic or purpose.

C. Architecture Proposal

Presented prototype is a typical 3-layer client-server model containing a database, back-end and front-end service; see Fig. 1. The analytical package (language R, RStudio) is an integrated module to meet requirements from the legislative and safety point of view. We tested this proof of concept in the conditions in which the elderly mainly verified the predefined scenarios. During the next testing in the larger group of participants, we will discuss relevant lessons learned and possible improvements, not only from the usability point of view but also on the technological side, e.g. to take an advantage of the cloud computing.

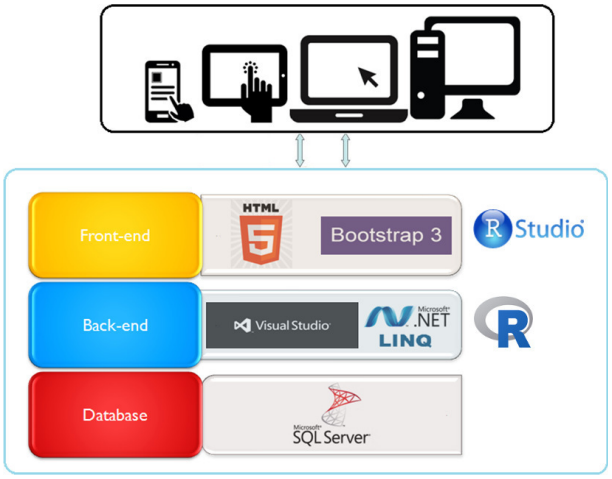

Fig. 1 Architecture with the relevant technologies

D. Analytical Services Proposal

Proposed analytical package includes the services necessary for storage, processing, analysis and knowledge base building. We generated initial decision rules and models through free available data samples for selected diseases to show a potential of this type of solution. In real operation, the system will replace this initial data within knowledge relevant to the current users and conditions, i.e. something like self-learning using the methods of artificial intelligence. We organised the whole analytical process in accordance with the CRISP-DM methodology which represents widely accepted approach on how to manage this process effectively [20]. We selected the decision trees based on their ability to process different types of input data, to process data with missing values and the most important factor was a simple understandable visualisation of the generated outputs for people with less knowledge from data mining or machine learning.

We used C4.5 [17] and CART [2] to extract possible interesting rules for diagnostics that were further added to the knowledge base. For example, IF a *female* is more than 70 years *old* AND *triceps skinfold thickness* is more than 28.5 mm AND *the level of insulin* is more than 15.15µIU/l THEN diagnosis of the Mild Cognitive Impairment is positive. Alternatively, IF *average level of blood glucose over the previous 3 months* was more than 4.4 AND *the level of insulin* is more than 27.1µIU/l THEN diagnosis of the Metabolic Syndrome is positive. It is important to say that all included rules need to be verified by cooperated medical experts and it is possible to use them only to support the decision, not as the final diagnosis.

E. Current Prototype

Tested prototype (available in Slovak language) contained all presented features that were available through a simple and intuitive user environment; see Fig. 2.

Users could read the articles from their favourite web newspapers (Noviny) and watch the weather forecast for the selected location (Počasie). They could create an own profile included hobbies or health problems (Profil) and based

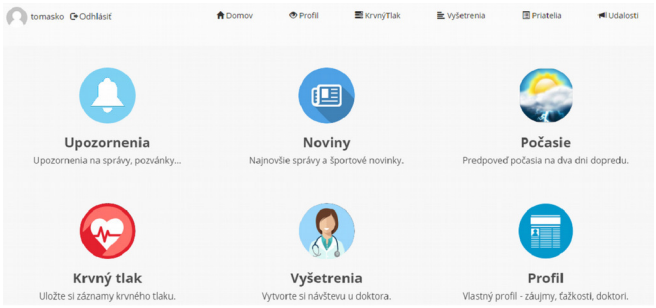

Fig. 2 Main page of the proposed system

recommendation generated from this data find a new friend. In order to improve the health status, they could import their measurements from medical devices (Krvný tlak) with a possibility to visualise (see Fig. 3) and export in the selected format; or create a database containing information about relevant doctors and planned examinations (Vyšetrenia). In addition, a possibility to analyse the collected medical data was at disposal, but the final diagnostics is the responsibility of the general practitioner or specialist.

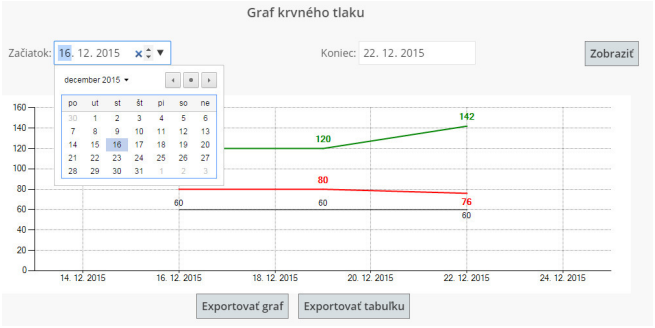

Fig. 3 Visualisation of imported blood pressure measurements

F. Testing

One of the main reasons why it is not possible to present the proposed system as a finished solution, but only as a proof of concept, is the current legislative in Slovakia covering protection of personal data and e-Health. However, this situation is changing every year under the influence of the various initiatives on the European Union level. We tested our prototype with a small group of elderly in order to evaluate their satisfaction and overall potential of this type of system in Slovak conditions. Elderly realised predefined test scenarios representing typical uses for such systems and answered a predefined questionnaire. This testing confirmed our initial hypotheses such as elderly enjoy the graphical design of the system and it meets relevant requirements and best practices. Also, elderly are satisfied with a set of offered features and with an approach how these features are provided to the users, i.e. the system is easy to use without necessary deep knowledge from the ICT domain. The system helps elderly to reach more active life; to make their daily routine more pleasant and to make their contact with an external environment more intensive. The participated medical expert evaluated the generated models and extracted decision rules based on her knowledge and existing

literature, e.g. accordance to the IDF (International Diabetes Federation) definition of the Metabolic Syndrome.

III. Conclusion

The article presents the design and development of the customised web-based system, which would help elderly to the living that is more active and better health status. We aimed to solve some gaps as a possibility to recommend a friend based on similar characteristics or to analyse the data about health status through the simple decision support system. The positive results of the testing confirm our expectations and motivate our future work devoted to the e.g. automatic creation of the user profile based on his behaviour and typical daily habits, or a self-learning and adapting mechanism for created knowledge base. In this case, we will continue to use the methods of artificial intelligence in combination with actual trends in domains as Internet of things, home health care and robotics. In addition, we can understand this version as a proof of concept that creates a good foundation for our future research activities oriented to the H2020 project proposal.

Acknowledgment

The work presented in this paper was partially supported by faculty internal research project no. FEI-2015-2 and by the Slovak Grant Agency of the Ministry of Education and Academy of Science of the Slovak Republic under grant No. 1/0493/16.

***Abstract*—In this paper the application of a new method of features selection was presented. Its effects were compared with several other methods of features selection. The study were performed using a data set containing samples of the sound signal emitted by the arteriovenous fistula. The aim was to create a solution with multiclass classification based on the k-NN classifier family allowing for effective and credible assessment of the state of arterial-venous fistula.**

I. Introduction

EACH classification process is based on the set of features delivered to the classifier on the basis of which a decision is taken and the result obtained. Proper selection of a set of features significantly improves the quality of the classification process.

The approach ensuring the best quality is to test all possible non-empty subsets of the input set. Unfortunately, the number of non-empty subsets of n-element is $2^n - 1$, which implies the possibility of a full review of the subsets only for the n that does not exceed a dozen elements. Full analysis for larger values of n is too time-consuming. It is therefore the use of quasi-optimal methods, which is determinative of a subset of the features of possible high efficiency of classification.

K-NN is the most popular minimum distance classifier. It assigns the unknown sample to the class most often representing its neighborhood[14][15]. There are many variants of this method. They differ among themselves, inter alia, by methods of calculating the distance and the method of voting that determines the result.

The most common variation of k-NN is weighted k-NN , in which weight of the neighbor of samples $\boldsymbol{x}$ depends on its distance from the $\boldsymbol{x}$[13]. An interesting solution is the Diplomatic Nearest Neighbors (k-DN) [12], which seeks k neighbors of each class separately, and then selects the class for which the average distance from the found neighbors to the tested sample is the smallest.

Due to its flexibility, simplicity and the possibility of use in tasks of classification and regression k-NN is popular despite its flaws: it requires storage in the memory the whole training set and high demand for computing power, especially for large training sets.

II. Data set

In the studies the data set consisting of sounds emitted by the arteriovenous fistula was used. The studies to date [1][2] show that the character of the sound emitted by the blood flowing within the fistula differs depending on the condition of the fistula.

The research data set was collected from 19 patients with radiocephalic fistula. Aquisition of the material consisted in recording the sound of the blood flowing through the arteriovenous fistula. Material was collected using a dedicated head equipped with an electret microphone CZ034 manufactured by Ringford, with a sensitivity of -42dB (0dB=1V/Pa, 1kHz), ie. 8mV/Pa and an interval signal/noise ratio greater than 60dB. To register a signal, an integrated sound card was used as part of the RV730 Radeon 4000 manufactured by AMD as well as dedicated software running under the Linux operating system. Sampling frequency was set at 8 kHz.

Numerical processing of data was performed using WEKA 3.7.13 package running with the JRE Oracle Java 1.8. The calculations were performed on a computer with Intel Core 2 T6570 2.1GHz under the Linux operating system. During the measurements the algorithms time requirement only a single core processor was used.

Fistulas were rated as effective, however, to differing degrees. Eight groups representing a fistula with varying degrees of stenosis were extracted. A total of 1190 samples was collected.

The groups were lettered with labels ***a-h*** , wherein the group ***a*** were fistulas in the best condition and in the group ***h*** in the worst condition. With the collected data set 23 features were extracted; 6 in the time and 17 in the frequency domain. Features in the time domain named t0, t4, y0, y4, p0 and p4 describe the timing, amplitude and shape of the signal envelope within a single period of the rhythm of the heart. Features in the frequency domain named f1-f17 describe the density of the frequency spectrum of the recorded signal at specific intervals from the scope of 20-600Hz.

III. METHODS

In this study five methods of feature selection were tested. Each of them belongs to a different category of methods (Figure 1).

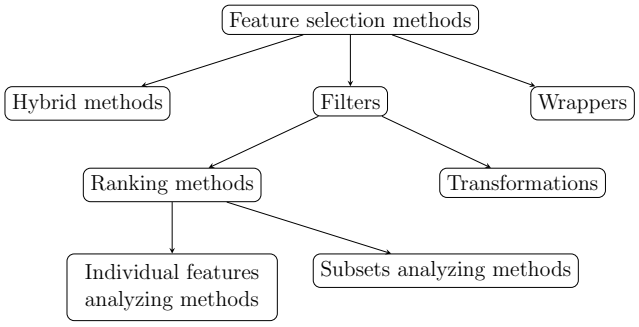

Fig. 1: Feature selection methods

The first four are commonly known and available in the WEKA package. The fifth is an own method developed proprietarily to the needs of this particular task.

The methods used are:

- *Correlation* - builds ranking of features evaluating the characteristics of each of them individually. The rate criterion is the absolute value of the correlation of coefficient feature with the class. The higher the correlation, the higher the position of feature in the ranking.
- *SVMeval* - evaluates the worth of an attribute by using an SVM classifier. Attributes are ranked by the square of the weight assigned by the linear SVM classifier.
- *PCA* - performs a linear transformation of the features into another space in which features included in the new set are mutually uncorrelated and sorted with respect to the amount of input information in the classification process.
- *Forward search* - wrapper method building the set of features starting from one and gradually adding these features that provide the best quality of classification. This method is based on a classifier to be used in the target solution - in this case the k-NN.
- *Joined pairs* - a method developed by the author. It creates a ranking of features based on the ability of pairs of features for classification. In the first stage, a collection of all possible two-element subsets of features is formed. Then, basing on each subset of features a classifier is constructed and evaluated. As a result, each two-element subset is assigned a numerical value that indicates the quality of classifier built on the basis of this subset. Finally, the ranking of features is created. Features are added into in order indicated by quality of classifiers built in the previous step. The principle of operation of the method is shown in algorithm1.

The method has been tested using four selected data sets available from the UCI Machine Learning Repository[16] – glass, vote, segment challenge and wine quality. In each of the cases a rapid convergence of the level of quality classifications

Algorithm 1: Joined pairs

```
input : tf: table of features
output: fr: features ranking
// variable: pair of features
def pof: structure:
    featureA
    featureB
    quality
for each possible pairs of features from tf do
    add new pair to pof
    pof.quality ← classifierQuality(pof.featureA, pof.featureB)
Sort(pof) by pof.quality, ascending
for each pof do
    if pof.featureA ∉ fr then
        add pof.featureA to fr
    if pof.featureB ∉ fr then
        add pof.featureB to fr
return fr
```

to the maximum value was obtained, indicating that the joined pairs method works properly Figure 2 shows the graphs indicating the level of quality of classification described by the F-measure as a function of features number taken into account during the classification process. Number of features included was increased by adding features one by one, in the order indicated by the ranking produced by joined pairs algorithm.

In the study, k-NN classifier with distance weighing was used. For the distance measure the Manhattan metric was used:

$$d(X,Y) = \sum_{i=1}^{N} |X_i - Y_i|, \tag{1}$$

where X and Y are the points in N-dimensional space of features and d is a distance betwen these points. The tested element was assigned to a class on the basis of the vote. The weight of the vote of the $i-th$ neighbor was distance weighed according to the formula:

$$w(i) = \frac{1}{d(i) + 0.0001}. \tag{2}$$

Value of 0.0001 in the denominator is added to the distance in order to avoid division by zero when the distance is equal to zero[6].

Quality rating of classification was based on the F-measure[1] indicator. The indicator can be betwen 0 and 1 and the quality of classification is the higher the F-measure value is closer to 1. The test method was 10-fold cross-validation.

IV. Results and discussion

The quality of feature sets obtained using each method was evaluated by construction of the k-NN classifier and assessment of its quality. For each set of the features, 23 subsets of features were generated, containing from 1 to 23 features. In the next subsets the features were included in the order indicated by the ranking. For each subset of features, 15 classifiers differ by a n parameter were generated. Parameter n was varied from 1 to 15. Summary of rankings of features for each method are schown in table.I.

TABLE I: Features ranking

no.	Correlation	SVMeval	PCA	Forward search	Joined pairs
1	f14	f11	v1	f3	-
2	f15	f5	v2	f13	f3,f13
3	f8	f14	v3	f11	f11
4	f16	f16	v4	y4	f1
5	f7	f13	v5	f10	f12

7	f13	f15	v7	f1	f9
8	f9	f3	v8	f14	f2
9	f5	f8	v9	f15	f7
10	f4	f12	v10	f16	f5
11	f10	f6	v11	f9	f10
12	f12	f7	v12	f8	f8
13	f11	f10	v13	t4	y4
14	f3	f1	v14	f7	t4
15	f1	f2	v15	f12	f14
16	f2	f4	v16	fm	f15
17	fm	fm	v17	f2	fm
18	t1	y4	v18	f5	y0
19	y0	t4	v19	t1	t1
20	p4	y0	v20	p4	f16
21	t4	t1	v21	y0	f6
22	y4	p1	v22	f6	p1
23	p1	p4	v23	p1	p4

Graphical comparison of results of calculations for the classification was presented in figure 3.

The worst result was achieved by the correlation method with its F-measure not exceeding 0.93. Not much better were SVMeval and PCA methods for which F-measure reached a value of 0.94. All the above methods have achieved the maximum quality for $n \geq 15$.

The best was the Forward search method, which reached a maximum value of F-measure equal to 0.97 for $n = 9$. In addition, a large area, stretching from $n \in \langle 8-18 \rangle$ and $k \in \langle 5-15 \rangle$, for which $F-measure \geq 0.95$ provides a good stability of the solution. Comparable in quality but far superior in the minimum amount of features was Joined pairs method. The maximum value specified by $F-measure = 0.96$ was achieved for $n = 6$ and $k = 12$.

A tabular summary of the F-measure for selected values of k was presented in Table.II.

The chart shows that the *Joined Pairs* method attains the best F-measure using the smallest set of features. However, an increase in the feature count causes quality loss, which is regained only for $n = 15$ and $n = 16$. The Forward Search method achieved a stable maximum for n=9. Other schemes generated feature sets that were best for high values of n, yet none reached the quality level of *Joined Pairs* or *Forward Search*.

The *PCA* method allows the use of non-empirical methods for selecting the amount of features (eg. the igenvalues criterion), therefore evaluation time assumed zero. Evaluation time for *Forward search* method is zero because the evaluation of set is made up to date during the construction of the rankings.

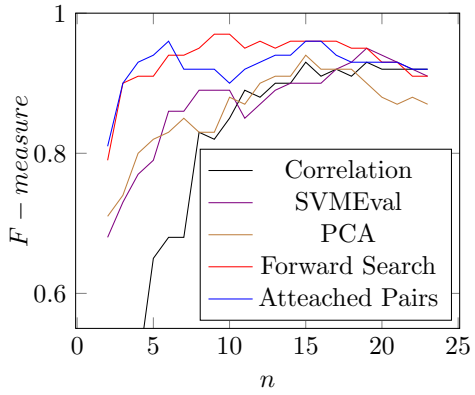

Fig. 4: F-measure as a function of n for optimal k

Table III summarizes the results for all the feature selection methods. Its first part presents the time requirements for each schema, including the time needed to generate the ranking and the time necessary to assess the quality of respective sets of features. The filtering methods (*Correlation* and *SVMeval*), unsurprisingly used the smallest amount of time. Similarly, the time requirements of the *PCA* method were negligible. The running time of both *Forward Search* and *Joined Pairs* was significantly slower. The *Forward Search* method used 276 classifiers: 23 one-feature classifiers, 22 two-feature classifiers, 21 classifiers that used three features, and so on. This was the main source of higher time requirements. The *Joined Pairs* method analyzed all the pairs of features and thus built in total 253 classifiers. Due to lower complexity of the classifiers, this approach needed less time that the *Forward Search* method. The quality of the ranking for *Correlation*, *SVMeval* and *Joined Pairs* methods was based on generation and quality assessment for all the feature sets for n from 2 to 23 and each k from 1 to 15. Since the only variable components of

TABLE III: Summary of results

	Correlation	SVMeval	PCA	Forward search	Joined pairs
rankings construction time	00:00:01	00:00:10	00:00:01	02:48:35	01:40:27
sets evaluation time	00:17:03	00:17:03	0	0	00:17:03
total time	00:17:04	00:17:13	00:00:01	02:48:35	01:57:30
optimal n	15	19	15	9	6
optimal k	12	10	8	7	12
F-measure	0,93	0,95	0,94	0,97	0,96

the ranking process were the fearure sets, the running time was the same for all of them. The *PCA* method allowed for non-empirical ways of choosing the size of feature sets (for example, the Kaiser criterion or scree plots).

As this algorithms are not computationally-heavy, their time-requirements were assumed to be zero. The running time of quality assessment for the *Forward Search* method was assumed to be zero as well, because the method does the necessary calculations online, while generating the ranking. The second part of Table 4 presents the optimal values for k and n with the respective F-measure.

All methods of feature selection achieved similar quality indicators of the constructed models.

V. Conclusion

It is possible to notice the general principle that computing power consumption feature selection algorithm translates into the quality of the obtained subsets of features. Undemanding methods of filter group indicated subsets of more features than other methods. The *Joined pairs* algorithm gives good results in the classification task.

With respect to the problem of evaluation of the arteriovenous fistula it can be concluded that the results are very good. Each of these methods has allowed to obtain a very high quality classification. It is suspected that, such optimistic results may be the effect of insufficient amount of analyzed data. Vectors describing individual patients form in the a feature space the easily separated clusters.

Verification of the results should be made on unrelated set of test data and having regard to a greater number of patients and samples.

Therefore, it would be appropriate to extend the scope of the study, increasing the set of input data.

***Abstract*—Medical and healthcare study programmes are quite complicated in terms of branched structure and heterogeneous content. In logical sequence a lot of requirements and demands placed on students appear there. This paper focuses on an innovative way how to discover and understand complex curricula using modern information and communication technologies. We introduce an algorithm for curriculum metadata automatic processing -- automatic keyword extraction based on unsupervised approaches, and we demonstrate a real application during a process of innovation and optimization of medical education. The outputs of our pilot analysis represent systematic description of medical curriculum by three different approaches (centrality measures) used for relevant keywords extraction. Further evaluation by senior curriculum designers and guarantors is required to obtain an objective benchmark.**

I. Introduction

THE domain of medical and healthcare curriculum harmonization captures the systematic transmission of specialized required knowledge based on a suitable combination of theoretically focused courses and clinical teaching training [1]. It links traditional proven pedagogical approaches and medical expertise with computer sciences and technologies with a view to the discovery of an innovative way to understand the complex structure and content of medical and healthcare study programmes. The proper use of data extracted from curriculum management systems can significantly improve the global overview on entire curriculum including performing up-to-date information in real time. The attention of this paper is paid to the core technologies of automatic processing for documents classified as a supervised machine learning task called automatic keyword extraction, and its real application on curriculum metadata. Automatic Keyword Extraction (AKE) is a research topic focusing on the identification of a small set of words, key phrases, keywords, or key segments from a document that can describe the meaning of the document [2]. The aim of keyword assignment is to find a small set of terms that appropriately describes a specific document, a medical discipline in our particular case, independently of the domain it belongs to. Here are two fundamental issues, which are supposed to be answered by our research: (i) Are we able to automatically generate sets of keywords? Are the extracted keywords relevant? Do they express properly individual medical discipline? (ii) Which kind of centrality does identify the most accurate set of keywords and what is the proper value of determined threshold?

II. Methods

The research methods stems from our previously published and reviewed papers [3]–[5], wherefrom the well-known and proven step-by-step data mining guide CRISP-DM (CRoss-Industry Standard Process for Data Mining) [6]. We have used the CRISP-DM reference model, which was primarily developed by means of the effort of a consortium from the business sphere, as a powerful scientific technique to excavate the knowledge and patterns concealed in the diversely complex mountain of medical and healthcare education data [7]. This standardized methodology provides the complete process model for exploring data. Below, all the CRISP-DM steps are described in accordance with determined research questions.

A. Business understanding

In this stage, we focus on the understanding the research objectives from the perspective of curriculum mapping. In general, curriculum mapping is a procedure that creates visual representation of the curriculum based on real time information, as a way to increase collaboration and collegiality in higher education institutions. This phase also involves more detailed fact-finding about all of the resources, constraints, assumptions, published results and other factors that should be considered in determining the goals analysis [8].

Two main objectives were identified: (i) to make the curriculum more transparent to all stakeholders; (ii) to demonstrate the links between the various components of the curriculum (such as modules, disciplines, courses and learning units) [9]. In terms of new trends and reforms in medical education, we have proposed a general model for curriculum management and harmonization supported by our

original web-oriented platform called OPTIMED[1] [10]. This innovative and dynamic platform provides a clear way how to describe medical curriculum with the use of given text attributes including links to relevant study materials. We set up the structure of curriculum, which covers study programmes (e.g. General Medicine), specialized modules (e.g. Theoretic sciences), medical disciplines (e.g. Anatomy), courses (e.g. Anatomy I – lecture), and learning units (e.g. Central nervous system). This phase involves more detailed fact-finding about a systematic keyword generation of individual medical disciplines from various metadata sources stored in the OPTIMED database.

For the pilot experiment two disciplines were chosen (Nursing and Psychiatry), which are both used for the acquisition of knowledge and skills and also allow the development of so-called "soft skills". Both disciplines are taught at different periods of study. While Nursing has been lectured almost on the beginning of the medical study (in the second year) and is focused on basic knowledge and skills in caring (helping with basic needs of patients and also caring for patients with different types of illness). Psychiatry is taught as one of the last courses of undergraduate study of general medicine. Both courses include theoretical instruction in the classroom and subsequently clinical placement where students should use knowledge and skills obtained in the previous tuition and both of them are not accepted as the core medical disciplines.

B. Data understanding

Data understanding starts with initial data collection and proceeds with activities that enable to become familiar with the data, to evaluate the quality of data, to discover first insights into the data, and/or detect interesting subsets to form hypotheses regarding hidden information. The following metadata attributes describing medical curriculum was mined from PostgreSQL database and divided into the classes in accordance with fields of medicine. Names of the attributes, data types in squared brackets and samples are shown below in Table I.

TABLE I.
SELECTED ATTRIBUTES OF A CURRICULUM

Attribute (data type)	**Sample value**
Name of learning unit (varchar)	Biologic therapy in psychiatry
Importance of learning unit (text)	The aim of the study unit is to introduce types of biological therapy in psychiatry, including psychopharmacotherapy, electroconvulsive therapy, Recently, modern neurostimulative methods such as repetitive transcranial magnetic stimulation …
Description of learning unit (text)	Psychopharmaceuticals can be classified in several ways. Lehman s diversification is often used and is based on effects on three mental functions: vigilance, effectivity and mental integration (thinking). Vigilance is positively influenced by nootropics, cognitives and psychostimulants, negatively by hypnotics…
Group learning outcome (varchar)	Main indications, differences from adults (indications, efficacy), adverse effects, ethical aspects.
Index (varchar)	Psychopharmacological drugs in relation to children, Antipsychotics, antidepressants, stimulants, thymoprophylactics.
Learning outcome (varchar)	Student knows key indicators relating to psychopharmacological drugs.

C. Data preparation

Data preparation covers all activities needed to construct the final dataset from the initial raw data. First of all, table, record and attribute selection as well as data pre-processing covering transformation and data cleaning procedure were automatically done. The input data set consists of information-rich attributes (name, importance, description of learning units and all related learning outcomes including indexes) mined from OPTIMED. The data preparation phase appears again at the end of the modeling process described in the next section. An output of an algorithm for keyword extraction is very compact list of keywords including just the self-sorting information. For the purposes of plotting the graph the simplified table combined with products is created during the calculation. This final data connection is executed every time when a user starts to explore new discipline keyword dataset.

D. Modeling

In this section, we propose a novel algorithm for keyword extraction that forms the basis of the modeling and visualization stages, which are also introduced here.

The algorithm is based on two main components: word2vec model and network/graph centralities. Word2vec model proposed by Mikolov [11] is a word embedding model that belong to a wide class of distributed representations models. It arises from predicting the neighbors of words using a deep neural network – roughly said, the weights in the neural network between input and hidden layer constitute the vector representations of words. For our purposes, we have created a word2vec model over TC wikipedia[2] using the following main parameters: model = CBOW, dimension = 200. The concept of selected network/graph centrality measures was firstly developed in social network analysis. We successfully used these methods in our previous work [3], [4], namely we deal with the closeness, betweenness, and eigenvector centralities.

Input data for the algorithm are represented by trained word2vec model, given document (bag of words for individual medical disciplines), word similarity threshold `t`, number of keyword `n`. (1) Select all terms that are contained in the document at least two times. (2) For all pairs of terms, compute the cosine similarity of their word2vec representations. (3) Create the graph `G` in a following way: Vertices are the terms (obtained in the Step 1). Two vertices are connected with an edge if and only if their mutual cosine

[1] http://opti.med.muni.cz/en/

[2] http://nlp.cs.nyu.edu/wikipedia-data/

similarity is at least `t`. (4) Compute closeness, betweenness and eigenvector centrality of vertices in the graph `G`. Select `n` terms with the highest values of various centrality and set them up as keywords.

Finally, we have implemented a new online dynamic visualization as a feature of the OPTIMED reporting tools[3], which is based on outputs from described algorithm above. Innovative graphical interpretation allows users to create complex data overview, which cannot be achieved with basic data views. In our case, the simple network visualization was created with the D3.js JavaScript library. We decided to integrate a force-directed graph (see Fig. 1) displaying complex structures with expand-on-demand clusters and convex hulls around leaf nodes [12].

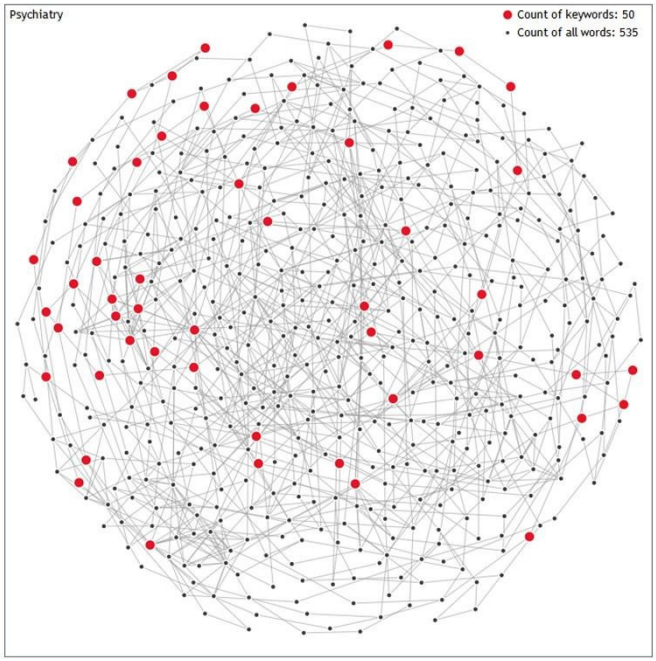

Fig. 1 The force-directed graph of Psychiatry (based on closeness centrality, cosine similarity is higher than 0.6)

The graphs include two types of keyword representation – red nodes (bigger) for more frequent keywords and black nodes (smaller) with less frequent keywords. Moreover, we wanted to determine what kind of centrality type (closeness, betweenness or eigenvector) and what value of the cosine similarity (> 0.6; > 0.5; or > 0.4) would be the most suitable and could the most accurately describe concrete medical discipline. Using advanced filters included in web reporting service, we are able to modify the final visual interpretation of available preprocessed data in accordance with selected parameters – medical discipline, centrality type, cosine similarity threshold (see Fig. 2).

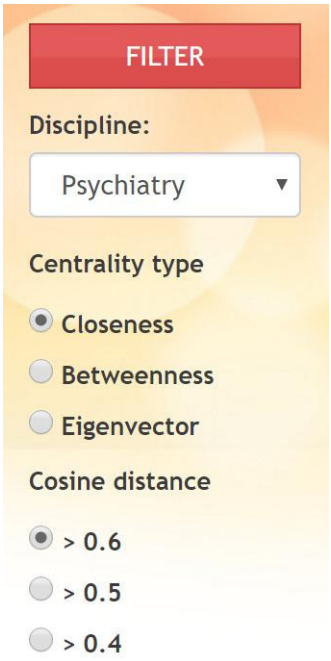

Fig. 2 The force-directed graph filter

E. Evaluation and Deployment

A checking procedure is performed in this stage in order to find the right meaning of analytical outputs. The obtained results were verified by representatives of the faculty management, in order to confirm the final interpretation [3]. Based on the assessment of the graphical presentation of the subject Psychiatry we decided that the best threshold for cosine similarity is 0.6 (see Fig. 1) and the most suitable centrality type is closeness. Table II shows keywords concerning different type of centrality. As you can see the first column (type of centrality – closeness) includes keywords especially in view of the clinical description of psychiatric illness, the second column (type of centrality – betweenness) cannot be held as summary of clear signs of typical keywords rather confusing mix of terms and third column (type of centrality – eigenvector) includes keywords focused on describing the pathophysiology and chemical substances important in Psychiatry, followed by keywords of clinically important symptoms of disorders as well as therapeutic modalities and drugs. So, different type of centrality enables to view the discipline from different perspectives through the different sample of keywords. What has to be highlighted that when we used higher cosine similarity we could identify less duplicate terms and terms which are not describing the key issues (as nouns or verbs) and we could identify them as „stop-words“ without any informative value.

19	psychiatric	particular	prefrontal
20	emotional	emotional	benzodiazepines

III. Discussion

The possibility to graphically visualize and interpret medical curriculum and content of the individual courses through keywords from different scientific disciplines allow teachers to identify the main issues discussed in the concrete tuition. The identification could help them to explore whether the main keywords correspond to any other keywords as descriptors of the main themes or major topics representing individual similarly or differently oriented teaching units. We have used the dynamic visualization using force-directed graph with clusters of key points (point graphs) and tables while we have identified 50 keywords as a border (maximum evaluated number of keywords for one visualization).

We could say that generally description of Nursing disciplines is not so straightforward, clear and simply as for Psychiatry. This can be explained mainly by the fact that the content of the discipline is very inhomogeneous. From the description of the summary of keywords for nursing evidently arise higher amount of duplicated terms and "empty" or so-called "stop words", which do not bring additional value for improvement of orientation in the curriculum content not only for teachers neither for students. This fact should not affect the view of usability of curriculum content visualization but rather to encourage the prudent use and analyses of the information gathered and from data mining and also in feedback when assessing the homogeneity of data.

IV. Conclusion and Future Work

In this work we have proposed a novel method for identifying key terms from a free text covering medical curriculum. This method is based on computing node centralities in a similarity graph of terms contained in the given medical and healthcare discipline description, whereas the similarity is obtained by a popular word2vec model. First results seem to be promising in terms of face validity. Methodologically sound evaluation of this method and comparison with traditional methods of keyword extraction - even on different domains - is a current issue. Centrality measures in word2vec graphs can also serve as features in supervised machine learning algorithms for keyword extraction. In the near future this approach is also planned to be investigated.

***Abstract*— Automated hand detection is useful for applications requiring reliable hand posture and hand gesture processing. Such applications include human-computer/human-robot interfaces for rehabilitation, serious games, or non-invasive medical diagnosis. Hence, in this paper, we focus on the design and development of a robust and fast hand detection and tracking (HD) system. The design of our HD system involved the study of the human skin colour and people's foreground properties, in order to merge these information for an efficient hand detection and tracking. Experiments have been carried out in real-world environment and have demonstrated the excellent performance of our HD system.**

I. Introduction

Hand detection and tracking are the actions of automatically locating and following human hands to extract information useful for various applications, which involve interactions of humans with computers (HCI) [1] through interfaces such as mouses [2], gloves [3], interactive tables [4], or natural gestures [5].

Automated hand detection could be applied for multimodal interactions of humans within augmented-reality frameworks, e.g. game control [6], character animation [7], etc., or it could be used for secure and safe interactions of humans within real-world environment. Indeed, hand detection could be used in biometrics [8], since palms of the human hands contain unique patterns of ridges and valleys, in the same way that fingerprints, whereas presenting much larger areas and thus being even more distinctive than the fingerprints [9]; in surveillance for abnormal behaviour detection [10] or in crime prevention [11].

Medical applications involving the monitoring of human interaction with robots (HRI) [12] can embed hand detection, e.g. for functional rehabilitation [13] such as exercises of patient's interaction with objects s/he grasps [14] to improve stroke recovery [15].

Moreover, hand detection and tracking is promising in diagnosis of neurologic disorders such as Parkinson's disease. Indeed, this progressively degenerative movement disorder [16] implies quantitative evaluations of hand movement as well as hand tremor for neurological examination [17]. These measurements could be based on the visual tracking of patient's hand motion [18] or on the paced finger tapping test [19] assessed with visual rating scales such as the Unified Parkinson's Disease Rating Scale (UPDRS), rather than on the traditional invasive methods such as electroencephalograms (EEGs) [20].

Other applications of hand detection and gesture recognition could improve the communication and interaction of people presenting difficulties [21]. For example, hand detection in context of sign language could help deaf people naturally interacting with machines or non-deaf people interacting with deaf ones [22].

The main challenge of vision-based hand detection is to cope with the large variability of human hand's appearance due to a huge number of degrees of freedom (DoFs) of the hand's movements, to different skin-colour possibilities as well as to the variations in view points, scales, and speed of the camera capturing the scene [21].

Hence, hands have been represented as 2D [23] or 3D models [24], and various methods have been proposed, involving eigen-based hand model [25], hand/not-hand SVM classifier [26] or AdaBoost-based hand detector [27], to automatically recognize human hands in images or videos. Despite their effectiveness, these methods lack of detection accuracy in some real situations.

In this work, the adopted approach for hand detection is focused on robustness, and it combines threshold-based colour detection with background subtraction. Moreover, enhanced Adaboost face detection [28] is used to differentiate hands from the human face region, while hand tracking is achieved by adding the foreground extraction obtained from one frame to another.

Hands could be visually detected or tracked by a range of sensors [29], such as ego-centric/self-mounted cameras [30], stereo camera [31], or Kinect [32]. In this paper, we focus on hand detection and tracking solely based on a single, static camera feed, which is a non-invasive and low-cost solution, leading to a convenient, computer-vision-based system.

The product developed in this work is capable of both effectively detecting human hands without building a hand model, but instead applying pixel thresholding based on a skin-colour model, and efficiently tracking an individual's hand movement based on the foreground blob and background subtraction information. This HD system could be used for numerous real-world purposes, and in particular for medical applications.

The original contribution of our work is twofold and consists in the design and development of a new hand detection and tracking system based on features such as colour and motion as well as in a study of the colour skin appearance within YCbCr colour space.

978-83-60810-90-3/$25.00

The paper is structured as follows. In Section II, we present our hand detection and tracking (HD) system, while in Section III we report and discuss the carried out experiments which results show the developed HD system has excellent performance on real-world video datasets. Conclusions are drawn up in Section IV.

II. Our Method

The developed HD system as depicted in Fig. 1 uses skin-colour thresholding as explained in Section II-A. Foreground detection and background subtraction are described in Section II-B. Head detection is computed in order to discard that region to improve hand detection accuracy in case of full-body tracking as mentioned in Section II-C. Moreover, the fusion of all the computed information to detect the hands as well as the tracking process of the hand are presented in Section II-D.

A. Skin-Colour Detection

Let us consider a colour image or video frame $I(x, y)$ with M and N, its width and height, respectively.

At first, our system performs skin thresholding [33]. Among major colour spaces such as RGB [34], HSV [35], or YIQ [36], our system uses YCbCr colour space for thresholding to distinguish between skin and non-skin colours. Indeed, the YCbCr colour space is the most popular choice in skin-colour detection methods, because its luminance component Y as well as chrominance components Cb and Cr are separated and could be easily computed from RGB values [37]. This RGB-YCbCr transformation possibility as well as the explicit separation of luminance and chrominance components, which furthermore brings some degree of robustness to illumination variations [38], make this colour space attractive for skin-colour modeling [39].

Moreover, YCbCr colour space is used in our work due to the fact it has a good skin feature clustering as different human skin colours from different races fall in a compact region in the YCbCr colour space [40]. On the opposite, the RGB colour space, which is the basic colour space of image processing, cannot be segmented by simple thresholding [41], because RGB colour space has perceived non-uniformity [42]. Although it may be possible to detect one skin colour using other colour spaces, it would be not possible to detect with the RGB colour space the perceived colour of human skin which varies greatly across human races or even between individuals of the same race. So, to increase invariance against illumination variability, our HD system operates in the YCbCr colour space in order to approximate the chromaticity of skin rather than its apparent colour value.

Indeed, in our system, the distribution of skin pixels values is highlighted based on Cb and Cr components [40] as an additional threshold conditions reported in Fig. 2, whereas the luminance component is eliminated to remove the effect of shadows, illumination changes, and modulations of orientation of the skin surface relative to the light source(s) [38].

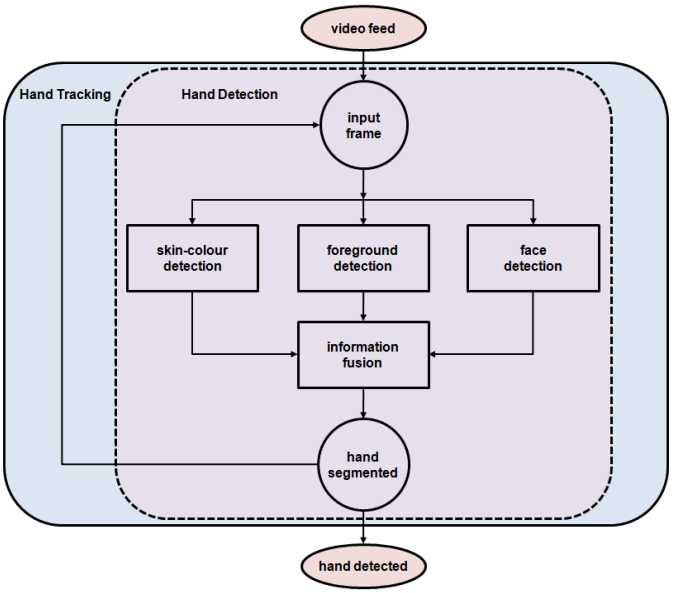

Fig. 1. Overview of our hand detection and tracking (HD) system.

So, the adopted YCbCr colour threshold detection values are as follows:

$$Cb = 0.148 \times R - 0.291 \times G + 0.439 \times B + 128, \quad (1)$$

$$Cr = 0.439 \times R - 0.368 \times G - 0.071 \times B + 128, \quad (2)$$

where the skin region is segmented based on the thresholding values [43] defined as $140 \leqslant Cb_{skin} \leqslant 195$ and $140 \leqslant Cr_{skin} \leqslant 165$.

B. Foreground Detection

To extract the foreground blob, we combine frame difference and background subtraction techniques [44]. This consists in computing in parallel, on one hand, the difference between a current frame $I_k(x, y)$ and the previous one $I_{k-1}(x, y)$, and on the other hand, the difference between the current frame $I_k(x, y)$ and a background model of the scene, and afterwards, to combine both results in order to extract the foreground in the corresponding view [44]. It is worth noting that background subtraction is based on the assumption that the camera does not move with respect to the static background.

To model the background, we adopt the running Gaussian average (RGA) [45], which is suitable for real-time tracking, and which is characterized by the mean μ_b and the variance $(\sigma_b)^2$.

Hence, the foreground is determined by

$$F(x, y) = \begin{cases} 1 & \text{if } |F_f(x, y) \cup F_b(x, y)| = 1, \\ 0 & \text{otherwise,} \end{cases} \quad (3)$$

with

$$F_f(x, y) = \begin{cases} 1 & \text{if } |I_k(x, y) - I_{k-1}(x, y)| > tf, \\ 0 & \text{otherwise,} \end{cases} \quad (4)$$

and

$$F_b(x,y) = \begin{cases} 1 & \text{if } |I_k(x,y) - \mu_b| > n \cdot \sigma_b, \\ 0 & \text{otherwise,} \end{cases} \quad (5)$$

where tf and $n \in \mathbb{N}_0$ are the thresholds for frame difference and background subtraction processes, respectively [44].

Finally, to compute a blob defined by labeled connected regions, morphological operations [4], [46], such as dilation, filling, etc. are applied to the extracted foreground F, in order to exploit the existing information on the neighboring pixels, in the frame:

$$f(x,y) = Morph(F(x,y)). \quad (6)$$

C. Face Detection

Face detection is performed using the lighting-variable Adaboost algorithm [28], relying on global image intensity [28] and Haar-like features [47] rather than face skin-colour as in [48], in order to robustify the HD system against illumination changes.

Hence, based on the gray image $I_g(x,y) = 0.299\,R(x,y) + 0.587\,G(x,y) + 0.114\,B(x,y)$,, the average value $I_{g_{AVG}}$ of the global image intensity is defined as

$$I_{g_{AVG}} = \frac{1}{M\,N} \sum_{x=1}^{M} \sum_{y=1}^{N} I_g(x,y), \quad (7)$$

while local Haar-like features f [47] encode the existence of oriented contrasts between regions in the processed image, and are computed by subtracting the sum of all the pixels of a subregion of the local feature from the sum of the remaining region of the local feature using the integral image representation $II(i,j)$ which is defined as follows:

$$II(i,j) = II(i-1,j) + II(i,j-1) - II(i-1,j-1) + I(i,j), \quad (8)$$

where $I(i,j)$ is the pixel value of the original image at the position (i,j).

This detection system requires a training phase during which it builds strong classifiers based on cascades of weak classifiers [28]. In particular, to form a T-stage cascade, T weak classifiers are selected using the AdaBoost algorithm [47]. In fact at a t stage of this cascade, a sub-window u of an image from the training set is computed by Eq. (8) and it is passed to the corresponding t^{th} weak classifier. If the region is classified as a non-face, the sub-window is rejected. If not, it is passed to the $t+1$ stage, and so forth. Consequently, more stages the cascade owns, more selective it is, i.e. less false positive detections occur. However, that could lead to the increase in the number of false negative detection.

In order to select at each t level (with $1 < t < T$) the best weak classifier, an optimum threshold θ_t is computed by minimizing the classification error due to the selection of a particular Haar-like feature value $f_t(u)$. The resulting weak classifier k_t is thus obtained as follows:

$$k_t(u, f_t, p_t, \theta_t) = \begin{cases} 1 & \text{if } p_t f_t(u) < p_t \theta_t, \\ 0 & \text{otherwise,} \end{cases} \quad (9)$$

where p_t is the polarity indicating the direction of the inequality.

Then, a strong classifier $K_T(u)$ is constructed by taking a weighted combination of the selected weak classifiers k_t according to

$$K_T(u) = \begin{cases} 1 & \text{if } \sum_{t=1}^{T} \alpha_t k_t(u) \geq \frac{1}{2} \sum_{t=1}^{T} \alpha_t, \\ 0 & \text{otherwise,} \end{cases} \quad (10)$$

where $\frac{1}{2} \sum_{t=1}^{T} \alpha_t$ is the AdaBoost threshold and α_t is a voting coefficient computed based on the classification error in each stage t of the T stages of the cascade [47].

Next, the lighting-adaptable strong super-classifier $\mathcal{K}(u)$ is defined as

$$\mathcal{K}(u) = \begin{cases} K_L(u) & \text{if } I_{g_{AVG}} > I_{g_{th}}, \\ K_D(u) & \text{if } I_{g_{AVG}} \leq I_{g_{th}}, \end{cases} \quad (11)$$

where $I_{g_{th}}$ is the global image intensity threshold and where D and L (with $D \geq L$) are the numbers of the weak classifiers for dark and light images, respectively.

In this way, the system allows to automatically select the number of stages of the AdaBoost cascade accordingly to the lighting conditions expressed in Eq. (11) by $I_{g_{AVG}}$ and could be applied on any new input frame [28].

D. Hand Detection and Tracking

Information fusion between the skin-colour detection, foreground detection, and additional face detection is performed in order to detect the hand(s) as illustrated in Fig. 1. Indeed, the skin detection (Section II-A) allows the HD system to remove the forearm from the detected foreground (Section II-B), while the hand blob complements the skin-detected region in order to have a precise detection of the human hand(s) as shown in Fig. 3 (d). In case a face is detected (Section II-C) in a frame containing the full body, this head region is discarded to avoid confusion between regions containing skin colour and to extract only hands' regions as in Fig. 4 (d).

As the detection method is fast enough to operate at image acquisition frame rate, it can be used for hand tracking. Tracking hands is difficult since hands can move very fast and their appearance can change vastly within a few frames. Tracking hands is defined in the HD system as the frame-to-frame correspondence of the segmented hand regions (see Fig. 1). Tracking provides the inter-frame linking of hand/finger appearances. This provides trajectories of features in time. These trajectories convey essential information regarding the gesture [38] and might be used either in a raw form (e.g. in hand-guided control applications) or after further analysis (e.g. in hand gesture recognition).

III. Experiments and Discussion

Our HD system and its components have been tested on real-world videos captured at 25f/s and with a resolution of 640x360 pixels. All the experiments have been carried out on a computer with an Intel Core (TM) 2 Duo CPU @2.5GHz processor, with a 2Gb RAM, and running MatLab software.

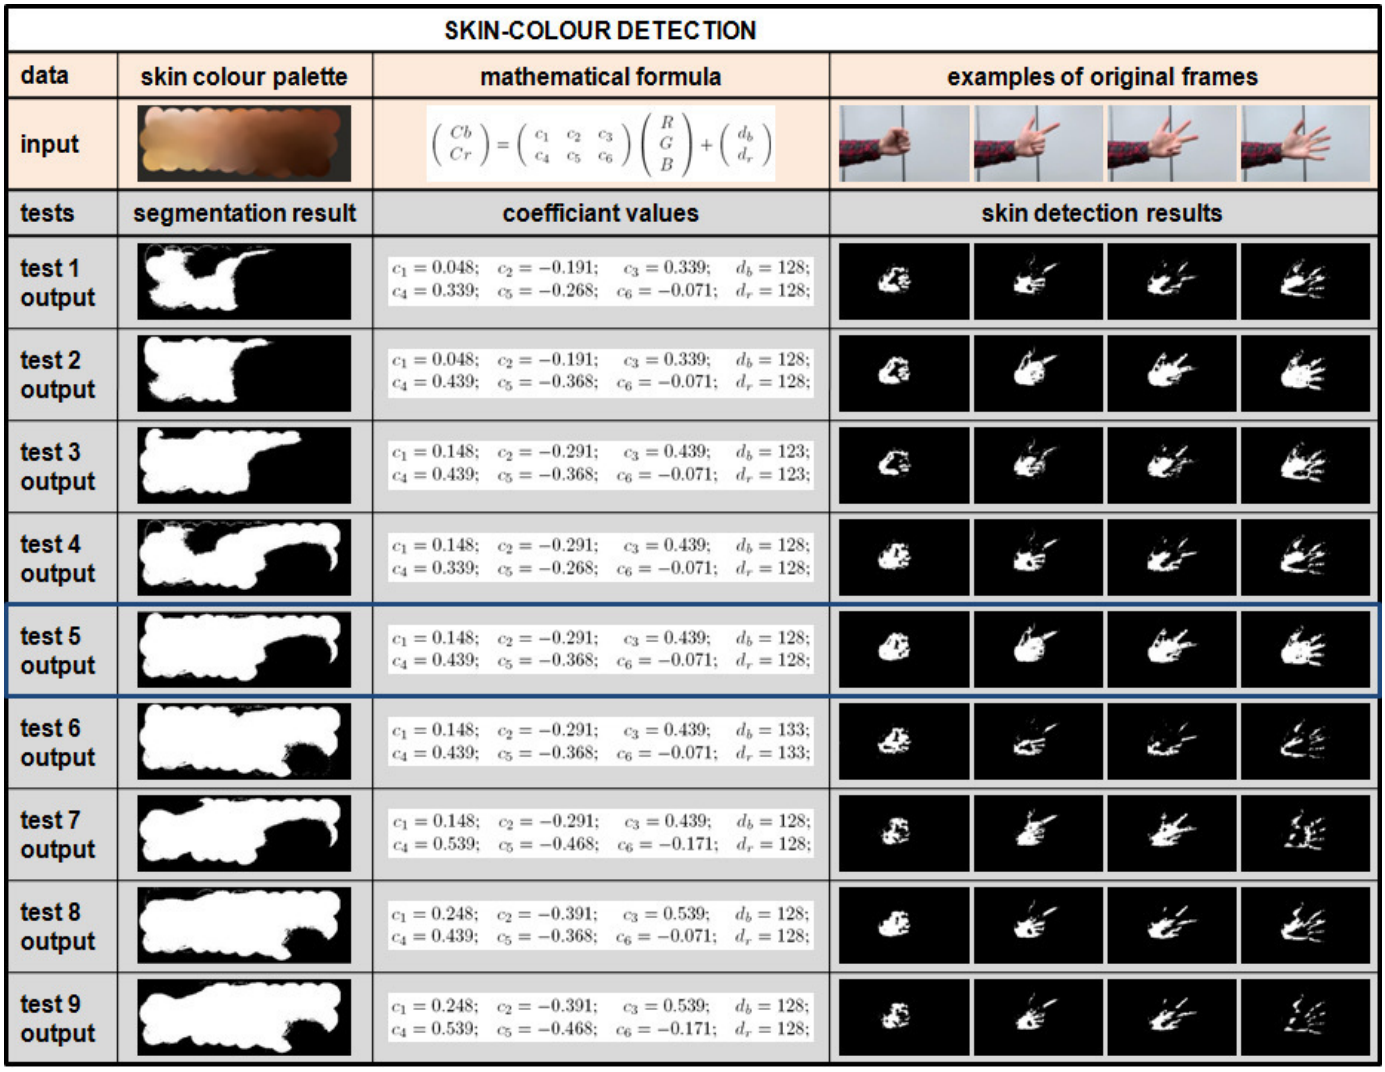

Fig. 2. Results of the skin-colour modeling and detection tests with different coefficient values.

A. *Experiment 1*

The first experiment consists in skin-colour detection and it evaluates the colour distributions from the hand in order to improve overall detection performance as illustrated in Fig. 2. Indeed, in the YCbCr colour space, Cb and Cr channels are employed owing to their relative insensitivity to the lighting variations [49].

In test 1, decreasing both $c1 - c3$ and $c4 - c6$ coefficient values came to no positive effect, showing a decrease in lighter and darker skin tones compared to the original palette, and resulting in poor hand detection. In test 2, decreasing $c1 - c3$ threshold values reduces system's capability to detect darker skin regions, and thus is not recommended to use with different skin tones and environmental changes e.g. light, shading and backgrounds. The purpose of the test 3 is to determine if changing the end values for both $c1 - c3$ and $c4 - c6$ thresholds would have any effect on results. The difference is easy to see between this test and the original, as the darker skin region is not significantly detected. In test 4, decreasing the $c4 - c6$ values demonstrated no positive changes to that of the original one. Lighter skin tones are not as visible and darker ones have not particularly changed. Once again, this can be demonstrated within frame results as, in this case, half of the hand seems missing in some frames. In test 5, this model accepts a wide range of skin colours, although it can be seen within the skin colour palette that it has had issues with detecting darker skin regions. In test 6, most of skin regions of the palette have been detected. However, within the frames tested, one can see that less of the hand is detected. Within test 7, darker regions have had minimal change between this and the original palette, but it is the lighter skin tones that have lost parts. This is demonstrated within the frame results as the hand in some frames becomes barely visible. In test 8, it is noticeable that the detection of darker region has increased, although it has also decreased detected regions within lighter skin tones. This can also be highlighted within the same test on the running frames, as in many parts of the hands, detection is missed. In test 9, by increasing both $c1 - c3$ and $c4 - c6$ coefficient

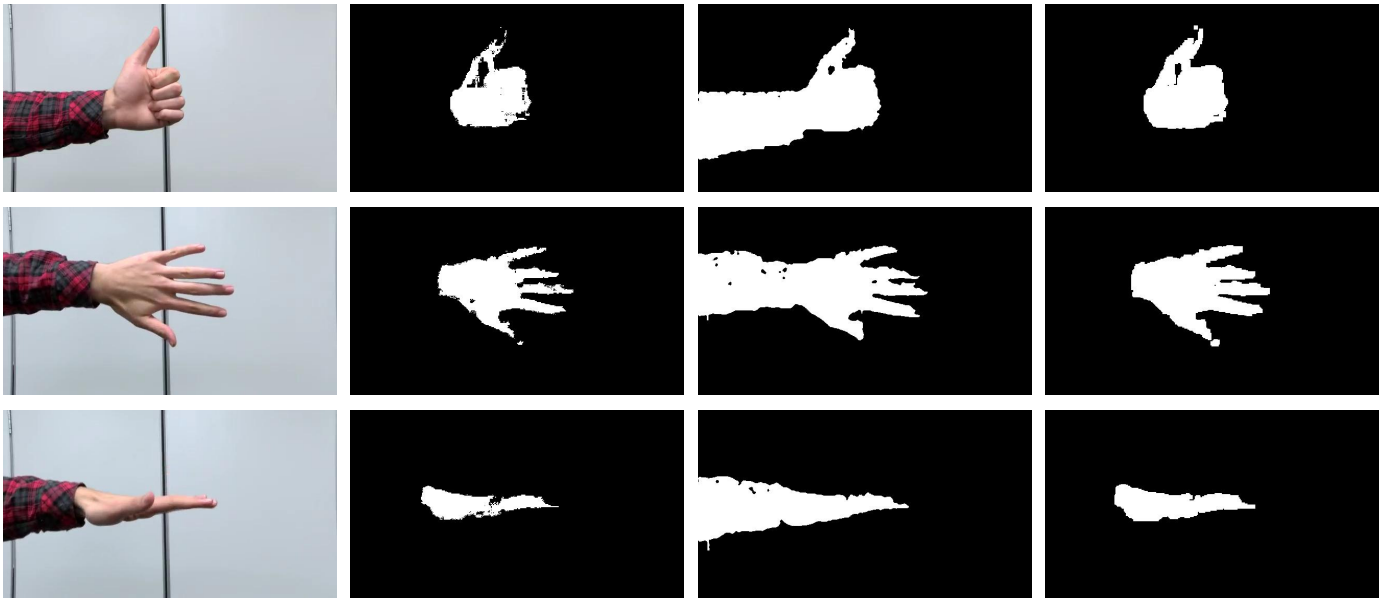

Fig. 3. Samples of our HD system for (a) input frame (1st row: frame 91, 2nd row: frame 288, 3rd row: frame 374); (b) skin-colour detection; (c) foreground detection; (d) hand detection.

values at the same time, there is a decrease within the detection of lighter skin tones and an increase in detection of darker skin tones. However, it is very prone to noise as demonstrated within each of the tested frames.

Finally, the adopted model is the one from the test 5, since the palette has been well respected and the hand has been the most clearly detected in all frames.

B. Experiment 2

Experiment 2 considers the hand detection in sequences without visible face. So, it tests the skin-colour detection and the foreground detection as well as the fusion of the related information for the hand detection.

Moreover, the background noise removal value was tested between the range of 0 and 1000, and morphological methods were also attempted. The skin colour was set to range of values in proportion to standard skin colours as described in Section III-A, the challenge being to detect darker shades of skin, nails, red tints within skin and shadows.

Results demonstrate the effectiveness of our HD system, since at all time the hand (Fig. 3(a)) is correctly detected (Fig. 3(d)), leading to 100% accuracy. Figure 3 clearly shows the blobs of the skin-detected wrist (Fig. 3(b)) and the foreground forearm (Fig. 3(c)) as well as the combined final result provind the detected hand (Fig. 3(d)) in each frame.

C. Experiment 3

The third experiments are testing the entire HD system for scenarios where other commonly visible, skin-colour-like body parts appear in the frames (Fig.4(a)), the face for instance. Hence, the HD system computes the skin colour objects (Fig. 4(b)), the foreground (Fig. 4(c)) as well as the face (Fig. 4(d)) which is detected within the frame by the lighting-variation-robust cascade object detector. Then, the HD system uses this information to remove the detected face blob, while the remaining skin-colour objects and the foreground are combined together in order to allow accurate hand detection (Fig. 4(e)).

The hand itself has been detected at all times, which gives a 100% detection rate, which is an excellent results compared to typical values for hand detection using blob approach (96.77%) [50], Histogram of Gradient (HOG) method (94.40%) [51], and Skin Colour Histogram of Gradient (SCHOG) technique (97.80%) [51]. Moreover, the running time of our overall HD system has been assessed, and it allows real-time hand tracking.

IV. Conclusions

The human hand has crucial importance to many actions that may occur in a person's day-to-day life, e.g. person-to-person interactions or person-to-object interactions. Hence, this paper focuses on the automatic detection of hands, with the use of background subtraction, foreground detection, and skin-colour thresholding methods. With these techniques combined, our HD system is capable of detecting human hands in a number of different scenarios such as person hand detection and tracking for Parkinson's disease diagnosis or for stroke recovery monitoring. Other potential applications could be 3D hand tracking [52] and gesture control for serious game [53], HRI and rehabilitation interactions [54] as well as individual finger processing for sign-language communication between deaf/non-deaf people [55].

***Abstract*—We deal with the problem of initial analysis of data coming from evaluation sheets of subjects with Autism Spectrum Disorders (ASDs). In our research, we use an original evaluation sheet including questions about competencies grouped into 17 spheres. In the paper, we are focused on a feature selection problem. The main goal is to use appropriate data to build simpler and more accurate classifiers. The feature selection method based on random forest is used.**

I. Introduction

AUTISM is a brain development disorder that impairs social interaction and communication, and causes restricted and repetitive behaviors. Autism spectrum disorders can dramatically affect a child's life, as well as that of their families, schools, friends and the wider community.

The main aim of our research is to adapt computational intelligence methods for computer-aided decision support in diagnosis and therapy of persons with ASDs. In the first step of our research, we are interested in initial analysis of data coming from evaluation sheets of subjects with ASDs. The evaluation sheet, we use in the research, is an original sheet including questions (more than 300) about competencies of the subjects grouped into 17 spheres, among others, self-service, communication, cognitive, physical, as well as the sphere responsible for functioning in the social and family environment.

An initial analysis is focused on the data preprocessing step. The preprocessed data can be used to build simpler and more accurate classifiers. It is obvious, that an increasing number as well as complexity of classification rules make it difficult to be validated by domain experts. Experiments showed that in case of our evaluation sheet, over 300 features corresponding to questions (even divided into spheres) lead to less accurate classifiers with complex classification rules. Therefore, there is an important problem to select appropriate data to build (train) classifiers. In general, there is a variety of data preprocessing operations concerning both cases (instances) and features in datasets (cf. [1], [2], [3]). In [4], our consideration was focused on the case selection problem. Now, we deal with the feature selection problem.

Efficient analysis and retrieval of regularity from data is an extremely important task in the case of aggregation of vast amounts of data. Data mining processes are exposed to many aspects which cause failures. The large number of objects and variables, insignificance of some variables for the classification, interdependences between some part of variables, uneven distribution of target classes, and other difficulties are the reason to develop methods for effective selection of significant feature subsets.

There are three major categories of feature selection methods: filter, wrapper and embedded methods. The first one scores variables individually using different measures and eliminates some of them before a model is constructed [5]. In turn, wrapper methods investigate the prediction accuracy of a model directly measuring the value of a feature set. Although effective, the exponential number of possible subsets places computational limits for the wide data sets that are the focus of this work. The last type, embedded methods firstly develop a learning model and then analyze the model to estimate the relevance of a feature. Effects are dependent on methods used for model generation. During our experiments the Boruta algorithm [6] for feature selection was used.

Experiments showed that selected datasets enabled us to build simpler and more accurate classifiers, both decision tree based and rule based ones.

II. Input Data

Experiments which test the relative effectiveness of our approach have been performed on data describing over 70 cases (subjects) classified into three categories: high-functioning ($HIGH$), medium-functioning ($MEDIUM$), or low-functioning (LOW) autism. Each subject has been evaluated using an original sheet including questions about competencies grouped into 17 spheres marked with Roman numerals (only spheres used in our experiments are listed):

- VI. Support for active communication.
- VII. Active communication concerning objects, people, parts of the body.
- VIII. Imitation, the length and complexity of the utterance.
- IX. Needs, emotions, moods.
- X. Object communication (the level of specific symbols).
- XI. Symbolic communication.
- XII. Requests.
- XIII. Choices.
- XIV. Communication in a pair (with a contemporary, with an adult).
- XV. Social communication competences.
- XVI. Communication in a group and in social situations (in a team, at school, in the closest social environment).

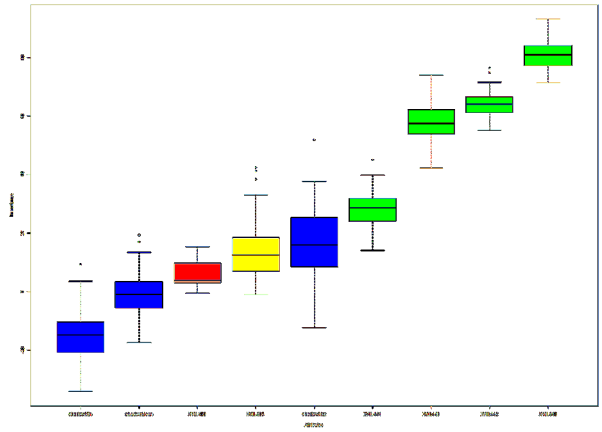

Fig. 2. Results of the feature selection process for sphere XVIII

TABLE I
A NUMBER OF FEATURES IN DATASETS

Dataset	#All features	#Confirmed features	#Tentative features
VI	18	5	4
VII	14	11	1
VIII	87	29	10
IX	51	21	6
X	3	1	0
XI	12	8	1
XII	9	1	2
XIII	14	11	3
XIV	13	11	1
XV	34	11	7
XVI	25	10	9
XVIII	6	4	1
XIX	7	6	1
XX	9	6	2
XXI	8	3	3
XXII	13	10	1
XXIII	13	8	2

- XVIII. Vocabulary.
- XIX. The degree of effectiveness of information.
- XX. The degree of motivation to communicate.
- XXI. The degree and type of hint in communication.
- XXII. Building the utterance - the degree of its complexity and functionality.
- XXIII. Dialogues.

Each case is described by over 300 features. Four values of features are possible, namely 0, 25, 50, and 100. They have the following meaning:

- 0 - not performed,
- 25 - performed after physical help,
- 50 - performed after verbal help/demonstration,
- 100 - performed unaided.

III. TOOLS

To solve a feature selection problem, we have used the Boruta algorithm. This algorithm applies random forest to determine all-relevant feature subset from datasets. It was designed as a wrapper method. Trees are independently developed on different bagging samples of the training set. The importance estimation of an attribute is gathered as the loss of accuracy of classification caused by a random permutation of attribute values between objects. It is computed separately for all trees in the forest which use a given attribute for classification. After that, the average and standard deviation of the accuracy loss are computed. Thus, the Z score computed by dividing the average loss by its standard deviation can be used as an importance measure [6], [7]. Boruta separates attributes into three categories:

- confirmed,
- tentative,
- rejected.

Figures 1 and 2 show some examples of results of feature selection processes. The confirmed attributes are marked with green, tentative - with yellow, and rejected with red.

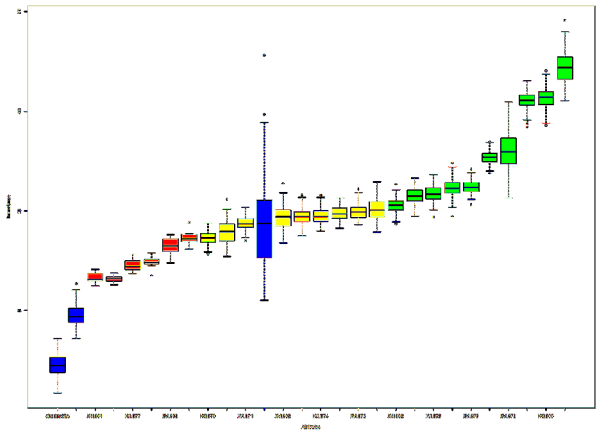

Fig. 1. Results of the feature selection process for sphere XVI

The datasets, after the feature selection processes, have been used to build decision tree and rule based classifiers.

For building classifiers, we have used two machine learning computer tools:

- RSES - a toolset for analyzing data with the use of methods coming from rough set theory [8].
- Orange - a comprehensive, component-based software suite for machine learning and data mining [9].

In RSES, we have used the LEM2 algorithm [10] for rule generation. LEM2 is most frequently used for rule induction. LEM2 explores the search space of feature-values pairs. It is based on lower and upper approximations of decision classes defined in rough set theory [11]. The expected degree of coverage of the training set by derived rules was set to 0.9. In a classification process, conflicts were resolved by standard voting (each rule has as many votes as supporting cases).

In Orange, we have used an algorithm for generation of decision trees based on the Gini criterion [1]. The following values of pruning parameters were set:

- minimum instances in leaves: 2,
- limit of the depth: 100.

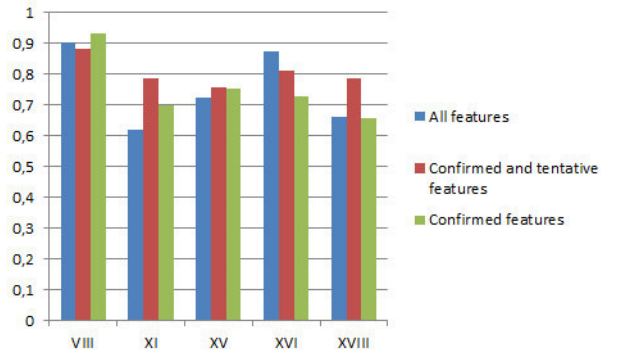

Fig. 5. Selected results of experiments with LEM2: classification accuracy

IV. Results

In this section, we give selected results of experiments with the Boruta feature selection algorithm and classification algorithms (the algorithm of decision tree generation implemented in Orange and the LEM2 algorithm for rule generation implemented in RSES).

In our experiments, each data set has been treated separately. It enabled us to assess the evaluation sheet with respect to individual spheres. The results can be used in further development of the sheet. In the future, any adding, removing, and modifying of questions are allowed. Especially, the questions corresponding to rejected features should be checked.

Table I shows the effects of applying a feature selection procedure in terms of a number of features. Next, we present the results of assessment of classifiers for selected datasets (spheres), see Figures from 3 to 8. To estimate the accuracy of classifiers, ten-fold cross-validation method was used.

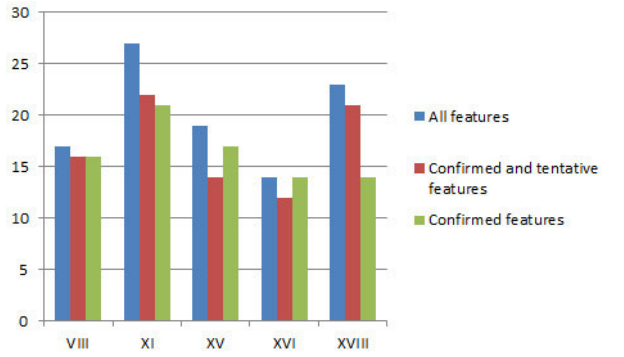

Fig. 3. Selected results of experiments with LEM2: a number of rules

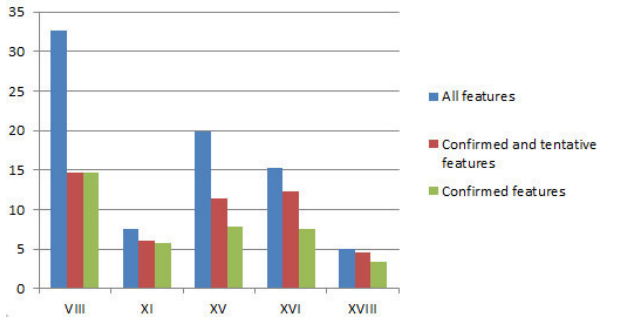

Fig. 4. Selected results of experiments with LEM2: mean of rule premise length

In case of complexity of classifiers, we have taken into consideration:

- a number of rules and mean of rule premise length (for a rule based classifier),
- a number of nodes and a number of leaves (for a decision tree based classifier).

In general, a feature selection procedure in the preprocessing step causes the decrease in the complexity of classifiers. In case of decision trees, a feature selection procedure positively influences the classification accuracy. In the case of rules generated by LEM2, taking into consideration the confirmed and tentative features seems to be more appropriate.

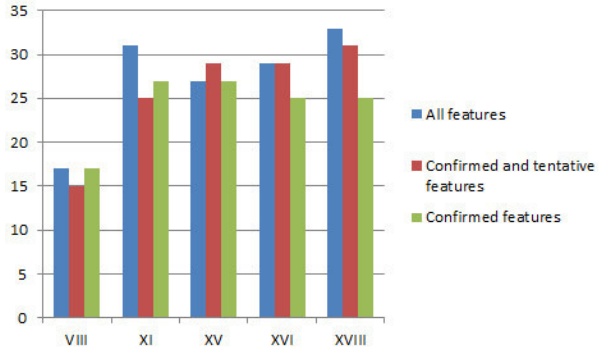

Fig. 6. Selected results of experiments with a decision tree: a number of nodes

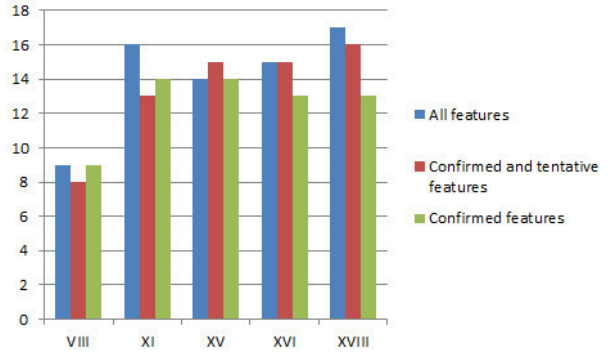

Fig. 7. Selected results of experiments with a decision tree: a number of leaves

V. Conclusions and Further Work

In the paper, we have examined the Boruta algorithm to solve the feature selection problem for data coming from evaluation sheets of subjects with Autism Spectrum Disorders (ASDs). Simultaneously our research is also focused on the case selection problem [4]. Our main goal is to create hybrid

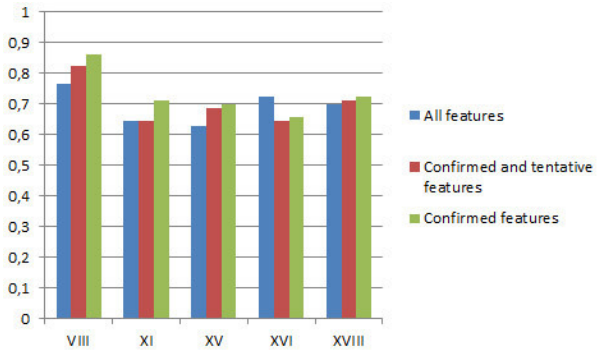

Fig. 8. Selected results of experiments with a decision tree: classification accuracy

classifiers combining a wide range of approaches that will be implemented in a dedicated computer tool supporting diagnosis and therapy of persons with ASDs.

***Abstract*—Body surface area (BSA) may be computed using a variety of formulas, but the computed BSA differs from real BSA values for particular subjects. This is presented in the paper by computing BSA values for selected subject and comparing them to the real BSA value obtained with the use of a 3D body scanner. The results show inequalities in the relevant BSA computing formulas. Hence, there is a need to determine a method that will allow to select the best formula for calculating BSA in a particular case. For this purpose, the pairwise comparisons (PC) method is suggested. This article presents a proposition of using consistency-driven PC, as well as the basic and most important aspects of using PC to determine the appropriate BSA calculation formula.**

I. Introduction

During the last century, many different body surface area (BSA) formulas have been developed for use as the indicator of patient-focused health outcomes [1]. Commonly used BSA formulas had been reported as having different properties and accuracy in determination of real BSA values.

BSA is a parameter commonly used in medicine, mainly in oncology and burns treatment [1], [2]. It is crucial to determine the exact BSA value of the patient with minimal error using only the knowledge of patient's height and weight. Height and weight can be relatively easy to obtain especially when working under time pressure, which makes those factors suitable for medical examination. The existing methods used to compute BSA prove to be inaccurate and may cause ineffective chemotherapy or burns treatment. This article presents a proposition for evaluation and selection of appropriate BSA formula. The consistency-driven pairwise comparisons (PC) method is proposed to be used as an examination method for choosing a BSA formula for individuals based on a series of weighted parameters. Pairwise comparisons were also used in [3]–[5].

II. BSA calculation methods

Since 1879 many BSA calculation formulas were developed, 25 of which are most common. To determine the BSA value these formulas use the patient's weight W (in kilograms) and in most cases also patient's height H (in centimetres). The formulas under question are listed in Table I.

III. BSA calculation errors

The early BSA calculation formulas were developed using different coating methods in order to obtain the patient's real BSA value. The accuracy of the methods depended not only on the type of mathematical approximation but also on the quality of the measuring methods. In the process of obtaining real BSA values the authors used subjects from a limited range of race, sex, and age, often generalizing the outcome BSA formula for an entire population.

In modern times, different methods of obtaining real BSA values were used. Still, when using the BSA calculation formulas the computed BSA values for the same patient vary in an extensive way. The results are not equal and differ one from another. This should not surprise when using old calculation formulas, but this regularity is true even for modern formulas.

To elucidate this phenomena a real BSA value was obtained from a female patient with the use of a body scanning device, specifically build for the purpose of scanning human bodies and obtaining high precision BSA. The scan was performed

with the use of Artec Eva 3D Scanner. The testes subject was a young 22-year-old female, of a body height of 171 cm and weight of 55.8 kg (Fig. 1a). After obtaining her real BSA value (1.633 m^2), formulas presented in Table I were used to calculate individual BSA values. The results are shown in Fig. 1b. For most cases the results are greatly inconsistent with the real BSA value. The calculated BSA values span from 1.538 m^2 (for the Meeh method) to 1.937 m^2 (for the Nwoye method). Fig. 2 presents percentage values of errors between the real BSA value obtained through scanning and the formulas shown in Table I. The errors show that in most cases the formulas indicate BSA values lower than the real one. When taking into consideration the Meeh and Nwoye formulas, the maximum error that can be made in calculating BSA is 24.46%. Therefore, it is important to develop the best method to select the right BSA calculation formula. For this purpose the PC model was selected.

To evaluate the above mentioned observation, a similar procedure concerning BSA calculation was performed in the case of 42 patients. The results are shown in Fig. 3. The patients used for this study were 20 to 28 year old, healthy Caucasians, both males and females. As it can be seen, the highest error values were obtained for the Nwoye method (12-15 percent in general) whereas the lowest error values characterizes the Yu, Lo and Chiou BSA calculation method (about 5 percent).

IV. DEFINITION OF WEIGHTS USED FOR BSA FORMULA SELECTION

The PC method requires describing weights that are used in the selection process. They should be distinctive to the analysed process and represent the subjective assessment performed by a specialist (e.g., a physician) on the scale from 0 to 5.

In the research process all scanned subjects can be divided to five groups based on their physique, age or medical history: normal, obese, after/during chemotherapy, elderly, and children. To each of these groups five factors are used in order to describe individual patients: degree of obesity, height to volume ratio, anthropological ancestry and race, type of body physique (athletic, deformed or similar), and degree of skin corrugation. The above mentioned classification and rating process is shown in Fig. 4.

V. THE PC METHOD PRELIMINARIES

The pioneer of PC is Condorcet [34]. He used PC in 1785 in the context of counting political ballots. In 1860, however, Fechner provided further, yet limited, psychometric information about this method. By way of refining the method, Thurstone [36] described the PC method as a statistical analysis and proposed a solution. In 1977 Saaty [37] introduced a hierarchy instrument for practical applications.

The PC method is outlined in Appendix A [31]–[33], [39]. It creates a matrix A of values a_{ij} of the i-th candidate (or alternative) compared with the j-th candidate. A scale $[1/c, c]$

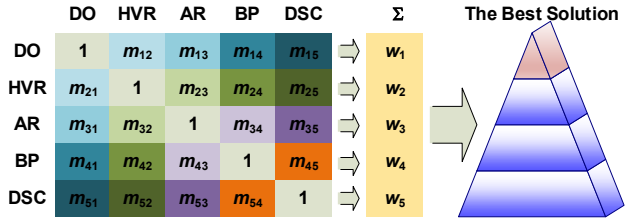

Fig. 5. The PC table of criteria and selection process.

is used for i to j comparisons where $c > 1$ is a small real number (5 to 9 in most practical applications). It is usually assumed that all the values a_{ij} on the main diagonal are equal to 1.

Using a scale of 1 to 5, the relative importance of each of the five groups are entered and objects are compared in the smallest subgroup. For example, degree of obesity and height to volume ratio are compared to each other in the subgroup and given 4 out of 5 (which can be changed for every clinical case to which this instrument is applied). In the case of inconsistency of the resulting matrix, the following formula [32] can be applied:

$$ii = \min(|1 - a_{ij}/(a_{ik} \cdot a_{kj})|,\ |1 - a_{ik} \cdot a_{kj}/a_{ij}|) \quad \text{for } i = 1,\ j = 2, \text{ and } k = 3 \qquad (1)$$

An example of a PC table of criteria and the selection process is presented in Fig. 5. The above presented factors are compared and relevant comparison values are assigned. Then the summed up weights of particular rows are compared with each other, thus providing an indicator for which of the tested solution is the best in the case.

As explained by Koczkodaj [32], [39], the weights w_1 to w_5 are computed as normalized geometric means of the matrix rows. The example is presented to illustrate the method, not the real instrument.

VI. Conclusion

BSA is often a major factor in determining of the course of treatment. A series of formulas to simplify the process have been developed throughout the years. However, the choice of a particular formula is a difficult task. Therefore, there is a need to develop additional methods to help in the selection of an appropriate formula for individuals.

Although the PC method was originally used over 200 years ago, it has not been utilised to refine the properties of quality of life instruments. The method can strengthen the BSA calculation instrument by providing an additional layer of selection.

Evidently, not all objects on the BSA instrument are of equal importance. Appreciation of their relative differences adds to the measure's precision. The inconsistency analysis further strengthens the measure by bringing the most problematic but often crucial comparisons of the instrument items. A challenge to the multiple experts in this tool's development can be "averaging" their individual assessments in the assumed model. Clinical trials and statistical analysis need to follow the model enhancement.

The proposition presented in this paper show that it is possible to use the pairwise comparison in order to select a BSA calculation formula conformed to a specific situation. The enhancement may be a challenging undertaking for years to come. Refinement of the BSA may improve understanding of physiology as well as improve health care professional practices in their efforts to assess quality of life.

APPENDIX A
BASIC CONCEPTS OF PAIRWISE COMPARISONS

An n by n pairwise comparisons matrix is defined as a square matrix $A = [a_{ij}]$ such that $a_{ij} > 0$ for every $i, j = 1, ..., n$. Each a_{ij} expresses a relative preference of criterion (or stimulus)s_i over criterion s_j for $i, j = 1, ..., n$ represented by numerical weights (positive real numbers) and w_i and w_j respectively. The quotients $a_{ij} = w_i/w_j$ form a pairwise comparisons matrix:

$$A = \begin{bmatrix} 1 & a_{12} & \cdots & a_{1n} \\ \frac{1}{a_{12}} & 1 & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{1}{a_{1n}} & \frac{1}{a_{2n}} & \cdots & 1 \end{bmatrix}$$

A pairwise comparisons matrix A is called *reciprocal* if $a_{ij} = 1/a_{ji}$ for every $i, j = 1, ..., n$ (then automatically $a_{ii} = 1$ for every $i = 1, ..., n$ because they represent the relative ratio of a criterion against itself). A pairwise comparisons matrix A is called *consistent* if $a_{ij} \cdot a_{jk} = a_{ik}$ holds for every $i, j, k = 1, ..., n$ since $w_i/w_j \cdot w_j/w_k$ is expected to be equal to w_i/w_k. Although every consistent matrix is reciprocal, the converse is not generally true. In practice, comparing of s_i to s_j, s_j to s_k, and s_i to s_k often results in inconsistency amongst the assessments in addition to their inaccuracy; however, the inconsistency may be computed and used to improve the accuracy.

The first step in pairwise comparisons is to establish the relative preference of each combination of two criteria. A scale from 1 to 5 can be used to compare all criteria in pairs. Values from the interval $[1/5, 1]$ reflect inverse relationships between criteria since $s_i/s_j = 1/(s_j/s_i)$. The consistency driven approach is based on the reasonable assumption that by finding the most inconsistent judgments, one can then reconsider one's own assessments. This in turn contributes to the improvement of judgmental accuracy. Consistency analysis is a dynamic process which is assisted by the software.

The central point of the inference theory of the pairwise comparisons is Saaty's Theorem [37], which states that for every n by n consistent matrix $A = [a_{ij}]$ there exist positive real numbers $w_1, ..., w_n$ (weights corresponding to criteria $s_1, .n.., s$) such that $a_{ij} = w_i/w_j$ for every $i, j = 1, ..., n$. The weights w_i are unique up to a multiplicative constant. Saaty (1977) also discovered that the eigenvector corresponding to the largest eigenvalue of A provides weights w_i which we wish to obtain from the set of preferences a_{ij}. This is not the only possible solution to the weight problem. In the past, a least squares solution was known, but it was far more computationally demanding than finding an eigenvector of a matrix with positive elements. Later, a method of row geometric means was proposed (Jensen, 1984), which is the simplest and most effective method of finding weights. A statistical experiment demonstrated that the accuracy, that is, the distance from the original matrix A and the matrix AN reconstructed from weights with elements $[a_{ij}] = [w_i/w_j]$, does not strongly depend on the method. There is, however, a strong relationship between the accuracy and consistency. Consistency analysis is the main focus of the consistency driven approach.

An important problem is how to begin the analysis. Assigning weights to all criteria (e.g., $A = 18, B = 27, C = 20, D = 35$) seems more natural than the above process. In fact it is a recommended practice to start with some initial values. The above values yield the ratios: $A/B = 0.67$, $A/C = 0.9$, $A/D = 0.51$, $B/C = 1.35$, $B/D = 0.77$, $C/D = 0.57$. Upon analysis, these may look somewhat suspicious because all of them round to 1, which is of equal or unknown importance. This effect frequently arises in practice, and experts are tempted to change the ratios by increasing some of them and decreasing others (depending on knowledge of the case). The changes usually cause an increase of inconsistency which, in turn, can be handled by the analysis because it contributes to establishing more accurate and realistic weights. The pairwise comparisons method requires evaluation of all combinations of pairs of criteria, and can be more time consuming because the number of comparisons depends on n^2 (the square of the number of criteria). The complexity problem has been addressed and partly solved by the introduction of hierarchical structures [37]. Dividing criteria into smaller groups is a practical solution in cases in which the number of criteria is large.

APPENDIX B
CONSISTENCY ANALYSIS

Consistency analysis is critical to the approach presented here because the solution accuracy of *not-so-inconsistent* matrices strongly depends on the inconsistency. The consistency driven approach is, in brief, the next step in the development of pairwise comparisons.

The challenge to the pairwise comparisons method comes from a lack of consistency in the pairwise comparisons matrices which arises in practice. Given an n by n matrix A that is not consistent, the theory attempts to provide a consistent n by n matrix AN that differs from matrix A "as little as possible". In particular, the geometric means method produces results similar to the eigenvector method (to high accuracy) for the ten million cases tested. There is, however, a strong relationship between accuracy and consistency.

Unlike the old eigenvalue based inconsistency, introduced in [37], the triad based inconsistency locates the most inconsistent triads [32]. This allows the user to reconsider the assessments included in the most inconsistent triad.

Readers might be curious, if not suspicious, about how one could arrive at values such as 1.30 or 1.50 as relative ratio judgments. In fact the values were initially different, but have been refined and the final weights have been computed by the consistency analysis. It is fair to say that making comparative judgments of rather intangible criteria (e.g., overall alteration and/or mineralization) results not only in imprecise knowledge, but also in inconsistency in our own judgments. The improvement of knowledge by controlling inconsistencies in the judgments of experts, that is, the consistency driven approach, is not only desirable but is essential.

In practice, inconsistent judgments are unavoidable when at least three factors are independently compared against each other. For example, let us look closely at the ratios of the four criteria A, B, C, and D in Figure $C1$. Suppose we estimate ratios A/B as 2, B/C as 3, and A/C as 5. Evidently something does not add up as $(A/B)@\ (B/C) = 2 \cdot 3 = 6$ is not equal to 5 (that is A/C). With an inconsistency index of 0.17, the above triad (with highlighted values of 2, 5, and 3) is the most inconsistent in the entire matrix (reciprocal values below the main diagonal are not shown in Figure $C1$). A rash judgment may lead us to believe that A/C should indeed be 6, but we do not have any reason to reject the estimation of B/C as 2.5 or A/B as 5/3. After correcting B/C from 3 to 2.5, which is an arbitrary decision usually based on additional knowledge gathering, the next most inconsistent triad is (5,4,0.7) with an inconsistency index of 0.13. An adjustment of 0.7 to 0.8 makes this triad fully consistent ($5 \cdot 0.8$ is 4), but another triad (2.5,1.9,0.8) has an inconsistency of 0.05. By changing 1.9 to 2 the entire table becomes fully consistent. The corrections for real data are done on the basis of professional experience and case knowledge by examining all three criteria involved.

An acceptable threshold of inconsistency is 0.33 because it means that one judgment is not more than two grades of the scale 1 to 5 away (an off-by-two error) from the remaining two judgments. There was no need to continue decreasing the inconsistency, as only its high value is harmful; a very small value may indicate that the artificial data were entered hastily without reconsideration of former assessments.

***Abstract*—The classification of leukocyte subtypes is a routine method to diagnose many diseases, infections, and inflammations. By applying an automated cell counting procedure, it is possible to decrease analysis time and increase the number of analyzed cells per patient, thereby making the analysis more robust. Here we propose a method, which automatically differentiate between two white blood cell subtypes, which are present in blood in the highest fractions. We apply generalized pseudo-Zernike moments to transfer morphological information of the cells to features and subsequently to a classification model. The first results indicate that information from the morphology can be used to obtain efficient automatic classification, which was demonstrated for the leukocyte subtype classification of neutrophils and lymphocytes. The approach can be extended to other imaging modalities, like different types of staining, spectroscopic techniques, dark field or phase contrast microscopy.**

I. Introduction

WHITE blood cells (WBCs) are also called leukocytes. These cells protect the body from infections caused by viruses and other foreign invaders like bacteria or fungi, which make WBCs an important part of the immune system. Leukocytes are produced and derived from the bone marrow and circulate through the bloodstream. A change of the number of different WBC subtypes in the blood is utilized as marker for various diseases. Therefore a blood cell count is often utilized for a routine health examination or diagnosis of specific conditions of a patient. There are five major subtypes of WBCs [1], [2]:

- neutrophils (50-70%);
- lymphocytes (25-30%);
- monocytes (3-9%);
- eosinophils (0-5%);
- basophils (0-1%).

The ranges within the brackets display the percentage of the corresponding cell subtypes in the blood, which are typical ratios for a healthy person. There are various classification approaches, which can be roughly divided into manual and automated methods of cell classification.

The manual classification is performed by a pathologist through the subjective recognition of cell subtypes on microscopic images of stained cells. This type of analysis does not require complex equipment or highly specialized chemical reagents. To simplify the identification, cells are usually stained with the Kimura stain, which colors cell nuclei in blue. Manual differentiation between varying subtypes is accomplished based on characteristics of the cell morphology, like cell size, transparency, granularity, and the shape of the cell nucleus, which are the major differences between the subtypes. Manual classification is widely used in some specific cases of diagnosis and as a “gold standard” for scientific purposes. However, variation of cell morphology within the same cell subtype is very high, and manual classification efficiency is dependent on the pathologist’s qualification and experience.

On the other side, there are various automated classification methods, based on different physical and chemical characteristics of the cells. The main advantage of the automated devices is that they efficiently analyze large number of cells in a short time. Unfortunately, their analyzing workflows include very specific combinations of chemical and physical processes. The complexity of the analysis does not allow the design of a simple portable device. Therefore, automated blood cell counting machines are usually big and expensive.

An alternative approach is an automatic image analysis of microscopic images of stained cells. In a combination with a small camera this method can become a useful tool for doctors, providing them an instant access to the information about WBCs population at bedside of a patient. There are some studies that show efficient leukocyte identification [3], [4] and segmentation [5], [6] within microscopic images. However, these studies are focused on the leukocyte count without the classification of the leukocytes into subtypes. That leads to the loss of important information about the proportions of each cell subtype. In distinction to the mentioned studies, the current manuscript describes an algorithm for the classification

of WBCs, focusing on the textural features analysis of single cell images.

The concept of the work is to extract quantitative features related to the cell morphology from the microscopic images. Subsequently, these features are used to train and evaluate a statistical model for cell subtype identification. Moreover, the same type of images as for manual classification is used, therefore, this approach allows a direct comparison to the "gold standard". In order to use these images for an automated image analysis, standardization and preprocessing have to be carried out. However, during the pretreatment step, it is important to eliminate corrupting effects, such as uniformities in staining and lighting, but to keep the morphological information for further analysis steps.

The textural information extraction from preprocessed images can be carried out by various methods [7], [8]. However, image description by means of pseudo-Zernike (PZ) moments [9] was chosen for the cell subtype identification because it was proven to be a reliable method for the recognition of shapes [10], characters [11], [12], faces [13], [14], [15], and viruses [16]. An advantage of the representation by PZ-moments is that their absolute values are independent from image rotation, which is necessary due to random orientation of the cells on a microscopic slide. The PZ-moments are derived from PZ-polynomials, which are orthogonal to each other and can be used in further statistical analysis, thus an automated classification technique can be established.

The proposed automated cell classification method is aimed to combine the simplicity of the manual classification and the advantages of automatization. The approach is based on the analysis of images, which are similar to the images used for manual "gold standard" method and are produced by common microscopy from a blood sample after non-complicated preparation. On the other side, due to automatization, extremely short classification times and objectivity, comparable with a human observer, can be achieved.

II. Materials and Methods

A. Sample preparation

Leukocytes were isolated from the venous blood of patients admitted to the intensive care unit with informed consent according to the Ethics Committee of the Jena University Hospital (Ethic vote n 4004-02/14). Briefly, 2.7ml of blood in ethylenediaminetetraacetic acid (EDTA) was drawn freshly from an existing catheter using the BD monovettes. In case of healthy donor, blood (about 100μl) was collected from fingertip using lancet. Red blood cell lysis was carried out by mixing the blood with an ammonium chloride solution with a ratio of 1:5 in a 50ml falcon tube. After 5 minutes of incubation at room temperature (RT), the mixture was centrifuged for 10 minutes at 400g at RT. The WBC pellet at the bottom of the falcon tube was collected by discarding the supernatant and suspending it in a phosphate buffer solution (PBS). The WBCs were chemically fixed with 4% formaldehyde for 10 minutes, followed by washing the cells successively with PBS and 0.9% NaCl. The cells were coated on slides using cytospin and stained with a Kimura staining solution (which stains only the cellular nucleus) and washed with distilled water. The slides were dried at RT and stored at $4\,^{\circ}\mathrm{C}$ for maximum one hour until further use. The Kimura stained images of the WBCs (Fig. 1 *a,b*) were captured with an upright epifluorescence microscope (Axioplan 2, Carl Zeiss, Germany) equipped with an AxioCam HRc camera (Carl Zeiss, Germany). Images were acquired using Zeiss Axio Vert software (Carl Zeiss, Germany).

B. Calculations

All calculations reported in this work were carried out in Gnu R (version 3.0.2) [17] running on a Windows 7 Professional 64-bit system (Intel® Core™ i5-4570 CPU @ 3.20 GHz 2.70 GHz with 8GB RAM). In addition to the base R package, which contains the input/output, basic programming support, and arithmetic functions, some more specific algorithms were utilized from other packages. For orthogonal moment analysis the "IM" package [18] was used. A support vector machine (SVM) classification model was built with the "e1071" package [19]. Parallel computing was obtained by functions from "foreach" [20] and "doParallel" [21] package. K-means clustering from the "stats" package [17] was utilized for the background removal. The functions for principal component analysis (PCA), nonlinear least squares estimation, and the fast Fourier transform (FFT) are all contained in the base package [17]. JPEG files were loaded into the R environment via the "jpeg" package [22].

Prior to analysis, each image was converted from *sRGB* color space to *Lab* color space, one of the most common color spaces for image analysis applications. It was chosen due to the fact that, unlike additive or subtractive color models (for example *RGB* or *CMYK*), it is not optimized for image representation on a screen or for printing, but is adapted to cover the entire range of colors distinguishable by the human eye and to match the perception of these colors. In this color space, a and b components are related to chromatic color values. The L component of *Lab* color space closely matches the human perception of lightness, which allows to expect that in this representation cell subtypes can be identified based on their morphology. The conversion of the color space was performed by base R function "convertColor".

Subsequently to the color space conversion, other steps, such as noise reduction, background removal and intensity normalization were performed. The details of these preprocessing steps are described in the "Results and discussion" section.

C. Pseudo-Zernike (PZ) Moments

As mentioned previously, PZ-moments were chosen for feature extraction from the images. These orthogonal, complex-valued moments are defined on a unit disk and are widely used for pattern recognition. The PZ-moments can describe a 2-dimensional function on the unit circle. However, the function $f(x, y)$ can represent an image if two arguments, x and y, are related to a pixel position and the function value is related to

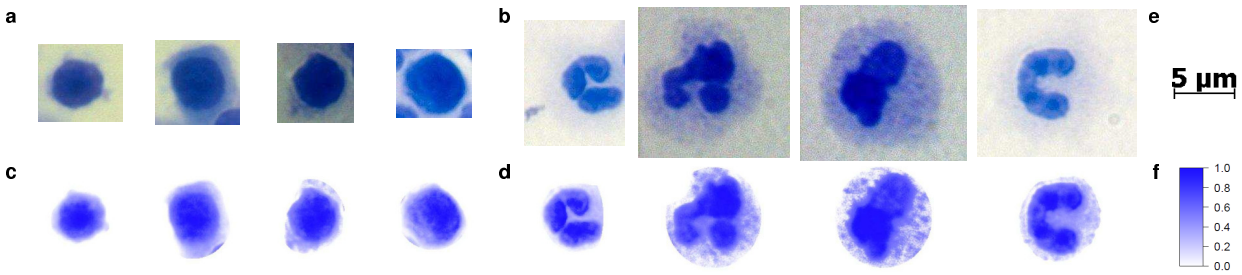

Fig. 1. Original images of two Kimura stained cell subtypes from the patients are displayed in the first row: lymphocytes (a), which are characterized by deep staining of the nuclei and a relatively small amount of cytoplasm, and neutrophils (b), which are the most common subtype that normally contain a nuclei divided into 2-5 lobes. All images are sized according to the scale (e). At the bottom preprocessed false-color equivalents of the presented images (c, d) normalized to the unit scale (f) are shown.

lightness or another color component in that pixel. The PZ-moments (A_{nl}) of an image on a unit disk are defined in radial coordinates by [23]:

$$A_{nl} = \frac{n+1}{\pi} \int_0^{2\pi} \int_0^1 [V_{nl}(r\cos\theta, r\sin\theta)]^* f(r\cos\theta, r\sin\theta)\, r dr d\theta \ .$$

In this equation $n = 0, \ldots, \infty$ represents the order, the repetition is denoted by $l \leq n$, and f is the value related to the current pixel position: $0 \leq r \leq 1$ and $0 \leq \theta \leq 2\pi$ (polar coordinates of the pixel). V_{nl} is the orthogonal set of complex-valued PZ-polynomials, which can be written as:

$$V_{nl}(r,\theta) = R_{nl}(r)\, e^{jl\theta} \ ,$$

where R_{nl} represents radial polynomials with integer coefficients $D_{n,m,s}$:

$$R_{nl}(r) = \sum_{s=0}^{n-|l|} D_{n,|l|,s} r^{(n-s)} \ ,$$

$$D_{n,m,s} = \frac{(-1)^s (2n+1-s)!}{s!(n-m-s)!(n+m-s+1)!} \ .$$

Both the order n and the repetition l are related to the spatial frequencies of the image. However, the order n represents the spatial frequency along the unit disk's radius, while the repetition l represents the spatial frequency along the unit disk's angular coordinate. Moreover, by clarifying the idea behind order n and repetition l, the respective moments can be interpreted. Therefore, the classification model can be checked, analyzed and the morphological differences between the cell subtypes can be examined.

As it is seen from the formulas, the angular coordinate is included in the PZ-moments only within the multiplier $e^{jl\theta}$, which is related to the phase of the complex value [9], [10], [12]. Due to this fact, the absolute values of moments are independent from a rotation of the coordinate system. Thus, they are independent from the spatial alignment of the cell within the image and from the orientation on the microscopic slide. Other advantages of these particular moments are their low sensitivity to noise [10] and that the PZ-moments are orthogonal to each other.

III. Results and Discussion

A. Data set

Taking into account the extremely low number of monocytes, eosinophils, and basophils in the data, only two major subtypes could be investigated in the current study. These both subtypes represent about 90% of WBCs in the blood and were included in the statistical evaluation. Thus, the training data included 28 lymphocytes and 45 neutrophils from 6 patients which were showing signs of inflammation. On the other side, the test data included 128 cells from two healthy volunteers. Unlike the training set, where some cell subtypes were sorted out, the test data included randomly selected cells without presorting or labeling according to their subtypes.

The cell subtypes included in the training data are different in sizes and cell nuclei morphology (see Fig. 1). Most notable is that the neutrophils are relatively big and have multi-lobed nuclei, while lymphocytes have almost round nuclei and are smaller. Other WBC subtypes, which were not included in the training data, are characterized by their granularity and the following properties of the cell nuclei: monocytes have kidney shaped nuclei, eosinophils have relatively small bi-lobed nuclei, and basophils have bi-lobed or tri-lobed nuclei. Although each subtype has a typical average cell size and other specific characteristics, each single cell varies from that average characteristics, which make some of its parameters dissimilar to the typical characteristics of its subtype.

B. Workflow

To obtain a stable and efficient analytical system, an image processing workflow was developed and optimized for the specific task of leukocyte subtype classification. The data was loaded, preprocessed, and represented as a set of pseudo-Zernike moments based invariants for further analysis. The workflow is presented in more detail in Fig. 2.

Important and nontrivial steps are the image preprocessing and standardization, which have to be optimized. These procedures should reduce the variations of brightness and color tones between the images of cells within the same sample and occasional appearing variations caused by the sample preparation routine for images taken from different samples. If

the workflow presented here is applied to other imaging modalities, like holographic imaging and phase contrast microscopy, these variations are expected to be less significant. Therefore, the preprocessing procedure has to be modified individually for each microscopic imaging technique and classification task.

For the construction of the classification model based on image analysis, the measured cells were labeled according to the classification made by the pathologist. The labeled and preprocessed training data were subsequently divided into three batches for cross-validation of the model. This step of the workflow was of enormous importance for setting model parameters and estimating the model quality. Thereafter, it should not be underestimated.

Leave-batch-out-cross-validation of SVM classification was performed on the training data with different combinations of input variables. This cross-validation procedure was designed to avoid any relations between different batches of cells. Therefore, the data splitting into three batches was arranged so, that the batch reflect the measurement dates and patient's origin. Thus, the generalization performance for the prediction of an independent dataset is well estimated by the leave-one-patient-out-cross-validation. Consequently, classification models with various numbers of PZ-moments' orders and principal components were compared. The variable selection was carried out according to the highest sensitivity for cross-validation of SVM classification model. The model with highest sensitivity was chosen as an optimal one and further used for the test data prediction.

Besides high identification efficiency, the proposed algorithm has to be suitable for real-life applications. Therefore, the workflow was optimized by parallelization of each single image loading, preprocessing, and calculation of the moments. Thereby, the parallelization on hardware with a multi-core processor should decrease the calculation time for a large amount of data roughly by a factor related to the number of calculation units. We chose the number of clusters for parallel calculation as one less than the number of processor cores, which was three for the PC on which the analysis was performed. During the preliminary study stage, the amount of data was relatively small, and thus, the parallelization of calculations had a negligible effect. However, despite the insignificant improvement on a small data set, parallelization is highly important for further applications and implementation of the algorithm, especially for the case if the number of analyzed cells is on the order of thousands.

C. Preprocessing

Examples of WBC images are shown in Fig. 1 *a,b*. As it can be seen by naked eye, differences between some images, which are not related to the cell's morphology, occur. These fluctuations originate from the sample preparation procedure, which is simple and standardized. There are some systematic deviations between the cells of different patients, but also the images of cells from the same patient can differ due to the spatial alignment of the cells and non-uniform coloring of samples along microscopic slides. Moreover, parts of other

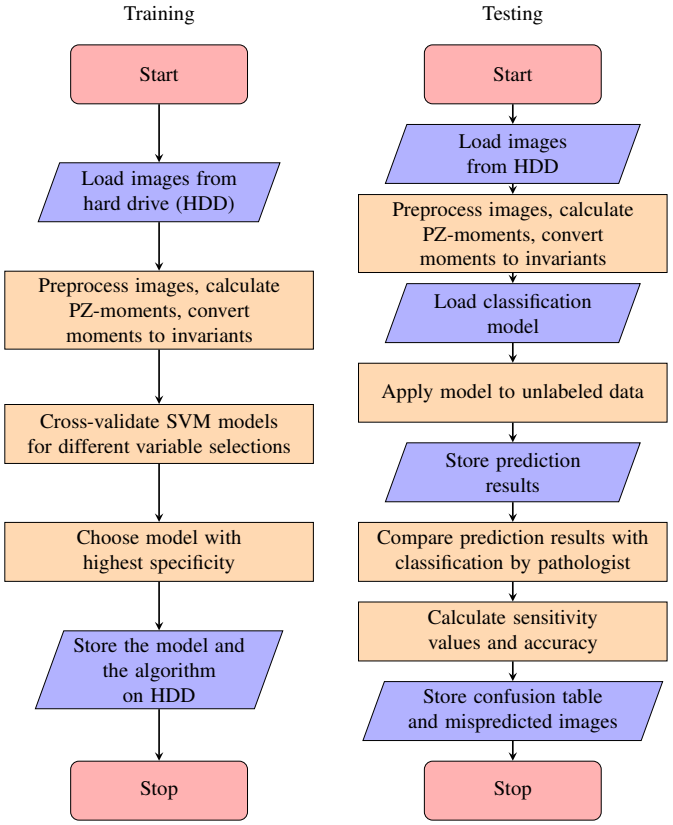

Fig. 2. Schematic workflow of the presented algorithm and the model validation.

cells are visible within some images and, additionally, other influences on the brightness, contrast, and tone are present on the microscopic images. To reduce the discussed corrupting effects, an advanced preprocessing has to be carried out before the feature extraction procedure.

According to the chosen concept of the analysis, it was important to keep the morphological features which can be distinguished visually. The automation of the preprocessing procedure took an important part in the development of the algorithm. The original images were stored in the standard *sRGB* representation, which is designed to display images in electronic systems, such as a computer's screens. However, analysis of the color channels separately from each other can be problematic and leads to a high complexity of the classification model. Switching to a single component can be circumvented by applying a more convenient color space. As it was mentioned in "Materials and methods", the lightness L of *Lab* color space is closely related to the human visual perception of images. In order to keep the features used for manual classification, the *Lab* color space was used in the further analysis. Moreover, the cells used for analysis were colored by Kimura staining, which highlights the cell nucleus in blue. Due to monochromatic coloring, all variations of the chromatic values are only related to the deviations of the sample preparation process and staining. Thus, related color components (a and b) were skipped and only the lightness

L was analyzed. However, for staining procedures which stain different cell organelles or cytoplasm in different colors, normalized a and b components should be also included in the analysis.

Due to high variations between different images, even for the single L-component, the automation of preprocessing took an important part in the analysis development. Pretreatment was aimed to decrease deviations of the features extracted from images within the same cell subtype and to increase the overall identification accuracy. Consequently, the background, or non-cell area of the images, was cut off via the unsupervised k-means clustering of lightness values within each image. In order to improve the background removal, an FFT-filter was applied to the images prior to the clustering. After the background removal, the lightness distribution within each cell was standardized by means of normalization to the unit interval and equalization of the histogram.

Subsequently to the lightness standardization of the images, a 2-dimensional Gaussian function was fitted to each cell image using nonlinear least squares. Based on the coefficients of the fitted function, centers and estimated radii were determined for each cell. As the next step, background-free images of the single cells were cropped according to the estimated cells' radii. This procedure was performed, to preserve the full region of the stained nucleus with a cytoplasm area and to exclude regions of other cells, non-cell area, or unexpected artifacts which were present in some images outside of the cell area. After cropping, images were placed on frames with a determined preset size, which was chosen to fit the biggest cell expected among the analyzed cell subtypes: 13x13 μm, which was equivalent to 200x200 pixels. On this step the centers of the cells were also matched to the centers of the frames. Pretreated images are shown in Fig. 1 *c,d*.

D. Features extraction

As quantitative features which can be used to describe the morphology of cell images, the complex-valued pseudo-Zernike moments where chosen. However, the position of each individual cell on a slide is random and it is necessary to operate with rotationally independent features. Since the phase of the moment is related to the angular coordinate within the image plane, complex-valued moments were converted to absolute PZ-moments and then normalized to the zero-order moment. Therefore, invariants, which are not dependent on the image rotation and scale, were produced. These invariants skip all information about the phase (angular coordinate), and thus, the obtained variables are independent of the image rotation.

Unfortunately, as it is shown above in the "Materials and methods" section, the calculation of PZ-moments requires a double integration of a two-dimensional function which is a costly CPU process. Because the pre-computed images were transferred to a frame with a preset size, the algorithm for the PZ- moment calculation can be simplified. Instead of the integration, the sum of a scalar product of the image with a pre-computed complex matrix can be used. The matrices related to each moment can be generated once and then stored on a hard disk drive for the further use.

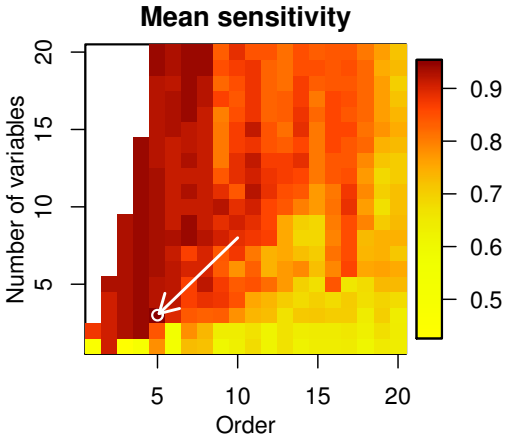

Fig. 3. Mean sensitivity of SVM leave-batch-out-cross-validation of training data. Classification models were created for a different number of selected orders of moments and for a different number of principal components (called variables in the image). The maximum value, which is related to the optimal model, is indicated with a white arrow.

		Predicted		
		Lymphocytes	**Neutrophils**	**Sensitivity**
True	**Lymphocytes**	26	2	0.893
	Neutrophils	1	44	0.978

E. Statistical model establishment and evaluation

To avoid an overfitting of the statistical model, the dimensionality of the data was reduced. A dimension reduction was obtained via a principal component analysis (PCA). The dimensionality of the retaining data set was optimized based on a leave-batch-out-cross-validation of the training data set. The parameter intervals checked for the feature extraction was 1 to 20 for orders, while repetition was chosen maximal. The score dimension of the PCA was evaluated from 1 to 20. For each parameter set the model performance was estimated based on the mean sensitivity. These values are summarized in plot Fig 3. The maximal sensitivity is marked on the plot with an arrow. This parameter set defines the optimal combination of input variables (3 principal components, based on PZ-moments up to 5th order). The model trained with these parameters was further analyzed and visualized. In table I a confusion table of training data cross-validation is given. In Fig. 4 a histogram of its probability scores, which represents SVM decision values rescaled to the unit range, is plotted.

F. Blind prediction

Model validation was performed by applying the established model to the independent data, which contained 163 microscopic images of stained WBCs. All preprocessing and feature extracting steps were performed on these unlabeled

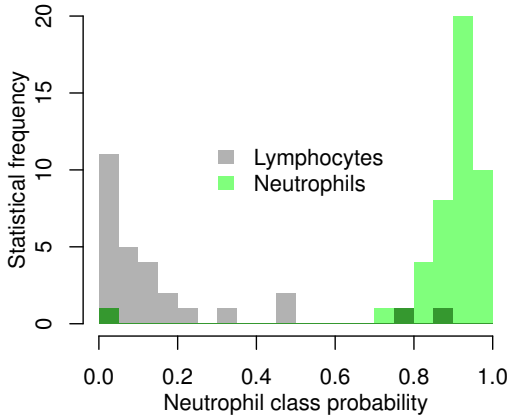

Fig. 4. Histogram for SVM posterior probabilities calculated by a leave-batch-out-cross-validation of the training data with the optimal number of variables are shown. Classification was performed between lymphocytes (gray bars) and neutrophils (green bars). The overlap of the groups is indicated within the histogram by dark green bins.

images in the same way as for the training data. In order to avoid the influence of the operator's subjectivity, a double blind prediction was carried out. Images were classified in manual mode by an experienced pathologist independently from the automated prediction. Subsequently, the statistical predictions were compared with the manual classification results. A summary of the results is visualized by a confusion table (see table II). Another representation of the classification performance is shown by means of a ROC curve in Fig 5. This curve, built for the threshold of the SVM decision values of the test data prediction, illustrates the high performance of the prediction. Moreover, the area under ROC curve (AUC) is about 0.984, which indicates an almost perfect classification. A perfect binary classification is characterized by an AUC equal to 1. Among 155 cells, which were classified as lymphocytes or neutrophils in manual mode, three images were wrongly identified by the statistical model. Such a low misclassification rate of independent test data corresponds to a high accuracy of the 2-class prediction. This accuracy was higher as 97%. Additionally, cells of the subtypes, which were not included in the training set, were present in the test data. These cells (five eosinophils and two monocytes), were predicted within the same class as neutrophils. This behavior was expected, since they feature a similar morphology as neutrophils compared to lymphocytes. Additionally, neutrophils, eosinophils, and monocytes feature a higher biological similarity and higher subjective similarity of the images. These classification results of the eosinophils and monocytes indicate that an extension of the presented model may be possible. A hierarchic layout of the classification seems optimal to incorporate eosinophils and monocytes.

IV. Conclusion

In this work, we presented an algorithm for a highly efficient classification between two dominant subtypes of leukocytes. The special feature of the proposed method is that by means

of PZ-invariants the cell morphology is represented as a quantitative marker for the cell subtypes. Therefore, a combination of such common statistical methods as principal component analysis and support vector machine classification was applied to build the classification model. This approach showed a high stability against patient to patient and sample to sample variations. Moreover, an advanced image preprocessing made a further contribution to the robustness of the model. The standardization of the images decreased deviations, which occur between samples due to the sample preparation routine. Additionally, the automated framing and centering of the analyzed images of cells led to the replacement of the double numerical integration, performed for PZ-moment calculation, with a matrix product. This simplification of the calculation procedure resulted in the reduction of computation time and allowed the analysis to be performed in real-time. The classification results showed that WBCs subtypes as monocytes and eosinophils (which were not included in the model due to their low quantity in the training data) were predicted within the same class. Due to this fact, it can be assumed that the classification can be improved and extended to other cell types by a multilevel model. However, that requires a statistically significant amount of microscopic images for each leukocyte subtype in the training data set. The described approach can be applied for microscopy images taken of other staining types. Only important is that the images display the cell morphology. The method presented here may be also applied to images obtained with techniques such as fluorescence, dark field, or phase contrast microscopy.

ACKNOWLEDGMENT

Financial support of the BMBF via the integrated research and treatment center "Center for Sepsis Control and Care" (FKZ 01EO1502) and from the EU via the project "Hemo-Spec" (FP 7, CN 611682) is highly acknowledged. The authors thank Katrin Ludewig and Frank Brunkhorst for data collection and their support.

***Abstract*—Computer-aided schizophrenia diagnosis is a difficult task that has been developing for last decades. Since traditional classifiers have not reached sufficient sensitivity and specificity, another possible way is combining the classifiers in ensembles. In this paper, we take advantage of random subspace ensemble method and combine it with multi-layer perceptron (MLP) and support vector machines (SVM). Our experiment employs voxel-based morphometry to extract the grey matter densities from 52 images of first-episode schizophrenia patients and 52 healthy controls. MLP and SVM are adapted on random feature vectors taken from predefined feature pool and the classification results are based on their voting. Random feature ensemble method improved prediction of schizophrenia when short input feature vector (100 features) was used, however the performance was comparable with single classifiers based on bigger input feature vector (1000 and 10000 features).**

I. Introduction

SCHIZOPHRENIA (SZ) is a severe and chronic neurodevelopmental disorder with unknown etiology. Patient's response to the treatment is uncertain and early diagnosis could increase the probability of remission. Since nowadays the diagnostics is based on interview, self-report and psychiatrist's observation, there are efforts to develop a diagnostic tool that could support establishing diagnosis of the first episode of schizophrenia in a more objective way.

Involvement of modern imaging methods in the last decades has opened up new possibilities in brain research. These methods include for instance, magnetic resonance imaging (MRI), computed tomography or positron emission tomography. Especially MRI techniques offer good contrast and spatial resolution. Thus, morphological abnormalities and relations between brain structures and functions can be studied with the use of imaging data. Since the differences between schizophrenia patients and healthy controls (HC) have been already found with the use of manual segmentation of region of interests [1] or automated morphometry methods such as voxel-based morphometry [2] or deformation-based morphometry [3], many scientists have been recently trying to create computer-aided diagnostic tools based on neuroimaging data. The outcomes of such tools have not reached sufficient sensitivity and specificity for implementation into the psychiatric clinical practice yet, and hence the demand still persists. The application of classification methods with self-adapting strategies known as machine learning is a challenging task in the schizophrenia research.

Artificial neural network (ANN) is a model inspired by how the brain works. Since the backpropagation algorithm [4] was invented as a technique for learning ANNs, they have been used widely in many applications and have achieved success at least in two areas of brain image processing: segmentation [5], [6] and classification [7]–[11]. Those results have shown that ANNs deserve attention of neuroimaging community investigating how to recognize mental diseases in imaging data.

Several authors have already tried to classify schizophrenia based on diffusion tensor data [7] using several types of neural networks: backpropagation neural networks, radial basis function networks, learning vector quantization neural networks and probabilistic neural networks. Other studies [8], [12] used backpropagation neural network on functional magnetic resonance imaging (fMRI) data or resting-state fMRI. Other papers discussed the use of ANN for classification of other brain diseases such as Alzheimer's disease [9], [10] or brain cancer [11] – based on structural MRI data.

The power of such single models can be further improved by the means of ensemble learning. This approach employs set of classifiers to determine the object's class by voting. To ensure a necessary assumption, which is the disparity among the classifiers, variability in the training process must be somehow acquired. Many methods have been invented for this purpose, such as random subspace ensemble [13], random forests [14], bagging [15], boosting (e.g. AdaBoost [16]), rotation forests [17] and others. The first one is explored in this paper in combination with ANNs. Several ensemble methods were applied to investigate neuroimaging problems. For instance, Yang et al. [18] classified schizophrenia using ensembles of support vector machines (SVM) trained by modified AdaBoost algorithm that besides boosting performed also simultaneous feature selection from

fMRI and single nucleotide polymorphism data. They reached an overall accuracy of 87% when both data sets were combined. Janousova et al. [19] based their ensemble for schizophrenia prediction on different image features extracted from MRI data (MR intensities, grey matter densities and local deformations) and on three various types of classifiers, and achieved the accuracy of 81.6%. Lebedev et al. [20] used random forests for Alzheimer's disease (AD) detection and achieved overall accuracy of 91%. Liu et al. [21] proposed local patch-based subspace ensemble method combined with a classifier based on sparse representation of data and improved the performance of classification performance of AD and mild cognitive impairment up to 3% compared to the use of a single classifier.

To the best of our knowledge, this is the first time that random subspace ensemble ANNs are used for schizophrenia classification based on the structural MRI data. The paper is organized as follows: Section II outlines the basics of ANNs and random subspace ensemble. The experiment and results of classification are summarized in section III. Section IV discuss the results and concludes the paper.

II. METHODS

A. Dataset and Image Processing

We used the same dataset as in [22]. It consisted of MRI data of 52 schizophrenia patients and 52 age- and sex-matched (only men) healthy control subjects without family history or personal history of axis I psychiatric conditions. Patients' and healthy controls' median age was 22.9 years (range 17-40 years) and 23.0 years (range 18.2-37.8 years) respectively. Images of all subjects were acquired on 1.5 T magnetic resonance imaging machine Siemens Symphony at University Hospital Brno, using a 3-D acquisition with IR/GR sequence, TR 1700 ms, TE 3.93 ms, TI 1100 ms, flip angle 15°, 160 slices, voxel size 1.17 × 0.48 × 0.48 mm, FOV 246 × 246 mm, and matrix size 512 × 512 voxels .

Gray matter tissue segments were obtained from all images after a correction of bias-field inhomogeneity, spatial normalization, segmentation, modulation and Gaussian smoothing. All the steps followed the pipeline of the optimized voxel-based morphometry [23]. The last step - smoothing the gray matter segments with an isotropic Gaussian kernel - spreads the information to the neighboring voxels and compensates the inexact nature of the spatial normalization step [24]. Furthermore it ensures more normally distributed data for further parametric statistical analyses used for feature selection [25]. After this image preprocessing, a binary mask of a brain normalized to the stereotactic space was used to erase the voxels representing extracerebral tissues.

B. Feature Pool Preparation

Before applying the classifiers, it was necessary to select only those features - gray matter density voxels - which represented the information useful to discriminate between the two classes, and conversely to exclude those voxels without any helpful information, and thus to improve signal-to-noise ratio and create more accurate classifier. The feature selection step is also important to tackle the problem of the curse of dimensionality – well-known in neuroimaging community [26].

Voxel-wise two-sample t-tests were the instrument for feature selection. This method selected only those voxels which showed significant differences in gray matter density between the groups. Such a very naïve approach might be less prone to overfitting than selection the features with the highest discrimination power derived from correlation with the classification outcome. In addition, it is important that the whole volume of gray matter was explored with no arbitrarily predefined regions of interests, as morphological abnormalities in schizophrenics' brains have been uncovered with automated brain morphometry methods in many different brain regions [2].

C. Multi-layer Perceptron

Multi-layer perceptron (MLP) is the most traditional type of ANN. It maps relations between inputs and desired outputs. MLP consists of three or more layers formed by neurons - basic computational units - and are adapted in a supervised learning manner using the backpropagation algorithm. The information is passed through the layers in input-output direction. The equation of a neuron is:

$$y = \left(w_0 + \sum_{i=1}^{n} w_i x_i\right) \tag{1}$$

where y is the output, w_i are weights, x_i are inputs, n is the number of neuron inputs, is the activation function – hyperbolic tangent for hidden layers and linear functions in the output layer.

The output layer comprises two neurons; each represents one class, so the subject is classified according to the comparison of their values after the excitation. Furthermore, the softmax function is applied on these two neurons:

$$y_i = \frac{e^{\xi_i}}{\sum_{j=1}^{n} e^{\xi_j}}, \tag{2}$$

where n is the number of outputs, ξ_i and ξ_j are net activations of $i-th$ and $j-th$ output neurons. This function ensures that the outputs are non-negative and their sum is equal to 1. Such results can be interpreted as posterior probabilities [27].

In this project, the MLPs are trained by minimization of cross-entropy using the scaled conjugate gradient backpropagation algorithm that has been found to be fast in preliminary experimentation. Since neural networks have many parameters to be predefined - both for architecture creation and for adaption - it is difficult to set them to the optimal configuration. We kept the implicit learning parameters i.e. learning rate 0.01, maximal number of epochs 1000, minimum gradient 10^{-6} and regarding architecture and we used two-layer network with 10 hidden neurons, which achieved a good performance during experimentation. Since the weights were initialized

randomly, adaptation of the network was repeated 11 times and the classification of the testing subject was based on voting.

The Neural Network Toolbox for Matlab R2014b (The MathWorks, Inc.) was used here for all the described experiments.

D. Random Subspace Ensemble Principle

The datasets in neuropsychiatric research usually suffer from small sample size while their dimensionality is huge - often hundreds of thousands or even millions of voxels are used to describe each of subjects in the dataset. Hence, it is a hardly feasible task to avoid overfitting on a validation set by termination of neural network adaptation. Ensemble methods help to tackle overfitting and to improve the generalization ability.

In random subspace ensemble method, the variability is reached by a random selection of features from the set of all preselected features – a feature pool (FP). Each single classifier is adapted on one subset of feature which is less dimensional than the original feature space.

E. Validation and Evaluation

In order to report unbiased results, we used leave-one-out cross-validation strategy: one subject was left as a testing subject and the rest subjects composed a training set. This process was repeated *n* times, where *n* was the sample size. Since even only one testing subject withdrawn from the feature selection might have influenced the result, especially when the sample size was small, it was necessary to validate both features selection and classification.

For evaluation of the classification results, we used overall accuracy, sensitivity and specificity. The overall accuracy refers what proportion of subjects was classified correctly, whereas sensitivity and specificity say what the ability of diagnostic test is to reveal diseased and healthy person respectively.

III. Experiment and Results

The experiment was configured with many parameters – particularly size of the feature pool, number of chosen features and ensemble size. In order to achieve a reasonable computation time, we investigated only several predefined configurations. First, we defined a size of the feature pool as the 10000, 20000, 50000 and 100000 most significant voxels based on two-sample t-test criterion. This FP was used as the bag from which the features were chosen randomly.

The second parameter was a number of features used for the adaptation of the classifiers. We trained both MLP and SVM classifier on the different number of the most significant features - as shown in Fig. 1 - to find the optimum. The best performance was reached with the use of MLP on 1000 features and with the use of SVM on 100 features. Adding more features to the models did not reveal any trend in the classification performance - increasing or decreasing - so we later experimented with 3 options - 100, 1000 and 10000 - in order to explore both small and big dimensionality of the feature space. The MLP revealed higher accuracies compared to the SVM in most configurations.

The last investigated parameter was the number of voting classifiers in ensemble, which was set to 31. This odd number ensures that the subject is always assigned to one of the classes – SZ or HC.

Since outcomes from the whole ensemble were available, i.e. 31 units, we could use for evaluation any combination of 1, 3, 5 etc. classifiers from this ensemble. Hence, we computed performance measures on all, but maximally 10000 combinations in order to gain nonrandom and computationally accessible outcomes. Furthermore, the subsets of features were chosen randomly, all experiments were repeated 10 times and the measures of the classification performances were averaged.

Figures 2-5 show the experimental results. In each figure, the outcomes computed on the different size of the feature pool are displayed.

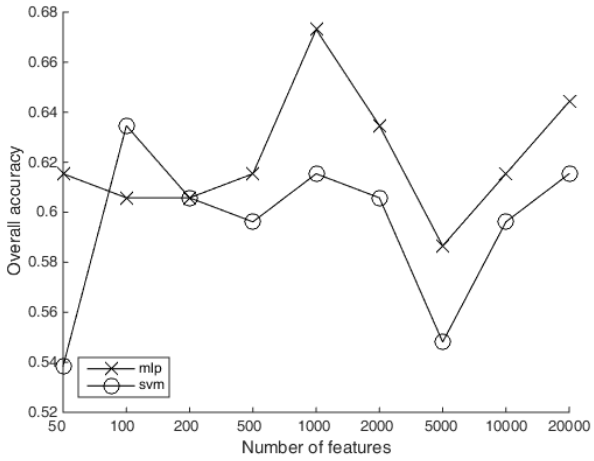

Fig. 1 The overall accuracy of the MLP and SVM dependent on the number of the most significant features selected with voxel-wise two-sample t-tests.

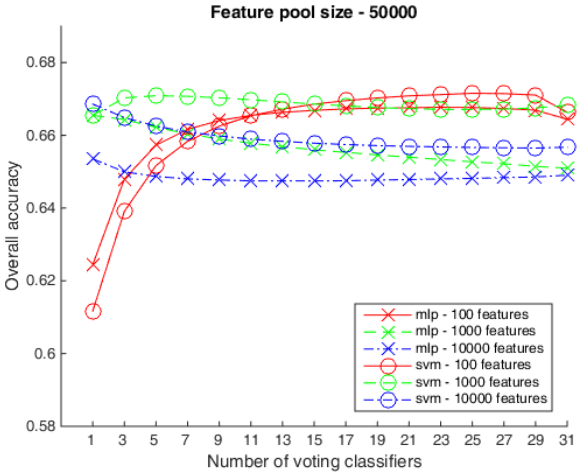

Fig. 4 Results of ensemble voting based on the feature pool with the size of 50000 selected features.

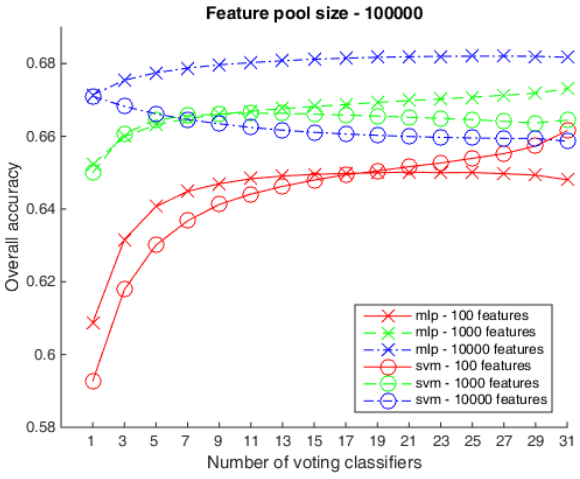

Fig. 5 Results of ensemble voting based on the feature pool with the size of 100000 selected features.

IV. Discussion and Conclusions

In this paper, we explored the random subset ensemble method for first-episode schizophrenia classification with the use of multi-layer perceptron and performed a comparison to ensembles of SVM classifiers.

We selected the features with a naïve approach based on voxel-wise two-sampled t-tests. We believe that this approach may be less prone to overfitting than other more complex methods. More sophisticated and often computationally more time-consuming methods such as sequential forward/backward feature selection or multivariate extraction methods are left for our future research.

Since the neighboring voxels could have been correlated due to the smoothing in the image preprocessing phase, we assumed that higher amount of features in the feature pool enabled to capture the discriminative information in more parts of the brain, and therefore improved the classification performance. This improvement is observable when the Fig. 2 and 4 are compared.

Multi-layer perceptron was more effective when smaller feature pool was used. With the use of bigger feature pools, both classification methods yielded more similar outcomes.

Increasing the number of voting classifiers surprisingly improved the classification accuracy only in case of small number of input features. The increasing trend in the accuracy reached a level similar to as the models with more inputs and the increasing trend did not continue. The SVM with 100 features adapted on FP with 100000 features was improved by 6.88% and MLP with the same number of input features adapted on FP of size 50000 achieved improvement of 4.33% when compared to single variants of the classification methods.

The best outcomes were revealed with the use of MLP on 100000 input features and 29 voting classifiers that have the highest overall accuracy of 68% (sensitivity 67%, specificity 69%).

Finally, we compare our results of schizophrenia prediction to other studies dealing with MLP or ensemble learning. Jafri and Calhoun [8] achieved 75.6% with MLP based on fMRI data (38 SZ + 31 HC). Savio et al. [7] reached 100% on diffusion imaging data containing 20 male subjects using both neural networks and SVM. Yang et al. [18] also reached much higher overall accuracy 87% with SVM classifier ensemble based on AdaBoost, but besides small sample size (20 SZ + 20 HC) they admit the patients were chronic and under an antipsychotic medication. These studies could suffer from small sample size, since models tend to reach more variable outcomes and therefore it is easier to reach good (as well as poor) classification performance [28]. Since Janousova et al. [19] exceeded 81% with a similar number of subjects, we propose that an involvement of other classifiers and various feature extraction methods may be helpful in our framework too.

We conclude that the random feature ensemble method in combination with MLP and SVM improved prediction of schizophrenia from MRI data only in case of short feature vectors (100 features) – when compared to the use of single MLP or SVM classifiers. The classification accuracy achieved with the ensembles was not much different from

the accuracy of the single classifiers with feature vectors of higher dimensionality (1000 and 10000 features).

***Abstract*—This paper concerns automated identification of intrauterine growth restriction (IUGR) types by use of machine learning methods. The research presents a comparison of supervised and unsupervised learning covering single and hybrid classification, as well as clustering. Supervised learning techniques included bagging with Naïve Bayes, k-nearest neighbours (kNN), C4.5 and SMO as base classifiers, random forest as a variant of bagging with a decision tree as a base classifier, boosting with Naïve Bayes, SMO, kNN and C4.5 as base classifiers, and voting by all single classifiers using majority as a combination rule, as well as five single classification strategies: kNN, C4.5, Naïve Bayes, random tree and sequential minimal optimization algorithm for training support vector machines. Unsupervised learning encompassed k-means and expectation-maximization algorithms. The major conclusion drawn from the study was that hybrid classifiers have demonstrated their potential ability to identify more accurately symmetrical and asymmetrical types of IUGR, whereas the unsupervised learning techniques produced the worst results.**

I. Introduction

IN MEDICINE there are many diseases and diagnoses where identification of their subtypes affects medical treatment. Many research papers concern cancer diagnosis, appropriate feature selection techniques [1]–[3], and its classification based on gene expression [4]. A big challenge is an accurate classification of medical imaging and sound recordings (see [5] and [6]). Moreover, in many cases classification process is performed on labelled and unlabelled data [7]. It may take place in situations where a medical expert diagnosis is imprecisely outlined, as described in this paper.

Intrauterine growth restriction (IUGR) is a fetal growth disorder which is associated with fetal hypoxia and increased perinatal mortality. IUGR may cause a significant risk factor for the development of many cardiovascular, metabolic, and pulmonologic diseases in adult life ([8]–[10]). It is a challenging problem for obstetrician, neonatologists and pediatricians, as the diagnosis is based on non-consistent definitions (see [11] and [12]). It occurs in about 3-10% of live-born newborns, and the most serious problem of IUGR exists in developing countries where it concerns up to 20-30% of newborn infants [13]. The comparisons of absolute measurements of the fetuses with reference values, as well as birth weight percentiles, allow detection of deviations between expected and actual fetal growth and identification of newborns being possibly at risk for adverse health events [14].

Two types of IUGR can be distinguished: symmetrically impaired and asymmetrically impaired. Foetuses of the first type tend to have a decrease in all dimensions of the body and internal organs, and usually face a higher risk of reduction in growth potential. The problems occur in the first or second trimester of pregnancy and are often encountered in foetuses with infection or genetic and anatomic defects [15]. The second type - asymmetrical - constitutes 75-80% of all cases born as IUGR. It develops in the late second and third trimester of pregnancy and is a consequence of abnormal cell growth, rather than their quantity. In this type, infants have a low birth weight while body length and head circumference remain normal [16]. As asymmetric IUGR infants are more likely to have major anomalies than symmetric IUGR infants or non-IUGR infants [17], there is a need to distinguish between those two patterns of IUGR. Moreover symmetric and asymmetric growth restriction may have different influence on growth and development in preterms from birth to 4 years [18].

To discover risk factors and any parameters that impact IUGR, or to state the dependencies IUGR impacts on, it is necessary:

- to distinguish IUGR from normal fetuses,
- to identify the symmetrical or asymmetrical type of IUGR.

The problem of separating IUGR from normal fetuses has been the subject of analysis for researchers in the field of medicine, as well as computer science, including machine learning and artificial intelligence.

The authors of [19] used multiparametric classifier based on k-mean cluster analysis to separate pathological and normal fetuses. The identification of the intrauterine growth-restricted fetuses was performed on the basis of fetal heart rate variabil-

978-83-60810-90-3/$25.00

ity analysis in the antepartum period. The results attained up to 82.4% of accuracy.

In [20] an artificial neural network (ANN) classifier was developed to identify normal and abnormal fetuses based on features from ultrasound images. The accuracy of the classification equalled over 90%. Two ANN models, Multilayer Perceptron using Back propagation algorithm and Radial Basis Function, were also studied and used for IUGR identification in [12].

Lunghi et al. in [21] applied support vector machine algorithm for normal and pathological (IUGR) fetuses classification, based on the analysis of fetal heart rate recordings. The correct classification rate was high enough, above 84%. However, as a concluding remark for future work, the authors suggested using combined classifiers for better discrimination results.

In [22] statistical analysis (contingency tables, analyses of variance, and multiple regression) was applied to identify the problem of placental lesions associated with normal and abnormal fetal growth in infants delivered for obstetric indications at less than 32 weeks' gestation.

Although there are many studies that concern IUGR problem and its identification, few such studies explore different classification techniques. Therefore, automated or semi-automated identification of IUGR patterns is still an open topic.

The aim of this paper is to identify an appropriate classification technique as applied to the problem of intrauterine growth restriction types. Even though classification methods have been studied extensively over the past few years ([23]), no exact solution has been discovered. Moreover, the authors usually focus on one group of machine learning techniques: supervised or unsupervised, without comparisons between the groups. This research not only constitutes an independent contribution to the relevant literature , but also attempts to find a successful way to perform accurate classification of IUGR type.

The rest of the paper is organized as follows. Section II corresponds to the medical data used in this research and is followed by the description of methods used in the experimental part of the paper. Section III is dedicated to the experiments conducted on sample data and the results. Finally, in Section IV, the concluding remarks are discussed.

II. Materials and Methods

The proposed methodology of indicating the best machine learning method to use in IUGR types identification consists of three steps:

- applying supervised learning by single classification methods,
- performing multiple classification,
- carrying out clustering as an example of unsupervised learning,
- comparing results of classification techniques by methods of statistical analysis.

TABLE I: Characteristics of the groups

Parameter	IUGR-1 Avg ±SD (*)	IUGR-2 Avg ±SD (*)	p-value
Birth weight(g)	2556.91 ± 145.52	2516.77 ± 301.68	<0.001
Birth length(cm)	52.68 ± 1.51	50.06 ± 2.40	<0.001
Head circ.(cm)	33.37 ± 0.96	32.24 ± 1.13	<0.001

(*) described as average values ± standard deviations

A. Data Description

The research was based on a group of 68 children aged 5-10 years (average 7.4 ± 1.36) born on term with IUGR and birth weight below 10 percentile according to gestational age for the Polish population [24]. It consisted of 35 girls and 33 boys. All patients were selected during prospective studies at the Pediatric Cardiology and Rheumatology Department of Medical University of Lodz in 2010-2013. The study was approved by Medical Ethical Committee of the Health Sciences Faculty of Lodz University (No: RNN/760/10/KB).

Two subgroups were distingushed according to the type of hypotrophopy:

- IUGR-1 – asymmetrically impaired based on birth weight and an appropriate remainder of the parameters (body length and head circumference above 10 percentile),
- IUGR-2 – symmetrically impaired, where all parameters to be considered (birth weight, body length and head circumference) were below 10 percentile.

Both subgroups were equinumerous - consisted of 34 cases. The IUGR-1 group was constituted by 15 boys and 19 girls, whereas IUGR-2 included 18 boys and 16 girls.

The characteristics of all parameters subjected to further analysis differed significantly between IUGR-1 and IUGR-2 (see Table I).

B. Supervised Learning by Single Classification Method

Classification is the form of supervised learning, which means assigning objects into pre-defined sets of categories or classes. The main purpose of classification is to identify which set of categories a new observation belongs to. This is performed on the basis of a training set consisting of instances that are already labelled the known classes.

A classifier is a mapping function that can be defined by (1):

$$A^i \rightarrow C \tag{1}$$

where:

$a_1, \ldots, a_i \in A$ – are i features that characterize a set of n input instances $x_1, \ldots, x_n$

$y_j \in C = c_1, ..., c_m$ – are desired class labels.

C. Multiple Classification

Multiple classification combines individual classifiers in order to obtain a classifier that outperforms every single one.

There are two main questions that should be considered while performing multiple classification:

- the types of classifiers, that should be chosen,
- the way classifiers are combined to obtain a single classification result.

In the literature, there are two terms that refer to multiple classification: "ensemble methods" and "hybrid classifiers". The first one usually refers to collections of models that are minor variants of the same basic model, whereas hybridization allows combining classifiers from different families.

Regarding to combination rules for classifiers, in practice plurality voting is usually implemented (besides unanimity and simple majority) [25], [26]. It takes the result with the higher number of single classifiers' votes, which can be written as (2):

$$class(x) = \underset{c_i \in dom(y)}{arg\,max} \Big(\sum_k g(y_k(x), c_i) \Big) \tag{2}$$

where:

x – is an instance to be classified,
$dom(y) = \{c_1, c_2, ..., c_k\}$– constitutes the set of labels,
$y_k(x)$ – is the classification of the k^{th} classifier,
$g(y, c)$ – is an indicator function defined as:

$$g(y,c) = \begin{cases} 1 & y = c \\ 0 & y \neq c \end{cases}$$

Bagging and boosting are techniques that improve the accuracy of a classifier by generating a composite model that combines multiple classifiers derived from the same inducer.

The term bagging was introduced by Breiman in [27] as an acronym for Bootstrap AGGregatING. The idea of bagging is to create an ensemble classifiers based on bootstrap replicates of the training set. The classifier outputs are combined by the plurality vote [28].

A variant of bagging is a random forest [29]. It is a general class of ensemble building methods using a decision tree as the base classifier.

Boosting improves the performance of a weak learner as the method iteratively invokes a classifier on training data that is taken from various distributions. The classifiers are generated by resampling the training set and then combined into a single strong composite classifier. Boosting was based on an on-line learning algorithm called Hedge(β) [30]. This approach allocates weights to a set of strategies used to predict the outcome of a certain problem. The distribution is updated after each new outcome and strategies with the correct prediction receive higher weights while the impacts of the strategies with incorrect predictions are reduced.

One of the most popular ensemble algorithm that improves the simple boosting algorithm by an iterative process is AdaBoost (Adaptive Boosting). It was first introduced in [30]. The basic AdaBoost algorithm deals with binary classification. The classification of a new instance is performed according to (3):

$$class(x) = \underset{y \in dom(y)}{arg\,max} \Big(\sum_{t: M_t(x) = y} \log \frac{1}{\beta_t} \Big) \tag{3}$$

where:

x – is an instance to be classified,
$dom(y) = \{c_1, c_2, ..., c_k\}$– constitutes the set of labels,
M_t – is a base classifier,
β_t – is defined as: $\beta_t = \frac{\varepsilon_t}{1-\varepsilon_t}$,
ε_t – is defined as: $\varepsilon_t = \sum_{i: M_t(x_i) \neq y_i} D_t(i)$,
D_t – is a distribution defined as:
$D_1(i) = 1/m;\ i = 1, \ldots, m$
(m is a size of a training set)

$$D_{t+1}(i) = D_t(i) \cdot \begin{cases} \beta_t & M_t(x_i) = y_i \\ 1 & Otherwise \end{cases}$$

Bagging and boosting use votes to combine the outputs of different classifiers. However in boosting, each classifier is influenced by the performance of predecessors, which means that the new classifier pays more attention to classification errors that were done by the previously built classifiers. Besides in boosting, instances are chosen with a probability that is proportional to their weight, whereas in bagging, each instance is chosen with equal probability.

Hybrid classifiers [25], [26], [31], [32] (also named multiple classifier systems) are designed to increase the accuracy of a single classifier by training several different classifiers and combining their decisions to output a single class label. The hybridization exploits the strength of each component [33] and it prevents the need to try each classifier and simplifies the entire process [31].

For hybrid approach, the diversity is supposed to provide improved accuracy and classifier performance [34]. Therefore most works try to obtain maximum diversity by different means: introducing classifier heterogeneity, bootstrapping the training data, randomizing feature selection, randomizing subspace projections or boosting the data weights. Nevertheless, the diversity hypothesis has not been fully proven [34].

D. Unsupervised Learning with Clustering

Cluster analysis groups objects taking into account a certain similarity metric. The algorithms divide all objects into a predetermined number of groups in a manner that maximizes a similarity function. There are two different approaches, that are commonly used in medical studies ([35] and [36]): the Expectation Maximization (EM) probabilistic method and deterministic k-means algorithm.

An expectation-maximization (EM) algorithm performs repeatedly 2 steps: an expectation (E) and a maximization (M). The first step (E) results in an expectation of the likelihood for observed variables, whereas the second step - maximization (M) computes the maximum expected likelihood found during the E step. EM generates a probability distribution to each instance which indicates the likelihood of its belonging to each cluster [37]. The number of clusters can be designated by cross validation. It is worth emphasizing, that the EM algorithm computes classification probabilities, not exact assignments of observations to clusters.

The k-means algorithm divides a data set into k clusters, where k is a user-defined value. The algorithm starts with k random clusters, and next moves objects between those groups to minimize variability within each of them and maximize variability between clusters. Usually, the means for each cluster on every dimension are calculated to assign objects into the closest group [39]. In most of the cases Euclidean metric is considered as the distance function for k-means algorithm [37], [40].

E. Statistical Analysis

Statistical analysis is a required part of any research investigations, including proposing new methods or comparing existing ones in any field of science. Many researchers in machine learning confirmed the need for statistical validation of results.

In cases where comparison of two classifiers is performed, the McNemar test and 5x2 cross validation were recommended [41]. The situation where many classifiers are verified, is more complex from statistical point of view. Although many research papers draw conclusions based on matrix of tests comparing all pairs of classifiers (e.g. a matrix of the McNemar tests), an appropriate test for multiple comparisons should be used. The Friedman test with the corresponding post-hoc analysis was proved to be suitable for comparison of many classifiers [38], [45].

The Friedman test was firstly introduced in [42], [43] for non-parametric measures. The goal of the test is to determine - basing on samples - that there is a difference among classification results. The original results are changed into ranks starting from the best one and the null hypothesis states that all algorithms give same results and their ranks are identical. The Friedman statistics is computed as follows (4):

$$\chi_F^2 = \frac{12n}{k(k+1)} \left[\sum_j R_j^2 - \frac{k(k+1)^2}{4} \right] \tag{4}$$

where:

n – is the number of datasets being considered
k – is the number of algorithms
R_j – is the average rank of *j*th algorithm

If the null hypothesis is rejected, a post-hoc analysis should be performed to compare classifiers with each other and find statistically significant differences. The Nemenyi test can be applied. It states that two classifiers differ significantly if their ranks vary at least by the critical difference (5):

$$CD = q_\alpha \sqrt{\frac{k(k+1)}{6n}} \tag{5}$$

where:

q_α – are critical values based on the Studentized range statistic divided by $\sqrt{2}$.

TABLE II: Single classification results

SMO	73.91	0.775	0.739	0.746

III. Results and Discussion

The purpose of experiments was to find the best method for IUGR type identification by examining the accuracy of different classification approaches, including single and hybrid classifiers, as well as clustering techniques.

The experiments were conducted on a real dataset consisted of 68 cases. Each case was described by 3 numerical attributes: birth weight, body length and head circumference according to the description presented in Section II-A.

The aim of the classification was to distinguish automatically symmetrical or asymmetrical type of IUGR. Therefore the set of labels consisted of two classes.

All experiments were based on WEKA Open Source Data Mining Tool [44].

In order to assess the performance of various classification methods, following comparison criteria have been used: accuracy (ACC), precision (PREC), sensitivity (SENS) and the area under ROC curve (AUROC). To verify experimental results, a detailed statistical evaluation was performed with use of Friedman test and post-hoc analysis.

A. Single Classification

In the first step of the experiments, single classification algorithms were applied. Eight approaches were considered: k-nearest neighbours (kNN), C4.5, logistic regression (Logistic), decision table, Naïve Bayes (NaiveBayes), random tree (a tree that considers K randomly chosen attributes at each node), stochastic gradient descent (SGD) and sequential minimal optimization algorithm for training support vector machines (SMO). The results of classification are presented in Table II.

The best single classification results attained 80% for logistic regression and 79% for SGD algorithm in terms of classification accuracy. Moreover, logistic regression and NaiveBayes gave the best results of AUROC (0.874 and 0.846 respectively) The average accuracy of single classification approach equalled 76.7%.

B. Multiple Classification

Next step of the experiments concerned performing classification using hybrid classifiers. Different combinations were applied:

- bagging with C4.5 and SMO as base classifiers,
- random forest as a variant of bagging with a decision tree (DTree) as a base classifier,

TABLE III: Hybrid classification results

Method	Base	ACC [%]	PREC	SENS	AUROC
Bagging	C4.5	79.41	0.799	0.794	0.852
Bagging	SMO	77.94	0.782	0.779	0.833
RandomForest	DTree	76.47	0.765	0.765	0.843
AdaBoost	DTable	80.88	0.824	0.809	0.835
AdaBoost	C4.5	80.88	0.809	0.809	0.826
AdaBoost	SGD	82.35	0.824	0.824	0.876
AdaBoost	SMO	77.94	0.780	0.799	0.806
Hybrid	all single	80.88	0.812	0.809	0.810

TABLE IV: Results of clustering

Method	No of cases in clusters	ACC [%]	PREC	SENS	AUROC
k-means	28 / 40	64.71	0.625	0.735	0.647
EM	63 / 5	57.35	1.000	0.147	0.574

- boosting with decision table (DTable), SMO, C4.5 and SGD as base classifiers, and
- hybridization by use of all single classifiers with majority voting as a combination rule.

The results of multiple classifications are shown in Table III. The best hybrid classification accuracy attained 82.35% for AdaBoost algorithm with SGD as a base classifier, whereas the worse one equalled 76.45% for RandomForest method. The average accuracy for all hybrid classification methods achieved 79.59%.

C. Clustering

The last step referred to clustering techniques. According to the methodology, two different approaches were considered: k-means algorithm and Expectation-Maximization method. Using EM algorithm we firstly used 10 fold cross-validation [37] to obtain clusters automatically, however it resulted in one cluster only. Therefore, for both techniques we defined 2 groups: for symmetrical and asymmetrical IUGR cases. The results of clustering are shown in Table IV.

One can notice that in the case of IUGR dataset, unsupervised techniques did not meet the expectations. Both algorithms resulted in accuracies below 65%, which is not satisfactory enough to implement this approach in practice.

D. Classification Comparison and Statistical Analysis

To compare the classifiers, the Friedman test and the corresponding post-hoc analysis were performed. The final results of absolute differences between average ranks for classifiers are presented in Table V where significant values are in bold, italic and underlined.

The results of the post-hoc tests can be clearly visualized with the diagram [38]. Figure 1 shows the results of the analysis of the data from Table V. The diagram compares all the algorithms against each other. The top line of the diagram is the axis on which we plot the average ranks of each method. Each number represents subsequent classification method sorted by the values of classification accuracy in the descending order, i.e. the lowest and best ranks are to the right. As a result we start with number 1 for boosted SGD and end with number 18 for EM clustering. The positions of average ranks for each classifier are marked with vertical lines and captioned with their names. Moreover, the groups of algorithms that are not significantly different in terms of accuracy are connected with horizontal lines. Consequently, we can easily notice, that there is no significant difference between boosted SGD and hybrid approach, however both of them achieved statistically better accuracies when compared with, inter alia, NaiveBayes, SMO or kmeans.

To summarize the experimental studies, one can see, that none of the classification techniques significantly outper-

formed the rest of them. However, it should be emphasized, that multiple classifications mostly exceeded single classifiers and grouping techniques in terms of classification accuracy. Even SGD - one of the best single classification method - when boosted, improved the accuracy to 82%.

IV. Conclusions

Classification of medical datasets is regarded as a challenging task, requiring extremely high accuracy. Therefore researches on finding the most appropriate methods for precise classification are conducted. Multiple classifiers constitute one of the most important advances in machine learning in recent years. In the absence of detailed a priori knowledge of the problem, they provide better performance.

The identification process of IUGR pattern (symmetrical or asymmetrical) is an important medical problem to solve, as symmetric and asymmetric growth restriction may have different influence on growth and development in childhood. Moreover asymmetric IUGR infants are more likely to have major anomalies than symmetric IUGR infants or infants appropriate for gestational age.

By comparing hybrid classifiers algorithms, single classification methods and clustering, it was demonstrated that the hybrid strategy resulted in the most satisfactory outcomes and confirmed other up-to-date researches on multiple classifier systems. Clustering, which is supposed to give good results in terms of unlabelled data and situations where label definitions are not precise, did not succeed in the case of IUGR classification.

In order to find the optimal solutions, future studies ought to involve other algorithms and strategies as well. Other combinations of various classifiers should be also investigated in depth. Furthermore, fuzzy logic can be applied to the problem of IUGR classification, as its results on medical data proved their efficiency [47]–[49].

Abstract—**Reliability is an important characteristic of any system. Healthcare systems are typical examples of such systems. In reliability engineering, such systems are considered as complex, inhomogeneous, and uncertain, and require special mathematical representations. The structure function is a suitable model representing real systems. Methods of system reliability evaluation based on the structure function are well established but deterministic. This restricts its use for uncertain or incomplete data. A structure function can be created only for system in which correlations of all components are indicated and all component states are known. In this paper, a new method for structure function construction is proposed. Incomplete data is analysed using Fuzzy Decision Trees (FDTs), where input and output attributes are interpreted as component states and values of the structure function, respectively. This method is applied to reliability analysis of healthcare system. For illustration, we considered the system laparoscopic surgery that has 4 components and 36 state vectors. In addition we evaluate proposed method by 3 benchmark's systems with 243, 108, and 512 state vectors, respectively. Two of these benchmarks have 5 components and one has 4 components. Uncertainty is simulated by randomly deleting between 5% and 90% of all state vectors before constructing the structure function. With 50% of deleted stages, the error rate is below 0.2% for all three systems. We conclude that FDT-based reliability analysis is applicable for incomplete data in medical systems, too.**

I. Introduction

THE investigation in reliability engineering of healthcare system has started as analysis of medical devices and equipment [1]. Until recently, reliability quantification of equipment and devices has been a principal tendency in medicine [2, 3, 4]. Independently, the human factor in medicine has been investigated.

A special area in reliability engineering investigating the influence of human factor is named *Human Reliability Analysis* (HRA). HRA aims at identifying the potential failure of the system resulting from human errors, analyzing causes and identifying appropriate countermeasures to prevent and reduce the linked risks as much as possible. Failures in healthcare are called Medical Errors, if the patient's condition worsens or if patients develop additional illnesses. As documented in [5], the number of deaths due to these causes is 225,000 annually, with in-hospital medical errors causing 44,000 to 98,000 deaths, and 3,000,000 injuries annually. Of course, such situation must be changed.

A first step of improvement is to investigate causes and specifics of medical error. A human error in a healthcare system is considered as independent problem of reliability analysis [5, 6, 7, 8]. Authors of papers [7, 8, 9] have indicated methods that are most useful for medical error analysis. In these papers and other investigations, authors provide the adaptation of well-known and popular HRA-methods for the medical domain. The background of HRA methods is discussed in [9].

A healthcare system includes components of different types, such as technical components (equipment/devises) and the human factor. Therefore, this system is inhomogenous in the view of reliability engineering [3, 4, 7], and the construction of mathematical representation including all types of component become challenging [3, 7, 10]. The simplest decision is obtained for system of stationary states, where the time dependence of system behavior can be ignored. One of possible representation for this condition is a structure function. This is a deterministic model and all possible component states and performance levels must be indicated and reflected in the structure function. However, complete information of healthcare systems cannot be obtained, since the observation of all situations is impossible: some of them agree with hazard of patient's health. For example, author in [3] consider reliability and safety of pacemaker application that is interpreted as system with uncertainty. Furthermore, parts of the information are deducted from expert's experiences. This information is ambiguous and unequal, It can be considered with just some reliability or confidence. Therefore, the structure function of healthcare systems must be constructed based on uncertain data.

In this paper, a novel method for constructing the structure function is proposed. We take into account the uncertainties of initial data and suggest a method that is based on the *Fuzzy Decision Tree* (FDT). FDTs are widely used in data mining for analysis of uncertain data and

This work was supported by the grant of 7th RTD Framework Program No 610425 (RASimAs)

decision making in ambiguities [11, 12]. FDTs can be used naturally to analyze fuzzy data. Therefore, the initial data used to construct the structure function can be fuzzy. To transform a real system's performance level and its component states into an exact model, such as the structure function, fuzziness of bounds of performance levels/states are considered. In addition, FDTs allow to take into account uncertainties caused by incompletely specified data. This is still possible if it is expensive to obtain all data about the real system's behavior, if there is only sparse data, or if data s acquired incompletely due to poor documentation.

As a rule, if the exact value of the actual data about the system behavior cannot be determined, we need to rely on more data to give additional information necessary to correct the theoretical model used [13]. An FDT allows reconstructing these data with different levels of the confidence [14]. The use of FDTs for the construction of the structure function assumes the induction of a tree that is based on the data (fuzzy and/or crisp). The values of the structure function are then defined by the FDT for all combinations of the component states.

This paper is structured as follows. Section II discusses the concept of structure function. Principal steps of the proposed method are considered in Section III. The detail description of all steps is given in Section IV. The results of method evaluation are presented in Section V, and the discussion and conclusion are given in Section VI.

II. The Structure Function in Healthcare Analytics

A. Structure Function

The concept of structure function is introduced in reliability engineering in order to mathematically describe the real system that is studied. In this case, the system is represented as a mapping that assigns a system state to every possible profile of component states. Therefore, the system performance level is defined from the states of all its components, and all possible component states as well as all performance levels must be indicated and reflected in the structure function.

The structure function allows to represent the system's reliability behavior for two typical mathematical models, i.e. the *Binary-State System* (BSS) and the *Multi-State System* (MSS). BSS permits only two states to investigate the system and its components: perfect functioning and complete failure. However in practice, many systems can exhibit different performance levels between these two extremes of full function and fatal failure [15, 16]. MSS is a mathematical model that is used to describe a system with several (more than two) levels of performance [15, 17, 18].

The concept of the structure function is used to represent BSS and MSS, and associates the space of component states and system performance levels:

$$\phi(x_1,\ldots,x_n)=\phi(\boldsymbol{x}):\\ \{0,\ldots,m_1-1\}\times\ldots\times\{0,\ldots,m_n-1\}\to\{0,\ldots,M-1\}, \quad (1)$$

where $\phi(\boldsymbol{x})$ is the system state (performance level) from failure ($\phi(\boldsymbol{x})=0$) to perfect functioning ($\phi(\boldsymbol{x})=M$ -1); $\boldsymbol{x}=(x_1,\ldots,x_n)$ is a vector of system component's states (state vector). The state $\phi(\boldsymbol{x})=0$ represents the total failure of the component while state $\phi(\boldsymbol{x})=m_i$ -1 corresponds to perfect functioning of the i-th component.

Therefore, (1) defines the MSS structure function of n components (subsystems). The state of each component can be denoted by a random variable, x_i, and every component of the MSS is characterized by probabilities of its states:

$$p_{i,s}=\Pr\{x_i=s\},\quad s\in\{0,\ldots,m_i-1\}. \quad (2)$$

As it is shown in [10], reliability analysis of healthcare systems can be provided if the system is represented by a structure function (1). Then, the typical measures of reliability, e.g., the system availability (probabilities of the system performance levels), can be calculated by the structure function [18, 10]:

$$A_j=\Pr\{\phi(\boldsymbol{x})=j\},\ j=0,\ldots,M\text{-}1. \quad (3)$$

For example, consider a simple system to indicate medical errors of two components: a doctor (x_1) and diagnostic device (x_2). Suppose three levels in the doctor work: 0 is interpreted as fatal error, 1 is incorrect work (without fatal result) and 2 is perfect work. The devices can have two states only: 0 is failure and 1 is proper function. The system quantification has three levels: 0 is incorrect diagnosis with fatal consequence for the patient, 1 is incorrect diagnosis without fatal consequence for the patient, and 2 is correct diagnostics. This system (the medical error identification) is represented by the structure function in Table I. The probability of every performance level (availability) of this system is calculated according to (3):

$$A_0=\Pr\{\phi(\boldsymbol{x})=0\}=p_{1,0}\cdot p_{2,0},$$
$$A_1=\Pr\{\phi(\boldsymbol{x})=1\}=p_{1,0}\cdot p_{2,1}+p_{1,1}\cdot p_{2,0},$$
$$A_2=\Pr\{\phi(\boldsymbol{x})=2\}=p_{1,1}\cdot p_{2,1}+p_{1,2}\cdot p_{2,0}+p_{1,2}\cdot p_{2,1}$$

TABLE I.
THE STRUCTURE FUNCTION OF THE MEDICAL ERROR IDENTIFICATION

The system components		$\phi(\boldsymbol{x})$
x_1	x_2	
0	0	0
0	1	1
1	0	1
1	1	2
2	0	2
2	1	2

There are a lot of methods to estimate different aspects of the system's reliability based on the structure function [3, 10, 15, 17, 18]. Therefore, the structure function allows for investigating the system's reliability. In some applications – such as the medical domain – the construction of the structure function is a complex problem, because the structure function (1) usually is assumed to be exact and ambiguities are not taken into account. Since data about real

systems is uncertain, the structure function may not be realistic, which is – as a rule – typical for healthcare systems [7].

B. The Structure Function for Healthcare Systems

From the point of view of reliability analysis, estimating preventable medical errors in healthcare system is the principal goal.

During the past decade, healthcare delivery has seen the introduction of ever more sophisticated and complex equipment for preventable medical errors. Furthermore, the human factor still is an important component of such systems. The persistence of medical errors according to [7] suggests that there is either an absence of reliability engineering analysis or a gap in the reliability analysis currently being performed. The decision of this problem can be implemented by changing the process design of healthcare system and/or performing the reliability analysis of healthcare system's exploitation. It supposes the adaptation and application of reliability analysis methods for healthcare system.

The first step in reliability estimation of any system is to determine a mathematical model (representation). Such mathematical model of a healthcare system is:

- complex, the system cannot be represented by a typical structure (series, parallel, *k*-out-of-*n* etc.) only;
- inhomogeneous, it implies different types of the system components (hardware, software, human factor);
- uncertain, it is caused by human factor influence.

In case of the structure function, complexity and inhomogeneity of healthcare systems can be realized in a mathematical representation without special algorithms [15, 19]. In the construction of the structure function for healthcare system, the uncertainty of the initial data needs adaptation and the reasons of this uncertainty must be considered. According to (1), the structure function is defined if all of possible components and system states are indicated. As a rule, it is impractical to wait until all the component states are indicated. The first factor then is incomplete specification of data, because some values of the system component's states or performance levels cannot be obtained. In substitution, extra data on the healthcare system can be obtained through expert analysis. The second factor of uncertainty of initial data is the ambiguity and vagueness of collected data values. This type of ambiguity can be caused by an expert's subjective evaluation etc. For example, two experts can set different values of system performance level for equal situation [20, 21]. Therefore, uncertainty of initial data must be considered when constructing the structure function.

Uncertainties and ambiguities of a real system have been dealt with in reliability analysis using of the likelihood concept [13, 19]. However, uncertainties that are caused solely in evaluation by an expert's experience and judgement are not random in nature. This uncertainty can't be indicated in a quantitative form by probability theory.

Fuzzy logic, however, makes it possible to define the structure function in a more flexible form than the probabilistic approach. Consequently the structure function of a healthcare system must be constructed based on fuzzy data and incomplete samples. It is a typical problem in data mining. Therefore, we propose the use of the Fuzzy Decision Tree (FDT), which has been used widely in data mining, for analysis of uncertain data, and decision making with ambiguities. Here, collected data for structure function construction can be defined and characterized by likelihood (likelihood) or confidence if there is little data about the real system's behavior. An FDT allows to reconstruct these data with different levels of likelihood (confidence) [12, 14]. Applying FDT, we propose a new method for the construction of the structure function to mathematically represent healthcare system.

FDTs imply a tree based on the data about the system, which can be fuzzy and/or crisp, and the data can be specified incompletely. The values of the structure function are then defined for all combinations of component states by the FDT: component states are interpreted as FDT attributes and the structure function value agrees with one of the M values (classes) for the system performance level.

III. A Novel Method for Structure Function Construction by FDT

The structure function is a construct of mathematical representations that can be defined by a system structure analysis or that can be based on expert data [13, 22]. The structure function for system that includes a human factor is funded based on the evaluation by an expert's experience and judgment. Any healthcare system is a typical example of such a system.

The construction of a structure function representing expert's data requires special analysis and transformation of the initial system's data [7, 23], because expert's data is uncertain as a rule. This uncertainty can be caused by a lot of factors, but we have considered two of them. The first factor is incompletely specified data, because some values of system states or performance levels cannot be obtained. For example, it can be expensive or it might need unacceptable long time to get the data. The second factor is ambiguity and vagueness of collected data values. This type of ambiguity can be caused, for instance, by inaccuracies or errors of measurement, or subjectivity of expert's evaluations.

Therefore, the construction of the structure function must appreciate two aspects. The first is a mapping assigning the system performance level to each possible profile of component states (for example, see Table I). The second is addressed by interpreting it as classification problem for uncertain data, which is typical for data mining. One of the possible options is applying decision trees or FDT [31-34].

Our approach is based on FDTs [24, 25] and includes the following steps (Fig.1):

- Collection of data in the repository according to requests of FDT induction;

• Representation of the system model in the form of an FDT that classifies component states according to the system performance levels;

• Construction of the structure function as decision table that is created by the inducted FDT.

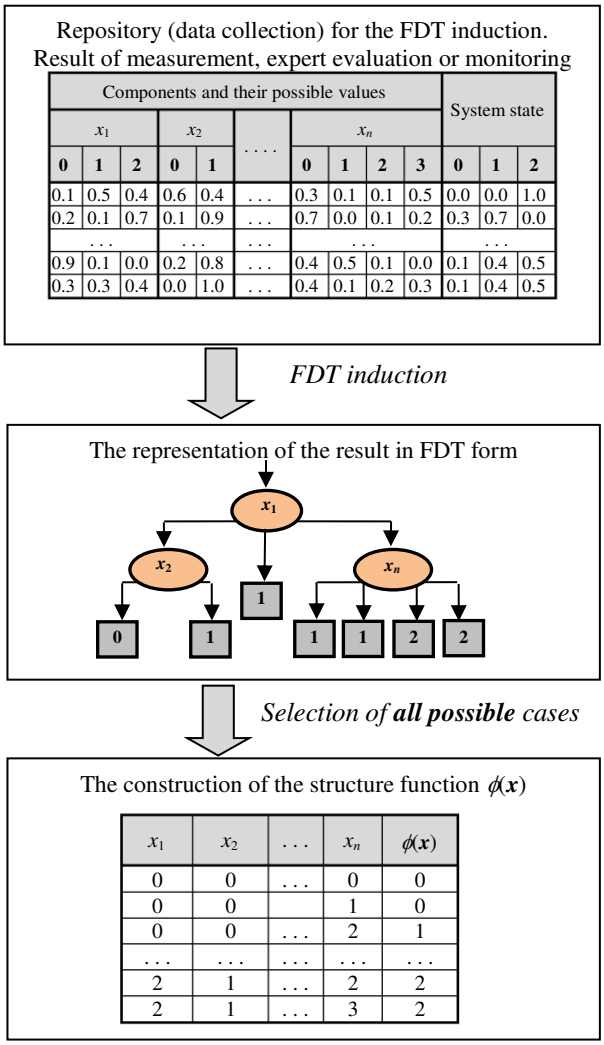

Fig. 1 Principal steps in the structure function construction based on FDT application

Therefore, the structure function is constructed as decision table that classifies the system performance level to each possible profile of components states. The decision table is formed based on a FDT that provides the mapping for all possible component states (input data) in M performance levels. FDT is inducted by uncertain data that is presented in form of specified repository.

IV. Principal Steps of the Method

A. The Repository for Data Collection

Collection of data in the form of a repository is provided by the monitoring or expert evaluation of values of the system's component states and the system's performance levels (Fig.1). Data for a repository is collected by monitoring if it is possible (for example, for some devises or equipment). It is expert evaluation dominantly in case of the system with analysis of human factor that is important component of any healthcare system. Therefore data for the construction of the repository for the analysis of healthcare system collects the expert experience. The experts propose an estimation of every situation (state vector) and resulting system state (system performance level) with some possibilities (likelihoods). The transformation of expert knowledge into quantification data is implemented based general rules that used for the analysis of experts' knowledge. Some of such methods are presented and discussed in papers [20, 21]. Need to note that initial data structuration and the repository preparation is important step and can be considered as separate problem for investigation and development.

The column number is n+1 (for indication of n components and the system's performance level). All of the n columns are separated into m_i sub-columns, and the column for the system's performance level has M sub-columns. The sub-column is assigned with one of the values for component states or performance levels. Every row of the table represents one monitoring situation or evaluation. The table cell includes number (from 0 to 1) that interpreted as the likelihood of this value. Note that the sum of these possibilities for each value equals 1. Such data can be obtained from experts' evaluations or possibility of fuzzy clustering [26, 27]. These possibilities correspond to a membership function of fuzzy data [28]. This demand for initial data representation is caused by the method of FDT induction. Therefore, values of the i-th component state and the performance levels are defined by possibilities. These possibilities indicate ambiguity of collected data values for the analysis. Having indicated and considered the uncertainty of the monitoring data, the resulting accuracy of data analysis is increased.

For example, consider a simple laparoscopic surgery procedure [7]. It is typical healthcare system with human component. Let us indicate 4 components (n = 4) of this system: device (a laparoscopic robotic surgery machine [29]), two doctors (anesthesiologist and surgeon) and a nurse. Let us interpret this system as *Multi-State System* MSS and introduce the numbers of states for every component and number of performance levels of the system. Let this system has three performance levels (M = 3):

0 – non-operational (fatal medical error),

1 – partially operational (some imperfection),

2 – fully operational (surgery without any complication).

The device has two states (m_1 = 2):

0 – failure, and

1 –functioning.

The work of anesthesiologist is indicated by two states (m_2 = 2):

0 – non-operational (medical error),

1 – fully operational (without any complication).

TABLE II.
THE COLLECTED DATA FOR ANALYSIS OF LAPAROSCOPIC SURGERY SUCCESSFUL

No	x_1		x_2		x_3			x_4			$\phi(x)$		
	0	**1**	**0**	**1**	**0**	**1**	**2**	**0**	**1**	**2**	**0**	**1**	**2**
1	0.6	0.4	0.9	0.1	0.1	0.9	0.0	0.2	0.6	0.2	0.9	0.1	0.0

4	1.0	0.0	0.1	0.9	1.0	0.0	0.0	0.1	0.9	0.0	0.8	0.2	0.0
5	0.9	0.1	0.0	1.0	0.1	0.2	0.0	0.1	0.9	0.0	1.0	0.0	0.0
6	1.0	0.0	0.0	1.0	0.0	0.0	1.0	0.0	1.0	0.0	0.0	1.0	0.0
7	1.0	0.0	0.0	1.0	0.0	0.1	0.9	0.0	0.3	0.7	0.1	0.8	0.1
8	0.0	1.0	1.0	0.0	0.0	1.0	0.0	0.0	0.6	0.6	0.1	0.9	0.0
9	0.1	0.9	0.1	0.9	0.1	0.1	0.8	1.0	0.0	0.0	0.1	0.8	0.1
10	0.3	0.7	0.9	0.1	0.0	0.0	1.0	0.0	0.5	0.5	0.0	0.1	0.0
11	0.2	0.8	0.0	1.0	0.9	0.1	0.0	0.0	1.0	0.0	1.0	0.0	0.0
12	0.0	1.0	0.0	1.0	0.1	0.9	0.0	0.8	0.2	0.0	0.0	1.0	0.0
13	0.1	0.9	0.2	0.9	0.1	0.8	0.1	0.0	0.6	0.4	0.0	0.0	1.0
14	0.2	0.8	0.0	1.0	0.0	0.1	0.9	1.0	0.0	0.0	0.1	0.8	0.1
15	0.3	0.7	0.0	1.0	0.0	0.1	0.9	0.1	0.8	0.1	0.0	0.1	0.9

The work of surgeon and the nurse can be modelled both by 3 levels ($m_3 = m_4 = 3$), i.e.:

0 – (the fatal error),

1 – (sufficient), and

2 – (perfect or the work without any complication).

The structure function of the system for analysis this simplified version of a laparoscopic surgery is composed of 36 situations (state vectors). The monitoring and expert analysis of this system permits to obtain some samples that represent the system behavior. In Table II, 15 samples are shown. In this table, 15 of 36 possible state vectors are indicated only. However, this information is uncertain because the data from real monitoring is incomplete and values are ambiguous. The monitoring does not allow obtaining information about all possible samples (situations) for fatal medical errors, because it would imply patient's health. So, the expert (or experts) adds some information about the system behavior, which can be uncertain, too. For example, an expert can indicate for the sample under the consideration the system performance level with likelihood only: as operational ($\phi(\boldsymbol{x}) = 2$) with the likelihood of 0.0, partly operational ($\phi(\boldsymbol{x}) = 1$) with likelihood 0.1 and non-operational ($\phi(\boldsymbol{x}) = 0$) with the likelihood of 0.9.

Table II illustrates the correlation of monitoring data and the structure function for this system. The monitoring data can be transformed into the structure function (1) for the system based on the following rule: only the value with the highest likelihood is considered. For example, the variable x_1 in Table II has value 0 with the likelihood of 0.6 and value 1 with the likelihood of 0.4. The resultant value is defined as 0 in this case, but some of the state vectors are absent in the repository. Traditional mathematical approaches for system reliability analysis are based on the structure function, which cannot be used in this case. Therefore, the construction of a structure function (1) based on incomplete data requires a special transformation and the development of new methods.

B. Representation of system model in the form of an FDT

A decision tree (and FDT in particular) can be considered as an alternative form of the structure function. The structure function maps state vectors to each equivalence class of the system's performance levels. At the same time, a decision tree is a formalism for expressing mappings of input attributes (component's states) and output attribute/attributes (system performance level/s), consisting of an analysis of attribute nodes, which are linked to two or more sub-trees and leaves or decision nodes that are labeled with a class (in our case it is the system performance level) [14]. The outcome of the analysis is based on attribute values of a sample, where each possible outcome is associated with one of the sub-trees. A sample is classified by the starting at the root node of the tree. If this node is not a leaf, the outcome for the instance is determined and the process continues using the appropriate sub-tree. If a leaf is encountered, its label directs to the predicted class of sample. The system's component states are interpreted as values of the input attributes. The system's performance levels are considered as an instance that is classified into M classes.

FDT is one of the possible types of decision trees that permit to operate with fuzzy data (attributes) and methods of fuzzy logic. The construction of a FDT-based structure function assumes ambiguous data and that the analysis of such data can be implemented based on the methods of fuzzy logic [11, 30, 31]. The ambiguity of data values may be present in the attributes (system components states) and the exact class of the instance (system performance level).

There are different methods to induct a FDT [11, 24, 25, 31]. The principal goal of all methods is to select expanded attributes and determine the leaf node. The FDT induction is implemented based on some initial data that is interpreted as a training test. Every training sample includes n attributes A_1, ..., A_n and an output attribute B. The construction of the structure function supposes its correlation with the FDT (Table III): the system performance level is the output

attribute and the component's states (state vectors) are input attributes. Each input attribute (component state) A_i ($1 \le i \le n$) is measured by a group of discrete values from 0 to m_i-1 that agree with the values of the i-th component states: $\{A_{i,0},\ldots,A_{i,j},\ldots,A_{i,m_i-1}\}$. The FDT assumes that the input set A_1, ..., A_n is classified as one of the output value attributes B. The output attribute value B_w agrees with one of the system's performance levels and is defined by M values ranging from 0 to M -1 ($w = 0,\ldots, M$ -1).

For example, set input attributes $\{A_1, A_2, A_3, A_4\}$ and output attribute B for the success of laparoscopic surgery are indicated in Table IV according to FDT terminology. Each attribute is defined as: $A_1=\{A_{1,0}, A_{1,1}\}$, $A_2=\{A_{2,0}, A_{2,1}\}$, $A_3=\{A_{3,0}, A_{3,1}, A_{3,2}\}$, $A_4=\{A_{4,0}, A_{4,1}, A_{4,2}\}$ and $B = \{B_0, B_1, B_2\}$.

TABLE III.
CORRELATION OF THE TERMINOLOGIES OF FDT AND RELIABILITY ANALYSIS

FDT	System reliability
Number of input attributes: n	Number of system components: n
Attribute A_i ($i = 1, \ldots, n$)	System component x_i ($i = 1, \ldots, n$)
Attribute A_i values: $\{A_{i,0},\ldots,A_{i,j},\ldots,A_{i,m_i-1}\}$	The i-th system component state: $\{0, \ldots, m_i-1\}$
Output attribute B	System performance level $\phi(\boldsymbol{x})$
Values of output attribute B: $\{B_0, \ldots, B_{M-1}\}$	Values of the system's performance levels: $\{0, \ldots, M-1\}$
Decision table	Structure function

A fuzzy set A with respect to an universe U is characterized by a membership function $\mu_A : U \to [0,1]$, assign a A-membership degree, $\mu_A(u)$, to each element u in U. $\mu_A(u)$ gives us an estimation of u belonging to A. The cardinality measure of the fuzzy set A is defined by $M(A) = \Sigma_{u\in U}\, \mu_A(u)$, which is the measure of the size of A.

For $u\in U$, $\mu_A(u) = 1$ means that u is definitely a member of A and $\mu_A(u) = 0$ means that u is definitely not a member of A, while $0 < \mu_A(u) < 1$ means that u is partially a member of A. If either $\mu_A(u) = 0$ or $\mu_A(u) = 1$ for all $u \in U$, A is a crisp set. The set of input attributes A is crisp for which $\mu_A(u) = 0$ or $\mu_A(u) = 1$. The values of input and output attributes are defined by the membership function. They are obtained from the monitoring data (Table II) according to the correlation shown in Table IV. Indicated attributes values are used as a training test to construct the FDT.

In this paper, we adopt the FDT induction principle to construct the structure function based on cumulative information estimates [24, 25]. The cumulative information estimates allow defining the criterion of expanded attribute selection to induct FDT with different properties. These estimates are calculated by measures of entropy and information. Entropy and information have been introduced to the information theory as a probabilistic approach. The application of these measures assumes that the sum of possibilities of all values of every attribute equals 1 [26, 27, 28]. Note that the likelihood of attribute's value in terms of FDT induction is measured as confidence degree or degree of truth in this value.

TABLE IV.
ATTRIBUTES VALUES OF SYSTEM FOR LAPAROSCOPIC SURGERY PROCEDURE

Structure function	Attribute	Attribute values	Description of attribute values
The first component state, x_1	A_1	$A_{1,0}$	Device failure
		$A_{1,1}$	Devise working
The second component state, x_2	A_2	$A_{2,0}$	Error of anesthesiologist
		$A_{2,1}$	Anesthesiologist work without complication
The third component state, x_3	A_3	$A_{3,0}$	Error of surgeon
		$A_{3,1}$	Sufficient work of surgeon
		$A_{3,2}$	Perfect work of surgeon
The forth component state, x_4	A_4	$A_{4,0}$	Error of nurse
		$A_{4,1}$	Sufficient work of nurse
		$A_{4,2}$	Perfect work of nurse
System performance level $\phi(\boldsymbol{x})$	B	B_0	Fatal medical error
		B_1	Some imperfection
		B_2	Surgery without any complication

Figure 2 depicts the FDT for the laparoscopic surgery example. This FDT has 4 levels and includes all input attributes. This implies that all input attributes are considered to be significant for this system. The attribute A_3 is most significant as it agrees with the surgeon's work. Therefore, A_3 is associated with the FDT root (top node). This attribute can have the values $A_{3,0}$, $A_{3,1}$, and $A_{3,2}$, which are associated with branches of the FDT. Each branch agrees with a block of the output attribute values, and the confidences of every value of the output attributes are indicated. This block is a leaf if one output attribute has a sufficient level of confidence. In the other case, the FDT provides the analysis of the next input attribute. In this example, the value $A_{3,1}$ and $A_{3,2}$ of the attribute A_3 supposes the analysis of the attribute A_1 and A_2, respectively. The sufficient value of the output attribute is defined by the user between 0 to 1. For instance in the laparoscopic surgery example, this sufficiency of the FDT has been set to 0.750 (Fig. 2).

The FDT can be transformed into classification (decision) rules. A new sample e may be classified into different classes with different confidence. Let the FDT have R leaves $L = \{l_1, \ldots, l_r, \ldots, l_R\}$, then each leaf $l_r\in L$ corresponds to one (r-th) classification rule. The condition part of the classification rule is a group of conditions that is represented in the form: "attribute is attribute's value". Such conditions are interconnected with an AND operator. The attributes are associated with the nodes in the path from the root to the leaf l_r.

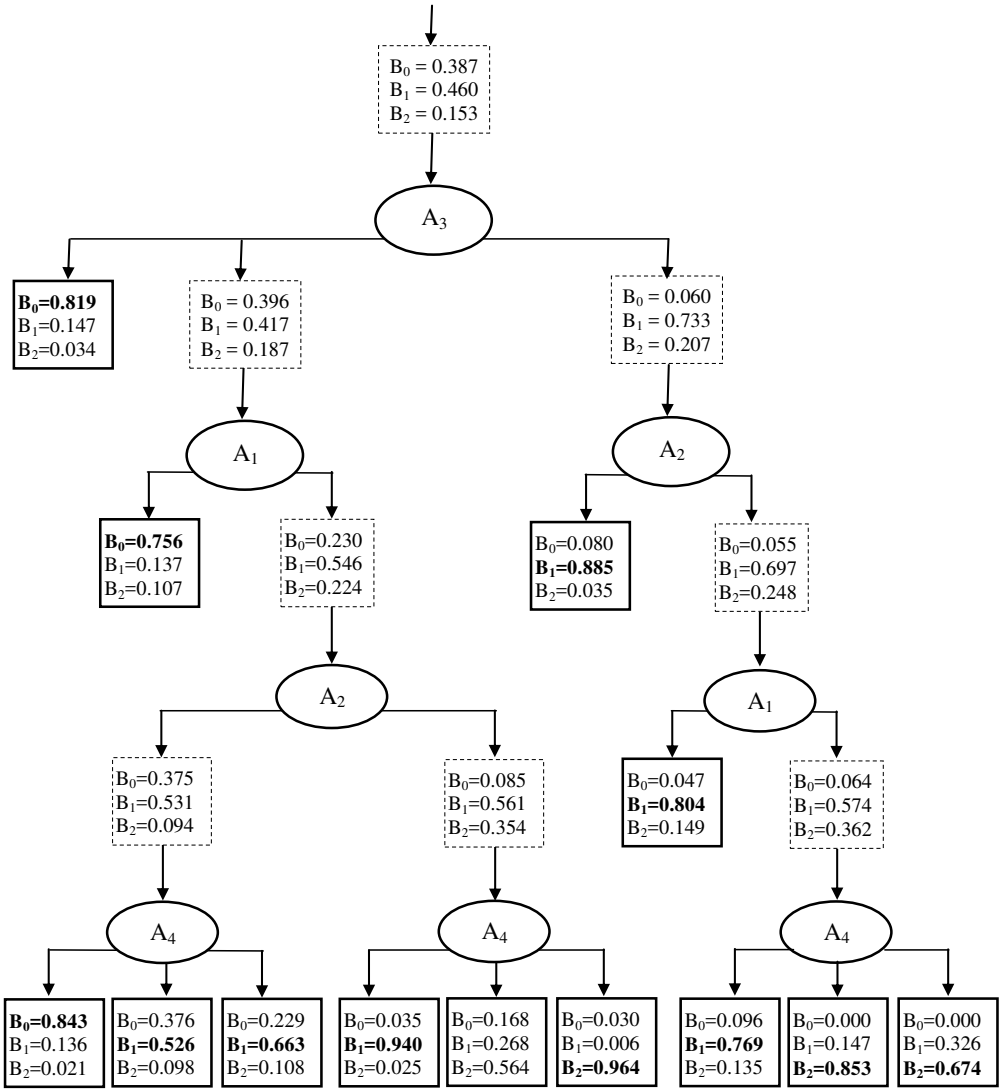

Fig. 2 The FDT for the construction of structure function to analyze laparoscopic surgery successful

The attribute's values are associated with the respective outgoing branches of the nodes in the path. Conclusions of the *r*-th rule are the values of class attribute B with their truthfulness vector $\mathbf{F}^r = [F_1{}^r;..., F_j{}^r;..., F_M{}^r]$ for each *r*-th leaf *l* and each *j*-th class B_j. Each value $F_j{}^r$ means the certainty degree (confidence) of the class B_j attached to the leaf node l_r.

Let's consider the path $P_r(e) = \{[A_{i_1 j_1}(e)]^r,\ldots,[A_{i_s j_s}(e)]^r,\ldots,[A_{i_S j_S}(e)]^r\}$ from the FDT root to the *r*-th leaf. This path $P_r(e)$ consist of *S* nodes which are associated with attributes $A_{i_1},.., A_{i_s},\ldots, A_{i_S}$ and respectively their *S* outgoing branches associated with the values $A_{i_1 j_1},.., A_{i_s j_s},\ldots , A_{i_S j_S}$. Then the *r*-th rule has the following form:

$$\text{IF } (A_{i_1} \text{ is } A_{i_1,j_1}) \text{ and } \ldots \text{and } (A_{i_S} \text{ is } A_{i_S,j_S}) \quad \text{THEN B (with truthfulness } \mathbf{F}^r) \tag{3}$$

The classification rules for the laparoscopic surgery example are shown in Fig.3.

C. Construction of the structure function based on the FDT

As it was shown in Section III, the structure function agrees with the decision table. The decision table can be constructed based on the FDT or classification (decision) rules or a [25]. A decision table indicates all possible values of input attributes and agrees with the structure function. Therefore, cal the decision table is calculated for all possible values of the component's states and considered as the structure function (1).

For the laparoscopic example, assume that the state vector is $\boldsymbol{x}$ = (0 1 1 0). According to the FDT (Fig. 2), the system output attribute for all possible vector states can have the value 0, 1, and 2 with the confidence of 0.387, 0.460, and 0.153, respectively. However, these confidences are under the given threshold of 0.750. Therefore, the analysis of the state vectors is implemented based on the FDT. It starts with the attribute A_3 (Fig. 2). The value of this component state is x_3 = 1 and the branch for the attribute value $A_{3,1}$ is

considered. The output attribute can have the value 0, 1, and 2 with the confidence of 0.396, 0.417, and 0.187, respectively. Again, all these confidences are below the threshold 0.750. Therefore, a decision about the value of the system's performance level is impossible and the analysis continues with the attribute A_1. The estimation of this attribute is implemented using a branch with attribute value $A_{1,0}$ because the specified state vector includes $x_1 = 0$. The branch of this value has the leaf-node. Therefore, the value of the output attribute is defined as the value with the maximal confidence, which is 0.756 for the value 0. Considering this, the system performance level for the specified state vector is $\phi(\boldsymbol{x}) = 0$. Therefore the fatal medical error is possible with confidence 0.756 if the level of the surgeon's work is sufficient and there is a malfunction of the laparoscopic robotic surgery machine. The analysis of other state vectors is similar and allows to obtain all possible values of the system performance level in the form of the structure function.

r=1 : IF A_3 is $A_{3,0}$ THEN B with $\mathbf{F}^1$ = [0.819; 0.147; 0.034];
r=2 : IF A_3 is $A_{3,1}$ *and* A_1 is $A_{1,0}$ THEN B with $\mathbf{F}^2$ = [0.756; 0.137; 0.107];
r=3 : IF A_3 is $A_{3,1}$ *and* A_1 is $A_{1,1}$ *and* A_2 is $A_{2,0}$ *and* A_4 is $A_{4,0}$ THEN B with $\mathbf{F}^3$ = [0.843; 0.136; 0.021];
r=4 : IF A_3 is $A_{3,1}$ *and* A_1 is $A_{1,1}$ *and* A_2 is $A_{2,0}$ *and* A_4 is $A_{4,1}$ THEN B with $\mathbf{F}^4$ = [0.376; 0.526; 0.098];
r=5 : IF A_3 is $A_{3,1}$ *and* A_1 is $A_{1,1}$ *and* A_2 is $A_{2,0}$ *and* A_4 is $A_{4,2}$ THEN B with $\mathbf{F}^5$ = [0.229; 0.663; 0.108];
r=6 : IF A_3 is $A_{3,1}$ *and* A_1 is $A_{1,1}$ *and* A_2 is $A_{2,1}$ *and* A_4 is $A_{4,0}$ THEN B with $\mathbf{F}^6$ = [0.035; 0.940; 0.025];
r=7 : IF A_3 is $A_{3,1}$ *and* A_1 is $A_{1,1}$ *and* A_2 is $A_{2,1}$ *and* A_4 is $A_{4,1}$ THEN B with $\mathbf{F}^7$ = [0.168; 0.268; 0.564];
r=8 : IF A_3 is $A_{3,1}$ *and* A_1 is $A_{1,1}$ *and* A_2 is $A_{2,1}$ *and* A_4 is $A_{4,2}$ THEN B with $\mathbf{F}^8$ = [0.030; 0.006; 0.964];
r=9 : IF A_3 is $A_{3,2}$ *and* A_2 is $A_{2,0}$ THEN B with $\mathbf{F}^9$ = [0.080; 0.885; 0.035];
r=10: IF A_3 is $A_{3,2}$ *and* A_2 is $A_{2,1}$ *and* A_1 is $A_{1,0}$ THEN B with $\mathbf{F}^{10}$ = [0.047; 0.804; 0.149];
r=11: IF A_3 is $A_{3,2}$ *and* A_2 is $A_{2,1}$ *and* A_1 is $A_{1,1}$ *and* A_4 is $A_{4,0}$ THEN B with $\mathbf{F}^{11}$ = [0.096; 0.769; 0.135];
r=12: IF A_3 is $A_{3,2}$ *and* A_2 is $A_{2,1}$ *and* A_1 is $A_{1,1}$ *and* A_4 is $A_{4,1}$ THEN B with $\mathbf{F}^{12}$ = [0.000; 0.147; 0.853];
r=13: IF A_3 is $A_{3,2}$ *and* A_2 is $A_{2,1}$ *and* A_1 is $A_{1,1}$ *and* A_4 is $A_{4,2}$ THEN B with $\mathbf{F}^{12}$ = [0.000; 0.326; 0.674];

Fig. 3 The classification rules for the construction of structure function for the analysis of successful laparoscopic surgery

It is important to note that this method of the structure function constructing based on FDTs permits to compute (restore) data missing from the monitoring. Therefore, probabilities of system performance can be calculated according to typical methods used in reliability engineering, i.e., based on the structure function. For example, the system availability (1) can be calculated for the system that is presented the laparoscopic surgery success based on the indicated values of the component state probabilities (Table V). The availability of this system according to (3) and data in Table V is calculated based on the structure function constructed through the FDT(Fig. 2):

$$A_0 = 0.098, \quad A_1 = 0.214, \quad A_2 = 0.688 \qquad (4)$$

TABLE V.
PROBABILITIES OF THE COMPONENTS STATES

System component description	Component's states probabilities		
	$p_{i,2}$	$p_{i,1}$	$p_{i,0}$
The laparoscopic robotic surgery machine functioning, x_1	—	0.98	0.02
The anesthesiologist's work, x_2	—	0.94	0.06
The surgeon's work, x_3	0.64	0.27	0.09
The nurse's work, x_4	0.47	0.35	0.18

The values of the availabilities in (4) imply that laparoscopic surgery can be with:

a) fatal medical error with probability 0.098,

b) sufficient result (some complications) with probabilities 0.214 and

c) perfect result 0.688 (without any complications).

Other measures can be computed by the structure function too. For example, importance measures for this system are defined according to the algorithms considered in [10, 30].

V. RESULTS

Our method has been investigated depending on the level specify of the initial data. We considered 3 benchmarks for the method evaluation [13, 15]:

- The system 1 has 3 performance levels, consist of 5 component and its structure function has 243 state vectors;
- The system 2 has 5 performance levels, consist of 4component and its structure function has 108 state vectors;
- The system 3 has 4 performance levels, consist of 5 component and its structure function has 521 state vectors;

The structure functions are known and defined for these systems. We have used this data to examine efficiency and accuracy of proposed method for the construction of the "new" structure function based on incompletely specified data. The incompleteness is modeled by random deleting of some state vectors and assigned performance level value. The range of deleted states is changed from 5% to 90%. The "new" structure function is constructed based these incompletely specified data and compare with initial structure function.

The constructed structure functions include individual or small groups of misclassified state vectors. Therefore, we have estimated this misclassification by an error rate. The constructed structure functions and initial completely and exact specified functions are compared and the error rate is calculated as the ratio of wrong values of the structure function to the dimension of unspecified part of the function. The experiments have been iterated 1000 times for every system. The error rate for every system and for different level of unspecified component states vector is shown in Fig.4. The error rate is depended on unspecified part of the initial data (state vectors) according results presented in

Fig.4. This error increases essentially, if the unspecified part is most than 80% for all investigated systems. We obtained an insignificant growth of the error rate if the unspecified part is less than 10%. Therefore according to this investigation we can declare recommended specify of initial data between 10% and 80%. This result is typical for FDT application [11, 12]. The specification of data less than 10% isn't sufficient for the correct construction of correlations between input and output attribute. And higher level of data specification (more 80%) restricts variations of FDT induction and causes misclassification values.

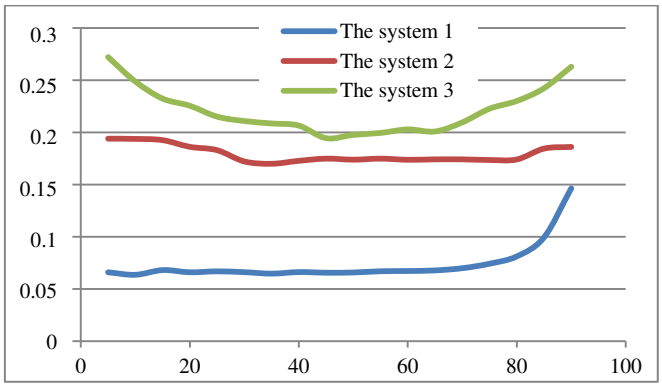

Fig. 4 The error rate for the construction of the structure function for three systems

VI. Discussion

The main contribution of this paper is that we have developed novel and original method for the construction of the structure function based on incompletely specified and ambiguous data. It directly supports MSS reliability estimation and can cope with uncertain data for the analysis of system reliability/availability. This is typical problem for reliability analysis of healthcare systems, where the data cannot be obtained for all possible situations.

The analysis of the error rate for the proposed method for the construction of the structure function based on FDT shows that this method has good efficiency. This method is acceptable for the incompletely data and the incompleteness of initial data can be indicated from 10% to 85%. The constructed structure function by the proposed method has less error rate than maximal error rate in interval of the incompleteness.

But error rate is not caused by range of incompleteness of initial data only. There are some factors that can influence to error rate. First of all it is specific properties of structure function. One of very important properties is monotony of structure function that is typical for coherent system [17, 30]. The structure function of the system 1 is monotonic and the error rate of this function is minimal. The structure function of the system 2 is monotonic too. Other property of structure function is "uniformity" that mean similar number of state vectors for all system performance levels. For example, the system 2 has maximal number of state vectors for one of performance level (46 of 108). Therefore range of incompleteness has small influence to error rate. Numbers of state vectors for every performance levels of the system 3 are similar. Therefore error rate increases for boundary range of incompleteness.

Beside the structure function properties, the system dimension (number of state vectors) influences to the error rate. This influence will be investigated in the future. Now, we can suppose that error rate decreases opposite to increasing of system dimension. The construction of the structure function of 50 state vectors is possible based on 20-30 state vectors (40-60% of defined state vectors). The structure function construction based on 5-10 state vectors (10-20%) is possible too. But level of accuracy depends on the quality of this set of state vectors. It will be essential to continue the verification and validation of our proposed method with data sets of different properties and sizes

Very important advantage of proposed method for constructing of the mathematical model of investigated system is possibility to ignore step of qualitative analysis that is typical in reliability analysis based on uncertain data. Methods for qualitative analysis (Failure mode and Effect Analysis (FMEA), Failure Mode Effects and Criticality Analysis (FMECA), Hazard Operability Study (HAZOP) etc.) are very good investigated in reliability engineering, but most of them include empirical evaluation of investigated system [8, 9, 13].Conclusion

Our comprehensive experiments have shown that reliability estimation of healthcare systems is possible with uncertain or incomplete data if the structure function is estimated using fuzzy decision trees. This opens a wide range of clinical applications for saver healthcare.

1st International Workshop on AI aspects of Reasoning, Information, and Memory

THERE is general realization that computational models of human reasoning can be improved by integration of heterogeneous resources of information, e.g., multidimensional diagrams, images, language, syntax, semantics, memory. While the event targets promotion of integrated computational approaches, we invite contributions from any individual areas related to information, language, memory, reasoning.

TOPICS

We welcome submissions of papers on the following topics, without limiting to them, across approaches, methods, theories, and applications:

- Reasoning systems — theories and applications
- Proof systems and model checkers
- Theories of computation and information
- Interactive computation and reasoning
- Computation and reasoning with heterogeneous information
- Space and time in information, language, memory, and reasoning
- Partiality, underspecification, vagueness, and possibilities
- Detection of and reasoning with inconsistency
- Logic and language — approaches, theories, methods
- Computational morphology, syntax, semantics, and interfaces between these
- Constraint-based and type-theoretic approaches and grammars
- Logical approaches to multilingual processing
- Logical and computational foundations in machine learning and information retrieval
- Mathematics for linguistics and cognitive science
- Reasoning, information, and memory in computational neuroscience and life sciences
- Interdisciplinary approaches to information, language, memory, and reasoning

EVENT CHAIRS

From Discourse Representation Structure to Event Semantics: A Simple Conversion?

Daniel Dakota and Sandra Kübler
Indiana University
Email: {ddakota, skuebler}@indiana.edu

***Abstract*—Many applications in Natural Language Processing require a semantic analysis of sentences in terms of truth-conditional representations, often with specific desiderata in terms of which information needs to be included in the semantic analysis. However, there are only very few tools that allow such an analysis. We investigate the representations of an automatic analysis pipeline of the C&C parser and Boxer to determine whether Boxer's analyses in form of Discourse Representation Structure can be successfully converted into a more surface oriented event semantic representation, which will serve as input for a fusion algorithm for fusing hard and soft information. We use a data set of synthetic counter intelligence messages for our investigation. We provide a basic pipeline for conversion and subsequently discuss areas in which ambiguities and differences between the semantic representations present challenges in the conversion process.**

I. Introduction

MANY applications in Natural Language Processing require a semantic analysis of sentences. However, automatic semantic analysis is a field in its infancy in Natural Language Processing. There is work on automatically analyzing semantic role labeling, as evidenced by two shared tasks at the Conference on Natural Language Learning [1], [2] and a special issue of the journal *Computational Linguistics* [3]. But for many downstream applications related to text understanding, semantic roles do not provide enough information. Our current work focuses on fusing soft and hard information, where soft information constitutes natural language. A fusion algorithm accepts information from different sources and provides an integrated, accurate, informative whole. While fusion algorithms for sensor data are advanced and reliable, efforts to include natural language are in their early stages [4]. When language is included, fusion often includes inference mechanisms [5]. In order to be able to integrate language information into a fusion approach, we need to provide the information in a variant of predicate logic, on which inference and fusion algorithms can work.

There are existing approaches to analyzing language into semantic representations based on different syntactic formalisms (cf. e.g., [6] for LFG and [7] for TAG). We focus here on truth-conditional semantics based on Combinatory Categorial Grammar (CCG) [8] since this grammar formalism provides the closest match to our needs in terms of the target predicate logic. CCG relies on combinatory logic, which is equivalent in expressive power to lambda calculus. One approach to parsing CCG is the C&C parser [9], [10], which can be used in combination with Boxer [11], [12], [13], a module that converts the CCG syntax to semantic representations in the form of Discourse Representation Structure (DRS) [14], [15]. Other CCG-based approaches attempt learning semantic representations from different sources directly (e.g. [16], [17]).

Our target semantic representation is a form of event semantics, which means that neither parser provides us with analyses that are usable directly. Thus, we present work on investigating a rule-based conversion from Discourse Representation Structure as provided by Boxer to our target event semantic representations.

The remainder of this paper is structured as follows: We first provide more details about the conversion task in section II, then we briefly introduce our target semantic representations in section III, focusing on those aspects and distinctions that we target in the conversion. We then describe the analysis pipeline in section IV and discuss cases that can be converted in a rule-based fashion in section V. Finally, we discuss linguistic phenomena that present challenges for a conversion in section VI and conclude with a discussion of approaches to handle those difficulties (section VII).

II. Task Overview

Our task is to perform a semantic analysis of sentences in order to use them in a data fusion model for fusing hard and soft information [18], [19]. The fusion model expects an analysis in terms of first order logic and can be extended to a Davidsonian model. In a Davidsonian model, semantics is non-propositional, and references are integrated into the semantic description. References between events are described using event variables.

Since an unlimited truth-conditional analysis of unrestricted sentences is a very challenging task and since we have a very specific task as downstream consumer of our annotations, we have decided to reduce the complexity of the task of semantic analysis by assuming an automatic syntactic simplification of the sentences to be analyzed. In contrast to standard approaches to sentence simplification, our syntactic simplification model (currently under development) will focus on specific syntactic phenomena and will simplify only sentences that display such phenomena. Simplification will be performed by a machine learning module trained on a small set of sentences displaying a specific phenomenon, based on a dependency parse. The simplified sentences will then be reparsed by the CCG parser.

978-83-60810-90-3/$25.00

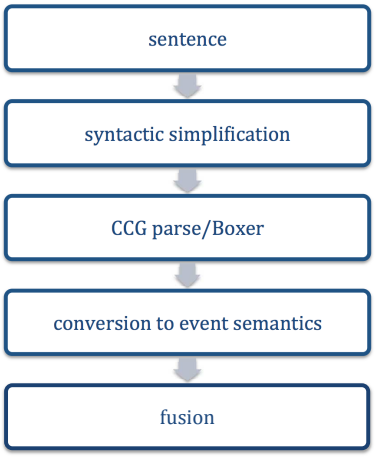

Fig. 1. Proposed Pipeline from the input sentence to information fusion.

The goal is a simplification without loss of information; we currently target coordination, reported speech, and passive sentences. Examples of simplifications are shown in examples (1)–(3). Note that in the case of reported speech, the reporting action is converted into an action and a certainty value (shown in square brackets), both of which can directly be used for information fusion.

(1) a. The man bought a book and a map.
b. The man bought a book. The man bought a map.

(2) a. The anonymous caller reported that an attack would happen next week.
b. An attack will happen next week. [action: report; certainty: 0.9]

(3) a. The man was given an object by a passer-by.
b. The passer-by gave the man an object.

As a consequence of the simplification step, we assume that the simplified sentences will be easier to parse by the CCG parser used in the semantic analysis. The final pipeline of the process is shown in Fig. 1.

III. The Annotated Data Set for Event Semantics

We use the SYNCOIN data set [20] for our experiments. SYNCOIN is a synthetically created set of counter insurgency scenarios in the form of collections of intercepted phone conversations and intelligence reports. The data set was designed to support approaches towards the fusion of hard and soft information.

We have access to truth-conditional semantic annotations of a set of sentences that constitute five "threads". These sentences were annotated within our project. The annotation scheme is based on Davidsonian event semantics [21], and the annotations are mostly rather surface oriented, in order to allow for robust automatic processing. The annotations are based on the following principles:

TABLE I
Annotation Scheme

Annotation	Description
x	named entity: person, group, or organization
y	a location
t	a time variable
e	an event variable
z	any other object

Since verbs report actions, they introduce event variables, and their syntactic arguments function as logical arguments in the following order: event, subject, direct object, and indirect object. We show an example sentence and its annotation in (4). Here, the verb *refuse* is analyzed as the 50th event in the thread, and it has two arguments, `x6` referring to *men* and `e2` referring to `attack`. Note that the annotation also states that the agent/subject of the attack are the men (`x6`).

(4) a. The men refuse to reveal operational details of the attack.
b. refuse(e50,x6,e51) ∧ men(x6) ∧ reveal(e51,x6,z14) ∧ details(z14,e44) ∧ operational(z14) ∧ attack(e14,x6)

There are two more points worth mentioning concerning the example: 1) Verbs are not the only concepts that introduce events. In the example, the nominalization *attack* is also represented as an event. 2) Both the men and the attack were mentioned previously in the text, which is indicated by shared variables. Thus, we integrate coreference information across sentence boundaries into the annotations.

The annotation scheme uses five types of variables, as shown in Table I. Nouns typically introduce variables of types `x` or `z` whereas the type `e` is typically introduced by verbs and nominalized verbs. Variable types `y` and `z` may be introduced by a wider range of parts of speech. Depending upon context, a word can potentially belong to more than one category.

All variables introduced by indefinite noun phrases and verbs are existentially quantified. However, existential quantifiers are not included as part of the semantic annotation. They are assumed to have scope over all sentences in the annotated document. Modifiers are introduced by adjectives, adverbs, and prepositional phrases. Adjectives typically introduce a new predicate, which is a property of objects as seen in (4) in the phrase *operational details*. Adverbs also introduce a new property. However, since they typically modify events, they have an event variable as argument, as seen in (5). Names are introduced by a predicate *named*. Possessive pronouns introduce a modifier which is annotated as a separate predicate as seen in (6). Units of measurements are introduced by a special predicate introducing the unit of measure and the numerical value, see the example in (7).

(5) a. The car drove fast.
b. car(z1) ∧ drove(e1,z1) ∧ fast(e1)

(6) a. John's car departed.

b. car(z1) ∧ possessive(x1,z1) ∧ named(x1,John) ∧ departed(e1,x1)

(7) a. 250 gallon tanks
b. tanks(z1) ∧ size_in_gallon(z1, 250)

Temporal phrases normally modify events, but can also introduce dates as seen in (8). Quantification is handled in a surface oriented way, as shown in (9). However, existential quantification over events is introduced by negation (see (10)) and questions.

(8) a. The man arrived on 01\05\10.
b. man(x1) ∧ arrived(e1,x1) ∧ on(e1,x1) ∧ date(t1,010510)

(9) a. Omar Khrayesh visits several bookstores in Adhamiya.
b. visit(e3,x1,y1) ∧ named(x1, Omar Khrayesh) ∧ bookstores(y1) ∧ several(y1) ∧ in(y1,y2) ∧ named(Adhamiya).

(10) a. Mallahati did not respond.
b. named(x1, Mallahati) ∧ not(∃e respond(e,x1))

IV. Analyzing Sentences Using DRS

A. Parsing

As discussed above, we utilize Combinatory Categorial Grammar [8] since it provides a clearly defined interface between syntax and truth-conditional semantics, making it ideal for our purposes. We use the C&C parser [9], [10] in combination with Boxer [11], [12], [13]. The parser provides pre-trained models based on CCGbank [22], sections 02-21 and MUC 7 [23]. We parse single sentences of SYNCOIN data into a CCG derivation. These derivations then serve as input for Boxer.

B. Boxer's DRS Analyses

Boxer is a module that uses the CCG derivations produced by the C&C parser to generate semantic representations in the form of Discourse Representation Structures (DRS), which are based on Discourse Representation Theory [15]. The theory assumes that hearers incrementally build a mental representation of a discourse, the DRS, which is a representational and non-compositional semantic representation. A DRS mainly models the referents of a discourse and the conditions that hold. A referent is an entity within the discourse while a condition is a predicate demonstrating properties of the respective referents.

A DRS consists of two parts, describing the referents and the conditions respectively. One important deviation from standard Discourse Representation Theory in Boxer is the use of a Neo-Davidsonian analysis of events and thematic roles [11]. This means that the representations provided by Boxer are close to our target event annotations, but that we need to abstract away from the semantic role representation and the more structured representation of referents.

DRS conditions are either basic or complex[1]. Complex conditions express phenomena such as implication or negation. In this paper, we focus on basic conditions, which express equalities, one-place relations, two-place relations, names, or time expressions. One-place relations are introduced by nouns, verbs, adjectives, and adverbs while two place relations are used to express verb roles and prepositions.

[1]A full account of Boxer's DRS representations can be found at http://svn.ask.it.usyd.edu.au/trac/candc/wiki/DRSs

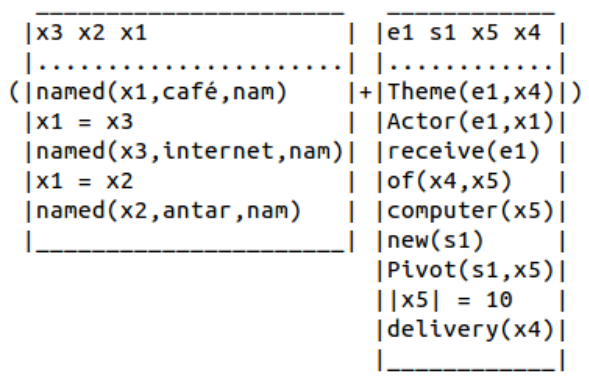

Fig. 2. Boxer DRS for sentence (11) in box format.

Boxer provides its analyses in two forms: a box representation and the same information in PROLOG style. The DRS structure of the SYNCOIN sentence (11) in box form is shown in Fig. 2. Each box, representing a single DRS, has the referents at the top, and the conditions within the box. The conditions of the second box show that the *café* is considered the actor and *delivery* the theme of the receiving event. The plus sign indicates the merging of the two basic DRS structures into a more complex one.

(11) The Antar Internet Café received a delivery of 10 new computers.

The second representation that Boxer offers is in PROLOG style, as shown in Fig. 3 (for example (11)). Here, the complex DRS is indicated by the merge operation. Since this representation is more easily processed automatically, we use it in our conversion to event semantics.

There are two primary types of information in the PROLOG representation, individual properties of the token and the semantic information of the tokens in the DRS. These two pieces of information are distinct, particularly as there are often tokens that do not have a semantic role in the DRS. Every token has an identification number indicating the position of the token in the sentence. This is accompanied by the original token, the part-of-speech (POS) tag of the token, the lemma, and information whether it is a named entity.

In regard to the semantic information in Fig. 3, we focus on two different types of conditions, predicates (pred) and relations (rel). Examining pred(x4,delivery,n,0)] more closely, a predicate consists of the referent (`x4`), the lemma (*delivery*), a general POS tag (n), and the word's named entity status (0 indicating false). A relation is represented as rel(e1,x1,'Actor',0) consisting of the event (`e1`), the first referent (`x1`), the thematic role of the referent (Actor), and the sense (0 indicating

none). The sense of the word will not be further addressed since it is not utilized in the conversion.

V. From DRS to Event Semantics

Our goal is to convert Boxer representations to our event semantic annotation scheme as accurately as possible. In the current paper, we first investigate the degree to which the required information is available from the Boxer analysis. A successful conversion can be hampered by several different issues: when information required in semantic representation is not present in Boxer's analyses, when Boxer is not consistent in representing a specific phenomenon, or when the analyses are incorrect. We present a basic methodology for the conversion, highlighting areas in which a successful conversion can be achieved with a high degree of success. We use Boxer given the following settings: PROLOG output format (but for readability, we present example in box format below), using DRS representations, using standard thematic proto-roles, and distinguishing variable types (into events, arguments, and modifiers).

A. Basic Conversion Principles

The PROLOG syntax allows for the ability to scan all aspects of the parse and develop checking mechanisms. The output is systematic in its structure, which allows an easy identification and isolation of referents and relations if they are produced by Boxer. In order to facilitate a closer examination of the conversion, we simplify example (11) to *café received a delivery*. The corresponding part of the DRS is presented in Fig. 4, the event semantic representation in (12).

```
1004:[tok:'Café',pos:'NNP',lemma:'Café',namex:'O'],
1005:[tok:received,pos:'VBD',lemma:receive,namex:'O'],
1007:[tok:delivery,pos:'NN',lemma:delivery,namex:'O'],
rel(e1,x4,'Theme',0)
rel(e1,x1,'Actor',0)
[1004]:named(x1,café,nam,nam)
[1005]:pred(e1,receive,v,0)
[1007]:pred(x4,delivery,n,0)])
```

Fig. 4. PROLOG representation for *café received a delivery*.

(12) a. café received a delivery
b. café(y1) $\wedge$ received(e1,y1,z1) $\wedge$ delivery(z1)

Relation representations vary in the information they represent, but they always provide information about the event, the referent, and the relation. We use regular expressions to extract all relations in the PROLOG representation, identifying the referents involved, and cross-reference them. In Fig. 4, there are two relations (Actor and Theme) which are captured and then cycled through. Once the referent has been identified, the corresponding predicate is extracted using additional regular expressions in order to extract relevant information: the referent, the lemma, and an indication of a general POS category.

We isolate the thematic role within each relation (in our case Actor and Theme). Based on the specific role, we need to employ specialized conversion strategies since a Pivot, for example, provides more complex information than an Agent. Once a relation type has been identified, the referents are extracted. For the case of Actor, we extract `e1` and `x1`. In this relation, the first argument, `e1`, refers to the first event introduced in the sentence. The second argument, `x1`, refers to an argument identified by the event. We then subsequently extract information on the corresponding predicate.

As mentioned in Section III, we introduce arguments of events in a specific order: the event, then the subject, then the direct object. This is demonstrated in (12), where the subject is represented by `y1` and the direct object by `z1`. In general, there are no discrepancies between the ordering of thematic roles and grammatical functions since we assume that passive sentences have been simplified to active ones.

B. Challenges

Our main challenge is to correctly identify and convert the PROLOG variables into our event semantic variables. As presented in Table I, there are five possible variables types in the event semantics. As the PROLOG representation for events is `e`, these events are easily transferable to our scheme. However, as explained in Section III, verbs are not the only type of concepts that introduce events, and there is no direct correlation between other event types in the Boxer representations and in the event semantics. For example, verbal nominalizations, such as *attack* in example (4) are treated as referents like any other nouns in Boxer. Thus, in order to handle such cases properly, we will need to use additional

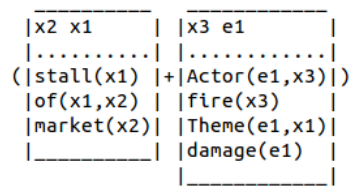

Fig. 5. Passive example.

semantic resources as well as event anaphora detection and resolution strategies.

In addition to event variables, we have four distinct argument variables. Returning to example in (12) and Fig. 4, the subject (*café*) is a named entity with an unknown tag in the PROLOG representation, thus the challenge is to correctly identify that the variable associated with the referent is of type `y` given that it is a location. The direct object (*delivery*) is assigned `z1` since it is the first non-named entity argument that is not a location. If the parser recognizes named entities, then they can be directly converted to corresponding variables (e.g., org $\rightarrow$ `x`). The difficulty lies in distinguishing between any two non-event labels for given tokens, particularly objects and locations, as although named entities are often detected by the parser while parsing the SYNCOIN data, they are frequently mislabeled, as many of these entities cannot be found in the training data of the parser. Thus, we must distinguish the possible named entities and their associated variables in our conversion (e.g. *Antar café* vs. *weapons cache*). This problem will be further addressed in section VI.

Additionally, the conversion requires multiple checks. One issue concerns the numbering of types of variable, i.e., how many events have been introduced, to correctly assign a number to a newly introduced variable. Another complexity arises from the fact that multiple variable types in the event semantic representations are represented by a single variable in Boxer; thus we need strategies to determine the resulting variable types via heuristics. For example, a referent of Boxer's type `x` can be of any type shown in Table I.

One discrepancy between the two semantic annotations concerns the thematic roles used by Boxer and the more surface oriented annotations in the event semantics that are based on syntactic arguments rather than thematic roles. The thematic roles generally correspond to syntactic arguments of a specific event and relation. For example, the role Actor is associated with the subject and Theme with a direct object. For many sentences, the order of the arguments is associated with the same sequence as our annotation scheme. However, there is an issue with passive sentences where there is no direct correspondence between roles and grammatical functions, as in Fig. 5 when parsing the passive sentence in (13).

(13) The market stalls were damaged by fire.

Here, strictly associating the Theme with a direct object position, and Actor with the subject, when introducing arguments of an event would result in an incorrect conversion. For such

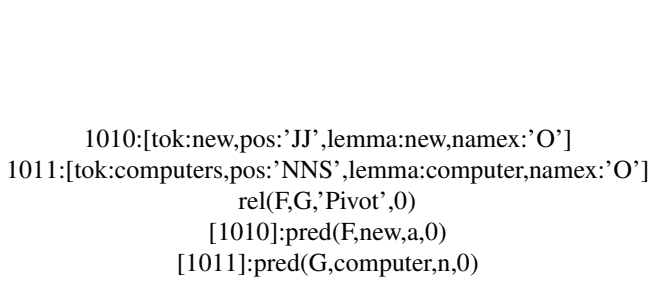

Fig. 6. PROLOG representation of the modification example in (14).

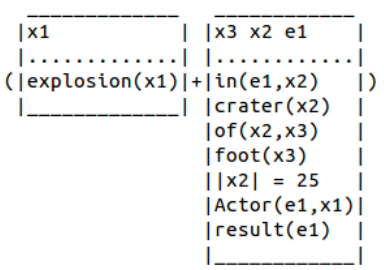

Fig. 7. DRS representation of the sentence in (15).

cases, we rely on sentence simplification to resolve the issue. Otherwise, we would have to go back to the CCG derivations and extract the syntactic arguments.

Another challenge arises from the representation of nominal modifiers. While the event semantic scheme opts for a surface oriented representation, converting these modifiers into predicates, Boxer uses Pivot roles, which capture direct relationships between referents and modifiers, such as between adjectives and nouns. Returning to the sentence depicted in Fig. 2, the adjective *new* modifies *computers* with the relevant PROLOG representation shown in Fig. 6. In this case, we need to extract the arguments of the Pivot and convert the modifier *new* into a predicate that directly applies to the argument `computers`. The result of this conversion is shown in (14).

(14) computers(z1) $\wedge$ new(z1)

Units of measurement are treated similarly. The DRS representation for the sentence in (15) is shown in Fig. 7. We can see that it contains both information that the referent is a number (specified by the cardinality information) and that it modifies the noun *crater* while the measurement *foot* is in an `of` relation to the number.

(15) a. The explosion resulted in a 25 foot crater.
b. crater(z1) $\wedge$ size_in_foot(z1,25)

Despite the differences described above, we can convert those concepts directly into event semantics due to the consistent and explicit relationship between nominals and their modifiers.

VI. Discrepancies

The basic conversion principles described above allow for an accurate transformation of many of the basic phenomena in sentences with a high degree of consistency. However, there are also discrepancies between the two representations that are less easily reconciled. We describe here the three

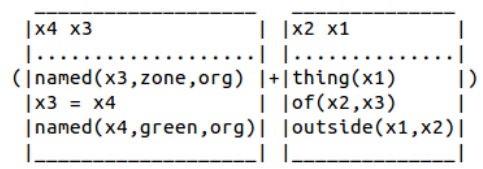

Fig. 8. DRS representation of *outside of the Green Zone*.

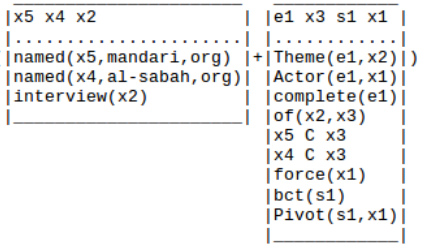

Fig. 9. DRS representation of *BCT forces*.

most important issues, namely the treatment of parsing errors, inconsistencies in the Boxer output, and coreference information.

A. Parsing Errors

While the C&C parser is an accurate parser, there are phenomena that are challenging for the parser, especially where Boxer does not have enough information to make correct decisions. To a certain degree, we anticipate such problems, such as coordination, which are challenging for any parser, and handle them in sentence simplification. Other phenomena, however, are more difficult to address.

1) Named Entity Referents: The C&C parser has a named entity recognizer [24], whose analyses are also used by Boxer. Named entities are categorized into various categories including geographical (geo), person (per), organization (org), and nam (unknown). This information provides the basis for determining the correct variable type in the event semantic representations (i.e., assigning `x` for a name or a person and `y` for a location). However, given the nature of the SYNCOIN data, there are many names that the parser mislabels, or occasionally fails to recognize. For example, *Green Zone* is correctly identified as a named entity but is consistently labeled as an organization rather than a location (see Fig. 8). In Fig. 9, the organization *BCT forces* is parsed as a referent *force* with a modifier (*BCT*) instead of being treated as a single multi-word named entity. We thus cannot always accept the named entity information provided for the correct categorization between `x` and `y` variables in the event semantics.

2) Recognizing Possessive Relationships and Compounds: Possessive relationship are represented with an `of` relation. This covers both cases where the possessor is nominal and pronominal. Fig. 10 shows the DRS representation for the sentence in (16). In this example, the pronoun *his* is converted into an `of` relation between *meeting* and a male referent.

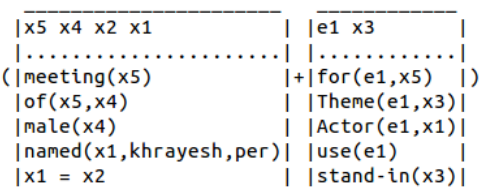

Fig. 10. DRS representation of the example in (16).

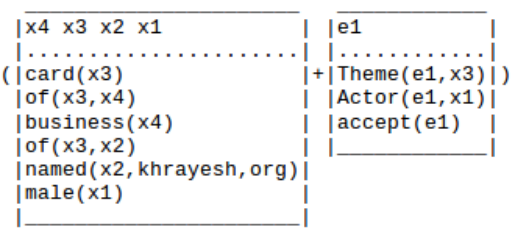

Fig. 11. DRS representation of the example in (17).

(16) a. Omar Khrayesh uses a stand-in for his meeting.
b. Omar_Khrayesh(x1) ∧ use(e1,x1,x2) ∧ stand_in_for(e2,x2,e3) ∧ meeting(e3,x3,x1)

However, the same relation is also used to represent noun-noun compounds. Fig. 11 shows the DRS analysis of the sentence in (17)[2]. Here, the compound *business card* is analyzed as *card of business*.

(17) a. He accepts Khrayesh's business card.
b. accept(e1,x1,z1) ∧ business_card(z1) ∧ named(x2,Khrayesh) ∧ possessive(x2,z1)

This parallel treatment of possessives and compounds in Boxer's DRS introduces the need to distinguish between the two usages since they differ in the event semantic representation: In the event semantics, the compound noun is retained (e.g., *business_card* in (17)) while the possessive pronoun is resolved into a possessive relation (e.g., *possessive*).

B. Inconsistencies

1) Adverbial Modifiers: In the DRS produced by Boxer, non-temporal modifiers are predominantly categorized in two different ways, as seen for the sentences in (18) and the DRS presented in Fig. 12 and Fig. 13 respectively.

(18) a. At approximately 1304hrs he appeared.
b. He is only interested in a prosperous Iraq.

For the first sentence, the adverb *approximately* is analyzed as being in a Pivot relation to the time. For the second

[2]Note that Boxer provides an option to analyze noun-noun compounds using prepositions [25]. However, this analysis introduces additional variation in the semantics-based relations between nouns, introducing an added level of complexity. For this reason, we choose not to utilize this option.

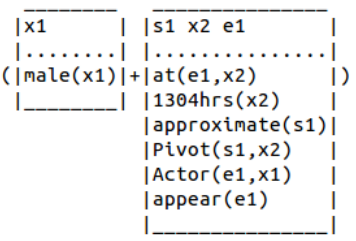

Fig. 12. Example of an adverbial pivot

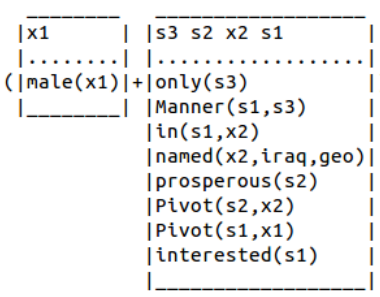

Fig. 13. Example of an adverb of manner

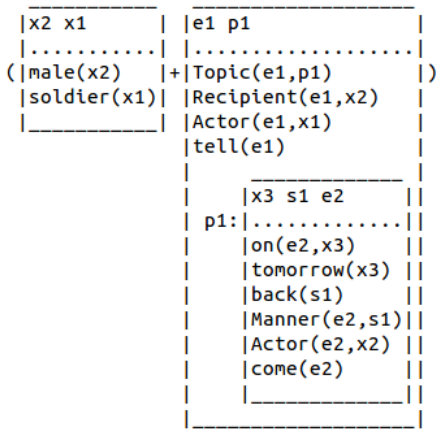

Fig. 14. Example of a temporal adverb

sentence, *only* as an adverb of manner. Both indicate that there is a type of relationship to a referent although they are being interpreted differently in terms of semantics. The pivot analysis overlaps with adjectival modifiers. The manner analysis overlaps with phrasal verbs, which will be addressed further in section VI-B3.

2) Temporal Modifiers: Time expressions are not consistently or accurately captured in every case [12]. This becomes evident in temporal modifiers. For example, the DRSs for the first two sentences in (19), depicted in Fig. 14 and Fig. 15, show that in the first case, the temporal adverb *tomorrow* is analyzed as being in an `on` relation to the event *come* while in the second case, the adverb *now* directly modifies the event *want*. Now, we could argue that the latter is a consequence of having fronted the adverb. However, if we use the adverb in

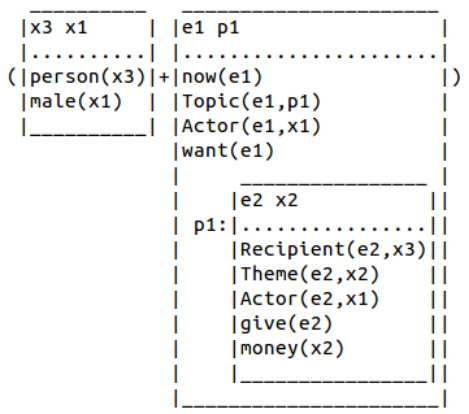

Fig. 15. Example of the temporal adverb fronted.

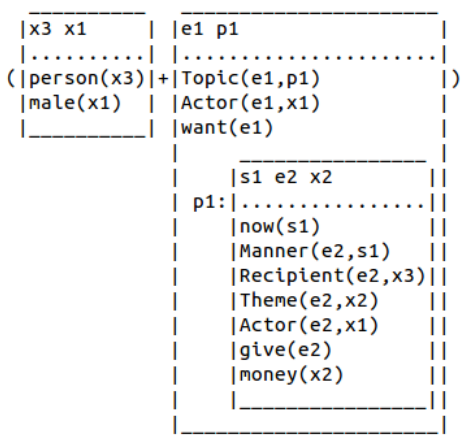

Fig. 16. Non-fronted example.

sentence final position, it receives the analysis in Fig. 16, in which it is analyzed as an adverb of manner, giving us a third analysis. Note that both versions of this sentence receive the same analysis in the event semantics, as shown in (19-d).

(19) a. The soldier told him to come back tomorrow.
b. Now he wants to give me money.
c. He wants to give me money now.
d. now(e1) $\wedge$ wants(e1,x1,give(e2,x1,x2,z1) $\wedge$ money(z1))

Furthermore, the representation of specific dates in the SYNCOIN data is not identified as a time referent by Boxer as seen in Fig. 17 for the sentence in (20).

(20) A meeting on 04/06/10 will work fine.

In the PROLOG representation, the date reference is marked as being a number, but not a time signature. Considering the importance of time in event semantics, the inconsistency in particular of temporal modifiers makes them a weak point in the conversion.

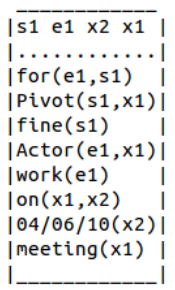

Fig. 17. Example of a date.

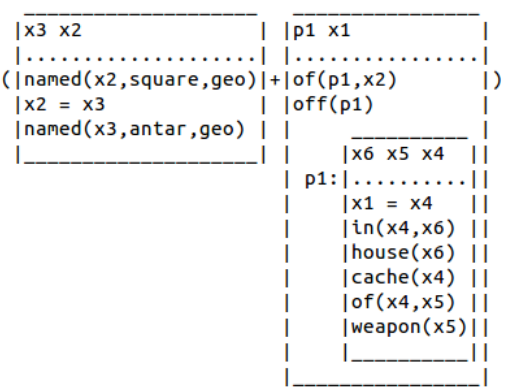

Fig. 18. Example of *off* as a preposition.

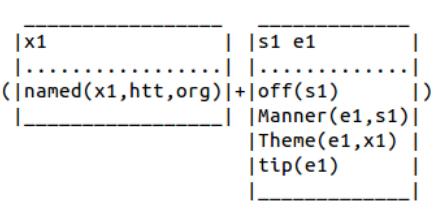

Fig. 19. Example of *off* in a phrasal verb.

3) Prepositions: In the event semantics, phrasal verbs are analyzed as multi-word expressions. Thus, in order to achieve a correct conversion from Boxer to event semantics, we need to be able to detect phrasal verbs as such. We show an example of a standard prepositional use of *off* and its use in a phrasal verb in (21). Their DRS analyses are shown in Fig. 18 and Fig. 19 respectively.

(21) a. There is a weapons cache in a house off of Antar Square.
b. HTT was tipped off.

In the DRS analyses, both usages of *off* are categorized similarly, once as a postmodifier, and once as a Manner relation, similar to adverbs. However, there is no indication that the latter is part of a phrasal verb. The corresponding analyses in event semantics are shown in (22).

(22) a. weapons_cache(y1) ∧ in(y1,y2) ∧ house(y2) ∧ off(y2,y3) ∧ named(y3,Antar Square)
b. HTT(x1) ∧ tip_off(e1,x1)

C. Coreference

Another major difference between Boxer's DRS and the event semantic representations is that the DRS is mostly an annotation on the sentential level while the event semantics also annotates discourse relations in form of coreference: Any coreferent entity in a text is referenced by the same variable. An example is shown in (23) where the *BCT patrol* is mentioned in two consecutive sentences, both times identified by variable `x2`, even though the surface representation is different.

(23) a. BCT patrol approached by man promising to reveal 2 additional weapons cache in Dour'a.
b. BCT reports little value in sites but pays man a small amount of cash
c. approach(e7,x4,x2) ∧ named(x2, BCT_patrol) ∧ man(x4) ∧ promise(e8,x4,e9) ∧ reveal(e9,y3) ∧ additional(y3) ∧ count(y3,2) ∧ weapons_cache(y3) ∧ in(y3,y10) ∧ named(y10,Dour'a))
d. named(x2,BCT) ∧ report(e10,x2,little_value(y3) ∧ sites(y3)) ∧ pay(e11,x2,z2) ∧ cash(z2) ∧ small_amount(z2)

The same also holds for event anaphora, for example in (24), where the *detonation* mentioned in the first sentence and the *attack* in the second sentence share the same event variable `e44`.

(24) a. Their description was passed to an Iraqi who subsequently apprehended them after a second failed attempt to detonate their satchel charge. . . .
b. The men detained for failed attack on 02/05/10 at the Soeudi Café, refuse to reveal operational details of the attack and deny being foreign insurgents.
c. pass(e41,x126,z10,x7) ∧ description(z10) ∧ possessive(x6,z10) ∧ iraqi(x7) ∧ apprehend(e42,x7,x6) ∧ after(e42,e43) ∧ attempt(e43,x6,e44) ∧ fail(e44) ∧ detonate(e44,x6,z11) ∧ satchel_charge(z11) ∧ possessive(x6,z11)
d. refuse(e50,x6,e51) ∧ men(x6) ∧ detain_for(e443,x129,x6,e44) ∧ fail(e44) ∧ attack(e44,x6) ∧ on(e44,t4) ∧ date(t4,020510) ∧ at(e44,y4) ∧ named(y4,Soeudi_Café) ∧ reveal(e51,x6,z14) ∧ details(z14,e44) ∧ operational(z14) ∧ deny(e52,x6,foreign(x6) ∧ insurgents(x6))

Boxer does have an option to perform coreference resolution using binding and accommodation theory to resolve the referents of pronouns and definite noun phrases. However, the

TABLE II
FREQUENCY OF PHENOMENA

Pivots	26
Units of measurement	3
Named entity referents	33
Possessive relationships / compounds	28
Adverbial modifiers	9
Temporal modifiers	6
Prepositions	7

module focuses on high precision, thus "definite descriptions and proper names are only linked to previous discourse referents if there is overlap in the DRS-conditions of the antecedent DRS ..." [26]. Additionally, it does not resolve event anaphora. Since, for our downstream application, the fusion algorithm, recall is extremely important, we will need a full coreference resolution integrated into our conversion procedure. This poses additional problems since especially event anaphora is an understudied process [27], [28].

D. Empirical Overview

We have looked at one of the threads in the SYNCOIN data in order to determine how frequent the phenomena are that we have discussed in the previous two sections. We have parsed those sentences using the C&C parser in combination with Boxer and then have inspected the resulting analyses manually to determine the frequency of the individual phenomena. The manual inspection was necessary since Boxer does not handle certain of those phenomena very well, as discussed in section VI. As a consequence of the necessary manual inspection, we chose the shortest thread, which consists of 21 sentences.

The distribution of phenomena is shown in table II. The numbers show that most of these phenomena occur with moderate frequency, on average in every third sentence. The exception are the named entities and the possessives, which occur on average more than once per sentence. These numbers show very clearly that the phenomena are frequent enough to necessitate a specialized treatment.

VII. FUTURE WORK

One of the major challenges in the conversion from Boxer DRS to event semantics is the underspecification and variance of specific phenomena in Boxer's DRS analyses. In order to ensure a fully automated high quality conversion, we will need to integrate tools and resources, along with machine learning algorithms to help resolve the ambiguities (e.g., to determine variable types). This includes the utilization of additional semantic resources such as PropBank [29] and full coreference to improve categorization. We will also explore the use of clustering to group frequently mislabeled words with words that most closely resemble their contextual behavior.

SYNCOIN data is full of infrequent words, particularly multi-word expressions of people and places, and given the nature of the data on which the C&C parser's models were trained, this makes it difficult to predict how an unknown word should be represented. Thus, we will investigate domain adaptation methods for all levels: parsing, named entity recognition, and DRS analysis. This is particularly necessary to resolve distinctions between proper names of people and proper names of places.

VIII. CONCLUSION

We have presented an investigation into the feasibility of converting from DRS to event semantics, demonstrating that it is a non-trivial task. We have started the conversion process using the PROLOG representation from Boxer to convert basic sentences via regular expressions that identify referents and relations to an event semantic representation. We have also highlighted areas that prove to be problematic in the conversion and require further exploration. We will expand the system beyond basic sentences and incorporate machine learning techniques and coreference resolution to increase the accuracy.

***Abstract*—This paper presents preliminary results of an application of artificial neural networks and Backpropagation learning algorithm to solve logical abductive problems. To represent logic programs in the form of artificial neural networks CIL^{2}P approach proposed by Garcez et al. [3] is employed. Our abductive procedure makes use of translation of a logic program representing a knowledge base into a neural network, training of the neural network with an example representing an abductive goal and translation of the trained network back to the form of a logic program. An abductive hypothesis is represented as the symmetric difference between the initial logic program and the one obtained after training of the network. The first part of the paper introduces formal description of the tools used to model the abductive process, while the second part illustrates our contribution with results of a few computational experiments and discusses the ways of possible improvements of the proposed procedure.**

I. Introduction

ABDUCTION is a kind of reasoning which allows to *fill the gap* between a knowledge base Γ and a puzzling phenomenon ϕ, unattainable from Γ (cf. [6, 14]). We follow the algorithmic point of view, according to which an abductive hypothesis H "is legitimately dischargeable to the extent to which it makes it possible to prove (or compute) from a database a formula not provable (or computable) from it as it is currently structured" [2, p. 88]. A short characteristic of abduction interpreted along these lines can be found in [9]. Our goal in this paper is to use definite logic programs to formalise a class of abductive problems and to apply neural networks as a tool for abductive hypotheses generation.

Definite logic programs are characterised in the first order language [11]. However, in our approach we use only grounded definite logic programs [3]. Therefore, the formalisation of the abductive problems is restricted to the classical propositional logic.

The connectionist approach that we adopt makes use of positive partially recurrent one hidden-layer networks. This is sufficient to deal with definite logic programs as indicated in [3].

An abductive problem is stated for definite logic programs and the abductive hypotheses are generated by means of neural networks. Therefore, we use Connectionist Inductive Learning and Logic Programming System's (C-IL^2P) translation algorithm proposed by Garcez et al. [3] to translate logic programs into neural networks. The learning process of the neural network is aimed at changing it in such a way that the abductive goal is attained. Subsequently, the neural network is translated back into a logic program. Differences between the initial logic program and the one obtained from the trained neural network may be interpreted as abductive hypotheses generated in the learning process.

There are a few ways to model abduction using C-IL^2P. Two of them were described in [4] and they employ either a connectionist modal logic or an neural-symbolic system for abductive logic program. The approach that we want to present takes advantage of network learning process (using Backpropagation algorithm) and program-to-network and network-to-program translation algorithms. The main advantage of this approach in comparison with the two previous ones lies in its flexibility: abductive hypotheses do not have to be reduced to the form of propositional formulas (in particular conjunctions of atoms). At the present stage of our research we consider only abductive goals represented by atoms, but our approach allows for any form of an abductive goal (atoms or other types of formulas). Abduction here can be seen as a process of training of a network previously obtained from a logical program. The program represents a knowledge base and an abductive goal is represented by a training example. The reverse translation of the trained network allows to obtain abductive hypotheses. Using this approach abductive hypotheses can be represented by new logical formulas that are extending initial knowledge base. However, it is also possible that modifications or even removal of clauses from a knowledge base will represent abductive hypotheses (some similarity can be found in *contraction* and *revision* operations in belief revision theory, e.g. [5]).

In order to better comprehend the stated problem let us consider the following abductive problem. Suppose that we established a general medical facts[1]: "If people suffer from a fatigue and a fever, then they have a flu". "If people suffer from a fever, then they are fatigued". "If people have a flu, then they

Research reported in this paper were supported by the National Science Centre, Poland (DEC-2013/10/E/HS1/00172).

[1]Please, note that that the presented problem is only a simple toy-example, advanced medical decision support systems are for example presented in [13, 15]

are fatigued". Now, we would like to know what should we check if we suspect that someone has a flu. Formally, this problem can be described in the following way: let the knowledge base be a set of formulas $X = \{B \wedge C \rightarrow A, C \rightarrow B, A \rightarrow B\}$ and the abductive goal be a formula A, where A means a person has a flue, B means a person is fatigued and C means that a person has a fever. We shall go back to this example in every section.

II. Logic programs

Definite logic programs are usually formalised in the first order language. However, for the translation of definite logic program to neural network it is required for the program to be grounded. Therefore, grounded definite logic program consists only of predicates with constants as arguments. This is the reason for using a simpler language than the first order language. We characterize definite logic programs following [3] and similarly to [11].

We use language $\mathcal{L}$, which consists of the following elements:

- $\{a_1, a_2, \ldots\}$ — an infinite, countable set of propositional letters,
- $\leftarrow$ — a primitive connective,
- , — a comma.

Atomic formulas are denoted by propositional letters a_1, a_2,....

Definition 2.1: Let a_i for $0 \leq i \leq n$ be an atomic formula. *Horn clauses* are formulas of the form:

$$h_i = a_{i_0} \leftarrow a_{i_1}, \ldots, a_{i_n}.$$

The atomic formula a_{i_0} from the definition of the Horn clause is called the *head* of the Horn clause h_i and will be denoted as *head*(h_i). Similarly, the set of atomic formulas $\{a_{i_1}, \ldots, a_{i_n}\}$ forms the *body* of the Horn clause h_i and will be denoted as *body*(h_i). It is possible that the body of a Horn clause contains no atoms. Such Horn clauses will be called *facts*.

Atomic formulas and Horn clauses are the only well-formed formulas we use.

Definition 2.2: The *set of well-formed formulas* is defined in the following way:

$$\mathit{Form} = \{f \mid f = a_i \text{ or } f = h_j\}.$$

Definition 2.3: Let h_i for $1 \leq i \leq n$ be a Horn clause. A *definite logic program* is denoted by $\mathcal{P}$ and defined as follows:

$$\mathcal{P} = \{h_1, \ldots, h_n\}.$$

Definition 2.4: Let $\mathcal{P}$ be a definite logic program. We define the set of all atoms that occur in $\mathcal{P}$ in the following way:

$$B_\mathcal{P} = \{a_i \mid \text{for every } h_k \in \mathcal{P} \text{ and for every } a_j \in \mathit{body}(h_k)\text{: } a_i = \mathit{head}(h_k) \text{ or } a_i = a_j\}.$$

$B_\mathcal{P}$ is called Herbrand base of program $\mathcal{P}$.

We are now going to define *Least Herbrand model* of a definite logic program $\mathcal{P}$ which in turn will be used in the definition of logical consequence of a definite logic program $\mathcal{P}$.

Definition 2.5: A mapping v : *Form* $\mapsto$ {*true*,*false*} is a *valuation* defined as follows:

- for every atomic formula a_i: either $v(a_i) =$ *true* or $v(a_i) =$ *false*,
- for every Horn clause h_i: $v(h_i) =$ *true* iff $v(\mathit{head}(h_i)) =$ *true* or for at least one $a_j \in \mathit{body}(h_i)$: $v(a_j) =$ *false*.

Definition 2.6: Let $\mathcal{P}$ be a definite logic program, $B_\mathcal{P}$ a Herbrand base of $\mathcal{P}$ and v a valuation. An (Herbrand) *interpretation of a program* $\mathcal{P}$ w.r.t. v is a set $I_\mathcal{P}$ of all atoms in $B_\mathcal{P}$ that are mapped by v to *true*:

$$I_\mathcal{P}(v) = \{a_i \mid a_i \in B_\mathcal{P} \text{ and } v(a_i) = true\}.$$

Atoms that do not belong to the interpretation $I_\mathcal{P}$ are mapped to *false*.

Definition 2.7: Let $\mathcal{P}$ be definite logic program, h_i be a Horn clause that belongs to $\mathcal{P}$ and $I_\mathcal{P}$ a Herbrand interpretation of $\mathcal{P}$ w.r.t. valuation v. *Model of* $\mathcal{P}$ is defined as follows:

$$m_\mathcal{P} =_{df} I_\mathcal{P}(v) \text{ such that for every } h_i \in \mathcal{P}\text{: } v(h_i) = \mathit{true}.$$

It follows from the definition 2.7 that models of definite logic program $\mathcal{P}$ are of the form of sets of atoms. Therefore, we can establish a hierarchy over those models and use it to define the smallest model of $\mathcal{P}$.

Definition 2.8: Let S be a set. Function $c : S \rightarrow \mathbb{N}$ returns the number of elements in the set S.

Definition 2.9: Let $\mathcal{P}$ be a definite logic program and $m_\mathcal{P}$ a model of $\mathcal{P}$. By $m_\mathcal{P}^{min}$ we denote a *minimal model of* $\mathcal{P}$ and define it in the following way:

$$m_\mathcal{P}^{min} =_{df} m_\mathcal{P} \text{ such that for every } m'_\mathcal{P}\text{: } c(m_\mathcal{P}) \leq c(m'_\mathcal{P}).$$

Definition 2.10: Let $\mathcal{P}$ be a definite logic program and $m_\mathcal{P}$ a model of $\mathcal{P}$. By $M_\mathcal{P}$ we denote the *least Herbrand model of* $\mathcal{P}$ and defined it in the following way:

$$M_\mathcal{P} =_{df} m_\mathcal{P} \text{ such that for every } m'_\mathcal{P} \neq m_\mathcal{P}\text{: } c(m_\mathcal{P}) < c(m'_\mathcal{P}).$$

Now we are going to define Immediate Consequence Operator denoted as $T_\mathcal{P}$. It „provides the link between the declarative and procedural semantics of $\mathcal{P}$" [11, p. 37]. Related definitions concerning lattices are standard, therefore they are included in the Appendix.

Definition 2.11: Let $\mathcal{P}$ be a definite logic program and $I_\mathcal{P}$ an interpretation. The mapping $T_\mathcal{P} : 2^{B_\mathcal{P}} \mapsto 2^{B_\mathcal{P}}$ is defined as follows:

$$T_\mathcal{P}(I_\mathcal{P}) =_{df} \{\mathit{head}(h_i) \mid h_i \in \mathcal{P} \text{ and for all } a_j \in \mathit{body}(h_i)\text{: } a_j \in I_\mathcal{P}\}.$$

Proposition 2.1: Let $\mathcal{P}$ be a definite logic program. Then the mapping $T_\mathcal{P}$ is continuous.

Proposition 2.2: Let $\mathcal{P}$ be a definite logic program and $I_\mathcal{P}$ be an interpretation. Then $I_\mathcal{P}$ is a model for $\mathcal{P}$ iff $T_\mathcal{P}(I_\mathcal{P}) \subseteq I_\mathcal{P}$.

Theorem 2.3: Let $\mathcal{P}$ be a definite logic program. Then $M_\mathcal{P} = \mathit{lfp}(T_\mathcal{P}) = T_\mathcal{P} \uparrow \omega$.

Proofs of the propositions 2.1, 2.2 and theorem 2.3 are described in [11, p. 37–38].

Definition 2.12 (Logical consequence of $\mathcal{P}$): Let $\mathcal{P}$ be a definite logic program and $M_{\mathcal{P}}$ be a least Herbrand model of $\mathcal{P}$. Atom a_i is a logical consequence of $\mathcal{P}$ iff it belongs to $M_{\mathcal{P}}$:

$$\mathcal{P} \models a_i \text{ iff } a_i \in M_{\mathcal{P}}.$$

Definition 2.13: Let $\mathcal{P}$ be a definite logic program and $M_{\mathcal{P}}$ the least Herbrand model of $\mathcal{P}$. a_i is an atom and is called the *abductive goal* for $\mathcal{P}$ (denoted by $\mathcal{G}_{\mathcal{P}}$) if it fulfils the following criterion:

$$\mathcal{G}_{\mathcal{P}} =_{df} a_i \text{ such that } a_i \notin M_{\mathcal{P}}.$$

Coming back to the abductive problem given in the Introduction, observe that the knowledge base can expressed as a logic program $\mathcal{P} = \{A \leftarrow B, C; B \leftarrow C; B \leftarrow A\}$ and the least Herbrand model $M_{\mathcal{P}} = \emptyset$ (because $T_{\mathcal{P}} \uparrow (\emptyset) = \emptyset$) does not contain fact A, which is the abductive goal. This means that A is not entailed by $\mathcal{P}$.

III. Neural networks

Definition 3.1: We use the following language $\mathcal{L}^N$ to describe neural networks:

- $\{\mathfrak{i}_1, \ldots, \mathfrak{i}_n, \ldots\}$ — an infinite, countable set of symbols for input neurons,
- $\{\mathfrak{h}_1, \ldots, \mathfrak{h}_n, \ldots\}$ — an infinite, countable set of symbols for hidden layer neurons,
- $\{\mathfrak{o}_1, \ldots, \mathfrak{o}_n, \ldots\}$ — an infinite, countable set of symbols for output neurons,
- $\{\mathfrak{n}_1, \ldots, \mathfrak{n}_n, \ldots\}$ — an infinite, countable set of symbols for meta variables representing any neuron,
- $\{n_1, \ldots, n_n, \ldots\}$ — an infinite, countable set of symbols for *labels* of neurons which are not associated with an atom from $\mathcal{L}$,
- *label* — an identification symbol for a neuron,
- t — a label denoting *truth neuron*,
- tn — a label denoting hidden layer neuron reserved for truth neuron,
- $g(x)$, $h(x)$ — neuron activation functions,
- $x \in \mathbb{R}$ — a weighted sum of the input signals for the neuron,
- $A_{min} \in \mathbb{R}$ — a value computed by algorithm [3, p. 48–50],
- $A^f_{min} \in \mathbb{R}$ — A_{min} enlarge factor,
- $\theta_i \in \mathbb{R}$ — threshold of a neuron,
- $\theta_a \in \mathbb{R}$ — threshold of additional neurons,
- $\beta \in \mathbb{R}$ — steepness of neuron activation function (used only for bipolar semi-linear activation functions),
- $W \in \mathbb{R}$ — a weight computed by the algorithm [3, p. 48–50],
- $W^f \in \mathbb{R}$ — W enlarge factor,
- $r \in \mathbb{R}$ — a variable,
- $l \in \mathbb{N}$ — the number of additional hidden layer neurons per each neuron in the output layer.

Definition 3.2: Input neurons are tuples of the form:

$$\mathfrak{i}_i =_{df} \langle label, g(x), A^m_{min} \rangle$$

where:

- $label$ — a symbol of the represented atom form $\mathcal{P}$,
- $g(x) = x$,
- $A_{min} \in \mathbb{R}$ — if $g(x) \geq A_{min}$ then $label$ is mapped to *true*,
- the output signal of the neuron is equal to $g(x)$.

Definition 3.3: Truth neuron is an input neuron with the following properties:

- *label* $= t$,
- *g(x)* $= 1$.

Definition 3.4: Hidden layer neurons are tuples of the form:

$$\mathfrak{h}_i =_{df} \langle label, h(x), \theta_h, A^m_{min} \rangle$$

where:

- $label$ — n_i associated with clause h_i from $\mathcal{P}$,
- $h(x) = \frac{2}{1+e^{-\beta(x-\theta_h)}} - 1$,
- $\theta_h \in \mathbb{R}$,
- $A_{min} \in \mathbb{R}$ — if $h(x) \geq A_{min}$ then $label$ is mapped to *true*,
- the output signal of the neuron is equal to $h(x)$.

Definition 3.5: Output neurons are tuples of the form:

$$\mathfrak{o}_i =_{df} \langle label, h(x), \theta_o, A^m_{min} \rangle$$

where:

- $label$ — a symbol of the represented atom form $\mathcal{P}$,
- $h(x) = \frac{2}{1+e^{-\beta(x-\theta_o)}} - 1$,
- $\theta_o \in \mathbb{R}$,
- $A_{min} \in \mathbb{R}$ — if $g(x) \geq A_{min}$ then $label$ is mapped to *true*,
- the output signal of the neuron is equal to $h(x)$.

Definition 3.6: Let $\mathfrak{i}_1, \ldots, \mathfrak{i}_n$ be input neurons. By $\mathcal{N}_I$ we denote the set of all input neurons:

$$\mathcal{N}_I = \{\mathfrak{i}_1, \ldots, \mathfrak{i}_n\}.$$

Definition 3.7: Let $\mathfrak{h}_1, \ldots, \mathfrak{h}_n$ be input neurons. By $\mathcal{N}_H$ we denote the set of all hidden layer neurons:

$$\mathcal{N}_H = \{\mathfrak{h}_1, \ldots, \mathfrak{h}_n\}.$$

Definition 3.8: Let $\mathfrak{o}_1, \ldots, \mathfrak{o}_n$ be input neurons. By $\mathcal{N}_O$ we denote the set of all output neurons:

$$\mathcal{N}_O = \{\mathfrak{o}_1, \ldots, \mathfrak{o}_n\}.$$

Definition 3.9: Let $\mathcal{N}_I$, N_H and N_O be the set of all input, hidden and output neurons respectively. By $\mathcal{N}$ we denote the set of all neurons:

$$\mathcal{N} = \mathcal{N}_I \cup \mathcal{N}_H \cup \mathcal{N}_O.$$

Definition 3.10: Let $\mathfrak{i}_i$, $\mathfrak{i}_k$ and $\mathfrak{h}_j$, $\mathfrak{h}_l$ were input and hidden layer neurons respectively. By $\mathcal{C}_{i \to h}$ we denote the set of the connections from input to hidden layer neurons. The connection runs from the first neuron in the tuple to the second:

$$\mathcal{C}_{i \to h} = \{\langle \mathfrak{i}_i, \mathfrak{h}_j \rangle, \ldots, \langle \mathfrak{i}_k, \mathfrak{h}_l \rangle\}.$$

Definition 3.11: Let $\mathfrak{h}_i$, $\mathfrak{h}_k$ and $\mathfrak{o}_j$, $\mathfrak{o}_l$ were hidden layer and output neurons respectively. By $\mathcal{C}_{h \to o}$ we denote the set

of the connections from hidden layer to output neurons. The connection runs from the first neuron in the tuple to the second:

$$\mathcal{C}_{h\to o} = \{\langle \mathfrak{h}_i, \mathfrak{o}_j\rangle, \ldots, \langle \mathfrak{h}_k, \mathfrak{o}_l\rangle\}.$$

Definition 3.12: Let $\mathfrak{o}_i$ and $\mathfrak{i}_j$ were output and input neurons respectively. By $\mathcal{C}_r$ we denote the set of the recursive connections from output to input neurons. The connection runs from the first neuron in the tuple to the second:

$$\mathcal{C}_r = \{\langle \mathfrak{o}_i, \mathfrak{i}_j\rangle \mid \mathfrak{o}_i(label) = \mathfrak{i}_j(label)\}.$$

Definition 3.13: Let $\mathfrak{n}_i$, $\mathfrak{n}_k$, $\mathfrak{n}_j$, $\mathfrak{n}_l$ be neurons. By $\mathcal{C}_a$ we denote the set of the additional connections. The connection runs from the first neuron in the tuple to the second:

$$\mathcal{C}_a = \{\langle \mathfrak{n}_i, \mathfrak{n}_j\rangle, \ldots, \langle \mathfrak{n}_k, \mathfrak{n}_l\rangle\}.$$

Definition 3.14: $\mathcal{C}$ is the set of all connections in the network:

$$\mathcal{C} = \mathcal{C}_{i\to h} \cup \mathcal{C}_{h\to o} \cup \mathcal{C}_r \cup \mathcal{C}_a.$$

Definition 3.15: Let $\mathfrak{n}_i$, $\mathfrak{n}_j$ be neurons. The function $w : \mathcal{C} \to \mathbb{R}$ establishes the weight of the connection between two connected neurons:

- if $\langle \mathfrak{n}_i, \mathfrak{n}_j\rangle \in \mathcal{C}_r$ then $w(\langle \mathfrak{n}_i, \mathfrak{n}_j\rangle) = 1$,
- if $\langle \mathfrak{n}_i, \mathfrak{n}_j\rangle \in \mathcal{C}_a$ then $w(\langle \mathfrak{n}_i, \mathfrak{n}_j\rangle) \in [-r, 0) \cup (0, r]$,
- otherwise $w(\langle \mathfrak{n}_i, \mathfrak{n}_j\rangle) = W^m$.

Definition 3.16: Let $\mathfrak{n}_i$, $\mathfrak{n}_j$ be neurons. The set of all weights is denoted by $\mathcal{W}$. It consists of the tuple, where on the first and second place are connected neurons and on the third the weight of the connection:

$$\mathcal{W} = \{\langle \mathfrak{n}_i, \mathfrak{n}_j, w(\mathfrak{n}_i, \mathfrak{n}_j)\rangle \mid \langle \mathfrak{n}_i, \mathfrak{n}_j\rangle \in \mathcal{C}\}.$$

Definition 3.17: Neural network denoted by $\mathfrak{N}$ is a tuple:

$$\mathfrak{N} =_{df} \langle \mathcal{N}, \mathcal{C}, \mathcal{W}\rangle.$$

Definition 3.18: Let $\mathcal{P}$ be a definite logic program and $\mathcal{G}_\mathcal{P}$ an abductive goal. By $T_{\mathcal{P}\to\mathfrak{N}}$ we denote the translation from $\mathcal{P}$ to $\mathfrak{N}$ w.r.t. the set of predetermined factors $\{l, A^f_{min}, W^f, \beta, \theta_a, r\}$:

$$T_{\mathcal{P}\to\mathfrak{N}}(\langle \mathcal{P}, \{l, A^f_{min}, W^f, \beta, \theta_a, r\}\rangle) =_{df} \langle \mathcal{P}, \mathfrak{N}\rangle,$$

$\mathfrak{N}$ is obtained from $\mathcal{P}$ in the following way:

1) Calculate the following values by means of the algorithm [3, p. 48–50]:
   - A_{min},
   - W.
2) Calculate the following values:
   - $A^m_{min} = A_{min} + A^f_{min}$,
   - $W^m = W + W^f$.
3) For every atom $a_i \in B_\mathcal{P}$ an input neuron $\mathfrak{i}_i$ is added to the set of input neurons $\mathcal{N}_I$. Properties of each input neuron are the following:
   - *label* $= a_i$.
4) For every clause $h_i \in \mathcal{P}$, if *body*$(h_i) \neq \emptyset$ then a hidden layer neuron $\mathfrak{h}_i$ is added to the set of hidden layer neurons $\mathcal{N}_H$. Properties of each hidden layer neuron are the following:
   - *label* $= n_i$,
   - θ_o is computed as in the algorithm [3, p. 48–50].
5) For every atom in $a_i \in B_\mathcal{P}$ an output $\mathfrak{o}_i$ neuron is added to the set of output neurons $\mathcal{N}_O$. Properties of each output neuron are the following:
   - *label* $= a_i$,
   - if $a_i \in B^h_\mathcal{P}$ then θ_o is computed as in the algorithm [3, p. 48–50], otherwise $\theta_o = \theta_a$.
6) For $\mathcal{G}_\mathcal{P}$, *name* = '$g\mathcal{G}_\mathcal{P}$' (letter 'g' is added to the propositional letter assigned to atom $\mathcal{G}_\mathcal{P}$) and:
   - if $\mathcal{G}_\mathcal{P} \notin B_\mathcal{P}$ then:
     - an input neuron is added to the set of input neurons $\mathcal{N}_I$ where: *label* = *name*,
     - an output neuron is added to the set of output neurons $\mathcal{N}_O$ where: *label* = *name*, $\theta_o = \theta_a$,
   - otherwise:
     - *label* fields in neurons associated with $\mathcal{G}_\mathcal{P}$ in input and output set of neurons are changed to *name*.
7) Truth neuron *t* is added to the set of input neurons $\mathcal{N}_I$.
8) A hidden layer neuron is added to the set of hidden layer neurons $\mathcal{N}_H$ with the following properties:
   - *label* = *tn*,
   - $\theta_h = 0$.
9) For each neuron in the set of output neurons $\mathcal{N}_O$ add *l* additional neurons to the hidden layer with the properties (the overall number of the additional neurons is: $k = l \cdot c(\mathcal{N}_O)$):
   - *label* $= an_i$, where $i \in [1, k]$,
   - $\theta_h = 0$.
10) Generate the set of all neurons $\mathcal{N}$.
11) For every $h_i \in \mathcal{P}$:
   - for every $a_j \in$ *body*(h_i) add a tuple $\langle \mathfrak{i}_j, \mathfrak{h}_i\rangle$ to the set $\mathcal{C}_{i\to h}$, where $\mathfrak{i}_j(label) = a_j$,
   - for $a_k = head(h_i)$:
     - if *body*$(h_i) = \emptyset$ then add tuple $\langle \mathfrak{h}_t, \mathfrak{o}_k\rangle$ to the set $\mathcal{C}_{h\to o}$, where $\mathfrak{h}_t(label) =$ *tn* and $\mathfrak{o}_k(label) = a_k$,
     - otherwise add tuple $\langle \mathfrak{h}_i, \mathfrak{o}_k\rangle$ to the set $\mathcal{C}_{h\to o}$, where $\mathfrak{o}_k(label) = a_k$.
12) For every $\mathfrak{o}_i \in \mathcal{N}_O$ add tuples $\langle \mathfrak{h}_j, \mathfrak{o}_i\rangle$ to the set $\mathcal{C}_a$, where $\mathfrak{h}_j(label) = an_k$. Every output neuron $\mathfrak{o}_i$ should be connected with l additional hidden neurons that are assigned to it[2].
13) For every $\mathfrak{o}_i \in \mathcal{N}_O$: add tuples $\langle \mathfrak{h}_t, \mathfrak{o}_i\rangle$ to the set $\mathcal{C}_a$ if :
   - $\mathfrak{h}_t(label) =$ *tn* and
   - $\langle \mathfrak{h}_t, \mathfrak{o}_i\rangle \notin \mathcal{C}_{h\to o}$.

[2]For example: we have 2 output neurons and we set the number of additional neurons per output neuron $l = 2$. In this case we establish connections between the first two additional hidden layer neurons with the first output neuron, and the other two additional hidden layer neurons with the second output neuron.

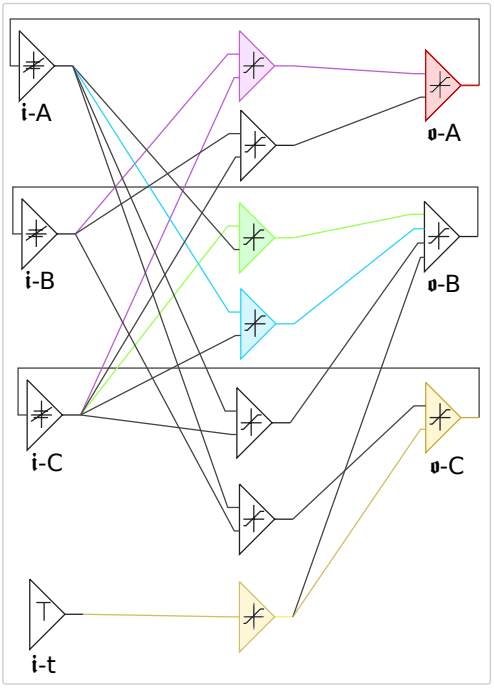

Fig. 1. A diagram of a neural network generated for the program in Example 1. The input neurons are labelled i-X, where X is a letter referring to an atom in the body of a clause, and output neurons are labelled o-Y, where Y refers to an atom in the head of a clause. The rest of the neurons are hidden layer units which represent possible clauses. Red color represents an abductive goal (fact A), purple color represents formula $A \leftarrow B, C$, green color represents formula $B \leftarrow C$, blue color represents formula $B \leftarrow A$. Yellow color represents the abductive hypothesis obtained for the problem (a fact C).

14) For every $\mathfrak{i}_i \in \mathcal{N}_I$, for every $\mathfrak{h}_j \in \mathcal{N}_H$: add tuple $\langle \mathfrak{i}_i, \mathfrak{h}_j \rangle$ to the set $\mathcal{C}_a$ if:
    - $\mathfrak{h}_j(\mathit{label}) \neq \mathit{tn}$ or
    - $\langle \mathfrak{h}_j, \mathfrak{o}_z \rangle \notin \mathcal{C}_{h \to o}$, where $\mathfrak{i}_i(\mathit{label}) = \mathfrak{o}_z(\mathit{label})$.
15) Generate the set of recursive connections $\mathcal{C}_r$.
16) Generate the set of all connections $\mathcal{C}$.
17) Generate the set of all weights $\mathcal{W}$.
18) Generate the neural network $\mathfrak{N}$.

The result of the application of the above procedure to the logic program obtained from the exemplary problem is depicted in Fig. 1.

Definition 3.19: Let $\mathfrak{N}$ be a neural network. By $T_{\mathfrak{N} \to \mathcal{P}}$ we denote the translation from $\mathfrak{N}$ to $\mathcal{P}$:

$$T_{\mathfrak{N} \to \mathcal{P}}(\mathfrak{N}) =_{df} \langle \mathfrak{N}, \mathcal{P} \rangle,$$

where $\mathcal{P}$ is obtained from $\mathfrak{N}$ by using the pedagogical approach described in [3, Chapter 5].

Using the naive version of pedagogical approach we simply map input neurons into output neurons in the following way: for each output neuron we check all combinations of input values for all input neurons relevant for this output neuron. In the case of the activation of the considered output neuron we associate the atom represented by this neuron with the following clause h_i: $\mathit{head}(h_i)$ is the considered atom and the body consists of the atoms represented by input neurons which were set to 1.0 and the negated atoms represented by input neurons that were set to -1.0. For example for output neuron with $\mathit{label} = C$ with only one relevant input neuron with $\mathit{label} = A$, if it is the case that for the considered input neuron $g(x) = 1.0$ and for the output $h(x) > A_{min}$ then we obtain the clause $C \leftarrow A$; analogically, if it is the case that for the considered input neuron $g(x) = -1.0$ and for the output $h(x) > A_{min}$ then we obtain the clause $C \leftarrow nA$ (where nA means negated A). The set of clauses extracted from a neural network is minimized by means of the the Quine-McCluskey algorithm [7, 12].

The results of learning and translation of the running example are presented in Section VI-A.

IV. Abduction

Traditionally abduction can be seen as a process of searching for explanations of a problem during which *additional* information is obtained (see [1, p. 74] on abductive explanatory characterization styles). Formally speaking, whenever we have some knowledge base K and abductive goal A , the abduction leads to generation of some additional formulas $h_1, \ldots, h_n$, that are not present in K, but which together with formulas in K enable derivation of A. In the approach presented in this paper, this does not necessarily has to be the case. It is possible that after a training of the network which represents logical program/knowledge base with an example that represents an abductive goal, translation of the trained network back to the form of logical clauses will change the initial program in other ways than just extending it. It may happen that some formulas will be modified (e.g. by removing or adding some atoms in the body of some clauses) or they can be even removed from the initial program (it is probably a matter of discussion whether it is a desirable phenomenon or not). In our approach each such modification can be seen as an abductive hypothesis, hence the term *hypothesis* gain somewhat dynamic character. This approach is more flexible than the traditional one and allows more interesting conceptual applications for the abduction, in particular accomodating substantial revisions of the initial knowledge base (see abductive schematics in [2, p. 47]). The general scheme of the proposed procedure is depicted in Fig. 2.

The abductive procedure begins in the left upper corner of the scheme presented in Fig. 2. The knowledge base is represented by the definite logic program $\mathcal{P}$ and there is a fact ϕ which cannot be derived from the knowledge base. The fact ϕ is of the form of an atom a_i and the abductive problem is represented by the fact that $a_i \notin M_{\mathcal{P}}$.

The first step of the abductive procedure is the translation of the $\mathcal{P}$ to a neural network $\mathfrak{N}$. The first step of the translation is obtained by means of the algorithm developed by Garcez in [3, p. 49]. The difference is that we add all atoms from the $B_{\mathcal{P}}$ along with the a_i to the input ($\mathcal{N}_I$) and output ($\mathcal{N}_O$) layer of the $\mathfrak{N}$ (steps 3 and 5 in $T_{\mathcal{P} \to \mathfrak{N}}$). In case of absence of the *facts* in $\mathcal{P}$, we also add a truth neuron t (which gives always 1 on the output) to $\mathcal{N}_I$ (step 7 in $T_{\mathcal{P} \to \mathfrak{N}}$). The hidden layer

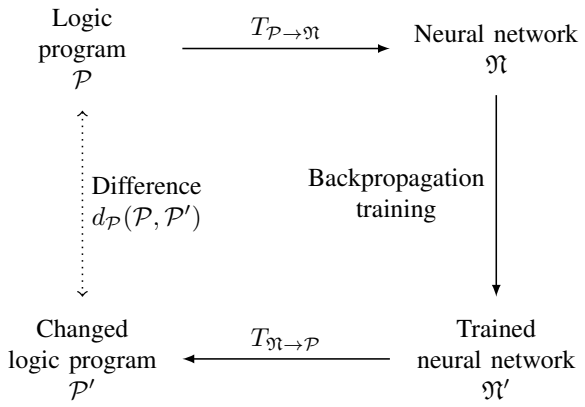

Fig. 2. A scheme of the abductive procedure

($\mathcal{N}_H$) is modified in the following way: we add *tn* neuron, which is reserved only for *t* neuron from $\mathcal{N}_I$, and a number of additional atoms per clause and a_i (steps 8 and 9 in $T_{\mathcal{P}\to\mathfrak{N}}$).

The set of all connections from input to hidden layer ($\mathcal{C}_{i\to h}$) is enriched by the additional connections running from every atom in $\mathcal{N}_I$ to $\mathcal{N}_H$ with the exception of *t* and *tn* neurons. There is a unique connection between *t* and *tn*. Additional connections do not double the connections obtained by the previous step. We also forbid additional connections from input to the hidden layer neurons that are connected with an output neuron with the same label as the neuron from input layer. In other words, additional connections cannot allow to formulate formulas of the form $A \leftarrow A$. There are also additional connections added to the set of connections from hidden to output layer ($\mathcal{C}_{h\to o}$). Those connections run from additional neurons assigned to the particular clause from $\mathcal{P}$ to the neuron which represents the head of the concerned clause. The neuron *tn* from the hidden layer connects with every neuron from output layer, except for the neuron which represents the fact ϕ denoted by a_i. The function w gives every additional connection a random value from the range $[-r, r]$ (with the exception of 0).

After the whole neural network $\mathfrak{N}$ is completed, the training begins with the use of the standard backpropagation algorithm. The training set consists of only one element: a table with all input atoms set to -1 and all output atoms set to 1. Error calculation is performed after $\mathfrak{N}$ achieves the stable state.

Trained neural network $\mathfrak{N}'$ is then translated back to logic program $\mathcal{P}'$. We define the difference between $\mathcal{P}$ and $\mathcal{P}'$ as $d_{\mathcal{P}}(\mathcal{P}, \mathcal{P}')$.

Definition 4.1: Let $\mathcal{P}$ and $\mathcal{P}'$ were a definite logic programs. The difference between $\mathcal{P}$ and $\mathcal{P}'$ is denoted by $d_{\mathcal{P}}(\mathcal{P}, \mathcal{P}')$:

$$d_{\mathcal{P}}(\mathcal{P}, \mathcal{P}') = (\mathcal{P}' \setminus (\mathcal{P} \cap \mathcal{P}')) \cup (\mathcal{P} \setminus (\mathcal{P} \cap \mathcal{P}')).$$

The change of the logic program defined as a symmetric difference is interpreted as a set of abductive hypotheses.

Definition 4.2: Let $\mathcal{P}$ be a definite logic program and $\mathfrak{N}$ a neural network obtained from $\mathcal{P}$ by the translation $T_{\mathcal{P}\to\mathfrak{N}}$. Let us further assume that $\mathfrak{N}'$ is obtained from $\mathfrak{N}$ by backpropagarion training described above. After translation of the $\mathfrak{N}'$ to $\mathcal{P}'$ by translation $T_{\mathfrak{N}\to\mathcal{P}}$ the set of abductive hypotheses $H_{\mathcal{P}}$ can be defined in the following way:

$$H_{\mathcal{P}} = d_{\mathcal{P}}(\mathcal{P}, \mathcal{P}').$$

V. Implementation

To implement the ideas given above, we have decided to use Framsticks software [10] — a versatile tool which among its many merits, gives the possibility to perform computational experiments concerning artificial neural networks. Framsticks platform is equipped with an advanced scripting language that easily enables any kind of experiment. This, together with an advanced network simulator, makes it a suitable tool for the research presented in our article. Apart from that, the software was already used in computational experiments concerning logical abduction [8, 9].

The whole implementation can be seen as a general framework consisting of scripts representing operations described earlier in the text. Hence, the whole abduction experiment can be represented as the knowledge flow between different scripts which is schematically depicted in Fig. 2.

The first important part implemented is the algorithm of translation of the default logic programs into one-hidden layer neural networks described in Sect. IV.

Next, Backpropagation algorithm with momentum has been programmed as it was not available in Framsticks software that is mainly focused on evolutionary optimisation. Finally, the algorithm translating (trained) neural networks into logic programs, described in Sect. IV has been also implemented. The whole learning procedure, however, has been modified (in comparison to the standard application of Backpropagation algorithm) and adapted to the needs of the presented research. The training set for any abductive problem consists of only one training example which in its input part contains only -1.0 values. This represents the situation where the operator $T_{\mathcal{P}}$ starts from the bottom of the lattice of all possible interpretations of $\mathcal{P}$. The values in the output part are now selected arbitrarily (apart from the value related to the neuron representing an abductive goal, which is always set to 1.0), but as mentioned later in Sect. VII solving this issue is one of the immediate future tasks. The scheme of learning is also modified as each change of the weights is based on the error calculation performed after the network achieves stable state (after several cycles of signal propagation). The network-to-program translation is implemented using the brute force approach (sometimes called *pedagogical*, which is of exponential complexity with respect to the number of input neurons), that is inefficient, especially for more complicated problems. However, as complexity-reducing approaches may be associated with lack of completeness and soundness of the translation [3, Chapter 5] and a general view on the abductive process is needed at the moment, we have decided to temporarily pay the price of the computational cost. The future plans include reduction of complexity of the used methods. Yet another issue related to the network-to-program

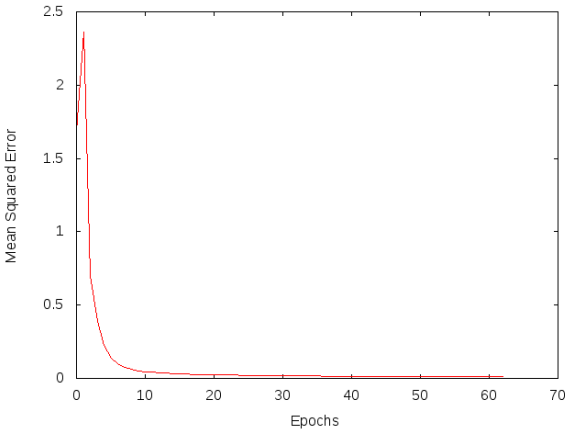

Fig. 3. A learning error chart for the Example 1.

translation is that it demands several stages of processing of the obtained clauses. In the present approach the first stage of translation may result in obtaining redundant information (e.g. two formulas of the form $A \leftarrow B, \neg C$ and $A \leftarrow B, C$ can be obtained, which should be reduced to $A \leftarrow B$).

VI. Results

This section presents preliminary results for two toy-example problems. The first example is presented in more detailed way to demonstrate how the procedure works and it concerns the problem provided in the introduction.

A. Example 1

The knowledge base for the Example 1 is $\mathcal{P} = \{A \leftarrow B, C; B \leftarrow C; B \leftarrow A\}$ and the abductive goal is a fact A. According to the procedure described in Sect. IV, the network obtained after translation of $\mathcal{P}$ is extended to contain additional hidden-layer nodes and connections to enable generation of new concepts in the knowledge base. To perform learning we prepared a training example in which every input neuron sends a signal of value -1.0 and every output value should be equal 1.0.

The learning procedure is a modified version of a Back-propagation algorithm, as mentioned earlier and in Sect. IV to let the network compute the fix point of the program.

The learning error is presented in Fig. 3. As it can be seen the error was minimized rather quickly (after a bit more than 60 epochs), which is not surprising as the training set contained only one example.

The translation of the network back to the form of a logical program resulted in the following set of formulas $\mathcal{P}_t = \{A \leftarrow B, C; B \leftarrow nC, A, t; B \leftarrow C, nA, t; B \leftarrow C, A, t; C \leftarrow nA, nB, t; C \leftarrow nA, B, t; C \leftarrow A, nB, t; C \leftarrow A, B, t\}$, where t stand for truth and n is a negation (which at this stage may be interpreted as negation as a failure — however it is removed during reduction of the obtained logic program). Further reduction of the obtained set of formulas resulted in the set $\mathcal{P}_{tr} = \{A \leftarrow B, C; B \leftarrow C; B \leftarrow A; C\}$. This means that the initial knowledge base was extended by a fact C, which is an abductive hypothesis for the problem.

B. Example 2

Example 2 demonstrates an effect of increase of the number of hidden neurons (which represent the potential concepts that can be learned by a network, see Sec. IV) and the role of the initial state of the network (represented by randomly initiated weights of the additional connections). In order to preliminarily examine these effects we performed the abductive procedure several times with other parameters fixed. The knowledge base is $\mathcal{P} = \{A \leftarrow B; A \leftarrow C; D \leftarrow E; C \leftarrow E; B \leftarrow C\}$ and an abductive goal is a fact A. The training example in the output part contained only 1.0 values. The most frequent program obtained from a network containing *one* additional hidden neuron per each output neuron is $\mathcal{P}_{t1} = \{A \leftarrow B; A \leftarrow C; D \leftarrow E; C \leftarrow E; B \leftarrow C; E\}$ — which means that the abductive hypotheses is E. The most frequent definite logic[3] program obtained from the trained networks with 17 additional hidden-layer neurons per output neuron is $\mathcal{P}_{t2} = \{A \leftarrow B; A \leftarrow C; D; C; B \leftarrow C; E\}$. This means that the abductive hypothesis is: E and change of formulas $D \leftarrow E$ and $C \leftarrow E$ into respectively D and C. This example illustrates two phenomenons. Firstly, the knowledge base can be modified during the learning process: for example clause $D \leftarrow E$ has been strengthened into a fact D. Secondly, the number of hidden-layer neurons can influence the obtained solutions for abductive problems. These two observations in turn mean, that a size of hidden layer represents a "reasoning potential" of a network and may possibly be used later to control the quality of obtained hypotheses. In the presented exemplary result, a greater number of the hidden neurons resulted in the lowered quality of the obtained hypothesis: this is because, D does not help with the derivation of A and the hypothesis contains redundancy as A can be derived from both E and C. Moreover, C can be derived from E. This lowers the internal minimality of the hypothesis, understood as non-derivability of one of the subformula of the hypothesis from another. Note, however, that the increased number of neurons is not completely unpromising, as the best solution (obtained most frequently for networks with the lower number of hidden neurons) also appeared in the set of possible solutions, but much less often.

Interestingly, further analyses revealed one more interesting issue related to the increased number of hidden neurons and connections. Apparently, in the larger networks the abductive processes became more sensitive to the initial state of the connections (with randomly initialized weights). The repetitions of the abductive experiments resulted in establishing different abductive hypotheses and this diversity was bigger than in the case of the network with lower number of neurons. The knowledge bases obtained from the subsequently trained networks with the larger number of neurons were represented i.a. by the

[3]In this work we purposely left out of analysis other kinds of logic programs, however the most frequent program obtained with these set of parameters was actually a general logic program.

following sets of formulas: $\{A \leftarrow B; A \leftarrow C; D \leftarrow E; C \leftarrow E; B; E\}$, $\{A \leftarrow B; A \leftarrow C; D \rightarrow E; C; B; E\}$. These few results preliminarily demonstrate that random initialization of the network which is capable of acquiring new concepts (due to the additional hidden neurons and connections), may influence the degree of modification of the initial knowledge and the quality of the abductive hypotheses.

VII. Summary and future work

In this paper we presented an attempt at synthesizing formal description of abductive problems with connectionist methodology based on work of Garcez et al. [3]. Contrary to the received approaches to the problem of logical abduction, we decided to employ Backpropagation algorithm to search for abductive hypotheses. The results of such experiments show that training of an artificial neural network can indeed be a method of filling a gap between a knowledge base and an abductive goal.

The neural networks obtained according to the presented procedure can be further used to solve real life problems as classifiers (just like traditional artificial neural networks are usually used) – examples of such applications of $C\text{-}IL^2P$ are presented in [3, Chapter 4]. Apart from that, the trained networks can be used as massively parallel deduction systems to solve logical problems. Yet another advantage of the presented approach, which at the same time distinguishes it from often discussed, pure logical accounts, is that it offers broad and flexible definition of the abductive hypothesis. The obtained hypotheses can either be additional formulas extending the initial knowledge base or some modifications done to the knowledge base. Finally, such methodology can be used for modelling abduction as a cognitive process, by combining connectionist structures, resembling in the limited sense the human brain, with rigours of the formal logic. The flexibility of the concept of the abductive hypothesis is likely to increase the accuracy of such modelling.

One of the interesting observations obtained at this preliminary stage of the currently presented research is the joint influence of the size of the trained network and its initial state on the obtained abductive hypotheses. While such observations may seem a little vague, more advanced computational experiments and quantitative analyses are currently under way. Among them, interesting research task is examination of the influence of the different parameters of the networks (i.e. biases of the additional neurons, initial weights of the additional connections, etc.) and parameters of training process (e.g. a form of the training example, value of learning rate or momentum) on the resulting knowledge. Research on the influence of interaction of these parameters with characteristics of the considered problems (e.g. a number of clauses in the knowledge base, a number of propositional variables, some more sophisticated structural traits) on the resulting knowledge (understood as a logic program obtained from the trained neural network) is also possible. This kind of research demands development of some measures of similarity between different knowledge bases, which is an interesting issue in itself and gives possibility of performing quantitative multi-dimensional analyses of the results of abductive process.

In the nearest future a number of improvements to the existing implementations are also in order. Among them, the most pending ones are: a decrease of computational complexity of the network-to-program implementation and intelligent automatic translation of an abductive goal into the form of a training example. This encompasses formulation of the training example in such a way that knowledge base is properly represented.

The further plans concern extension of our methodology to include more types of logic programs in order to introduce a negation, default or classical, into the researched abductive problems. The introduction of a negation will require even more sophisticated approach to generation of training examples containing representations of abductive goals. Additionally, as it is straightforward for our methodology, we would like to introduce the abductive goals in the form of formulas more complex than single atoms.

To solve the issue concerning generation of training examples a computational approach may be employed. The computational experiments may concern analysis of the impact of the desirable output values on the obtained modifications of the knowledge base. The potential results may shed light on how to construct an initial training example to properly reflect an abductive goal alongside desired concepts from the knowledge base.

Finally, a well-established abduction research requires employment of some quality-control mechanisms to obtain efficient abductive hypotheses. This goal is partially achieved in the presented approach heuristically, by removal of some unwanted connections, careful generation of the training examples and (possibly) by imposing restrictions on the size of the trained network. However, employment of some more sophisticated quality criteria is still a pending issue. An interesting approach concerning application of multi-criteria dominance relation [8, 9] to evaluate already generated abductive hypotheses gives the possibility to perform a comparative study with the methodology presented in this paper.

Appendix

Definition 7.1: A binary relation R on a set is called a *partial order* when it is reflexive, transitive and antisymmetric.

We will denote a relation which is a partial order by $\preceq$. A set S with a partial order $\preceq$ is called a *partially ordered set*.

Definition 7.2: Let S be a set with a partial order $\preceq$ and $x \in S$. We define the following:

- x is a *minimum* of S if for all elements $y \in S$: $x \preceq y$.
- x is a *maximum* of S if for all elements $y \in S$: $y \preceq x$.

Minimum and maximum of a set S are unique, if they exist, and will be denoted as *inf*(S) and *sup*(S) respectively.

Definition 7.3: Let S be a set with a partial order $\preceq$ and $R \subseteq S$. We define the following:

- An element $x \in S$ is an *upper bound* of R if for all elements $y \in R$: $y \preceq x$.

- An element $x \in S$ is an *lower bound* of R if for all elements $y \in R$: $x \preceq y$.
- An element $x \in S$ is *least upper bound* of R if x is an upper bound of R and $x \preceq z$ for all upper bounds z of R.
- An element $x \in S$ is *greatest lower bound* of R if x is an lower bound of R and $z \preceq x$ for all lower bounds z of R.

The least upper bound and the greatest lower bound of a set R are unique, if they exist, and will be denoted as $lub(R)$ and $glb(R)$ respectively.

Definition 7.4: Let S be a partially ordered set and $R \subseteq S$. We call S a *complete lattice* if $lub(R)$ and $glb(R)$ exist for every $R \subseteq S$.

Definition 7.5: Let S be a complete lattice and $R \subseteq S$. We call R *directed* if every finite subset of R has an upper bound in R.

Definition 7.6: Let S be a complete lattice, x and y be elements of S, and T: $S \to S$ be a mapping. The following holds:

- T is *monotonic* if $T(x) \preceq T(y)$, where $x \preceq y$.
- T is *continuous* if for every directed subset R of S: $T(lub(R)) = lub(T(R))$.

The collection of all Herbrand interpretations of a definite logic program P, which is $2^{B_\mathcal{P}}$, forms a complete lattice under the partial order of set inclusion. The top and the bottom element of $2^{B_\mathcal{P}}$ is $B_\mathcal{P}$ and $\emptyset$ respectively. There can be described a continuous and monotonic mapping from $2^{B_\mathcal{P}}$ to $2^{B_\mathcal{P}}$ which will serve in finding the least Herbrand model of P. The procedure is based on fixpoints of mappings on the set $2^{B_\mathcal{P}}$.

Definition 7.7: Let S be a complete lattice and $T : S \to S$ be a mapping. An element $x \in S$ is the *least fixpoint* of T if x is a fixpoint of T (*i.e.* $T(x) = x$) and for all fixpoints y of T: $x \preceq y$. An element $x \in S$ is the *greatest fixpoint* of T if x is a fixpoint of T and for all fixpoints y of T: $y \preceq x$.

The least fixpoint of T and the greatest fixpoint of T will be denoted as $lfp(T)$ and $gfp(T)$ respectively.

Proposition 7.1: Let S be a complete lattice and $T : S \to S$ be monotonic. T has $lfp(T)$ and $gfp(T)$.

The proof of the theorem 7.1 is described in [11, p. 28].

Now we want to define *ordinal powers of* T. The definition is based on properties of ordinal numbers described in [11, p. 28–29] or [3, p. 26].

Definition 7.8: Let S be a complete lattice and $T : S \to S$ be monotonic. Then we define:
$T \uparrow 0 = inf(S)$;
$T \uparrow \alpha = T(T \uparrow (\alpha - 1))$, if α is a successor ordinal;
$T \uparrow \alpha = lub(T \uparrow \beta \mid \beta \prec \alpha)$, if α is a limit ordinal;
$T \downarrow 0 = sup(S)$;
$T \downarrow \alpha = T(T \downarrow (\alpha - 1))$, if α is a successor ordinal;
$T \downarrow \alpha = glb(T \downarrow \beta \mid \beta \prec \alpha)$, if α is a limit ordinal.

Proposition 7.2: Let S be a complete lattice and $T : S \to S$ be continuous. Then $lfp(T) = T \uparrow \omega$.

The ω in theorem 7.2 denotes the first infinite ordinal. Proof of the theorem 7.2 is described in details in [11, p. 30].

***Abstract*—Mathematics, especially algebra, uses plenty of structures: groups, rings, integral domains, fields, vector spaces to name a few of the most basic ones. Classes of structures are closely connected – usually by inclusion – naturally leading to hierarchies that has been reproduced in different forms in different mathematical repositories. In this paper we give a brief overview of some existing algebraic hierarchies and report on the latest developments in the Mizar computerized proof assistant system. In particular we present a detailed algebraic hierarchy that has been defined in Mizar and discuss extensions of the hierarchy towards more involved domains. Taking fully formal approach into account we meet new difficulties comparing with its informal mathematical framework.**

I. Introduction

SINCE its development at the beginning of the 20th century abstract algebra has spread over to various branches of mathematics. One reason is the highly reusable results produced, not least due to the hierarchical structure of algebraic domains. This kind of reuse, of course, is also highly desirable in mathematical proof assistants. Consequently one naturally finds various systems in which algebraic hierarchies similar to abstract algebra have been constructed. However, most of them served to facilitate the formalization of a particular theorem or a particular application:

Though not in a proof assistant, but in a computer algebra system the – to the best of our knowledge – first algebraic hierarchy was constructed in **Axiom** [24]. Started back in 1978 – the first release under the name Axiom took place in 1991 – this was the first system in which types were connected to mathematical domains: Algebraic domains have types in their own right – called categories – that can be used to form hierarchies. So, for example, it is possible to define an operation `Fraction` that takes an argument of type `IntegralDomain` and returns its field of fractions. The algebraic hierarchy of **Nuprl** [23] was developed to support computational abstract algebra. In **Coq** [9] more than one algebraic hierarchy exists, we name two of them: One [11] was constructed as part of the FTA project to prove the fundamental theorem of algebra, another one was used in the formalization of the Feit-Thompson Theorem [12]. In the **HOL/Isabelle** Archive of Formal Proofs [22] one finds a number of proof libraries devoted to algebraic domains. Lately in **ACL2** [1] an algebraic hierarchy has been built in order to support reasoning about Common Lisp programs [21].

The Mizar system [5], [17], [31] provides a methodology to model algebraic domains based on attributed types [4]. Using so-called cluster registrations one can express (and prove) logical implications between attributes, in this way extending subtyping of attributed types. This allows not only to model algebraic domains in a generic way, but also to draw connections between – also already existing – algebraic domains. We claim that this approach is suitable to develop algebraic hierarchies that a) are generic in the sense that notations and theorems introduced in a class of algebraic domains are automatically available in subclasses b) are easily extensible by both algebraic domains and additional notations c) can automate a great deal of the natural switching between algebraic domains mathematicians are used to and d) are highly convenient for open repositories with lots of authors.

To support this claim we present in Section II a detailed hierarchy of rings up to fields, containing such algebraic domains such as unique factorization domains (UFDs), principal ideal domains (PIDs), and others. In Section III we show how homomorphisms can be incorporated into this hierarchy and how properties of homomorphisms can be used to automatically infer properties about the underlying algebraic domains. Finally, in Section IV, we discuss how to extend the hierarchy towards more involved domains such as polynomial rings and ordered fields. At the end we draw some conclusions.

II. An Intrinsic Hierarchy of Rings

In Mizar, algebraic domains are built based on structure definitions giving the signature – carriers and operations – of the domain. Informally, a ring is understood as *an algebraic structure consisting of a set of elements equipped with binary operations $+$ and $\cdot$ satisfying three sets of axioms*. More formally, usually this leads to understanding mathematical structures as ordered tuples, and in the case of a ring we have

$$\langle R, +, \cdot \rangle.$$

This could make potential troubles if we try to define rings through simpler notions, namely groups, which are usually

$$\langle G, + \rangle \quad \text{or} \quad \langle G, \cdot \rangle$$

978-83-60810-90-3/$25.00

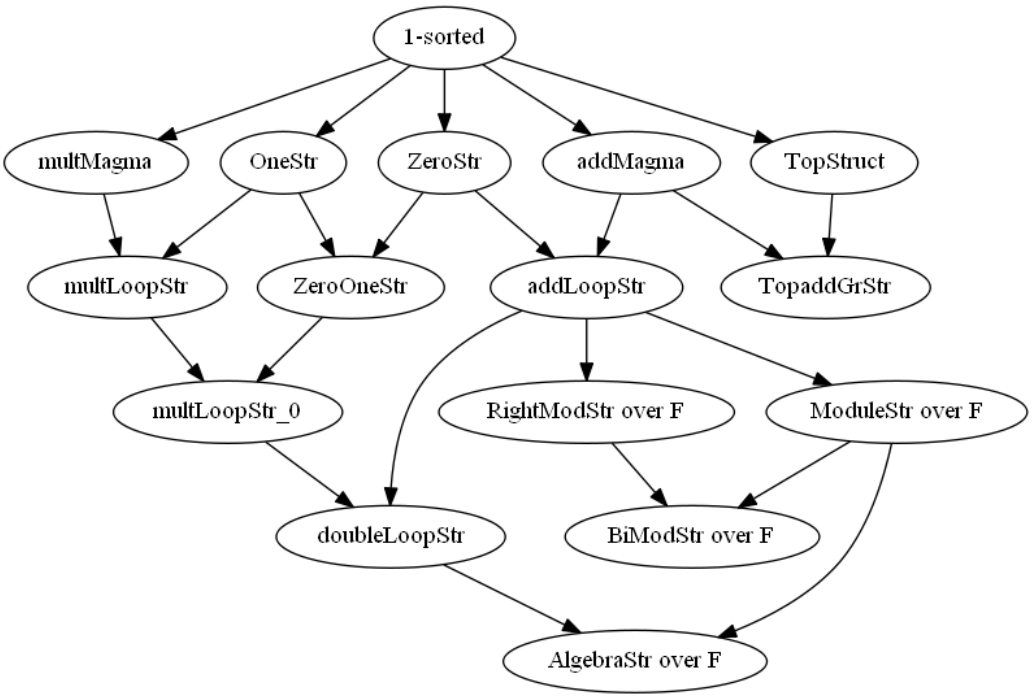

Figure 1. Net of basic algebraic structures in the Mizar Mathematical Library

(in additive or multiplicative notation, respectively). Of course then, ordinary concatenation of tuples does not work properly.

In the Mizar system, structures were implemented as partial functions with the syntax as below.

```
struct (Predecessor_List) Structure_Name
  (# selector_1 -> type_1,
     selector_2 -> type_2,
               ...
     selector_n -> type_n #);
```

This could lead to the tree, or rather a forest of 157 structures, as there are primitive structures other than `1-sorted`. However, as multiple predecessors are allowed, we should look at the diagram of interconnections as at a net. A part of such structure, dealing with basic algebraic signatures, is shown at Figure 1.

So, for example, central item in this hierarchy is

```
definition
  struct (addLoopStr, multLoopStr_0)
    doubleLoopStr
  (# carrier -> set,
     addF, multF -> BinOp of the carrier,
     OneF, ZeroF -> Element of the carrier #);
end;
```

which gives the signature of rings and fields (another one is `ModuleStr over F` which gives raise to the theory of vector spaces). Note that `doubleLoopStr` inherits from both `addLoopStr` and `multLoopStr_0`, that is it joins the signatures of additive and multiplicative groups. Particular properties such as commutativity or the existence of inverse elements are described by attribute definitions (see [35]). As a consequence, attributes defined for these become available and need not to be stated again. A ring is now just a `doubleLoopStr` with the appropriate collection of attributes:

```
definition
  mode Ring is Abelian add-associative
    right_zeroed right_complementable
    associative well-unital distributive
      non empty doubleLoopStr;
end;
```

Observe that because the Axiom of Choice is hardcoded in the Mizar checker, the collection of attributes clustered in the above definition of type should be shown to exist for at least one object; otherwise (with the illustrative example of *infinite empty set*) this should be contradictory. This is called the paradigm of non-emptiness of types in Mizar.

More interesting are different subclasses of rings that form a hierarchy according to their additional properties, e.g.

$$rings \supseteq commutative\ rings \supseteq integral\ domains \supseteq$$

$$\supseteq GCD\ domains \supseteq UFDs \supseteq PIDs \supseteq$$

$$\supseteq Euclidean\ domains \supseteq fields$$

to mention the most common ones. Each such subclass is easily characterized by adding an attribute describing its defining property, for example

```
definition
  let L be non empty doubleLoopStr;
```

```
  attr L is PID means
    for I being Ideal of L holds I is principal;
end;
```

Note that the definition does not use integral domains – in fact not even rings, but just their signature. The property of an ideal being principal just not relies on other properties such as commutativity or the absence of zero divisors (at least when defining the property; later on more properties may be necessary to show that this one is fulfilled in a particular domain – see [37]). The above hierarchy can now be established by observing that one defining property implies another – just like in mathematical textbooks:

```
registration
  cluster Euclidean -> PID for comRing;
end;
```

This way of defining the hierarchy has two major advantages. Firstly, a proof of the implication has to be given. This may be obvious, but we like to emphasize at this point, that proofs are an indispensable part of a repository. Note also, that the registration is about commutative rings, not about integral domains. Analogous to the definition of the attribute `PID` this points out, that Euclid's property implies that every ideal of the ring is principal even in presence of zero divisors – although both domains are usually defined as integral domains with the appropriate additional property.

Secondly, and more important here, cluster registrations extend automation of proving in Mizar, that is after the above registration the theorem like

```
theorem
  for R being Euclidean domRing holds
    R is PID domRing;
```

becomes obvious. Here `domRing` denotes integral domain, where in the attribute `domRing-like` the commutativity is not taken into account. Such granularity allows for better reuse of knowledge. As a secondary consequence all notations – definitions, predicates and also theorems – established for the subclass now are available for the superclass, too. In practice, this means that notations are generic: There is no need to define, for example, greatest common divisors in Euclidean domains. They can be already introduced in GCD domains (see [20]) and are therefore available in Euclidean domains, once Euclidean domains have been incorporated into the hierarchy.

The proofs necessary to built the above-mentioned hierarchy of rings have been carried out in a number of Mizar articles [2], [28], [30], [36]. Together they establish an environment in which arguing about different kinds of rings – and switching between them – can be performed in a way very similar to the usual mathematical processing.

First of all, the hierarchy can easily be extended when necessary or convenient: For example Noetherian rings are integral domains (rings) in which every ideal is finitely generated. Thus every PID is a Noetherian ring. The corresponding part of the hierarchy looks as follows:

```
definition
  let L be non empty doubleLoopStr;
  attr L is Noetherian means
    for I being Ideal of L holds
      I is finitely_generated;
end;

registration
  cluster PID -> Noetherian
        for non empty doubleLoopStr;
end;
```

Furthermore, concrete domains such as the ring of integers or the field of real numbers can be integrated in a straightforward way: a concrete domain is an instance of an abstract domain and can be introduced by just defining its concrete carriers and operations. The ring of integers, for example, is then given by

```
definition
  func INT.Ring -> doubleLoopStr equals
    doubleLoopStr(#INT,addint,multint,In(1,INT),
                  In(0,INT)#);
end;
```

and the following registrations then show that `INT.Ring` is both an integral and a Euclidean domain, hence connect `INT.Ring` with the hierarchy.

```
registration
  cluster INT.Ring -> non degenerated
    add-associative right_zeroed
    right_complementable distributive
    commutative associative Abelian
    domRing-like;
end;

registration
  cluster INT.Ring -> Euclidean;
end;
```

With these registrations all notations – definitions, predicates and theorems – established for the abstract domains become available for `INT.Ring`, too. Note that from this in particular follows – without any further proof, because this has been proven inside the hierarchy – that the ring of integers is both UFD and Noetherian, that is

```
theorem
  INT.Ring is UFD domRing;

theorem
  INT.Ring is Noetherian domRing;
```

are obvious. Moreover, it even does not matter which domain – Noetherian rings or the ring of integers – is added to the hierarchy first. In both cases the above theorems are obvious for the Mizar checker. Note however that in order to make this automation working, it is convenient to have a bunch of useful examples of concrete mathematical structures (just to assure that at least one object with desired properties exists).

At the end of this section it should be noted that the formal proof that UFDs are GCD domains has not been completed yet, but see [27] where the fundamental theorem of arithmetic – giving a blueprint for the proof – has been formalized.

III. RING HOMOMORPHISMS

When working with algebraic domains (ring-) homomorphisms are indispensable. Therefore homomorphisms are an essential part of an algebraic hierarchy. Homomorphisms are essentially mappings between rings with additional properties, that hence can again be defined by adding attributes describing these properties:

```
definition
  let R be Ring,
      S be R-homomorphic Ring;
  mode Homomorphism of R,S is
     additive multiplicative unity-preserving
     Function of R,S;
end;
```

The attribute `homomorphic` for `S` is necessary here, because Mizar does not allow empty modes: For each pair of parameters `R` and `S` it has to be proved that there exists a homomorphism from `R` into `S`. Therefore the definition of homomorphisms can take into account only such rings `S`, for which such a homomorphism indeed exists. This is ensured by adding the attribute `homomorphic`, which has the ring `R` as a parameter:

```
definition
  let R,S be Ring;
  attr S is R-homomorphic means
    ex f being Function of R,S
     st f is additive multiplicative
     unity-preserving;
end;
```

Note that together with the hierarchy presented in Section II this definition provides homomorphisms for all kinds of rings up to fields. By the way, homomorphisms are functions preserving the unity and the zero, but the latter one can be deduced (and really is in this framework) automatically, hence it is not explicitly given in this collection of attributes. Therefore additional properties of homomorphisms for more advanced rings can now be easily incorporated, for example that homomorphisms between fields are actually monomorphisms:

```
registration
  let F be Field, E be F-homomorphic Field;
  cluster -> monomorphism
           for Homomorphism of F,E;
end;
```

The property of being monomorphic is then automatically added when later working with homomorphisms of fields. The same holds naturally for properties of the image of homomorphisms:

```
registration
  let F be comRing, E be F-homomorphic Ring,
      f be Homomorphism of F,E;
  cluster Image f -> commutative;
end;
```

says that the image of a commutative ring is a commutative ring. So there is no need to distinguish homomorphisms between different kind of rings. In fact – as the last registration shows – it is even sufficient to claim that the homomorphism's codomain is an ordinary ring.

For a small example illustrating these techniques consider now rings R and S and a homomorphism $f : R \longrightarrow S$. The first isomorphism theorem then states that $R/(\ker f) \cong$ Image f. Quotient rings have been defined in [26]. The image of f is here understood as the subring of S with carrier range f, the operations of Image f are then just restrictions of the ones of S. This gives

```
definition
  let R be Ring, S be R-homomorphic Ring,
      f be Homomorphism of R,S;
  func Image f -> Ring means
    the carrier of it = rng f &
    the addF of it =
                (the addF of S) || (rng f) &
    the multF of it =
                (the multF of S) || (rng f) &
    the OneF of it = 1.S &
    the ZeroF of it = 0.S;
end;
```

Now the homomorphism $h : R/(\ker f) \longrightarrow$ Image$f$ given by $[a] \mapsto f(a)$ for $a \in R$ can easily be defined and shown to be bijective [28], so

```
theorem
  for R being Ring, S being R-homomorphic Ring,
      f being Homomorphism of R,S holds
    R / (ker f), Image f are_isomorphic;
```

Note that if R is a field we get that $R/(\ker f)$ is a field also: If R is a field, so is Image f, and hence its isomorphic copy $R/(\ker f)$. This argument can now be automated by observing that homomorphic images of fields are fields – as in the case of commutative rings from above – and reformulating the isomorphism theorem as a registration using the attribute `isomorphic` that is defined analogously to `homomorphic`.

```
registration
  let F be Field, E be F-homomorphic Ring,
      f be Homomorphism of F,E;
  cluster Image f -> almost_left_invertible;
end;

registration
  let R be Ring, S be R-homomorphic Ring,
      f be Homomorphism of R,S;
  cluster R / (ker f) -> (Image f)-isomorphic;
end;
```

These two registrations hence automate the argument above and therefore the following theorems are now obvious, that is are accepted by the Mizar checker without further proof.

```
theorem
  for F being Field, R being F-homomorphic Ring,
      f being Homomorphism of F,R holds
    Image f is Field;

theorem
  for F being Field, R being F-homomorphic Ring,
      f being Homomorphism of F,R holds
    F/(ker f) is Field;
```

IV. Extending the Hierarchy

A. Polynomial Rings

New domains are not always built solely by adding new properties, but may contain other (abstract) domains as parameters. The standard example here are vector spaces or modules that are built over a field or a ring, respectively. They, however, define new classes of algebraic domains.

More interesting are polynomial rings $R[X]$ realizing an operator within the class of rings. The standard definition of polynomial rings is well-known: Polynomials over R are sequences over R or functions $p : \mathbb{N} \longrightarrow R$, on which addition and multiplication are defined appropriately (see [29]):

```
definition
  let R be Ring;
  func Polynom-Ring R -> non empty doubleLoopStr
    equals
  doubleLoopStr (# Polys R, addpoly R,
    multpoly R, 1_.R, 0_.R #);
end;
```

Using registrations `Polynom-Ring R` can now be incorporated as usual into the hierarchy by showing that the carrier – the set of polynomials – fulfills the necessary properties, for example

```
registration
  let R be Ring;
  cluster Polynom-Ring R ->
        add-associative right_zeroed
        right_complementable;
end;
```

In fact it is not necessary for R to be a ring to prove each individual property – even when defining $R[X]$. In this registration, for example, distributivity and that polynomial addition forms a group are sufficient [29].

However, the hierarchy is able to deal with more involved properties of $R[X]$ also. For example, if R is without zero divisors, so is $R[X]$, which is described by the following registration.

```
registration
  let R be domRing;
  cluster Polynom-Ring R -> domRing-like;
end;
```

In this way additional properties of $R[X]$ are added depending on properties of R. When working with the hierarchy Mizar now automatically adds such properties to $R[X]$, if R fulfills the conditions of the registration.

In fact, the parameter R can even be a field F – based on the hierarchy of Section II the Mizar checker infers that F is a ring, so the notation `Polynom-Ring F` exists and one can formulate

```
registration
  let F be Field;
  cluster Polynom-Ring F -> Euclidean;
end;
```

So we automatically get that $F[X]$ is a PID and that gcds for polynomials over a field exist. Note also that `F_Real` is the field of real numbers; therefore real polynomials are now just given by `Polynom-Ring F_Real`.

In the context of polynomials another notation also becomes interesting: the notion of subring – $\subseteq$ for short – giving relations such as $\mathbb{Z} \subseteq \mathbb{Q}$, $\mathbb{Q} \subseteq \mathbb{R}$ or $\mathbb{Z}[X] \subseteq \mathbb{R}[X]$ – and for polynomial rings one often reads $\mathrm{R} \subseteq R[X]$ (see e.g. [39]). Now, the notation of a subring is easily defined by

```
definition
  let R be Ring;
  mode Subring of R -> Ring means
    the carrier of it c= the carrier of R &
    the addF of it =
        (the addF of R) || the carrier of it &
    the multF of it =
        (the multF of R) || the carrier of it &
    1.it = 1.R &
    0.it = 0.R;
end;
```

Then theorems for the above relations can easily be shown, for example

```
theorem
  INT.Ring is Subring of F_Real;

theorem
  Polynom-Ring INT.Ring is
    Subring of Polynom-Ring F_Real;
```

The property $R \subseteq R[X]$, however, cannot be shown; it is just not true: an element $a \in R$ is not a polynomial, so the carrier of R is not included in the carrier of $R[X]$ as it contains sequences or functions, that is ordinary set inclusion between carriers does not work here. The solution is found in the literature [39]:

> *We regard $F \subset F[X]$ by identifying the element $a \in F$ with the constant polynomial $a \in F[X]$.*

(More precisely, the identification $i : R \longrightarrow R[X]$, $a \mapsto a(x)$ is a monomorphism, and therefore allows to embed R into $R[X]$.) To formally reconstruct this identification in a repository one now has to construct a new ring R' with the corresponding carrier

$$(R[X] \backslash \{p \in R[X] : p \text{ is constant}\}) \cup R$$

and adapted addition and multiplication. This is both tedious and technical, but, what is more important, R' does not solve the problem, either: Though now one has $R \subseteq R'$, of course, R' is not exactly the polynomial ring $R[X]$ in the above sense, but only an isomorphic copy of it.

Modifying the definition of subring in the sense that a ring R is a subring of R' if R can be embedded into R' – that would allow to prove that R is a subring of $R[X]$ – is too liberal: It destroys the simplicity and elegance of the subring notation. As a consequence in mathematical repositories this kind of using the definition of subring can be modelled only at the level of morphisms, e.g. via theorems such as

```
theorem
  for R being Ring
   ex R' being Ring st R c= R' &
```

```
      R',Polynom-Ring R are_isomorphic;

theorem
  for R being Ring
   ex R' being Subring of Polynom-Ring R
   st R,R' are_isomorphic;
```

B. Ordered Fields

There are situations in which the extension of an algebraic domain can be realized in more than one way. The standard example here is the neutral element e, that is, for example added to semigroups in order to construct monoids. e can be introduced solely as an adjective in an attribute definition then claiming the existence of e – or as an additional part of the underlying structure then just claiming $a * e = a$ for all a in the carrier, where e is now the element given by the new part of the structure. Usually the second alternative is used here, because this allows for an equational definition of e's properties.

A similar situation occurs when the additional properties to be defined do not concern the domain at hand itself, but are described based on additional notations. A typical example are ordered domains, here the newly added properties concern a relation over the domain. A standard definition, for example, is:

> *An ordered field is a pair $(F, \leq)$, where F is a field and $\leq$ is a (total) relation being compatible with the field operations.*

So, ordered structures can be easily built using the second alternative from above by just adding an additional part for the relation to the underlying structure definition.

```
definition
  struct (doubleLoopStr) ordereddoubleLoopStr
    (# carrier -> set,
       addF, multF -> BinOp of the carrier,
       OneF, ZeroF -> Element of the carrier,
       OrdF -> Order of the carrier #);
end;
```

Then, based on an attribute `compatible_with` describing compatibility of the order with the field operations, one defines the mode `orderedField`. This allows to formalize and prove theorems such as follows:

```
theorem
  for F being orderedField holds 0.F <= 1.F;

theorem
  for F being orderedField,
      a being Element of F holds
    0.F <= a|^2;

theorem
  for F being orderedField holds -1.F <= 0.F;
```

Here `a <= b` denotes `[a,b] ∈ the OrdF of F`, if `a` and `b` are of type `Element of F`.

Also concrete domains, such as for example these over the set of all real numbers, fit into this approach. With `<=_R` being the usual order relation over the real numbers, the following definition establishes the real numbers as an ordered field.

```
definition
  func OF_Real -> orderedField equals
    (# REAL, addreal, multreal, In(1,REAL),
       In(0,REAL), <=_R #);
end;
```

In this case, however, introducing concrete domains this way turns out to be too restrictive: When fixing the field – of an ordered field – one immediately also has to fix the ordering. This results in inconveniences when further developing the theory. For real numbers, for example, there exists one ordering only. To formalize this within the above approach one needs to say that for two ordered fields, in both of which the field happens to be the real numbers, the orderings coincide:

```
theorem
  for F,E being orderedField
    st the doubleLoopStr of F = F_Real &
    the doubleLoopStr of E = F_Real
  holds the OrdF of F = the OrdF of E;
```

This is too clumsy to work with – and to be part of a contemporary repository. Of course, this does not bother mathematicians. If convenient they just fix the field and leave the ordering(s) as a parameter:

> *Let F be the field of real numbers. Let $\leq$ and $\leq'$ be orderings of F. Then $\leq = \leq'$.*

At this point it should be mentioned that apart of the abstract hierarchy shown at Fig. 1, another one, with the set of all real numbers fixed in certain places, is available in the MML. Such net of notions (see Fig. 2) is concentrated around the structure as follows:

```
definition
  struct (addLoopStr) RLSStruct
  (# carrier -> set,
       ZeroF -> Element of the carrier,
        addF -> BinOp of the carrier,
        Mult -> Function of
      [:REAL, the carrier :], the carrier #);
end;
```

and is still kept in the Mizar library for backward compatibility reasons. This was useful and handy some ten years ago for Mizar developers, but the approach was reimplemented. The mechanism of the identification of ordinary operations on reals with corresponding abstract field operations was discussed in detail in our paper [18]. There we described the usefulness of automatic consideration of core equalities via `identify` construction, which does not force the mathematician to add them explicitly to the proof.

For a reasonable formalization one also needs such a flexible way of talking about a domain and its (possible) orderings. Therefore one has to resign from the above, natural approach: The solution is not to extend the structure by another part, but to define the existence of an ordering externally – as an additional property. Then an ordered field is just a field for which (at least) one ordering exists:

```
definition
  let F be Field;
```

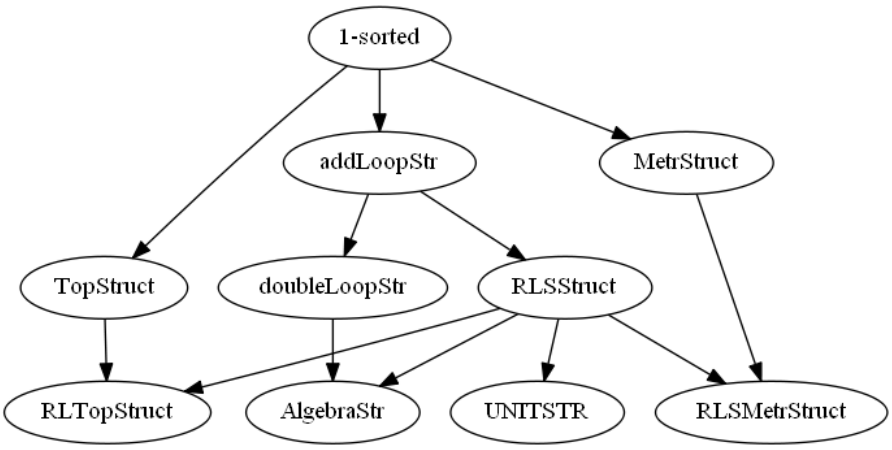

Figure 2. The correspondence of real-valued structures in the Mizar Mathematical Library

```
  attr F is ordered means
    ex O being Order of the carrier of F
      st O is compatible_with F;
end;
```

Now an ordered field is just an ordinary field, a concrete ordering has only to be fixed in the proof that the field can be ordered. This gives the above-mentioned flexibility: One can state that the real numbers can be ordered – by using the natural ordering <=_R. After that – now knowing that an ordering for a concrete or abstract domain exists – one can introduce one or more of them whenever necessary or convenient.

```
registration
  cluster F_Real -> ordered;
end;

theorem
  for O,P being Ordering of F_Real holds O = P;

theorem
  for F being ordered Field
  for O,P being Ordering of F
    st O c= P holds O = P;
```

Of course the theorems stated above for the first approach remain valid. However, they now look a little different, because the ordering has become a parameter of the theorems – as it is not fixed in the structure, here the ordered field, anymore.

```
theorem
  for F being ordered Field
  for P being Ordering of F
    holds 0.F <=_P 1.F;

theorem
  for F being ordered Field
  for P being Ordering of F,
  for a being Element of F
    holds 0.F <=_P a|^2;

theorem
  for F being ordered Field
  for P being Ordering of F
    holds -1.F <=_P 0.F;
```

Summarizing, it turns out, that for ordered fields adding a new part to the structure – the solution usually preferred – is inferior to describing the property of being ordered solely by an adjective, though this means that an existential quantifier occurs in the attribute definition.

V. Conclusion

We have illustrated how in Mizar a deep algebraic hierarchy has been built that to a great deal resembles the natural changing between algebraic domains known from mathematics. The key technique is the application of Mizar's attributed types: The adjectives defined by attributes enable the natural extension of existing algebraic domains by adding new properties. Furthermore, implications between adjectives can be formulated in the form of cluster registrations. These not only prove that, for example, an Euclidean domain is a UFD, but also automate inferring the implication. Summarizing the presented approach supports building algebraic hierarchies that are easily extended and refined when necessary.

Mizar structures together with *locales* – a similar concept implemented in Isabelle [3] can be a reasonable improvement in writing mathematical proofs and their automated discovery. Interesting categorical motivation of such an approach is presented in [7]. Modules can be treated globally for all proof assistants, and a kind of interface allowing for information interchange is proposed as MMT – a module system for mathematical theories with scalable formalism [34]. All axiomatic theories can be viewed from the metalevel, using the concept of *realms* – which could also enable reasonings via consolidating knowledge about theories.

The hierarchy of structures available in the Mizar Mathematical Library was described in [35] and was enriched during the formalization of the proof of Fundamental Theorem of Algebra [29]. However in 2007 a big refinement (a revision [19]) took place, and parts of the net of structures together with

corresponding attributes were a subject for refactoring. In that time the Library Committee of the Association of Mizar Users (with the two first authors of the current paper as its members) wrote a library item [30] which is now a backbone for all described constructions. This field of algebra is continuously formalized, and recent Mizar article [38] contains results about selected properties of polynomial ring.

In fact this methodology is not restricted to algebraic domains and algebraic hierarchies. In Mizar one finds similar hierarchies concerning a number of mathematical structures such as, for example, posets, lattices, topologies, topological groups, topological lattices, and graphs. In the Mizar repository there is a series of articles devoted to algebraic structures using multiplicative notation. Recently, Coghetto [8] made a monographic Mizar article which was a modification of already accepted ones with an addition as a basic binary operation (instead of a multiplication). Even if the work was not too much time-consuming, some of the library techniques can be further improved (e.g. in the direction of generic structures – because `addMagma` and `multMagma` could be potentially more unified, but this would require implementational work of the Mizar checker).

The direction of enhancing computer reasoning tools, which is quite popular and efficient, is to use external specialized software. In the case of Mizar some experiments were proposed by Naumowicz [32] with SAT solvers in order to improve the efficiency of boolean calculations. Of course, this could be taken into account in the area of algebraic domains. As another example, Grabowski succesfully used Prover9 for reasonings about lattices [14]. This is another field of research where efficient treatment of algebraic hierarchies is very important, and recent formalization of Stone algebras as generalization of Boolean algebras [15] shows the usefulness of the Mizar system.

***Abstract*—In the paper, we discuss the formal approach to Tarski geometry axioms modelled with the help of the Mizar computerized proof assistant system. Although our basic development was inspired by Julien Narboux's Coq pseudo-code and is dated back to 2014, there are significant steps in the formalization of geometry done in the last decade of the previous century. Taking this into account, we will propose the reuse of existing results within this new framework (including Hilbert's axiomatic approach), with the ultimate future goal to encode the textbook *Metamathematische Methoden in der Geometrie* by Schwabhäuser, Szmielew and Tarski. We try however to go much further from the use of simple predicates in the direction of the use of structures with their inheritance, attributes as a tool of more human-friendly namespaces for axioms, and registrations of clusters to obtain more automation (with the possible use of external equational theorem provers like Otter/Prover9).**

I. Introduction

FOR YEARS, foundations of geometry attracted a lot of interest of resarchers from various areas of mathematics. From the very beginnings, human thought was stimulated by geometrical objects, to take Thales as the prominent example of an ancient philosopher. Classical geometry involved illustrative examples and construction problems instead of a building strong axiomatic basis. However, from the modern viewpoint of automated theorem-provers, diagrams can deliver some really tough problems. Here an important example is the possibility of ruler-and-compass construction: impossibility of trisecting the angle and doubling the cube (as two out of four problems of antiquity), where the treatment of constructible numbers is way more efficient from the formal point of view.

Euclid and his *Elements* are often recalled as one of the first successful uses of an axiomatic method in mathematics, and such an approach can be formalized efficiently with the use of computer proof-assistants. Then, changing even simple notions with obvious (at least at the very first sight) properties, as parallel postulate (or Playfair axiom), gave rise to various geometries (e.g., Bolyai-Lobachevskian hyperbolic geometry). The same work can be modelled with machine formalizations, using various sets of axioms (creating *types*). Now, apart from the discussion whether the non-emptiness of types in Mizar is real difficulty (because from informal point of view one can consider an object with any properties, even mentioning their coherence), and how much more can be attained if the reimplementation of the Mizar type system will be done in the foreseeable future, we have to cope with the limitations of the existing type structure. On the other hand, type checking allows some errors to be caught early – when making mathematical definitions. In this context the requirement of constructing at least one object of the desired type is quite natural, as it prevents contradictory types. Similarly, the appropriate model had to be constructed either to assure that proposed axioms are correct (which is not very hard as they can be parsed by ordinary mathematician even straight from its corresponding Mizar source code), or (and this is probably even more important) to bind the fresh formal apparatus with the existing Mizar developments. Some of them are written in a language which is not as expressive as contemporary Mizar language is; in the time of the beginnings of the Mizar Mathematical Library (MML) as a tight collection of Mizar articles covering various branches of mathematics, geometry was an area which was developed quite dynamically.

The language of the Mizar system was influential for other systems for formalization of mathematics, e.g. `miz3` is a proof interface built on top of HOL Light interactive theorem prover, with the declarative language compatible with the Mizar language [47]. Recently, William Richter used `miz3` tool to formalize Tarski geometry axioms, with the ultimate aim to incorporate it in HOL Light, but of course part of his pseudo-code could be also treated both as a case study and as a good starting point for further work.

The choice of the topic is not accidental – recent code available in Coq [7] and the use of automated equational provers caught an eye of researchers and, as a by-product, some results, which shed some new light on the axiomatization of geometry, were published. One of the bright milestones was also the publication of the new issue of the classical textbook *Metamathematische Methoden in der Geometrie* by Wolfram Schwabhäuser, Wanda Szmielew and Alfred Tarski [40] (to which we refer by the acronym SST) with the foreword of Michael Beeson.

In this paper, we are not focused on any of geometric challenges known in the community, as proving Hilbert axioms from Tarski [7], or formalizing full SST in Mizar, although it can be definitely good starting point as in [38] we prove some Hilbert's axioms. What we were trying to do was to

978-83-60810-90-3/$25.00

increase of the integrity of (the geometrical part of) the MML as pointed out in the paper of Piotr Rudnicki and Andrzej Trybulec [39] and this could be a kind of partial realization of their postulates. This was done mainly via the mechanism of *revisions* of the repository – stepwise refinement of items already included in MML, done not necessarily by authors themselves [19]. An alternative approach – focusing on computations instead of proofs, and work in the analytic framework of Euclidean spaces $\mathbb{R}^n$ is also well-represented in the repository of Mizar texts, with the recent examples of Morley trisector theorem or Ceva theorem. The process of formalizing geometry within Mizar Mathematical Library started years before first Coq geometry formalizations; furthermore, constructive logic behind the Coq proof assistant naturally forces program extraction from proofs and intuitionistic setting of the reasoning. In Mizar the stress is put on three main issues:

- writing readable proofs using classical logic,
- possibility of cooperation with external theorem provers, and
- knowledge reuse (increasing possible connections between various developments, called *integrity of a repository*).

The outline of the paper is as follows. In Section II, we describe the history of formalizing geometry in Mizar, Section III presents the discussion on abstract and concrete mathematics; the next one outlines some basic constructions needed to understand our work, that is concrete translation of chosen properties straight from Tarski's axioms (A1)–(A7). In Section V and VI we give some insight on knowledge reuse and on its readability, respectively, while in the last part we describe related work, then we draw some concluding remarks and propose some future work.

II. Mizaring Affine Geometry

In Tarski's system of axioms [44] the only primitive geometrical notions are points, the ternary relation B of "soft betweenness" and quaternary relation $\equiv$ of "equidistance" or "congruence of segments". The axioms are reflexivity, transitivity, and identity axioms for equidistance; the axiom of segment construction; reflexivity, symmetry, inner and outer transitivity axioms for betweenness; the axiom of continuity, and some others. The original set consisted of 20 axioms for two-dimensional Euclidean geometry and was constructed in 1926–27, submitted for publication in 1940, and finally appeared in 1967 in a limited number of copies. There are many modifications of this system, and Gupta's work in this area [20] offers an important simplification. The strict betweenness was studied even before: it gave rise to "betweenness geometry" by Veblen in 1904.

Another notable axiomatization, proposed by Hilbert [21] in 1899, has three sorts: planes, points, and lines, and three relations: betweenness, containment, and congruence. In this sense it is a little bit more complex than Tarski's (but not necessarily in terms of numbers of axioms as it has also 20 of these). The two approaches establish a geometrical framework, in which theorems can be proven logically (remember Euclid's *Elements* proofs are mainly pictures or graphical constructions and rely heavily on the intuition). This allows to use a computerized theorem prover in order to find the proof or proof checker to check the theory for its correctness. In the paper, we deal with the proof checker Mizar, based on classical first order logic and Tarski-Grothendieck set theory (a variant of Zermelo-Fraenkel). Using this tool we describe, how Tarski's theory was built formally.

There are two significant connections of Andrzej Trybulec, the founder of the Mizar project, with persons involved in the area of Tarski's geometry. The first one and very influencial was the cooperation with Lesław W. Szczerba, the author of [42], in the early 80s of the previous century. Szczerba, who also submitted to the Mizar Mathematical Library twice, was at that time a head of the Institute of Mathematics in Białystok, Poland; the place the Mizar system was mainly developed (and that was also the affiliation of Trybulec). These contacts resulted in the research on the theory of interpretation and semantic foundations of logic in the sense of Epstein. At that time, Trybulec himself was not very active in formalizing geometry. The other connection was that after finishing his study in mathematics at the University of Warsaw under the guidance of Karol Borsuk (famous Polish topologist), Andrzej Trybulec took the position of an assistant in the Chair of Geometry, where Wanda Szmielew was a professor.

Although the very first approach to formal geometries we can consider the work of Wojciech A. Trybulec `INCSP_1` [45], at the state of its writing it was not tightly connected with the rest of the formal appproach to geometry in Mizar. Krzysztof Prażmowski (who is currently the head of the Institute of Mathematics, University of Białystok, Poland) created quite an active research group of fifteen people in the field of automated deduction in geometry, with the extensive use of the Mizar system. Main authors of these contributions were Krzysztof Prażmowski, Henryk Oryszczyszyn, and Wojciech Leończuk, all from former University of Warsaw, Białystok Branch. Together with the other authors, e.g., Kusak, Skaba, Muzalewski, and others, they wrote 43 Mizar articles on geometry (5 were removed later in the process of revisions). At the very beginning, there were many independent paths of formal development of various geometries (which expressed in various Mizar structures: directed vs. undirected parallelity relation, orthogonality, etc.).

Statistical data from Table I are not very impressive with respect to the current state of MML. The number of authors is quite big (six percent of all the authors of MML), hence the style of geometry in Mizar is not very uniform. The writing style can be measured by the percentage of zipped kBytes, which is higher than for the whole MML. This specific ratio (zipped instead of unpacked bytes) is usually taken when computing the so-called de Bruijn factor, showing how much additional code we should write comparing with informal proof to be fully understandable by computers. Furthermore, hierarchy of geometric objects is based on eight various structures, so it raises communication issues between various

TABLE I
STATISTICAL DATA ON THE FORMAL DEVELOPMENT OF GEOMETRY WITHIN MML

	Geometry	MML	Percentage
files	38	1,254	3.0
authors	15	255	6.0
kBytes	1.981	93.324	2.1
zipped kBytes	406	17,642	2.3
definitions	294	11,606	2.5
theorems	1,319	56,547	2.3
attributes	135	3,079	4.4
clusters	113	13,071	0.9
structures	8	157	5.0

approaches. The last article was PROJPL_1 dated back to 1994, and the series was not very actively developed (with the exception of the paper of the combinatorial Grassmannians COMBGRAS). But in 1990 Mizar articles on geometry were about 30% of the whole Mizar repository (out of 140 files). Of course, after that time revisions of this specific area were quite active: one of the main streams (done also by the current author) was to get separate axioms of selected properties instead of a large block for *the mode* (i.e., the constructor of the type in Mizar). As we can read from the table, the use of clusters (relatively new feature of Mizar language) is still very low comparing with the rest of MML, so there is a lot of work to be done. Affine approach to geometry was less important as there was another big challenge which for fifteen years stimulated geometry (in analytical setting, however): the proof of the Jordan Curve Theorem [23], which will be recalled in Section V.

As notable affine geometrical facts already formalized in Mizar we can enumerate:

- Hessenberg's theorem – HESSENBE;
- Desargues theorem (present in "Top 100 mathematical theorems") – ANPROJ_2;
- Pasch configuration axioms – PASCH;
- Fano projective spaces – PROJRED1;
- Desarguesian projective planes – PROJRED2;
- Pappus, Minor, Major and Trapezium Desargues axioms – AFF_2;
- Minkowskian geometry – ANALORT.

The "Top 100 mathematical theorems" list of important theorems in mathematics, proposed by Paul and Jack Abad at the end of provious century, is the popular collection of challenges for contemporary computerized proof-assistant systems; the list maintained by Freek Wiedijk described in [48] is available at http://www.cs.ru.nl/~freek/100/. Currently, the Mizar system holds the third position with 64 items formalized so far.

In our opinion, the unifiying approach in Tarski's spirit could be quite useful to bind all of these geometrical results together. Among another significant facts in geometry we can point out Morley trisector theorem [8], Ceva and Menelaus theorem [41]. These facts however deal with Euclidean plane, so the proofs are in the area of analytic geometry; they were developed more than ten years later than the foundations of geometry in Mizar, when Euclidean spaces were more thoroughly explored in MML.

TABLE II

Total	1254	100.0	91,846	100.0

III. THE CHOICE OF FORMAL FRAMEWORK: CLASSICAL VS. ABSTRACT MATHEMATICS

The distinction between classical and abstract mathematics (i.e. the one based on ordinary axioms of set theory, and all those using the notion of a structure, respectively) is important from the viewpoint of the organization of the Mizar repository. We had to choose between two paths:

- it is possible to formulate Tarski's axioms without the use of a structure, and also set theory could be meaningless for that framework, only the classical logic with Mizar predicates is enough (equality plays a special role in the system based on set theory [18]);
- the use of Mizar structures forces us paradoxically to use basics of set theory – defining a signature of Tarski's plane needed to give a type of congruence of segments and betweenness relation, which was set-theoretic (Mizar language is typed, and in the earlier case one should also give a type at least to points, but it can be defined as Mizar object).

The latter was also chosen by us as the whole geometry in MML is written in abstract style (as the majority of MML, as you can read from Table II) as structures in Mizar are present for a long time. Even if in ordinary mathematical tradition they are considered as ordered tuples, in the implementation in Mizar they are treated rather as partial functions, with selectors as arguments, and ordinary inheritance mechanism (with polymorphic enabled, which will be extensively used in our formalizations). The details of the implementation can be found in [16], we give here only general syntax of declaring Mizar structure:

```
struct (Predecessor_List) Structure_Name
  (# selector_1 -> type_1,
     selector_2 -> type_2,
                ...
     selector_n -> type_n #);
```

To every argument, its type should be declared, which corresponds to ordinary definition of the signature of an algebra.

In the contemporary MML, the basic Mizar article devoted to structures is [26]; it is dated as for 1995, earlier than the first article from MML on structures [45], i.e. 1989, because it was created much later as a result of revision. Its main step was introducing common predecessor of all structures – 1-sorted, and the name of the selector carrier was

chosen. Wojciech A. Trybulec proposed in [45] the formalization of Hilbert axioms (hence we have three sorts: points, lines and planes). Interestingly, the original name `Points` remained untouched (although many similar approaches were later unified).

```
definition
  struct IncProjStr
     (# Points, Lines -> non empty set,
           Inc -> Relation of
             the Points, the Lines #);
end;

definition
  struct (IncProjStr) IncStruct
   (# Points, Lines, Planes -> non empty set,
   Inc -> Relation of the Points, the Lines,
   Inc2 -> Relation of the Points, the Planes,
   Inc3 -> Relation of the Lines, the Planes #);
end;

definition
  let S be IncProjStr;
  mode POINT of S is
         Element of the Points of S;
  mode LINE of S is
         Element of the Lines of S;
end;
```

Introducing two different structures to host only points and lines in the first case was a result of revision allowing to use simpler structures to cope with planar geometry. Note however, that this disagrees with Tarski's single sort universe (of points); and this is quite a basic structure in MML, `1-sorted`, as we already mentioned. Based on this, other descendant objects can be defined:

```
definition
  struct (1-sorted) AffinStruct
    (# carrier -> set,
       CONGR -> Relation of
         [:the carrier,the carrier:] #);
end;
```

This was the very first approach, and in fact the article with MML identifier `ANALOAF` offered quite simple structure; here, `CONGR` is a relation on the Cartesian square of the carrier, and it is used mainly in the context of parallelity predicate. Merging it with another relation, the orthogonality, MML offers a variety of affine geometries. The outline of this universe is shown in Figure 1. It can be observed that the hierarchy is not very deep, as many approaches were done originally in parallel, without reusing notions or theorems between various paths of development. Furthermore, incidence structures are not descendants of `1-sorted`, which should be definitely corrected in the future.

```
definition
  struct (AffinStruct, OrtStr) ParOrtStr
              (# carrier -> set,
    CONGR, orthogonality -> Relation of
      [:the carrier,the carrier:] #);
end;
```

In the original form of [45], the number of axioms was introduced in the form of a single big formula introducing `mode IncSpace`. What is interesting, after the revision, and evolution of the Mizar system, the file is 10 kB smaller.

```
definition
  struct (1-sorted) TarskiPlane
    (# carrier -> set,
    Betweenness -> Relation of
      [:the carrier, the carrier:], the carrier,
    Equidistance -> Relation of
      [:the carrier, the carrier:],
        [:the carrier, the carrier:] #);
end;
```

Observe that the choice of the arity of the relation is really meaningless here: the betweenness relation can be treated as a ternary relation; but the choice of this concrete model was quite arbitrary as the difference between dealing with ternary relations and relations between ordered pairs and elements will not cause any major problems later (we use mainly predicates).

```
definition
  let S be TarskiPlane;
  mode POINT of S is Element of S;
end;

definition
  let S be TarskiPlane;
  let a, b, c be POINT of S;
  pred between a,b,c means
:: GTARSKI1:def 1
  [[a,b],c] in the Betweenness of S;
end;

definition
  let S be TarskiPlane;
  let a, b, c, d be POINT of S;
  pred a,b equiv c,d means
:: GTARSKI1:def 2
  [[a,b],[c,d]] in the Equidistance of S;
end;
```

One can mention possibly misleading type definitions for the betweenness relation (it can be considered as three-argument relation than as it is now, i.e. relation between an ordered pair and an element), and also – pretty technical – predicate `between a,b,c` for arbitrary points a, b, c. Of course, the notation could be changed easily into well-readable candidate `b is_between a,c` (maybe with the need for replacing arguments), but we have chosen this notation to be closer to SST. Brackets can be used as `between (a,b,c)`, but they can also be omitted, there is no strict obligation for using them.

IV. The Original Self-Contained Approach

In the very first version of Mizar formalization of Tarski's axioms done by William Richter with the help of `miz3`, we can find the remark:

> *In Mizar it isn't possible to define such a type (or model) without proving that some model exists. Trybulec's existence proofs runs over 450 lines. So we define a predicate 'S Tarski-model' which means that the plane S satisfies the axioms A1–A7, and*

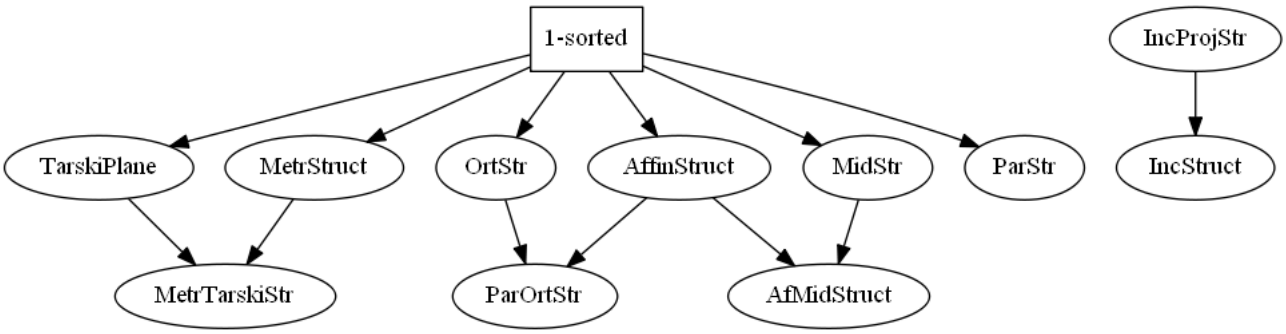

Fig. 1. Geometrical structures in the Mizar Mathematical Library

then prove trivial theorems A1–A7 which say that if S Tarski-model, then S satisfies an axiom A1–A7. The extra clutter involving the predicate Tarski-model, and the label TarskiModel which stands for the statement 'S Tarski-model' could be avoided by loading all our results into one gigantic theorem. Our approach seems preferable.

This motivation essentially caused the lack of the appropriate Mizar type. Indeed, Trybulec's existence proof gets even more lines (over 500), but it should be taken into account that [45] was one of the very first Mizar articles submitted to MML (numbered #25) and auxiliary set of handy lemmas or models was really modest at that time.

One can consider having predicates, but attributes instead of them seems to be better idea: we can have modular building of a complex structure, all other can be reused; hence in our Mizar article we focus on pure betweenness-equidistance part, not really mentioning the question of dimensions. We prove 44 theorems (properties of the predicates), with the Gupta's proof of Hilbert's I1 axiom (that two distinct points determine a line).

```
theorem ::: I1:
  a <> b & x <> y &
    a on_line x,y & b on_line x,y
      implies x,y equal_line a,b
   proof
     assume
H1:  a <> b & x <> y; then
P2:  b,a equal_line a,b by LineEqA1;
     assume
H2:  a on_line x,y & b on_line x,y;
     per cases;
     suppose x = b; then
       x,y equal_line b,a by H1, H2, I1part2;
       hence thesis by P2;
     end;
     suppose
       x <> b; then
P4:    x,y equal_line x,b by H2, I1part2; then
       x,b equal_line a,b
         by H1, I1part2Reverse, H2;
       hence thesis by P4;
     end;
  end;
```

TABLE III
THE STATISTICS OF THE CONTENT OF [38]

Items	Numbers
attributes	10
lines	1522
kBytes	50
theorems	47

Final Gupta's proof of I1 (GTARSKI1:46) above uses additional auxiliary predicates, e.g. `on_line`, which shortens the notation and provides future connections with Hilbert's axioms. Of course, at the end we are left with the proofs that the set of formulas (obtained by the so-called *definitional expansions* [24]), chosen formula can be deducted, but our attribute-steered approach seems to be better, not in terms of the efficiency of proving, but readability and usefulness for human mathematician.

Our Mizar versions of Tarski's axioms have descriptive names, and follow the ones from SST (using $\equiv$ for congruence of segments and B for betweenness relation):

- `CongruenceSymmetry` (A1): $\forall_{a,b}\ ab \equiv ba$,
- `CongruenceEquivalenceRelation` (A2): $\forall_{a,b,p,q,r,s}\ ab \equiv pq \wedge ab \equiv rs \Rightarrow pq \equiv rs$,
- `CongruenceIdentity` (A3): $\forall_{a,b,c}\ ab \equiv cc \Rightarrow a = b$,
- `SegmentConstruction` (A4): $\forall_{a,q,b,c} \exists_x\ B(q,a,x) \wedge ax \equiv bc$,
- `BetweennessIdentity` (A6): $\forall_{a,b}\ B(a,b,a) \Rightarrow a = b$,
- and `Pasch` (A7): $\forall_{a,b,p,q,z}\ \ B(a,p,z) \wedge B(b,q,z) \ \Rightarrow\ \exists_x\ \ B(p,x,b) \wedge B(q,x,a)$.

One attribute has the form which substantially differs from SST version: in order to shorten the notation, we introduced technical predicate

```
definition
  let S be TarskiPlane;
  let a, b, c, x, y, z be POINT of S;
  pred a,b,c cong x,y,z means
:: GTARSKI1:def 3
    a,b equiv x,y &
```

```
    a,c equiv x,z &
    b,c equiv y,z;
end;
```

denoting essentially SSS predicate for triangles. Using this notion, SST axiom (A5) could be encoded as follows:

```
definition let S be TarskiPlane;
  attr S is satisfying_SAS means
:: GTARSKI1:def 9
     for a, b, c, x, a1, b1, c1, x1
       being POINT of S holds
        a <> b & a,b,c cong a1,b1,c1 &
        between a,b,x & between a1,b1,x1 &
        b,x equiv b1,x1 implies
          c,x equiv c1,x1;
end;
```

that is,

$$\forall_{a,b,c,x,a',b',c',x'}\ (a \neq b \wedge ab \equiv a'b' \wedge bc \equiv b'c' \wedge ac \equiv a'c' \wedge$$
$$\wedge\ B(a,b,x)\ \wedge\ B(a',b',x')\ \wedge\ bx \equiv b'x')\ \Rightarrow\ cx \equiv c'x'.$$

It should be noted that the sequence of internal Mizar utilities can be run on the code, and hence proofs can be modified or even shortened. The remarkable case are the three assumptions from auxiliary lemmas added in the original `miz3` code, which was automatically removed as unnecessary. The usual running cycle of auxiliary programs like `relprem`, `relinfer`, `chklab`, and `inacc` is as follows: first, unnecessary premises are marked, then irrelevant (obvious for the Mizar checker) proof steps are marked as unused and eliminated, and finally the whole structure of the proof can be pretty-printed. Such "cleaning" cycle [16] caused the reduction of proofs of properties by more than 300 lines, not affecting readability that much. The net of connections between definitions, lemmas, and theorems obtained in this way can be further studied in order to get better refactoring of knowledge via dedicated techniques [17].

Having separate attributes for distinct axioms had already shown its usefulness in various geometrical settings. It could also allow later for defining equivalent axiom systems for Tarski geometry (and due to mechanism of clusters this equivalence will be obvious for the checker, once proven).

V. Introducing Metric Structure

It is well known fact that every metric space can be equipped with the natural topology. This informally obvious mathematical property brings some unexpected difficulties when dealing with structures if automated proof-assistants play a role. Namely then, if one considers topological spaces in a quite natural way, that is $\langle U, \tau \rangle$, and metric space as $\langle U, d \rangle$, respectively, one can rather naturally merge both structures into common $\langle U, \tau, d \rangle$.

During the formalization of the Jordan Curve Theorem in Mizar [23], however, another approach was chosen (and pushed consequently until the successful finale): `Euclid 2` denoted metric space concerned with the Euclidean plane, and then special functor converting any metric space into the topoogical space was applied to obtain `TOP-REAL 2` (of course the conversion can be made for arbitrary natural number n, not necessarily 2, but Jordan curves deal with two-dimensional case). The basic signature for metric spaces are `MetrStruct`, where distance is a function defined on the Cartesian square of the carrier with the real values. Then, metrics (or pseudo-, quasi-, semimetrics, etc.) can be defined in terms of attributes [22], that is properties of the distance function.

```
definition
  struct (MetrStruct,TarskiPlane) MetrTarskiStr
   (# carrier -> set,
     distance -> Function of
            [:the carrier, the carrier:], REAL,
     Betweenness -> Relation of
            [:the carrier, the carrier:],
              the carrier,
     Equidistance -> Relation of
            [:the carrier, the carrier:],
              [:the carrier, the carrier:] #);
end;
```

Then we have two worlds merged: affine, where we have two Tarski's relations, and Euclidean, where in terms of distance function, we can have betweenness relation and the the measure for segments. We argue that, regardless of all the complications caused by merging structures [12] (which increases the number of selectors, hence the chain of notions gets more complicated), such approach – not converting between two contexts, but rather to make reasoning in the world which is successor of both – allows for more flexible reuse of knowledge from two original areas.

```
definition let M be MetrTarskiStr;
  attr M is naturally_generated means
:: GTARSKI1:def 15
    (for a, b, c being POINT of M holds
      between a,b,c iff b is_Between a,c) &
    (for a, b, c, d being POINT of M holds
      a,b equiv c,d iff
        dist (a,b) = dist (c,d));
end;
```

In merged structure, we want to have two segments congruent, if they are equal in terms of distance, and betweenness relation uses the predicate `is_Between`, also given in terms of the sum of distances. To construct a model of the Tarski's space, such "one gigantic theorem" mentioned by Bill Richter in the quotation from the previous section can be somehow avoided. In Trybulec's paper [45], the massive construction of the appropriate space satisfying all incidence axioms was hidden under the existence proof of the following Mizar type:

```
registration
  cluster strict IncSpace-like for IncStruct;
end;
```

Recalling the previous discussion on the structure merging, the construction of such a space from scratch (essentially more or less modified copy-and-paste work on the proof from [45]) can be avoided with the help of some useful tricks, investigating knowledge already present in MML with its possible reuse. For example, based on the geometry on the real

line, appropriate geometrical structure from metric structure can be just an extension with properly defined distance.

```
definition
  func TarskiSpace -> MetrTarskiStr equals
:: GTARSKI1:def 22
    the naturally_generated TarskiExtension
      of RealSpace;
  coherence;
end;
```

Then, we can show that in such extension the metric is well defined, i.e. this space is reflexive, symmetric, and discerning. Furthermore, if we take into account "geometrical part", the following axioms can be proven true:

```
registration
  cluster TarskiSpace ->
    satisfying_CongruenceSymmetry
    satisfying_CongruenceEquivalenceRelation
    satisfying_CongruenceIdentity
    satisfying_SegmentConstruction
    satisfying_BetweennessIdentity;
```

VI. Human-oriented Representation of Knowledge in *Formalized Mathematics*

Of course, detailed proofs of all the work are already present in the Mizar Mathematical Library and were published in the special issue of *Formalized Mathematics* devoted to 25 years of MML. We tried to find subtle compromise between strict mathematical notation and a fluent text looking quite as good as that written by human – as the author has the opportunity of chosing the translation formats for newly introduced definitions (in XML stylesheet); the example of two automatically translated theorems are given on Figure 2 (versions straight from MML and FM).

```
theorem :: GTARSKI1:31 ::: GuptaEasy:
  a <> b & between a,b,c & between a,b,d &
    b <> c & b <> d implies not between c,b,d;

theorem :: GTARSKI1:32
  a,b,c cong a9,b9,c9 &
    between a,x,c & between a9,x9,c9 &
      c,x equiv c9,x9 implies b,x equiv b9,x9;
```

VII. Related Work

Although the history of the development of the axiom system for geometry by Tarski is not very clear from the beginnings (as the early works by Tarski seem to be postponed by the World War II), and even if the ultimate source of information is SST which was badly printed (the book was recently reissued with the foreword of Michael Beeson), now it attracted a lot of focus from automated deduction systems.

The remarkable item here is of course Julien Narboux's formal development of Tarski's system with the use of Coq [33]. We are planning to include some interesting results from GeoCoq in the Mizar system; Nakasho's et al. MML symbol reference system [32][1] offers quite user-friendly interface for browsing appropriate content. Of course, GeoCoq provides ready-to-use list of notions, which are connected only with the Tarski's system – that makes the browsing more convenient. Of course, after rescaling all definitions and theorems can be browsed within MML providing a look in the style of GeoCoq project.

Similar web-browsing system giving practical insight into Tarski's geometry is offered by the aforementioned Michael Beeson's *Tarski Formalization Project*. It offers linkages with underlying items from SST; the correctness relies on the Otter prover. Here the readability is not the main issue, however a few open questions was answered. Tim Makarios used Isabelle to formalize elliptic geometry in order to provide independence results for the parallel postulate [28]. Accidentally, this is one the items from the "Top 100 mathematical theorems", which is also challenging for us. It can be treated as a further development of axiomatical approach to geometry in Isabelle started by Meikle [31] (in Hilbert's *Foundations of Geometry* [21] style).

As we are concerned with the integrity issues for the Mizar Mathematical Library, we do not want to make basics from scratch, especially if the strong fundamentals are already done. There a need for further careful study of how much can be done in the direction of unveiling the knowledge included in the repositories of the Mizar system. Due to mechanism of revisions it is not the case that this work is just useless as it is very old. Mizar geometry just used the other way.

There are many simplifications of the original system by Tarski; e.g. by Tarski himself and his collaborators, Gupta's [20], or Makarios [28]. Also showing the correspondence between various axiom systems (with Hilbert's at the very beginning) for geometry is quite influencial and here provers can be quite useful. Of course, one of the well-advertised areas is the topic of axiom system for various equationally-defined classes of algebras, with the leading problem by Robbins and its solution by William McCune obtained in 1996 with the help of EQP/Otter equational theorem prover. But the question remains, how to cope with the space between obviousness for the human and for the machine, in the time before *QED Singularity*, as Michael Beeson (at QED+20 workshop in Vienna, July 18, 2014 [4]) called this time when formal proofs will be the norm in mathematics.

VIII. Conclusions and Future Work

In the paper, we have shown how already quite well established repository can be enhanced to cope with new capabilities of the Mizar system. We mention here a new approach to structures, including their merging, extensive use of attributes, and implemented automatization of definitional expansions. Also the issues of the integration with external provers should be taken into account.

We have created in [38] (and recent `GTARSKI2` [9]) complete formal axiomatization of Tarski's geometry which, at least in our opinion, has the advantage of higher readability for ordinary mathematicians than, e.g., Coq or Prover9 proof objects. In the same it is tightly connected with another

[1]The system can be browsed at http://webmizar.cs.shinshu-u.ac.jp/mmlfe/current/ with the official version of the Mizar system.

(31) If $A \neq B$ and B lies between A and C and B lies between A and D and $B \neq C$ and $B \neq D$, then B does not lie between C and D. The theorem is a consequence of (30), (21), and (18).

(32) Suppose $\triangle ABC \cong \triangle A'B'C'$ and X lies between A and C and X' lies between A' and C' and $\overline{CX} \cong \overline{C'X'}$. Then $\overline{BX} \cong \overline{B'X'}$. The theorem is a consequence of (5), (11), (8), (6), (12), (25), (7), (16), and (19).

Fig. 2. Screenshot of an excerpt from *Formalized Mathematics*

axiomatization of Euclidean plane, due to Hilbert, already available in MML. We have shown also that the real Euclidean plane satisfies all Tarski's axioms.

Of course, one of our aims is to do similar work to that of Michael Beeson's – the use of Prover9 to formalize practically everything from SST. But taking into account that Prover9 proof object can be relatively easily converted into working (and correct) Mizar proofs, it is important to construct appropriate background in order to have something which can offer a kind of help for a mathematician by the following requirements:

- it will reflect all theorems from SST;
- it will offer relatively high readability;
- the proofs can help to catch the idea of a proof, not necessarily will be just *l'art pour l'art*.

Translations from OTTER (at that time, currently Prover9) were helpful in the process of building various complemented lattices: Sheffer-stroke based and those needed in the Robbins algebras [13]. Also encodings of various short axiomatizations for Boolean algebras were easier with that tool; also in the area of rough sets [14] some results were obtained in that way [11]. On the other hand, fuzzy sets, which are much closer to set theory than rough sets, can be also nicely formalized [15].

We are also interested in building a Mizar model of elliptic geometry; Japanese team did some introductory work in [10], but it is not quite feasible now. This could help in showing that parallel postulate is independent from the other ones, which will solve another item from "Top 100 mathematical theorems", which is also an important issue. Further research on logical reasoning systems (as in the case of Tarski's system formulable in first-order logic with identity, set theory is not required) formalized by means of automated proof-assistants can be fruitful not only in the area of pure or applied mathematics, but also, e.g., in the area of argumentation theory, including legal expert systems [49].

We should definitely also have in mind the usefulness of the approach in the context of didactic use of the Mizar system. In order to achieve this goal, the existing state of geometry in MML should be made definitely more coherent, without the need of the creation of new special encyclopaedic articles which could serve better for students.

Modeling Co-Verbal Gesture Perception in Type Theory with Records

Andy Lücking

Email: luecking@em.uni-frankfurt.de

***Abstract*—In natural language *face to face* communication interlocutors exploit manifold non-verbal information resources, most notably hand and arm movements, i.e. gestures. In this paper, a type-theoretical approach using Type Theory with Records is introduced which accounts for iconic gestures within an information state update semantics. Iconic gestures are semantically exploited in two steps: firstly, their kinetic representations are mapped onto vector sequence representations from vector space semantics, modeling a perceptual gesture classification; secondly, these vectorial representations are linked to linguistic predicates, giving rise to a computational account to semantic-kinematic interfaces. Each of the steps involves reasoning processes, which are made explicit. The resulting framework shows how various resources have to be integrated in the update mechanism in order to deal with apparently simple multimodal utterances.**

I. Introduction

SEMANTIC theories, artificial intelligence and robotic systems developed for spoken face-to-face interaction eventually have to deal with non-verbal communication means like facial expressions, prosodic features, hand and arm gestures, or proxemic relations. This is because verbal and non-verbal means constitute an integrated communication system [1], [2]. Their tight coupling shows up strikingly in cases where non-verbal means are semantically significant, i.e. when they provide information beyond or even instead of the verbal one – respective data is given in Section II. We are concerned with *iconic* gestures in the sense of representational hand and arm movements in this paper, gestures which, roughly speaking, depict aspects of the scene talked about [3] (for an automatic gesture classification involving iconic ones see e.g. [4]). Such gestures are performed rather spontaneously and presumably do not obey formal constraints [2]. For this reason, they cannot be interpreted according to pre-defined lexical entries, contrary to emblematic gestures as, say, the *thumbs-up* symbol for indicating positive evaluation or agreement, or Karate postures [5] in physical instructions. Rather, the interpretation of such gestures is a challenge that is related to spatial perception [6]. Accordingly, a perceptually oriented iconic gesture classification is proposed which rests on an integration of various semantic resources, as envisaged by, e.g., [7]. The formal framework that provides a unified representational "home" for these resources is *Type Theory with Records* (TTR) [8]. In the following, TTR is applied to capture the semantic impact of co-verbal gestures by combining the following ingredients:

- a detailed kinematic gesture representation [9] – Section III-A;
- the gesture representation is mapped onto vector sequences from vector space semantics [10] – Section III-B;
- vector sequences are linked to the intensions of linguistic expressions along the lines of a formal semantics for perceptual classification [11], [12] – Section III-C;
- perceptual classification and linguistic semantics are finally related within a dynamic information state update semantics [11], [13] – Section III-C.

Finally, in Section IV the account is applied to the benchmark phenomena identified in Section II.

II. Some Data

The integration of speech and co-verbal gesture has been investigated, *inter alia*, by means of the (German) *Speech and Gesture Alignment Corpus* (SaGA) [9], from which the following examples are drawn. Examples are quoted according to their dialog number and start time (e.g. "V13, 3:36" means that the datum can be found in dialog V13 at minute 3:36 within the corresponding video file). Note that only the so-called *stroke* phase of gestures is considered here: it is assumed to be the "meaningful" part of a gestural movement, distinguished from a pre-stroke preparatory movement as well as from a post-stroke retraction movement, which may be required in order to bring hand and arms from an inactive rest position into an active position and back, respectively [14], [2]. The decorated screenshots are all taken from [12].

Fig. 1. *Staircases* (V10, 3:19)

978-83-60810-90-3/$25.00

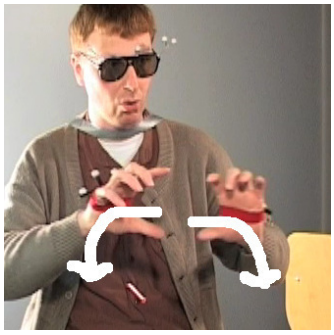

Fig. 2. *It has a concrete base* (V5, 0:39)

Fig. 3. *The house is like this.* (V11, 2:32)

In the first example – given in (1) –, which can be found in V10, 3:19, the speaker speaks about circular staircases. However, in her verbal description she just uses the hypernym *staircases*. The more specific circular information is provided by the affiliated gesture, which is shown in Fig. 1. The part of speech which roughly co-occurs with the gesture is indicated by brackets. Since the first syllable from the noun *Treppen* is not only part of the portion of speech which co-occurs with gesture but also has primary stress (indicated by capital letters), it is the first candidate for providing an integration point for gesture information [15], [12].

(1) *Ich g[laube das sollen TREP]pen sein*
I think that should staircases be

'I think that should be staircases' + Fig. 1

Thus, gestures can be used to specify linguistic expressions to their hyponym meanings.

In a similar manner, the gesture shown in Fig. 2 indicates the shape of a concrete base, which is introduced into dialog in the following way:

(2) *die Skulptur die hat 'n [BeTONsockel]*
the sculpture it has a concrete base

'the sculpture has a concrete base' + Fig.2

From the gesture, but not from speech, we get that the concrete base of the sculpture has the shape of a flat cylinder – the gesture acts as a nominal modifier. Note, however, that the gesture is incomplete since it only depicts about half of a cylinder [16]. Thus, its interpretation interacts with a *good continuation* extension known from gestalt theory.

In the datum given in (3), the speaker speaks about a U-shaped building. However, no shape predicate is given verbally, instead the full shape-representing burden is delegated to the gesture. The gesture in turn is produced within the scope of a verbal demonstrative, which induces a shift in focus to the speaker's gesture. In contrast to examples (1) and (2), the utterance in (3) is not even interpretable without the gesture.

(3) *dann ist das Haus halt so []*
then is the house just this []

'then the house is like this' + Fig. 3

These examples illustrate that the informational enrichment by gestures includes

- invoking hyponymic meanings of affiliated expressions,
- indicating linguistically unexpressed properties,
- providing complete demonstrations.

In the following sections, a type-theoretical model is given that aims at accounting for these gestural enrichments. This account extends previous accounts (most notably [12]) in that it implements a connection to dynamic semantic theories and provides a means for dealing with *good continuations* in formal analyses of co-verbal gestures for the first time. The focus on spontaneous iconic gestures goes beyond functionally restricted *click* or *draw* gestures as predefined in multimodal grammars or dialog systems [17], [18], [19] – see [20] for a comparison of various multimodal approaches.

III. A Type-Theoretical Account to Gestures

Type Theory with Records (TTR) [8] has been developed as a formal framework for natural language semantics which integrates insights from situation semantics [21], Discourse Representation Theory [22] and Montagovian λ-calculus [23]. The basic notion of TTR is a *judgment* of the form $a : T$, meaning that object a is of type T. In order to account for more complex kinds of judgments, TTR develops the notions of *record* and *record type*. The former are matrices of labels and objects, the latter are matrices of labels and types. Record types can be used to regiment records: a record r is of record type RT, $r : RT$, just in case each label of the record type also occurs in the record (the record may contain more fields, though) and the label assignments from the record obey the type constraints imposed by the record type, as schematically exemplified in (4).

(4) $\begin{bmatrix} l_1 & = & o_1 \\ l_2 & = & o_2 \\ l_3 & = & o_3 \end{bmatrix} : \begin{bmatrix} l_1 & : & T_1 \\ l_3 & : & T_2(l_1) \end{bmatrix}$,
just in case $o_1 : T_1$ and $o_3 : T_2(o_1)$.

Record types may depend on other records or record types. For example, type T_2 in (4) depends on object o_1. Dependent types can be used in semantics, for instance, to capture existence

presuppositions imposed by proper names, as illustrated in (5) by example of the name "Max":

(5) $\lambda r : \left[\text{x} \quad : \mathit{Ind}\right] \; . \left[\text{c}_{\text{pn}} \quad : \quad \text{named}(r.\text{x}, \text{“Max”})\right]$

The type in (5) is a functional type in which the value of the range depends on the value of the domain (which in turn is constrained to be of type *Ind(ividual)*) – see [8] for this and various others formal TTR notions.

A. A String Theory of Gesture Events

TTR comes with a string theory of events based on work by [24]. Basically, a(n) (complex) event is segmented into event "snapshots" that are combined by the string concatenator '^'. For example, the event e of opening a door involves the sequence of an agent x gripping the door handle a, pressing the handle and pushing the door b:

(6) $([e : \text{grip}(x, a)]^\frown[e : \text{press}(x, a)]^\frown[e : \text{push}(x, b)])$

Now, gestures can be considered to be events [12]. To begin with, a simple gesture can be represented as a record straightforwardly, as in (7):[1]

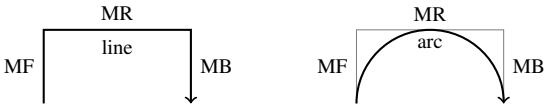
(7)
$$\begin{bmatrix}
\text{hand} & = & \text{right} & \\
\text{hs} & = & \text{claw} & \\
\text{carrier} & = & \begin{bmatrix} \text{boh} & = & \text{none} \\ \text{plm} & = & \text{none} \\ \text{wrst} & = & \text{MR>MB>ML} \\ \text{move} & = & \text{line>line>line} \end{bmatrix} \\
\text{sync} & = & \begin{bmatrix} \text{sloc} & = & \text{CBR-F} \\ \text{eloc} & = & \text{CBR-N} \\ \text{stime} & = & \text{2:32} \\ \text{etime} & = & \text{2:33} \end{bmatrix} \\
\text{rel} & = & \text{none} &
\end{bmatrix}$$

The record in (7) represents the gesture shown in Fig. 3 ('claw' is used to label the American Sign Language (ASL) hand-shape *bent 5*). The values from (7) come from gesture annotation and are imported into TTR as objects of type *annotation predicate* (AP) – see [9] for an overview of a kinetic gesture annotation of this kind. In order to prevent value mismatches like hand-shapes occurring as directions, respective sub-typing of annotation predicates may be employed. For instance, using a type hierarchy from unification-based grammars, the type *AP* can be extended in terms of several sub-types, corresponding to the different kinds of values [12]. By this means, the gesture record entries can be regimented quite specifically, for instance, all *carrier* fields can be required to consist only of movement predicates. However, this rather technical detail is ignored in the following for the sake of brevity and the general type *AP* is used throughout.

The mnemonic labels introduce values for the handedness ('hand'; *left*, *right* or *both*), hand-shape ('hs' according to the *American Sign Language* alphabet), the movement path (where the movement is carried out by one or more 'carriers' [26]) and the relation to the other hand ('rel') as well as the temporal and locational properties ('sync'), where locations follow the gesture space model from Fig. 4.

Gestural movement can be brought about by one or more of three possible movement carriers: back-of-hand (boh), palm (plm) or wrist (wrst). A movement is captured in terms of a *direction* seen from the speaker (e.g. *move forward* (MF)) and a concatenation type which distinguishes straight ('line') from roundish ('arc') trajectories. For example, the same sequence of direction labels, MF>MR>MB, can give rise to an open rectangle or a semicircle, depending on the type of concatenation, as illustrated in (8):

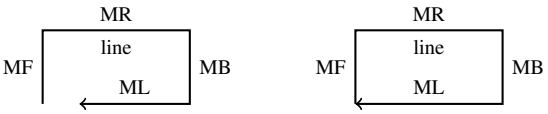
(8)



Note that the *sync*-feature's values allow to discriminate closed from incomplete shapes, which will be important for capturing gestalt properties (see Sec. IV below). For instance, the movement in (9) is underspecified with regard to the respective lengths of the movement parts. It can therefore represent both of the shapes illustrated in (10).

(9)
$$\begin{bmatrix} \text{wrst} & = & \text{MF>MR>MB>ML} \\ \text{move} & = & \text{line>line>line>line} \end{bmatrix}$$

(10)



The incomplete and the closed shape from (10) are distinguished in terms of their *sync* properties: closedness is defined as start (*sloc*) and end location (*eloc*) being the same, as expressed in the closeness condition **C-clos**.

C-clos:A gesture trajectory is closed iff start and end location are the same. The closure constraint has to distinguish one-handed from two-handed gestures:

- One-handed gesture: $\begin{bmatrix} \text{sloc} & : & AP \\ \text{eloc=sloc} & : & AP \end{bmatrix}$
- Two-handed gesture:
$$\begin{bmatrix}
\text{hands} & = & \text{both} & \\
\text{lh} & = & \left[\text{sync} : \begin{bmatrix} \text{sloc} : AP \\ \text{eloc} : AP \end{bmatrix}\right] \\
\text{rh} & = & \left[\text{sync} : \begin{bmatrix} \text{sloc=lh.sync.sloc} : AP \\ \text{eloc=lh.sync.eloc} : AP \end{bmatrix}\right]
\end{bmatrix}$$

The basic representation format introduced above describes gesture events in terms of their kinetic sub-events and can be hooked to the "string theory of gesture events" straightforwardly. The outright string representation for the closed path gesture from (9), for example, is given in (11), where the gesture gets the event variable e:

[1]Matrix-based representations of gestures have been used in robotics at least since [25] and can be considered a standard representation format for gestures already.

$$(11)\quad e : \begin{bmatrix}\text{wrst} = \text{MF} \\ \text{sync} = \begin{bmatrix}\text{sloc} = \text{p1} \\ \text{eloc} = \text{p2}\end{bmatrix}\end{bmatrix} \widehat{\textit{line}} \begin{bmatrix}\text{wrst} = \text{MR} \\ \text{sync} = \begin{bmatrix}\text{sloc} = \text{p3} = \text{p2} \\ \text{eloc} = \text{p4}\end{bmatrix}\end{bmatrix} \widehat{\textit{line}}$$
$$\begin{bmatrix}\text{wrst} = \text{MB} \\ \text{sync} = \begin{bmatrix}\text{sloc} = \text{p5} = \text{p4} \\ \text{eloc} = \text{p6}\end{bmatrix}\end{bmatrix} \widehat{\textit{line}} \begin{bmatrix}\text{wrst} = \text{ML} \\ \text{sync} = \begin{bmatrix}\text{sloc} = \text{p7} = \text{p7} \\ \text{eloc} = \text{p8} = \text{p1}\end{bmatrix}\end{bmatrix}$$

By and large, the string notation using '$\frown$' and the gesture annotation using '>' are equivalent. That is, any record of the form shown in (7) can be translated into the string format illustrated in (11) without loss of information. In order to account for straight and bend movements, however, a small modification to string concatenation has to be made, however: the (temporal) string concatenation '$\frown$' is bifurcated into two spatial variants, '$\widehat{\textit{line}}$' and '$\widehat{\textit{arc}}$'. The string representation of gestures facilitates a rather detailed descriptive resolution. For instance, in order to decide whether movements fragments compose into one gesture event or belong to different gestures, convention **C-loc** can be employed:[2]

C-loc: If the start location of a movement part is identical to the end location of the previous movement part, both movement parts are concatenated within one gesture.

If **C-loc** is fulfilled, the more compact representation in (12) is preferred over the more detailed string representation (11), however:

$$(12)\quad \begin{bmatrix}\text{wrst} = \text{MF>MR>MB>ML} \\ \text{move} = \text{line>line>line>line} \\ \text{sync} = \begin{bmatrix}\text{sloc} = \text{p1} \\ \text{eloc} = \text{sloc} = \text{p1}\end{bmatrix}\end{bmatrix}$$

B. Trajectories within Vector Space

Given a kinetic representation format for gesture events, we need to spell out a semantic interpretation thereof in order to get access to the informativity of co-verbal gestures. To this end, a record type *Vec*(tor) is introduced, which provides an abstract model for configurations or trajectories. Via *Vec*, gesture representations are linked to a vector space semantics as developed by [28], [10]. The linking element in this mapping is the notion of *gesture space* [2], which refers to an inherently oriented space delimited by the reach of the speaker's arms. A respective gesture space model is illustrated in Fig. 4. The central anterior cube of this $3 \times 3 \times 3$-grid of cubes, which is labeled 'CC', is located right in front of the speaker's stomach. Each part of the space can be addressed by a name, which consists of a positioning plus a distance label. For instance, 'CUR-F' (*central upper right far*) is the topmost cube on the right, following the perspective employed in Fig. 4. These names can be used in order to provide values for the locational gesture representation fields conventionally labeled 'sloc' and 'eloc' – see example (7) above. The cube model also provides a regulating screw for the spatial granularity of the gesture space: the more cubes are employed, the higher the spatial resolution. The 27 different regions from the model in Fig. 4 are quite detailed already and are sufficient for present purposes.

[2]For a more sophisticated identity condition for gesture events see the criterion of [12], drawing on the event metaphysics of [27].

TABLE I
DIRECTIONAL CONSTRAINTS DERIVED FROM THE SAGITTAL PLANE OF THE GESTURE SPACE (EXTRACT). THE VECTOR TRANSLATION v OF THE BASIC CONFIGURATIONS IS ALSO GIVEN.

Configuration	=	Vector π_v	→	Constraints π_d
Handshape $\in$ {C, 5, B, O, Y}	=	$\{\mathbf{u}\}$	→	volume
{MF, MR, MB, ML}	=	$\mathbf{u}$	→	translational
$\varnothing$	=	–	→	–
MF>MR + line	=	$\mathbf{u} \perp \mathbf{v}$	→	orthogonal
MF>ML + line	=	$\mathbf{u} \perp \mathbf{v}$	→	orthogonal
MF>ML + arc	=	$\mathbf{u} \circ \mathbf{v}$	→	quadrant
MF>MR + arc	=	$\mathbf{u} \circ \mathbf{v}$	→	quadrant
...	=	...	→	...
MF + ...+ MB	=	$\mathbf{u}, \mathbf{u}^{-1}$	→	inverse
ML + ...+ MR	=	$\mathbf{u}, \mathbf{u}^{-1}$	→	inverse
sloc = eloc	=	$\mathbf{u}(0) = \mathbf{v}(1)$	→	closed
sloc $\neq$ eloc	=	$\mathbf{u}(0) \neq \mathbf{v}(1)$	→	open
lh.sloc = rh.sloc +	=	$\mathbf{u}(0) = \mathbf{v}(0)$		
lh.eloc = rh.eloc [two-handed]	=	$\mathbf{w}(1) = \mathbf{x}(1)$	→	closed
quadrant + quadrant + invers				semicircle
semicircle + semicircle				circle
orthogonal + orthogonal + invers				rectangular
rectangular + rectangular				rectangle
...				...
translational + crossing planes				diag(onal)

The gesture model spans along the three body planes, transverse (up-down), saggital (left-right) and frontal (front-back). For each plane, rules for inferring vectorial constraints from kinetic gesture representations can be formulated. Additionally, some hand shapes function as "line-thickness modifiers" of the gesture trajectory, giving rise to a three-dimensional body rather than to a two-dimensional sketch (cf. the work of [29]). Some rules that will be used below are collected in Table I by example of the sagittal plane. The rules are the back-bone of the gesture vectorization function π – see (14) below.

The primitive mathematical notion of a vector is used to model *paths*, where a path is a function $\mathbf{p} : [0, 1] \mapsto \mathbf{V}$, $\mathbf{V}$ being a three-dimensional vector space (for reasons of

simplicity we constrain ourselves to a purely spatial model; accounting also for temporal aspects would require $\mathbf{V}$ to be four-dimensional). Simple paths (i.e. lines) can be described by one vector, more complex paths arise out of vector sequences (like MF>MR>MB, respectively its vectorization). Each single vector $\mathbf{u}$ from a vector sequence has its own length in $[0, 1]$, ranging from the origin $\mathbf{u}(0)$ to the end $\mathbf{u}(1)$ ($\mathbf{u}(0.5)$ denotes the half of $\|\mathbf{u}\|$). In a vector sequence like $\mathbf{u} \perp \mathbf{v}$ it holds that $\mathbf{u}(1) = \mathbf{v}(0)$, that is, the described path is consecutive. Additionally, there are various kinds of vectors, discriminating, amongst others, vectorial representations of locations (needed for example for prepositional modifications like "3 cm above x") and of shapes (figuring as spatial denotations of predicates like "round") [30]. Finally, the core vectorial representations are extended with some shape-related features like being translational or circular. These features are due to the work of [31] (who uses partly differently named features, though), where they are used as lexical constraints on path shapes of (mainly) motion verbs. Accordingly, *Vec* consists of three basic fields: *Vtype* determines the kind of vector sequence in question (i.e., axis, path, ...), *Vpath* stores the path's shape and *Vshape* introduces shape-related constraints. For two-handed gestures, each hand gives rise to a record of type *Vec*. In that case, an additional field (conventionally labeled "comb") also of type *Vec* is introduced, which captures hand-crossing, combined information (a simple example is given in Sec. IV by means of the *concrete base*-gesture from Fig. 2).

$$(13)\quad \mathit{Vec} =_{\text{def}} \begin{bmatrix} \text{vt} & : & \text{Vtype} \\ \text{pt} & : & \text{Vpath} \\ \text{sh} & : & \text{set(Vshape)} \end{bmatrix}$$

There is a functional type π which maps records of annotations (i.e., records with entries of type *AP*) – labeled Rec^{AP} for short – onto vectors (*Vec*). According to the division of labor between vectorization and representational feature decomposition (cf. Table I and the above-given explanation), π consists of two sub-types, π_v and π_d:

$$(14)\quad \pi : [[\pi_v : \mathit{Rec}^{AP} \rightarrow \mathit{Vpath}] \rightarrow \pi_d : \mathit{Vpath} \rightarrow \text{set(Vshape)}] \rightarrow \mathit{Vec}$$

Keeping vectorization and feature decomposition apart will also play a role in accounting for the *good continuation* in Sec. IV below.

The vector function π exploits the constrains from Table I and works schematically as follows:

$$(15)\quad \text{if } r\text{:} \begin{bmatrix} \text{hand} & : & \text{AP} \\ \text{hs} & : & \text{AP} \\ \text{carrier} & : & \begin{bmatrix} \text{boh} & : & \text{AP} \\ \text{plm} & : & \text{AP} \\ \text{wrst} & : & \text{AP} \\ \text{move} & : & \text{AP} \end{bmatrix} \\ \text{sync} & : & \begin{bmatrix} \text{sloc} : \text{AP} \\ \text{eloc} : \text{AP} \end{bmatrix} \end{bmatrix},$$

$$\text{then } \pi_v(r) = \begin{cases} \text{pt1} = \begin{bmatrix} v(r.\text{wrst},\ r.\text{move} \\ v(\text{sloc},\ \text{eloc})) \end{bmatrix} : \text{Vpath} & \text{if } r.\text{wrst} \neq \varnothing \\ \text{pt2} = \begin{bmatrix} v(r.\text{plm},\ r.\text{move} \\ v(\text{sloc},\ \text{eloc})) \end{bmatrix} : \text{Vpath} & \text{if } r.\text{plm} \neq \varnothing \\ \text{pt3} = \begin{bmatrix} v(r.\text{boh},\ r.\text{move} \\ v(\text{sloc},\ \text{eloc})) \end{bmatrix} : \text{Vpath} & \text{if } r.\text{boh} \neq \varnothing \end{cases}$$

$$\text{then } \pi_d(\pi_v(r)) = \begin{cases} \begin{bmatrix} \text{sh} = d(\text{pt1}) \end{bmatrix} : \text{set(Vshape)} & \text{if pt1} \neq \varnothing \\ \begin{bmatrix} \text{sh} = d(\text{pt2}) \end{bmatrix} : \text{set(Vshape)} & \text{if pt2} \neq \varnothing \\ \begin{bmatrix} \text{sh} = d(\text{pt3}) \end{bmatrix} : \text{set(Vshape)} & \text{if pt3} \neq \varnothing \end{cases}$$

Since a single gesture may involve more than one movement path – an example is given in Sec. IV below – π_v just numbers the 'pt' values from the possible movement carriers. The procedure is incremental in that immediate pairs as well as skip pairs of directional APs are considered and compared to the table entries above: that is, neighboring APs are evaluated in terms of being quadrant or orthogonal, longer sequences of APs are inspected for fulfilling inversion. The features collected in the constraints of Table I then give rise to shape descriptions. For instance, by dint of the cooperation of Table I and π, the sample gesture from (7) is translated into the following perpendicular vector sequence:

$$(16)\quad \text{a.}\quad \pi_v\left(\begin{bmatrix} \text{wrst} = \text{MR>MB>ML} \\ \text{move} = \text{line>line>line} \\ \text{sync} = \begin{bmatrix} \text{sloc} = \text{p1} \\ \text{eloc} = \text{p2} \neq \text{p1} \end{bmatrix} \end{bmatrix}\right) = \begin{bmatrix} \text{pt1} : \begin{bmatrix} \mathbf{u} \perp \mathbf{v} \perp \mathbf{w} \\ \mathbf{u}(0) \neq \mathbf{w}(\mathbf{1}) \end{bmatrix} \end{bmatrix}$$

$$\text{b.}\quad \pi_d\left(\begin{bmatrix} \text{pt1} : \begin{bmatrix} \mathbf{u} \perp \mathbf{v} \perp \mathbf{w} \\ \mathbf{u}(0) \neq \mathbf{w}(\mathbf{1}) \end{bmatrix} \end{bmatrix}\right) = \begin{bmatrix} \text{sh} : \{\text{rectangular, open}\} \end{bmatrix}$$

Note that the *Vtype* field is underspecified in (16) – there is nothing within the kinetic gesture representation that determines the kind of the vector. Vector types can be instantiated in interaction with the linguistic lexicon when combined with speech.

C. Linking Gesture Perception to Reasoning

In representing meaning, a dynamic information state update semantics as developed in [11] is used. There, the context (e.g., presuppositions) is explicitly separated from the content of linguistic expressions in terms of *backgrounded* (bg) and *foregrounded* (f) information. For instance, the proper name example "Max" from (5) above is recaptured as follows:

$$(17)\quad [\![\text{Max}]\!] = \begin{bmatrix} \text{bg} & = & \begin{bmatrix} \text{x} : \text{Ind} \end{bmatrix} \\ \text{f} & = & \lambda r : \text{bg}\left(\begin{bmatrix} \text{c}_{\text{pn}} : \text{named}(r.\text{x},\ \text{“Max”}) \end{bmatrix}\right) \end{bmatrix}$$

In order to implement the dynamic update of information, the functional type exemplified in (17) has to "accumulate" backgrounded information. This is expressed in terms of a *fixed point type* [8] – cf. also [11]. The fixed point type $\mathcal{F}$ corresponds to the unification of the domain and the range of a functional type. For instance, the fixed point type for the foregrounded meaning of "Max" from (17) is shown in (18):

(18) $\mathcal{F}([\![\text{Max}]\!].\text{f}) = \mathcal{F}(\lambda r : \left[\text{x} : \text{Ind}\right]\left(\left[\text{c}_{\text{pn}} : \text{named}(r.\text{x}, \text{“Max”})\right]\right))$
$= \begin{bmatrix} \text{x} & : & \text{Ind} \\ \text{c}_{\text{pn}} & : & \text{named}(\text{x}, \text{“Max”}) \end{bmatrix}$

In general, context update proceeds as formulated in **C-upc**, where agents' contributions extend their current information state (i.e. their "take of the situation" – see [11, p. 8]):

C-upc:**(preliminary version)** If the current information state s_t is compatible to the background information of expression e, then $[\![\text{e}]\!]$ can be added to s_t to form information state s_{t+1}:
If $s_t \sqsubseteq [\![\text{e}]\!].bg$ then $s_{t+1} = s_t \wedge \mathcal{F}([\![\text{e}]\!].\text{f})$

Operation '$\wedge$' in (18) is the type-theoretic analog to unification – see [8] for details. Gestures constitute a *display situation* (DP) [32] and as such are part of the publicly available information state. The value of DP is a list: every newly produced gesture is put into initial position while all possibly already present gestures are stacked and remain available for eventual repair or clarification.

C-upg:If $G = [v : Vec]$ is the vector interpretation of a gesture g produced at state s_t, the display situation list of s_t gets updated with G:
If $\pi(g) = G$ at s_t, then s_{t+1}.dp.rest = s_t.dp and s_{t+1}.dp.first = G

How is the link between display situations and dynamic meaning implemented? Following the exemplification [33] account of [12], space-related predicates are equipped with a *conceptual vector meaning* (CVM) which extends their intensions by means of vectorial constraints (cf. also the classification approach of [11] and the lexical decomposition approach of [34]). In particular, CVM information uses representations that are of type *Vec*. A spatial predicate like *U-shaped*, for instance, has the following extended dynamic meaning:

(19) $[\![\text{U-shaped}]\!] =$

$$\begin{bmatrix} \text{bg} & = & \left[\text{x} : \text{Ind}\right] \\ \text{f} & = & \lambda r : \text{bg}\left(\left[\begin{array}{l} \text{c}_{\text{u}} : \text{U-shaped}(r.\text{x}) \\ \text{cvm} = \left[\text{pt} : \left[\begin{array}{l} \text{vt} : \text{axis-path}(r.\text{x}, \text{pt}) \\ \text{pt} : \left[\begin{array}{l} \mathbf{u} \perp \mathbf{v} \perp \mathbf{w} \\ \mathbf{u}(0) \neq \mathbf{w}(1) \end{array}\right] \\ \text{sh} : \left\{\text{rectangular, open}\right\} \end{array}\right] : Vec\right] \\ \text{c}_{\text{shape}} : \text{shape}(r.\text{x}, \text{cvm}) \end{array}\right)\right) \end{bmatrix}$$

That is, part of the descriptive meaning of 'U-shaped' is that its argument has a certain perceived shape, namely an axis that is of a particular rectangular configuration. Spatial representations like those in (19) are related to *imagistic description trees* employed in [35] in order to facilitate online recognition of iconic gestures within an artificial intelligence application. There, gesture tracking data is mapped onto (parts of) prototypical object shapes. A similar set of features from a three-axial system has also been employed in [36]. In contrast to such AI recognition approaches, the focus here is on linking multimodal utterances to linguistics and dialog theory.

The occurrence of an iconic gesture adds respective information to the DP of the current information state. Although it is clear that there is an informational interaction between CVM and DP to the effect that the merge operation ('$\wedge$') rules out combinations of predicates and gesture trajectories that are conflicting with regard to their respective *Vec* type information, this is not yet covered by the general context update **C-upc**. Due to the differences of labeling, the revised and final formulation explicitly has to take care of relating "dp" to "cvm":

C-upc:**(final version)** The display situation punctually affects the update mechanism in that DP information has to be merged with linguistic information:
If $s_t \wedge_{s_t.\text{dp.first} \wedge e.\text{cvm}} \sqsubseteq [\![\text{e}]\!].bg$ then $s_{t+1} = s_t \wedge \mathcal{F}([\![\text{e}]\!].\text{f})$

C-upc now correctly predicts that it is not well-formed to co-produce, say, a rectangular gesture and an adjective denoting roundness. The update mechanism is clocked by events: occurrences of speech (words) as well as of gestures trigger **C-upc**. Co-verbal gestures are integrated to the co-occuring linguistic expressions. This provides a co-occurrence based association between gesture and speech events that is not prone to functional ambiguities of the system in [19]. Such ambiguities arise if there are two possible attachment points in speech (say, due to signals involving deictic *here*) but only one attaching (pointing) gesture. Although **C-upc** goes beyond functional systems, it fails to do justice to the temporal and coherence relations that govern speech-gesture integration, in particular with regard to *hold* gestures [37], that are "frozen" gestural configurations that persist beyond the short life of affiliated verbal utterances. In order to provide a more sophisticated account to multimodal integration, event-based information state update mechanisms have to be extended by more detailed grammatical constraints incorporating temporal, intonational and semantic information [38], [12].

IV. Hyponymy, Good Continuation, and Demonstration

The TTR framework for iconic gestures sketched in the previous sections is in the following sections applied to the phenomena from Sec. II, which motivated the semantic integration of gestures in the first place.

The first example in (20), which is repeated from (1), introduces a spiral trajectory into the current information state.

(20) *Ich g[laube das sollen TREP]pen sein*
I think that should staircases be

'I think that should be staircases' + Fig. 1

The gesture event is represented as follows:

(21)
$$\begin{bmatrix} \text{hand} & = & \text{right} \\ \text{hs} & = & \text{G} \\ \text{carrier} & = & \left[\begin{array}{l} \text{wrst} = \text{MU} \\ \text{boh} = \text{MR>MF>ML>MB>MR} \\ \text{move} = \text{arc>arc>arc>arc} \end{array}\right] \\ \text{sync} & = & \left[\begin{array}{l} \text{sloc} = \text{CR-N} \\ \text{eloc} = \text{CUR-N} \end{array}\right] \end{bmatrix}$$

The spiral gesture has two motion aspects: a rotation carried out in the back of the hand and a translation performed by lifting the hand (i.e. wrist) – cf. the decomposition of 'spiralness' given in [31, p. 411] and of the spiral gesture in [12, p. 238]. The vector interpretation thus returns the following record of type *Vec*, where any segment '$\mathbf{u} \circ \mathbf{v}$' indicates that the vector sequence in question describes the fourth of a circle (cf. Table I):

(22)
$$\begin{bmatrix} \text{pt1} & : & \begin{bmatrix} \mathbf{u} \circ \mathbf{v} \circ \mathbf{w} \circ \mathbf{z} \circ \mathbf{y} \\ \mathbf{u}(0) \neq \mathbf{y}(1) \end{bmatrix} \\ \text{pt2} & : & \mathbf{a} \\ \text{sh} & : & \{\text{translational, circle, open}\} \end{bmatrix}$$

Note that the translational component introduced by pt2 distinguishes spirals from circles. The current context thus provides a gesticulated witness for the spiral type within the display situation:

(23)
$$s_t = \begin{bmatrix} \text{dp} = \begin{bmatrix} \text{pt1} & : & \begin{bmatrix} \mathbf{u} \circ \mathbf{v} \circ \mathbf{w} \circ \mathbf{z} \circ \mathbf{y} \\ \mathbf{u}(0) \neq \mathbf{y}(1) \end{bmatrix} \\ \text{pt2} & : & \mathbf{a} \\ \text{sh} & : & \{\text{translational, circle, open}\} \end{bmatrix} \end{bmatrix}$$

The noun "Treppen" (*staircases*) is unspecific with respect to kind and shape. It has a number of sub-kinds, however, that are distinguished according to their layout. This hyponymic relationship is captured within the inheritance type hierarchy in Fig. 5, where descendants provide the informational difference to their parent.

Given s_t from (23) and given the hyponymic relationships in Fig. 5, there are two possible updates to reach state s_{t+1}: one update uses the literally uttered hypernym *staircases*, the other the more specific *spiral staircases*, for which the context provides information due to the iconic gesture (updating with *straight staircases* is blocked, however, due to incompatible CVM constraints). Since more specific updates are generally preferred, the gesture allows us to infer the kind of staircases talked about. After applying **C-upc**, information state s_{t+1} looks as follows:

(24)
$$s_{t+1} = \begin{bmatrix} \text{x} & : & \text{Ind} \\ \text{dp} & : & \begin{bmatrix} \text{pt1} : \begin{bmatrix} \mathbf{u} \circ \mathbf{v} \circ \mathbf{w} \circ \mathbf{z} \circ \mathbf{y} \\ \mathbf{u}(0) \neq \mathbf{y}(1) \end{bmatrix} \\ \text{pt2} : \mathbf{a} \\ \text{sh} : \{\text{translational, circle, open}\} \\ \text{vt1} : \text{axis-path(x, pt1)} \\ \text{vt2} : \text{axis-path(x, pt2)} \end{bmatrix} \\ \text{cvm=dp} & : & \textit{Vec} \\ c_{\text{u}} & : & \text{spiral-staircases(x)} \\ c_{\text{shape}} & : & \text{shape(x, cvm)} \end{bmatrix}$$

In example (2), re-given in (25), we observe a use of hand-shape that cuts out a volume rather than draws a trajectory on a plane (due to the "voluminous" hand shape 'C').

(25) *die Skulptur die hat 'n [Betonsockel]*
the sculpture it has a concrete base

'the sculpture has a concrete base' + Fig.2

The gesture that is part of (25) is produced with both hands, so kinetic features are distributed over the left and the right hand. Accordingly, the *Vec* type of the gesture has double entries, partitioned according to the carriers of the respective hand. Gesture representation and interpretation is shown in (26) and (27), respectively.

(26)
$$\begin{bmatrix} \text{hands = both} \\ \text{rh} = \begin{bmatrix} \text{hand} & = & \text{right} \\ \text{hs} & = & \text{C} \\ \text{carrier} & = & \begin{bmatrix} \text{wrst = MR>MF} \\ \text{move = arc} \end{bmatrix} \\ \text{sync} & = & \begin{bmatrix} \text{sloc=lh.sync.sloc = CC-N} \\ \text{eloc = CR-M} \end{bmatrix} \end{bmatrix} \\ \text{lh} = \begin{bmatrix} \text{hand} & = & \text{left} \\ \text{hs} & = & \text{C} \\ \text{carrier} & = & \begin{bmatrix} \text{wrst = ML>MF} \\ \text{move = arc} \end{bmatrix} \\ \text{sync} & = & \begin{bmatrix} \text{sloc = CC-N} \\ \text{eloc = CL-M} \end{bmatrix} \end{bmatrix} \\ \text{rel = axisymmetric} \end{bmatrix}$$

(27)
$$\begin{bmatrix} \text{pt1lh} & = & \begin{bmatrix} \{\mathbf{u} \circ \mathbf{v}\} \\ \mathbf{u}(0) \neq \mathbf{v}(1) \end{bmatrix} \\ \text{pt1rh} & = & \begin{bmatrix} \{\mathbf{w} \circ \mathbf{x}\} \\ \mathbf{w}(0) \neq \mathbf{x}(1) \end{bmatrix} \\ \text{comb} & = & \begin{bmatrix} \text{pt} = \begin{bmatrix} \mathbf{u}(0) = \mathbf{w}(0) \\ \mathbf{v}(1) \neq \mathbf{x}(1) \\ \mathbf{a} \circ \mathbf{b} \circ \mathbf{c} \\ \mathbf{a}(0) \neq \mathbf{c}(1) \end{bmatrix} \\ \text{sh} = \{\text{semicircle, volume, open}\} \end{bmatrix} \end{bmatrix}$$

The vector representation in the 'comb'-field introduces combined path information for both hands. In the example above, the two quartercircles from the axisymmetrical movement of the hands combine to a semicircle. Modeling two-handed gestures thus adds another level of complexity which can only be mentioned here (with the exception of the closure contraint in **C-clos** – see also Table I).

The lexical entry for *concrete-base* is underspecified with respect to shape and does not have any shape-related hyponyms:

(28)
$$\begin{bmatrix} \text{bg} & = & \begin{bmatrix} \text{x} : \text{Ind} \end{bmatrix} \\ \text{f} & = & \lambda r : \text{bg}\left(\begin{bmatrix} c_{\text{cb}} : \text{concrete-base}(r.\text{x}) \end{bmatrix}\right) \end{bmatrix}$$

The descriptive meaning in (28) imposes no top-down constraints on CVM or DP. Additionally, the gesture path violates the closure constraint **C-clos**. For these reasons, it is likely

$$[\![\text{staircases}]\!] = \begin{bmatrix} \text{bg} & = & \left[\text{x} : \text{Ind}\right] \\ \text{f} & = & \lambda r : \text{bg}\left(\left[\text{c} : \text{staircases}(r.\text{x})\right]\right) \end{bmatrix}$$

$$[\![\text{spiral-staircases}]\!] = \left[\text{f} = \lambda r : \text{bg}\left(\left[\begin{array}{l} \text{cvm} = \left[\begin{array}{l} \text{pt1} : \left[\begin{array}{l} \mathbf{u} \circ \mathbf{v} \circ \mathbf{w} \circ \mathbf{z} \circ \mathbf{y} \\ \mathbf{u}(0) \neq \mathbf{y}(1) \end{array}\right] \\ \text{pt2} : \mathbf{a} \\ \text{sh} : \left\{\text{translational, circle, open}\right\} \\ \text{vt1} : \text{shape-path}(r.\text{x, pt1}) \\ \text{vt2} : \text{axis-path}(r.\text{x, pt2}) \end{array}\right] : \mathit{Vec} \\ \text{c}_{\text{shape}} : \text{shape}(r.\text{x, cvm}) \end{array}\right)\right]$$

$$[\![\text{straight-staircases}]\!] = \left[\text{f} = \lambda r : \text{bg}\left(\left[\begin{array}{l} \text{cvm} = \left[\begin{array}{l} \text{pt} : \mathbf{u} \\ \text{sh} : \left\{\text{translational, diag}\right\} \\ \text{vt} : \text{axis-path}(r.\text{x, pt}) \end{array}\right] : \mathit{Vec} \\ \text{c}_{\text{shape}} : \text{shape}(r.\text{x, cvm}) \end{array}\right)\right]$$

Fig. 5. Type hierarchy showing the hypernym "staircases" and two of its hyponyms.

that the gesture path is elliptical. There are several (in fact, infinitely many) ways to close the path so that the vector sequence has at least two vectors whose coordinates coincide. Out if these options only one is a good continuation, namely that one which brings about the shortest closure while maintaining the concatenation type (*arc*, in this case). In other words, 'good continuation', *GoCont*, is a function mapping record types *Vec* to record types *Vec*, i.e. $\mathit{GoCont} : \mathit{Vec} \rightarrow \mathit{Vec}$. Since *GoCont* changes the vector sequence representation (but not the movement annotation, of course) of a gesture, it gives rise to a re-labeling by means of π_d (cf. (14) above). The above-given features of *GoCont* can be formulated as constraints over an input display situation 'dp_{in}' and an output display situation 'dp_{out}', both being of type *Vec*.

(29) $$\mathit{GoCont} =_{\text{def}} \lambda r : \left[\begin{array}{lcl} \text{ap1} & = & \text{open} : \mathit{AP} \\ \text{cc} & = & \{\circ \mid \perp\} : \text{Vpath} \\ \text{dp}_{\text{in}} & : & \left[\begin{array}{l} \text{sh} : \text{set(AP)} \\ \text{pt} : \text{Vpath} \\ \text{vt} : \text{Vtype} \end{array}\right] \\ \text{c}_{\text{memb}} & : & \text{member(ap1, dp}_{\text{in}}\text{.sh)} \\ \text{c}_{\text{conc}} & : & \text{member(cc, dp}_{\text{in}}\text{.pt)} \\ \text{cvm} & : & \varnothing \end{array}\right] \left(T = \left[\begin{array}{lcl} \text{spt} & : & \text{Vpath} \\ \text{c}_{\text{cond}} & : & \text{member}(r.\text{cc, spt}) \\ \text{dp}_{\text{out}} & : & \left[\begin{array}{l} \text{pt} = \left[\begin{array}{l} r.\text{dp}_{\text{in}}\text{.pt } r.\text{cc spt} \\ r.\text{dp}_{\text{in}}\text{.pt}(0) = \text{spt}(1) \end{array}\right] \\ \text{vt} = r.\text{dp}_{\text{in}}\text{.vt} : \text{Vtype} \end{array}\right] \end{array}\right]\right) . \pi_d(T),$$

where "$\{\circ \mid \perp\}$" means that the concatenation type is either arc-like ($\widehat{arc}$) or straight ($\widehat{line}$).

Applying (the two-handed extension of) *GoCont* to the path from (28) gives rise to a voluminous circle, that is, a cylinder:

(30) $$\mathit{GoCont}\left(\left[\begin{array}{lcl} \text{dp}_{\text{in}} & = & \left[\begin{array}{lcl} \text{pt1lh} & = & \left[\begin{array}{l} \left\{\mathbf{u} \circ \mathbf{v}\right\} \\ \mathbf{u}(0) \neq \mathbf{v}(1) \end{array}\right] \\ \text{pt1rh} & = & \left[\begin{array}{l} \left\{\mathbf{w} \circ \mathbf{x}\right\} \\ \mathbf{w}(0) \neq \mathbf{x}(1) \end{array}\right] \\ \text{comb} & = & \left[\begin{array}{l} \text{pt} = \left[\begin{array}{l} \mathbf{u}(0) = \mathbf{w}(0) \\ \mathbf{v}(1) \neq \mathbf{x}(1) \\ \mathbf{a} \circ \mathbf{b} \circ \mathbf{c} \\ \mathbf{a}(0) \neq \mathbf{c}(1) \end{array}\right] \\ \text{sh} = \left\{\text{semicircle, volume, open}\right\} \end{array}\right] \\ \text{cvm} & = & \varnothing \end{array}\right]\right)$$

$$\rightarrow \left[\begin{array}{lcl} \text{dp}_{\text{out}} & = & \left[\begin{array}{lcl} \text{pt1lh} & = & \left[\begin{array}{l} \left\{\mathbf{u} \circ \mathbf{v} \circ \mathbf{y}\right\} \\ \mathbf{u}(0) \neq \mathbf{y}(1) \end{array}\right] \\ \text{pt1rh} & = & \left[\begin{array}{l} \left\{\mathbf{w} \circ \mathbf{x} \circ \mathbf{z}\right\} \\ \mathbf{w}(0) \neq \mathbf{z}(1) \end{array}\right] \\ \text{comb} & = & \left[\begin{array}{l} \text{pt} = \left[\begin{array}{l} \mathbf{u}(0) = \mathbf{w}(0) \\ \mathbf{y}(1) = \mathbf{z}(1) \\ \mathbf{a} \circ \mathbf{b} \circ \mathbf{c} \circ \mathbf{d} \circ \mathbf{e} \\ \mathbf{a}(0) = \mathbf{e}(1) \end{array}\right] \\ \text{sh} = \left\{\text{circle, volume, closed}\right\} \end{array}\right] \end{array}\right]$$

The good continuation is accomplished by the combined path of both hands.

Since a cylinder is a regular shape that has a lexicalized verbalization, its CVM makes the connection between the trajectory from (30) and the intension of *cylinder* explicit:

(31) $$[\![\text{cylinder}]\!] = \left[\begin{array}{lcl} \text{bg} & = & \left[\text{x} : \text{Ind}\right] \\ \text{f} & = & \lambda r : \text{bg}\left(\left[\begin{array}{l} \text{c}_{\text{cy}} : \text{cylinder}(r.\text{x}) \\ \text{cvm} = \left[\begin{array}{lcl} \text{vt} & = & \text{shape-path}(r.\text{x, cvm}) \\ \text{pt} & = & \left[\begin{array}{l} \left\{\mathbf{a} \circ \mathbf{b} \circ \mathbf{c} \circ \mathbf{d} \circ \mathbf{e}\right\} \\ \mathbf{a}(0) = \mathbf{e}(1) \end{array}\right] \\ \text{sh} & = & \left\{\text{circle, volume, closed}\right\} \end{array}\right] : \mathit{Vec} \\ \text{c}_{\text{shape}} : \text{shape}(r.\text{x, cvm}) \end{array}\right)\right] \end{array}\right]$$

Given the good continuation and the DP triggering of the lexical resource from (31), the most informative information state update s_{t+1} is the following (using only combined paths):

(32)
$$s_{t+1} = \begin{bmatrix} \text{x} & : & \text{Ind} \\ \text{dp} & = & \textit{GoCont}\left(\begin{bmatrix} \text{pt} = \{\mathbf{a} \circ \mathbf{b} \circ \mathbf{c}\} \\ \text{sh} = \{\text{semicircle, volume, open}\} \end{bmatrix}\right) \\ & & \rightarrow \begin{bmatrix} \text{vt} & = & \text{shape-path(x, cvm)} \\ \text{pt} & = & \begin{bmatrix} \{\mathbf{a} \circ \mathbf{b} \circ \mathbf{c} \circ \mathbf{d} \circ \mathbf{e}\} \\ \mathbf{a}(0) = \mathbf{e}(1) \end{bmatrix} \\ \text{sh} & = & \{\text{circle, volume, closed}\} \end{bmatrix} \\ \text{cvm=dp} & : & \textit{Vec} \\ \text{c}_{\text{cb}} & : & \text{concrete-base(x)} \\ \text{c}_{\text{cy}} & : & \text{cylinder(x)} \\ \text{c}_{\text{shape}} & : & \text{shape(x, cvm)} \end{bmatrix}$$

The final example also concerns the depiction of shape that is not realized in speech. The difference, however, being that in the datum given in (33), replicating example (3), the shape of the house talked about is explicitly delegated to the co-verbal gesture due to the demonstrative "so":

(33) *dann ist das Haus halt so []*
then is the house just this []

'then the house is like this' + Fig. 3

For this reason, the DP triggers the (initially empty) shape field of the target noun *house* directly, rather then detouring *via* a collateral expression as in (32), although the resulting information state does not reflect this subtle difference any more.

The lexical entry for house is a standard one-place predicate whose shape-field is unfilled:

(34) $[\![\text{house}]\!] =$
$$\begin{bmatrix} \text{bg} & = & [\text{x} : \text{Ind}] \\ \text{f} & = & \lambda r : \text{bg}\left(\begin{bmatrix} \text{c}_{\text{hs}} : \text{house } (r.\text{x}) \\ \text{cvm} : \textit{Vec} \\ \text{c}_{\text{shape}} : \text{shape}(r.\text{x, cvm}) \end{bmatrix}\right) \end{bmatrix}$$

The information state after processing the noun has the following public information:

(35)
$$s_{t+1} = \begin{bmatrix} \text{x} & : & \text{Ind} \\ \text{c}_{\text{hs}} & : & \text{house (x)} \\ \text{cvm} & : & \textit{Vec} \\ \text{c}_{\text{shape}} & : & \text{shape(x, cvm)} \end{bmatrix}$$

The gesture, which has been described and related to the predicate *U-shaped* in (16) and (19) above triggers a further update **C-upc**, leading to identifying the gesture's trajectory and the exemplified predicate with the shape description of the house. The resulting state s_{t+2} is shown in (36):

(36)
$$s_{t+2} = \begin{bmatrix} \text{x} & : & \text{Ind} \\ \text{c}_{\text{hs}} & : & \text{house (x)} \\ \text{cvm=dp} & : & \textit{Vec} \\ \text{c}_{\text{shape}} & : & \text{shape(x, cvm)} \\ \text{dp} & = & \begin{bmatrix} \text{pt} : \begin{bmatrix} \mathbf{u} \perp \mathbf{v} \perp \mathbf{w} \\ \mathbf{u}(0) \neq \mathbf{w}(1) \end{bmatrix} \\ \text{sh} : \{\text{rectangular, open}\} \end{bmatrix} : \textit{Vec} \\ \text{c}_{\text{u}} & : & \text{U-shaped(x)} \end{bmatrix}$$

Note, however, that the *type* of the vector (the field labeled 'vt') with regard to the shape of the house is not specified. Since the lexical entry for *house* leaves shape information underspecified and the trajectory is neutral about its type, no type information is available from these resource. The most likely type 'axis-path' has to be inferred once again, but this inference is beyond the descriptive coverage of this paper.

V. Conclusion

A formal model has been sketched for relating the perception of iconic gestures to language within an artificial intelligence-oriented information state update framework. The interface between low-level perceptual features and semantic predicates is spelled out in terms of TTR, a large-scale formal theory for language, perception and interaction [39], [40]. The model accounts for semantic key phenomena of multimodal discourse by example of speech-gesture integration like meaning specification, speech-gesture mismatches and semantic enrichments. Following the general framework of [12], a characteristics is that iconic gestures are not interpreted extensionally directly, but rather related to percepts and intensional features of natural language predicates. As the dialog proceeds, gestures are stacked onto the "gesture storage", which allows to approximate the temporal interplay of speech and gesture. Contrary to spoken language, gestures can be "frozen" and kept persistent over a period of talking. Relating both communication means via dynamic information state update mechanisms paves the way for integrating a more detailed time-based notion like that of "communication channels" [37]. Further extensions include the integration of grammatical and dialog-interactive representations of information states as well as a broadened empirical range of non-verbal behavior. In particular two-handed gestures and the combined paths they give rise to need special treatment. Further descriptive extensions might involve methodological extensions as well: the gesture perception part is a typical application area for machine learning approaches.

Modeling conflicts between legal rules

Tomasz Zurek
Institute of Computer Science,
Maria Curie-Sklodowska University in Lublin
Ul. Akademicka 9, 20-033 Lublin, Poland
Email: zurek@kft.umcs.lublin.pl

***Abstract*—The main aim of this work is to formalize the mechanism of resolving conflicts between statutory legal rules with a view to implementing them into a legal advisory system. The model is build on the basis of the *ASPIC*$^+$ argument modeling framework. The paper presents a discussion and a formal model of the mechanism of conflict recognition as well as models of three different mechanisms of conflict solving and a discussion of the relations between them.**

I. Introduction

TYPICAL rule-based expert systems reasoning mechanisms require knowledge bases which are created upon a few spoken and unspoken features and assumptions, such as the closed world assumption, the lack of inconsistencies and circularities in the knowledge base, etc. All of these features allow for the utilization of simple and fast modus ponens-based forward and backward chaining mechanisms. Unfortunately, there are numerous expertise areas for which many of these assumptions cannot be implemented.

One of these areas is law. There certainly have been some experiments whose authors attempted to create legal expert systems, but only a very narrow portion of statutory administrative law appears suitable for implementation in a legal expert system [1], [2]; most of these implementations have also been widely criticized [3]. The main problem of the utilization of classical expert systems in legal expertise lies in the specificity of legal knowledge and a significant presence of commonsense knowledge in legal reasoning. Additionally, legal knowledge (and commonsense knowledge connected with it) very often cannot fulfill the above-mentioned features and assumptions of a properly constructed knowledge base: legal knowledge can be inconsistent, conflicting, imprecise, and there may always appear new circumstances which may change case evaluation. Law is not a perfect and complete system. Legislators cannot foresee all possible situations which should be regulated by law; legal norms may be conflicting, they may lead to unfair conclusions, they require interpretation because it is unclear if the conditions are satisfied, etc. All these reasons hinder the simulation of legal reasoning and creation legal expert systems. A number of models of legal reasoning allowing for the representation of some aspects of legal expertise have been developed, but none of them can be regarded as complete. Practical experience reveals that legal reasoning often makes use of very "peculiar" means of inference, going far beyond the standard modus ponens principle employed in expert systems. Most of these methods are very challenging to formalize; they also are defeasible and do not guarantee correct conclusions. On the basis of the above one may notice that modeling inference processes as performed by lawyers can be perceived as a way to create an advisory legal system. The range of issues connected with modeling legal reasoning includes the problem of resolving conflicts between statutory legal rules. Legal theory and practice have worked out some methods of resolving such conflicts, yet many of them are based on commonsense knowledge, which is extremaly difficult to formalize.

The main aim of this work is to formalize a mechanism of resolving conflicts between statutory legal rules with a view to implementing it into a legal advisory system. Another aim is to incorporate the model into *ASPIC*$^+$, one of the most comprehensive argumentation modeling frameworks, thanks to which the model can be applied to a wide range of real-life legal cases.

In order to create such a model as accurately as possible, it is necessary to make some assumptions. The first one is connected with focusing on statutory legal rules. Many authors (e.g. [4]) point out important distinctions between legal principles and legal rules, where principles are statements which may be applied to various degrees (especially in the case of a conflict), but rules may be either applied or not. If there is a conflict between two or more rules, only one of them may be applied; if there is a conflict between two or more principles, the degrees of how much each may be applied are weighted. In this work I am going to focus on resolving conflicts between legal rules only. The second assumption stems from the fact that to provide a legal opinion, a lawyer usually requires not only legal knowledge (legal rules, principles which are taken from statutes), but also commonsense knowledge and knowledge about mechanisms of legal interpretation and reasoning. In order to simulate such a process as accurately as possible, it is indispensable to make a clear-cut distinction between the provision itself, its interpretation, inference mechanisms, as well as commonsense knowledge required to implement legal provisions. This distinction would allow for preserving both the universal character of the provision and its applicability to various legal problems. The third assumption is connected with the second one: the model should precisely represent the wording of the legal act and as such should contain any provision-specific imperfections, including imprecision, undefined assumptions, loopholes, ambiguity, etc. Inference and interpretation engines should be endowed with mecha-

978-83-60810-90-3/$25.00

nisms allowing for overcoming legal knowledge imperfections. Such procedures should mirror mechanisms which are used by human lawyers in such situations.

Legal theory and practice worked out a group of mechanisms which allow for resolving conflicts between rules. Most of these methods are independent of the circumstances of a given case, yet one of them is based on commonsense relations between conflicting rules and another is based on the axiological estimation of a case. It is important to notice that conflicts may appear not only between literal interpretations of statutory norms. Legal theory says that such conflicts may appear between norms reconstructed by the utilization of any inference rules (per analogiam, a'fortiori, etc.) or interpretation mechanisms.

There are four methods of conflict solving:

- *lex superior derogat legi inferiori*,
- *lex posterior derogat legi priori*,
- *lex specialis derogat legi generali*,
- an axiological method: *argument from social importance*.

The methods do not have equal power: the weaker one is used only if the stronger one does not allow for solving the conflict. The first three methods will be discussed in section III but the fourth (and the weakest) one is presented and modeled in [5], hence the model of the argument from social importance will not be presented here, though it can be easily adopted into the model presented in this paper.

II. The notion of conflict between legal rules

In legal theory there are numerous doubts about the problem of deciding who is able to state the existence of a conflict between legal rules. This is also the crucial aspect of this study.

A. The notion of conflict in the literature

A detailed discussion of the problem of the notion of conflict between legal rules is presented in [5].

Usually, a conflict between the rules of the law is treated as a clash between two distinct arguments (or their subsets) leading to two mutually exclusive conclusions [6], [7], [8]. In [9] rules are deemed conflicting when one of them "attacks" the other one, i.e. when the conclusion of one rule is complementary to the conclusion or condition of the other one. The conflict model proposed by J. Hage [10] is relatively complex. It is based on the assumption that a conflict occurs only if the conclusion from one rule implies A and the conlusion from the other one implies non-A, though it may result from the commonsense-based limitations related to the circumstances analyzed. Comparing the model of conflict from [10] (Chapter 5 concerning the rule coherence) to other models presented in [7], [8], and [11], the author points out, inter alia, that the source of conflicts may not stem only from the complementary nature of the conclusions (P and non-P, referred to as a logical conflict), but also from the incompatibility of the factual states they describe. The compatibility (or incompatibility) of the factual states may be evaluated through additional constraints (the rules may be incompatible with respect to certain constraints) and rules, which may come from commonsense knowledge.

In my opinion the key point of the discussion of the problem of conflict between statutory legal rules lies in the impossibility to detect such a conflict without considering arguments in which such rules appear. Legal rules very seldom exist separately since they are usually used as a part of the whole argument in which other kinds of rules (mainly commonsense ones) also appear. I believe that a real conflict between rules can be discovered by taking into consideration the whole argumentation process.

One of the most recent and important approaches to modeling legal argumentation is *ASPIC*$^+$ presented (among others) in [12]. *ASPIC*$^+$ is a complete framework allowing for the modeling of legal argumentation, one of whose elements is a model of the relation of an attack of one argument on another. The issue of attacks on arguments was described in [13]. The authors of the paper distinguish and define three ways by which one argument can attack another: An undermining attack is an attack on the premises of an argument, an undercutting attack is an attack on the inference step and is a way to provide "exceptions to the rule," and finally, a rebutting attack is performed by constructing a contrary or contradictory conclusion for an attacked argument's (sub)conclusion.

This definition allows for a distinction between direct and indirect attacks: an argument can be indirectly attacked by directly attacking one of its proper subarguments.

The attack relation tells us which arguments are in conflict with each other: if two arguments are in conflict, then they cannot both be accepted. The resolution of such a conflict requires the declaration of additional knowledge. The authors of [12], [13], like many others, assume a binary ordering $\prec$ on the set of all arguments that can be constructed on the basis of the argumentation theory. On the basis of such orders, they define a relation of defeat:

- A successfully rebuts B if A rebuts B on B' and $A \not\prec B'$;
- A successfully undermines B if A undermines B on φ and $A \not\prec \varphi$;
- A defeats B iff A undercuts or successfully rebuts or successfully undermines B;

where A, B, B' are arguments, φ is a one of the premises of argument B.

The issue of conflicts in a knowledge base appears not only in legal decision support systems. For example, the authors of [14] discuss the mechanism of conflict detection in business intelligence systems.

B. *ASPIC*$^+$ argumentation framework

Since the *ASPIC*$^+$ framework is a very powerful and useful tool for legal argumentation modeling, I am going to build the model of legal rules' conflict resolution on the basis of this framework. An *ASPIC*$^+$ based model of conflict detection is presented in [5]; here I am going to sketch a few important aspects of the model.

Due to the length limitation, *ASPIC*$^+$ will not be presented here in detail. I am only going to discuss some basic defini-

tions, which may lead to a better understanding of my idea; a more detailed discussion of the framework can be found in [12], [13], and others.

Generally speaking, *ASPIC*$^+$ is a framework for structured argumentation representation. It is important to emphasize that it is not a system but a framework for specifying systems, hence it does not specify any logical language to represent arguments.

ASPIC$^+$ allows for the definition of the specific logical language $\mathscr{L}$ for the representation of an argument. Arguments are constructed from a knowledge base [12], [13]:

A knowledge base in an argumentation system is a pair $(K, \leq')$ where $K \subseteq \mathscr{L}$ and $\leq'$ is a partial preorder on $K \backslash K_n$. Here $K = K_n \cup K_p \cup K_a \cup K_i$ where these subsets of K are disjoint and there are (unattackable) premises called necessary axioms (K_n), (attackable) ordinary premises (K_p), assumptions (K_a) – which are a weak type of premise always defeated by an attack – and issues (K_i) which are premises that are not acceptable unless backed by further argument.

Below are presented some basics of the framework:

An *argumentation system* is a tuple $AS = (\mathscr{L}, \mathscr{R}, n)$, where [12]:

- $\mathscr{L}$ is a logical language closed under negation;
- $\mathscr{R} = \mathscr{R}_s \cup \mathscr{R}_d$ is a set of strict ($\mathscr{R}_s$) and defeasible ($\mathscr{R}_d$) inference rules of the form $\phi_1, ..., \phi_n \rightarrow \phi$ and $\phi_1, ..., \phi_n \Rightarrow \phi$, respectively (where ϕ_i, ϕ are meta-variables ranging over wff in $\mathscr{L}$) and $\mathscr{R}_s \cap \mathscr{R}_d = \emptyset$;
- n is a naming convention ($n : \mathscr{R} \rightarrow \mathscr{L}$).

An argument in *ASPIC*$^+$ is one of the following constructs:

- ϕ if $\phi \in K_n \cup K_p$;
- $A_1, ..., A_n \rightarrow \psi$ if $A_1, ..., A_n$ are arguments, $Conc(A_1), ..., Conc(A_n) \rightarrow \psi$ is a strict rule in $\mathscr{R}_s$ and $Conc(A_i)$ is a conclusion of an argument A_i;
- $A_1, ..., A_n \Rightarrow \psi$ if $A_1, ..., A_n$ are arguments, $Conc(A_1), ..., Conc(A_n) \Rightarrow \psi$ is a defeasible rule in $\mathscr{R}_s$, and $Conc(A_i)$ is a conclusion of an argument A_i;

A structured argumentation framework (*SAF*) is a triple $\langle \mathscr{A}, \mathscr{C}, \preceq \rangle$ where [12]:

- $\mathscr{A}$ is the smallest set of all finite arguments constructed from a knowledge base in AS;
- $\preceq$ is an ordering on $\mathscr{A}$;
- $(X, Y) \in \mathscr{C}$ iff X attacks (is in conflict with) Y.

ASPIC$^+$ is also meant to generate abstract argumentation frameworks in Dung's understanding [15]. Such frameworks are simply directed graphs in which arguments (nodes) are related to other arguments by attack or defeat relations (arcs).

C. Model of conflict of legal rules

The most important assumption is a clear-cut distinction between legal rules and ordinary commonsense rules. Only the authors of [16] present an approach to formalize legal norms in *ASPIC*$^+$, yet they miss the problem of conflicts between norms; also, their formalization of legal rules is different from the one presented in this paper. Distinguishing between legal and commonsense rules is important for several reasons: firstly, a model of statutory legal norms should mirror the wording of a legal act as precisely as possible and, secondly, the defeaters of legal rules should be, and usually are, precisely regulated by law. Therefore, they cannot be treated in the same way as ordinary commonsense arguments.

On the basis of the above we assume that a set $K_p \in K$ (ordinary premises) consists of two sets: K_l and K_c, where K_l is a set of legal knowledge and K_c is a set of commonsense knowledge. K_l and K_c are separate: $K_l \cap K_c = \emptyset$.

Since a conflict may appear between legal rules, we have to allow to add to a set K_l legal rules in the shape:

$r : Conditions \twoheadrightarrow c$

where *Conditions* is a formula whose satisfaction causes truthfulness of a conclusion c. The binary connective $\twoheadrightarrow$ is used to represent a legal rule, since K_l is in K_p, the legal rule can be defeated by other argument. The defeasibility characteristic of a legal rule differs from ordinary commonsense rules. For example, the authors of [12] discuss a new connective $\rightsquigarrow$ in $\mathscr{L}$ in which $p \rightsquigarrow q$ stands for *"if p then normally/typically/usually q."* Such a rule differs from the legal one in a few important points: firstly, a legal rule is valid not only "usually" or "typically," but it is valid constantly until it is defeated. Secondly, the defeating mechanism of a legal rule is, in opposition to an ordinary commonsense rule (like $p \rightsquigarrow q$), precisely regulated by law and there is no other way to defeat it.

Since we are going to solve the problem of conflict between legal rules, we have to define what is understood as a conflict between legal rules: The authors of *ASPIC*$^+$, on the basis of their previous works, identify three kinds of attack relation on an argument [13]: undercutting, rebutting, and undermining. Since undermining concerns an attack on a premise of an argument, it cannot be treated as an attack on a legal rule.

Undercutting and rebutting concern attacking an argument or its conclusion and if both conflicting arguments use legal rules (from a set K_l), then there may be a conflict between legal rules. If an undercutting attack concerns an inference step based on a legal rule from a set K_l or a rebutting attack concerns a (sub)conclusion of a legal rule and an attacking argument uses at least one legal rule, then there is a conflict between legal rules. More formally, legal rules $r_1, r_2 \in K_l$ are potentially conflicting if:

- A undercuts argument B (on B'), r_1 is used in argument A, r_2 is used in the top rule of B' and $r_1 \neq r_2$ (r_1 and r_2 are different).
  or:
- A rebuts argument B (on B'), r_1 is used in argument A, r_2 is used in argument B' and $r_1 \neq r_2$ (r_1 and r_2 are different).

Without an in-depth analysis of the context and meaning of both arguments, it is very difficult to recognize beyond doubt whether such a conflict exists between legal rules or other subarguments. It is important to notice that conflicting legal rules do not have to be top rules of both arguments (A and B'), except undercutting argument B', because such an attack should strictly address a rule which should be defeated. It is

much easier to discover such a conflict in the special situation when conflicting legal rules r_1, r_2 are the only defeasible rules in both arguments:
Legal rules $r_1, r_2 \in K_l$ are in conflict if:

- A undercuts argument B (on B'), $Defrules(A) = A_l$, argument $r_1 \in Prem(A_l)$, $r_1 \in K_l$, there are no other defeasible rules in A, $Defrules(B') = B_l$, $r_2 \in Prem(B_l)$, $r_2 \in K_l$, $r_1 \neq r_2$ and r_2 is the top rule of B'.
- A rebuts argument B (on B'), $Defrules(A) = A_l$, $r_1 \in Prem(A_l)$, $r_1 \in K_l$, there are no other defeasible rules in A, $Defrules(B') = B_l$, $r_2 \in Prem(B_l)$, $r_2 \in K_l$, $r_1 \neq r_2$ and there are no other defeasible rules in B'.

Where: $Prem(A)$ is a function which returns the premises of an argument (by $r \in Prem(A)$ we denote that a rule r is one of the premises of argument A), $Defrules(A)$ is a function which returns defeasible inference rules used in argument A.

It is important to notice that there will be a conflict between legal rules even if the attack relation is not symmetrical (argument A attacks argument B and argument B does not attack argument A). By $conflictingRules(A,B)$ we denote that two arguments A and B contain conflicting legal rules.

III. Methods of conflict resolving between legal rules

Although in this work I am going to focus on the Polish legal system, the mechanisms which are described here may be adjusted to other statutory law systems in a relatively easy way.

At the beginning we have to look at the problem of conflict resolution from a more general point of view. If we have recognized that there is a conflict between two (or more) legal rules and we know that we cannot overcome the conflict by reconciling the conflicting norms using other legal norms, then we have to use one of the conflict resolution methods. All of these methods work in a similar way: in the case of a collision between legal rules, on the basis of some reasons listed below it is recognized which of the conflicting rules has a higher priority and all conflicting rules with lower priorities are then excluded from the reasoning process.

The theory of law distinguishes 4 main ways of resolving conflicts between legal rules [17]:

1) *Lex superior derogat legi inferiori*, based on the structural nature of law, where every legal act has its own position in the hierarchy. If one of the conflicting norms comes from the act which is at a higher position in the hierarchy, then such a norm prevails over the one from the act which is at a lower position in the hierarchy.
2) *Lex posterior derogat legi priori*, based on the time of establishing a given legal act. A legal act established later prevails over an act established earlier.
3) *Lex specialis derogat legi generali* in which a specific act (provision) derogates from (prevails over) a general regulation.
4) The final and most controversial method, known as an argument from social importance, where a rule which is more important from the axiological point of view prevails over a less important one.

Ad 1. Discussing the problem of hierarchy between legal norms requires some consideration of legal norms form several points of view:

a the first one is based on a strict hierarchy of legal acts,
b the second one is based on the relation between general law and internal law,
c the third one is based on the relation between a law which binds over the whole country and a law which binds over a part of the country,
d the fourth one is based on the relation between national and international law.

ad [a] From the point of view of the strict hierarchy of legal acts, we may state that in Polish law the constitution prevails over a legal act, which prevails over a regulation (where a regulation is a normative act issued on the basis of a specific authorization contained in a legal act aiming to allow for the execution of the act).

ad [b] From the point of view of conflict between general and internal law, the theory of law states that general law prevails over internal law.

ad [c] From the territorial point of view, a law which binds over the whole country prevails over a law which binds over a part of the country.

ad [d] Relations between national and international law are not the topic of this paper because we are going to discuss only the relations between the norms of national law.

Ad 2. The *lex posterior* mechanism of conflict resolution is based on the analysis of the dates when legal acts were established: an act established earlier has a lower priority than an act established later. If there is a conflict between these acts, the second one prevails over the first one. It is important to notice that such a mechanism works only if both conflicting acts are at the same level in the hierarchy and it is not possible to determine whether either is more specific. In other words, the *lex posterior...* mechanism has a lower priority than *lex superior...* or *lex specialis...* and it can only be employed if the utilization of *lex superior...* or *lex specialis...* cannot resolve the conflict.

Ad 3. *Lex specialis derogat legi generali* is a principle under which a specific act (provision) derogates from (prevails over) a general regulation. This mechanism is based on the analysis of the scope of conflicting legal rules and it allows for resolving conflicts which may appear, unlike in *lex posterior* or in *lex superior*, between the rules from the same legal act. This is a very strong mechanism which should be used very carefully because it may even change the conclusion made on the basis of the *lex superior* principle. There is a problem of superiority of *lex superior* over *lex specialis* of which legal literature does not include a clear view. In general, *lex superior* prevails over *lex specialis* (for example in [18] it is stated that *lex superior* is absolutely valid) but sometimes it may not work (following [17]): a legal act (as a more specific one) may be an exception to a constitutional norm or a local law (as a more

specific one) may prevail over a national one. Unfortunately, [17] does not explain clearly when or in what conditions such exceptions may occur.

Ad 4. An argument from social importance is the most controversial one and it should be used only if other ways of conflict resolution do not allow for resolving an existing conflict. This mechanism is based on the distinction between axiological contexts of conflicting norms. One of the norms may be more significant from the point of view of social importance and this norm should prevail over the less significant one. Unlike the abovementioned mechanisms, this mechanism is based on reasons which come from outside the law, making it more difficult to justify and apply. One of the main problems connected with this conflict resolution method is the uncertainty of interpretation and evaluation of social importance. One of the most clear (though rather seldom) situations may appear when one of the conflicting norms is strictly based on an expressly stated legal principle, which clearly states this norm's social importance. In other situations it is very difficult to undoubtedly decide which of the analyzed norms is more significant from the point of view of social importance. This is the reason why such a method is used very seldom and usually only in higher courts. It is also important that an argument from social importance can be strengthened by supporting it by previously decided cases. A detailed discussion and the model of an argument from social importance can be found in [5].

IV. Model of conflict resolution

Since I am going to model conflicts between legal rules, it is necessary to make some assumptions with regard to modeling such rules. In order to keep the model simple, I am going to represent them using the propositional logic, but it is also possible to use more expressive logics (the example presented in the section VI will be extended with deontic modalities) as well as additional interpretation mechanisms (for example teleological, like in [19]) and inference mechanisms (like a'fortiori [20] or instrumental [21]). The utilization of such mechanisms is important because in the literature [17] it is emphasized that such conflicts may appear between the norms reconstructed by the utilization of any inference rules (per analogiam, a'fortiori, etc.) or interpretation mechanisms.

At the beginning we have to assume some elements of a language $\mathscr{L}$ which will allow for the representation of legal rules. We assume a set of operators $OP \subset \mathscr{L}$, where $OP = \{\neg, \sim, \vee, \wedge, \twoheadrightarrow, \supset\}$ which will be used to model legal rules.

- $\neg$ is classical (strong) negation;
- $\sim$ is negation as failure;
- $\vee$ is a disjunction;
- $\wedge$ is a conjunction;
- $\twoheadrightarrow$ is a binary connective which stands for a defeasible legal rule;
- $\supset$ is a classical (material) implication used in commonsense rules.

A language $\mathscr{L}$ can also include other operators (defeasible implication, etc.) which should allow for a more adequate representation of various kinds of commonsense arguments. Let $F = \{f_1, f_2, ...\}$ be a set of propositional atoms called facts. We assume that a legal rule is a formula in the form:

$$r_n : Conditions \twoheadrightarrow Conclusion;$$

where:

- n is a rule's name
- *Conditions* is a (possibly empty) antecedent formula;
- *Conclusion* is a rule's non-empty conclusion in the form: $Conclusion = (lx \wedge ly \wedge \ldots)$, where: lx, ly are atomic conclusions which can be positive (f) or negative facts (negated by classical negation only $\neg f$).

An antecedent formula is a formula: $c1$ ***func*** $c2$ ***func*** $\ldots$ cn, where ***func*** are the operators from the set $\{\vee, \wedge\}$ and $\{c1, c2, \ldots, cn\}$ are atomic conditions, each being either a positive fact(f) or one negated by classical negation ($\neg f$), negation as failure ($\sim f$), or both ($\sim \neg f$).

Legal reasoning uses various interpretation and reasoning mechanisms; however, the legal literature points out that the basic one is linguistic interpretation (a more detailed description of linguistic interpretation can be found in [19]). As an unstrict way satisfying a rule's antecedent we understand the satisfaction of a rule's condition by utilizing any non-standard (non-linguistic) interpretation mechanism, e.g. teleological (an example of a model of teleological interpetation can be found in [19]), systematic, etc. A detailed discussion of the issue of modeling legal interpretation can be found in [22], [23], and [24].

By $K \bullet Conditions$ we will denote that a knowledge base K satisfies the conditions of a given legal rule.

On the basis of the above, a new defeasible inference rule should be added to a set $\mathscr{R}_d$:

$$r_n : Conditions \twoheadrightarrow Conclusion \wedge K \bullet Conditions \Rightarrow conclusion$$

Most authors working on modeling the resolution of conflicts between legal rules assume the existence of an order between rules or prioritising them ([9], [7], [1], [10], [25], etc.). Such an order allows to decide which of the conflicting rules is strongest and prevails over the weaker ones. Unfortunately, in real-life situations it is difficult to assume in advance that one rule is always stronger than another. It usually depends on many circumstances, which are sometimes difficult to express. To overcome this disadvantage, G. Sartor and H. Prakken ([9], [25]) propose defeasible priorities and rules which allow for inference about priorities.

A. Model of lex superior...

An interesting model of *lex superior...* is presented in [26], where the authors treat the level of authority which establishes a norm as a root of preference between norms. Unfortunately, such a conception does not fit the Polish legal system in which the hierarchy of legal acts is not strictly based on authority hierarchy, but is established by legal theory.

The *lex superior...* principle is based on a hierarchy of norms. It is obvious that formalization of a legal norm should

represent the meaning of this norm in a most accurate way, with all its features and imperfections. If we try to reconstruct the content of a legal rule from a legal text, it is important not to forget that not only the strict wording of the norm is important. There is also some relevant information connected with the norm from which a given legal rule comes from, like the position in the legal system, the date of issue, etc. Since the model of the *lex superior...* principle requires information about the position of the analyzed norms in the legal system hierarchy, such information has to be added to our model.

Let us assume that there are 2 conflicting legal rules:

$$r_1 : Conditions1 \twoheadrightarrow Conclusion1$$
$$r_2 : Conditions2 \twoheadrightarrow Conclusion2$$

It is clear that we have to add some information about the source of the rule, on the basis of which we can conclude the hierarchy between rules. We have three main levels of the legal norms hierarchy: the constitution, a legal act, and a regulation; however, apart from the general, national law there are other acts: internal legal norms, local norms, norms whose scope is narrowed to some parts of the country, etc. As $HCH \in K_n$ we denote a set of the levels of a hierarchy ($HCH = \{hch_1, hch_2, \ldots\}$). A strict partial order $OH = (HCH, >_{hch}) \in K_n$ represents a hierarchy of norms. A set $ACT = \{act_1, act_2, \ldots\} \in K_l$ represents a set of all statutory legal acts. Let an act $act \in ACT$ be a set of legal rules. By $r_l \in act_x$ we denote that a legal rule r_l is taken from an act act_x. A function $H : ACT \to HCH$ assigns to a given legal act a hierarchy level.

Every act belongs to only one hierarchy level. By $H(act_n) = hch_m$ we denote that act_n belongs to hierarchy level hch_m.

If we recognize r_n and r_m as conflicting rules, then we can solve the conflict using the *lex superior...* principle $lexSuperior \in \mathscr{R}_d$:

$$lexSuperior : (r_n \in act_k) \wedge (r_m \in act_l) \wedge (H(act_k) = hch_x) \wedge (H(act_l) = hch_y) \wedge (hch_x >_{hch} hch_y) \wedge (r_n \in Prem(A)) \wedge (r_m \in Prem(B)) \Rightarrow A \succeq B$$

where A, B are arguments built on conflicting legal rules. If both of the arguments attack each other (rebut or undercut) and it is possible to conclude (on the basis of *lexSuperior*) an order $A \succeq B$, then argument A defeats argument B.

B. Model of lex posterior...

The *lex posterior...* principle is in some points similar to *lex superior...*: both of them are also based on the properties of legal acts from which the conflicting rules are taken. While *lex superior...* is based on the position of a statute in the legal system, *lex posterior...* is based on the date of issue of a statute. If we have two conflicting rules issued on different dates, then, on the basis of the *lex posterior...* principle, a rule issued later prevails over a rule issued earlier. Similarly to *lex superior...*, we have to rely on a specific feature of acts from which conflicting rules are taken.

Let us assume that we have 2 conflicting legal rules:

$$r_1 : Conditions1 \twoheadrightarrow Conclusions1$$
$$r_2 : Conditions2 \twoheadrightarrow Conclusions2$$

By $DATE \in K_n$ we denote a set of all dates of issue of all legal acts. A function $D : ACT \to DATE$ assigns date of issue to a given act. By:

$$D(act_m) = date_m$$

we denote that a norm included in act_m was issued on date $date_m$. A strict order between the dates of issue of norms $OD = (DATE, >_{time}) \in K_l$ reflects the later-sooner relation. By $date_m >_{time} date_n$ we denote that $date_m$ was earlier than $date_n$.

If we recognize r_n and r_m as conflicting rules, then we may solve the conflict using the *lex posterior...* principle ($lexPosterior \in \mathscr{R}_d$):

$$lexPosterior : (r_n \in act_k) \wedge (r_m \in act_l) \wedge (D(act_k) = date_k) \wedge (D(act_l) = date_l) \wedge (date_k >_{time} date_l) \wedge (r_n \in Prem(A)) \wedge (r_m \in Prem(B)) \Rightarrow B \succeq A$$

where A, B are arguments built on conflicting legal rules. If both of the arguments attack each other (rebut or undercut) and it is possible to conclude (on the basis of *lexPosterior*) an order $B \succeq A$, then argument B defeats argument A.

C. Model of lex specialis...

Since *lex superior...* and *lex posterior...* are based on the knowledge which comes from legal sources, their models do not require any external sources of knowledge. Unlike them both, the *lex specialis...* principle is based on commonsense knowledge, which makes modeling this method much more challenging, because the representation and collection of commonsense knowledge is still one of the most complicated and difficult problems in the field of artificial intelligence.

Lex specialis... in the literature:

The *lex specialis...* principle has been mentioned in many papers concerning the problems of defeasible reasoning, argumentation, or normative conflicts, but in most of these papers the authors do not make attempts to formalize its nature. They usually assume an order declared in advance, which represents a relation of generality. Only in [27] a model of such a mechanism is presented:

A *normative position np* in an activity state q is more specific than np' (denoted as $np \succ_S np'$), if $np \in N_q$ and $np' \in N_q^{in}$, where: *normative position* is a deontic state of activity, N_q is a set of normative positions of an activity state q, and N_q^{in} is a set of normative positions propagated from a state of a super activity to an activity state q.

Unfortunately, it is unclear what the authors of the paper understand as a relation of activity – super activity. It may be understood as a superclass – subclass relation or an aggregation (a super activity consists of activities). Following the example presented in the paper, the relation should be understood as a kind of aggregation. It is, in my opinion, an oversimplification of the problem because not every relation

of being more or less specific can be described in such a way. I believe that such a way of modeling is appropriate for only relatively small and well-structured cases like, for example, small multi-agent systems (for which the model described in [27] was designed). Real-life legal cases are usually too fuzzy and ambiguous to let us assume without any doubt that activity q_1 is a super activity to q_2.

The model presented in [27] is an interesting approach to discuss *lex specialis...*, but due to the abovementioned controversies, I am going to present my own version of the formalization of the principle, disregarding the already assumed relations of inheritance between activities.

The model

From the model presented in [27] we adopt the idea of utilization of a partial order representing the relation being more or less specific, but its origin will be different than in [27].

Let $SPEC = (K_l, >_{spec})$ will be a partial order representing a generality relation between legal rules.

Let us assume two conflicting legal rules:

$$r_1 : Conditions1 \twoheadrightarrow Conclusion1$$

$$r_2 : Conditions2 \twoheadrightarrow Conclusion2$$

We have to decide which of them is more specific. What does it mean? As stated earlier, this mechanism is based on the analysis of the scope of conflicting legal rules. A rule which is more specific (for example, r_1) regulates a group of cases which is a subgroup of cases regulated by a more general rule (for example, r_2). Basing on the above, we may state that the scope of a rule depends on the conditional (left-hand) part of the rule, because the decision which case can be classified within the range of the scope of the rule is based on this part of a given rule.

The issue of modeling of *lex specialis...* can be divided into two separate tasks: the first one is to recognize which (if any) of the rules is more specific; the second one is to model the process of defeating a more general rule. Firstly, I am going to focus on the first task and to look at the problem of *lex specialis...* from a purely theoretical point of view. If we are going to model the principle, then we have to investigate if a set of cases which satisfies the conditions of one of the conflicting rules subsumes a set of cases which satisfies the conditions of another one. More formally, the condition of subsumption of a rule's antecendent can be modeled in such a way:

Where $Conditions1$ and $Conditions2$ are antecedents of the conflicting rules, and if for any possible to occur case P expressed by wff of $\mathscr{L}$:

$$\forall_P((P \bullet Conditions1) \rightarrow (P \bullet Conditions2))$$

and,

$$\exists_P((P \bullet Conditions2) \not\rightarrow (P \bullet Conditions1))$$

then we recognize that in a view of more restrictive character of a rule r_1 we may conclude that a rule r_1 is more specific than a rule r_2. The key challenge of such a model is an unrealistic assumption in which we have to list all cases which satisfy a rule's conditions. Firstly, it is impossible to predict all possible real-life cases (except some trivial ones); secondly, how can we recognize if a given case can possibly occur?

Since we cannot foresee all possible real-life cases, our model does not allow for recognizing all general-specific relations between rules. The only thing we can do is analyze the antecedants of conflicting rules to discover whether the condition of subsumption is fulfilled. There are some kinds of specific situations which allow us to make inferences, for example:

- Restricting Rule
  $restrictingRule$:
  $(r_1 : Conditions1 \twoheadrightarrow Conclusion1) \wedge$
  $(r_2 : (Conditions1) \wedge (Conditions1a) \twoheadrightarrow Conclusions) \wedge$
  $(Conditions1 \neq Conditions1a) \Rightarrow$
  $r_2 >_{spec} r_1$
  If every case which satisfies the conditions of a legal rule r_2 also satisfies the conditions of r_1, then rule r_2 is more specific than r_1.
- Subsuming Rule:
  $subsumingRule$:
  $(r_1 : Conditions1 \twoheadrightarrow Conclusion1) \wedge$
  $(r_2 : (Conditions1) \vee (Conditions1a) \twoheadrightarrow Conclusion2) \wedge$
  $(Conditions1 \neq Conditions1a) \Rightarrow$
  $r_1 >_{spec} r_2$
  A legal rule r_1 is more specific than a rule r_2, because every case which satisfies conditions of r_1 also satisfies conditions of r_2.

Both restricting and subsuming inference rules are a part of $\mathscr{R}_d$ ($restrictingRule \in \mathscr{R}_d$, $subsumingRule \in \mathscr{R}_d$).

Looking at the problem of *lex specialis...* in a more general way one can notice that the above mechanism does not allow for the recognition of all general-specific relations between legal rules. However, it is also worth to emphasize that in real legal practice it is also not easy to recognize them without any doubts.

Having the order $>_{spec}$ representing the specificity-generality relation between legal rules, we can model *lex specialis...*: If we recognize r_n and r_m as conflicting rules, then we may solve the above conflict on the basis of the *lex specialis...* principle ($lexSpecialis \in \mathscr{R}_d$):
$lexSpecialis : (r_n >_{spec} r_m) \wedge (r_n \in Prem(A)) \wedge (r_m \in Prem(B)) \Rightarrow A \succeq B$

If A, B are arguments built on conflicting legal rules, both arguments attack one another (rebut or undercut), and it is possible to conclude (on the basis of $lexSpecialis$) an order $A \succeq B$, then argument A defeats argument B.

The *lex specialis...* principle is slightly different from the previous ones. The most important difference lies in the commonsense background of the method: both *lex superior...* and *lex posterior...* are based on purely legal knowledge taken from statutes, while *lex specialis...* is (similarly to argument from social importance [5]) based on commonsense knowledge.

V. Ordering of inference rules

Legal practice and theory have developed a collection of methods of legal rules' conflict resolution, but it is important to notice that their results do not have to be compatible in the sense that one of the methods can give preference to one rule and second method can give preference to another one. Generally speaking, if there is a conflict between two conflict resolution methods, the theory of law assumes the following order of methods: *lex superior* prevails over *lex specialis...* which prevails over *lex posterior...* which prevails over axiological methods. Unfortunately, it is not so obvious in real-life legal cases: sometimes, in specific cases, such an order does not work and, for example, *lex specialis...* defeats *lex superior...*. Prakken and Sartor's logic ([9], [25]) allows for reasoning about priorities between arguments and rules whose elements may be helpful in such conflict resolution.

However, for the sake of this study we assume that in the case of incompatibility of conflict resolution methods (two methods infer different results), the above order will be applied.

Although our conflict resolution inference rules can be seen as a kind of higher level inference rules, in the argumentation process they are treated in the same way as ordinary inference rules. Moreover, $ASPIC^+$ does not distinguish any particular kinds of arguments except strict and defeasible ones. Hence arguments created on the basis on our inference rules can be attacked and defeated by other arguments whose strength can be regulated by the above order. How can it be applied in our framework? First of all, we have to notice that not all conflict resolution methods work in all cases. If conflicting norms are at the same level in the legal act hierarchy and were released at the same time, the other methods (for example, *lex specialis...*) can be applied. Also, if two methods can be applied and their results are not compatible, the order:
$lexSuperior \succeq lexSpecialis \succeq lexPosterior \succeq$ axiological methods
allows for defeating the conflicting arguments.

VI. Example

Let us illustrate our ideas by a simple example. There are two legal defeasible rules:

$$r_1 : vehicle \twoheadrightarrow \neg allow(enterThePark)$$

$$r_2 : vehicle \wedge emergency \twoheadrightarrow allow(enterThePark)$$

as well as 3 necessary axioms:
$r_3 : ambulance \supset vehicle$
$f1 : ambulance$
$f2 : emergency$

$r_1 \in act_k$, $r_2 \in act_l$ $act_k, act_l \in K_l$
$r_3, f1, f2 \in K_n$

On the basis of the above knowledge, we may build two argument chains A and B:

$A_1 : f1$
$A_2 : A_1, r_5 \rightarrow vehicle$
$A_3 : A_2, r_1 \Rightarrow \neg allow(enterThePark)$
$B_1 : f1$
$B_2 : f2$
$B_3 : B_1, B_2, r_2 \Rightarrow allow(enterThePark)$

In the above example, argument A_3 attacks (rebuts) B_3 and B_3 attacks (rebuts) A_3. Since both arguments have only one defeasible rule (respectively r_1 and r_2), r_1 and r_2 are legal rules and $r_1 \neq r_2$, then we may conclude that r_1 and r_2 are in conflict.
Let us assume that both r_1 and r_2 are taken from acts which are at the same level in the hierarchy and have the same date of release:

$K_n \vdash (H(act_k) \not\succ_{HCH} H(act_l)) \wedge (H(act_l) \not\succ_{HCH} H(act_k))$.
$K_n \vdash (D(act_k) \not\succ_{time} D(act_l)) \wedge (D(act_l) \not\succ_{time} D(act_k))$.

The above knowledge does not allow us to solve the conflict on the basis of *lex superior...* or *lex posterior...*, hence the possibility of using *lex specialis...* will be checked.

We do not have any additional knowledge about the case, but if we compare two conflicting rules:

$r_1 : vehicle \twoheadrightarrow \neg allow(enterThePark)$
$r_2 : vehicle \wedge emergency \twoheadrightarrow allow(enterThePark)$

we can notice that on the basis of the *restrictingRule* inference rule, argument B_4 can be constructed:

$B_4 : r_1, r_2, restrictingRule \Rightarrow r_2 >_{spec} r_1$

and, on the basis of *lexSpecialis*, argument B_6 can be constructed:

$B_5 : B_4, r_2 \in Prem(B), r_1 \in Prem(A) \Rightarrow B \succeq A$

then since we know that B attacks A (rebuttal on A_3), $B \succeq A$ and the only defeasible steps in argument chains are rules based on r_1 and r_2, argument B defeats argument A.

VII. Conclusions and future work

Legal decision support systems as well as argumentation mining systems require an adequate and comprehensive formal model of various aspects of the argumentation process. AI and law researchers agree that legal reasoning cannot be seen as a simple, mechanical, deduction-based inference, like it was treated in classical expert systems. The key point lies in the issue of argumentation: Most legal decisions are, in fact, results of a trade-off between various arguments built on the basis of legal knowledge, commonsense knowledge, legal and non-legal inference rules. This is why formal modeling of argumentation is one of the crucial elements of legal advisory systems as well as argumentation mining systems (which are

probably the future of legal informatics and a tool which can help to search, analyze, and construct new arguments).

The problem of modeling of conflicting arguments has been widely discussed in the AI and law literature. A number of authors have presented their own models of the mechanisms of conflict resolution. However, most of the existing models do not distinguish between arguments based on legal statutes and ordinary commonsense reasoning, which, in my opinion, is an oversimplification. In legal reasoning, the issue of legal rules' conflict solving is very precisely regulated and cannot be treated the same way as it is in ordinary commonsense arguments.

The main aim of this work is to formalize the mechanism of resolving conflicts between statutory legal rules with a view to implementing it into the legal advisory system. The additional aim is to incorporate the model into *ASPIC*$^+$, one of the most comprehensive argumentation modeling frameworks, thanks to which the model can be used to represent a wide range of complex real-life legal cases including various kinds of arguments. The model was created on the basis of Polish law, however, it can be easily adapted into most statutory legal systems.

In summing up the above, the most important contributions of this paper are as follows:

- a discussion of the nature of conflict between legal rules,
- a comprehensive formal model of such a conflict,
- the distinction between legal and commonsense rules,
- a formal model of three main methods of conflict solving,
- the incorporation of the model into the APSIC+ argumentation framework.

There are two important issues calling for further discussion which I am going to elaborate in my future work. The first one is the problem of modeling the strength of an argument and the balance between two conflicting commonsense arguments. Real-life arguments are very often evaluated in the light of their strength, rightfulness, adequacy, etc., which are challenging to estimate and compare. However, this is the basis on which commonsense arguments defeat one another and it is difficult to imagine a system modeling real-life argumentation without a possibility of reasoning about its strength, rightfulness, adequacy, etc. The model of the strength of an argument will be tested by the MIZAR proof checker [28]. The second (parallel) direction of future work is implementation of the above model into a small decision support system similar to the ones presented in [29] or [30].

6th International Workshop on Advances in Semantic Information Retrieval

RECENT advances in semantic technologies form a solid basis for a variety of methods and instruments that support multimedia information retrieval, knowledge representation, discovery and analysis. They influence the way and form of representing documents in the memory of computers, approaches to analyze documents, techniques to mine and retrieve knowledge. The abundance of video, voice and speech data also raises new challenging problems to multimedia information retrieval systems.

We believe that our workshop will facilitate discussions of new research results in this area, and will serve as a meeting place for researchers from all over the world. Our aim is to create an atmosphere of friendship and cooperation for everyone, interested in computational linguistics and semantic information retrieval. The ASIR'15 workshop will continue to maintain high standards of quality and organization, set in the previous years. We welcome all the researchers, interested in semantic information retrieval, to join our event.

TOPICS

The workshop addresses semantic information retrieval theory and important matters, related to practical Web tools. The topics and areas include but not limited to:

- Domain-specific semantic applications.
- Evaluation methodologies for semantic search and retrieval.
- Models for document representation.
- Natural language semantic processing.
- Ontology for semantic information retrieval.
- Ontology alignment, mapping and merging.
- Query interfaces.
- Searching and ranking.
- Semantic multimedia retrieval.
- Visualization of retrieved results.

EVENT CHAIRS

- **Klyuev, Vitaly,** University of Aizu, Japan
- **Mozgovoy, Maxim,** University of Aizu, Japan

PROGRAM COMMITTEE

- **Carrara, Massimiliano,** Universita di Padova, Italy
- **Dobrynin, Vladimir,** Saint Petersburg State University, Russia
- **Goczyła, Krzysztof,** Gdansk University of Technology, Poland
- **Haralambous, Yannis,** Institut Telecom - Telecom Bretagne, France
- **Homenda, Wladyslaw,** Warsaw University of Technology, Poland
- **Jin, Qun,** Waseda University, Japan
- **Lai, Cristian,** CRS4, Italy
- **Leonelli, Sabina,** University of Exeter, United Kingdom

Game with a Purpose for Mappings Verification

Tomasz Boiński
Department of Computer Architecture
Faculty of Electronics, Telecommunication and Informatics
Gdańsk University of Technology
11/12 Narutowicza Street
80-233 Gdańsk, Poland
Email: tobo@eti.pg.gda.pl

***Abstract*—Mappings verification is a laborious task. The paper presents a Game with a Purpose based system for verification of automatically generated mappings. General description of idea standing behind the games with the purpose is given. Description of TGame system, a 2D platform mobile game with verification process included in the gameplay, is provided. Additional mechanisms for anti-cheating, increasing player's motivation and gathering feedback are also presented. Example of the system usage for verification of mappings between WordNet synsets and Wikipedia articles is presented. The evaluation of proposed solution and future work is also described.**

I. Introduction

NOWADAYS people tend to spend a lot of time playing computer games. Increased availability of powerful mobile devices further increases time spend on this form of entertainment. In 2012 Samsung Electronics Polska performed a study among people in Poland on the time spend on video games [1]. Almost half of the population aged 27-35 spends 1 to 2 hours weekly playing games and 14% spends over 20 hours a week. High percentage of the players use mobile devices like smartphones (20%) and tablets (5%). It can be seen that in many cases playing games occupies the amount of time equal to at least a part-time job. On the other hand many nowadays problems still cannot be solved by a computer algorithm and assigning human resources to perform such tasks is often economically inefficient.

The question arises what if we could use all that potential resources (time and knowledge of the users and hardware capabilities of their devices) to solve also non-algorithmic problems? One can imagine that if we would treat a group of users as a distributed system, then it is sufficient to divide a problem into small portions, distribute them to the players and finally aggregate achieved results. This however introduces some difficulties, from technical ones like how to divide a problem into sub-problems, how to distribute them and how to gather results, to more social oriented like how to trust the results and more importantly how to convince people to spend their time on solving our problem. Some research shows however that even educational games can be well perceived if constructed properly [2] so that an algorithm verification system within games seems plausible.

Numerically solvable problems adopted volunteer computing model [3] where the users donate the power of their machines when it is not needed (the calculations are done between the periods of active hardware usage). Using this model it is not possible to solve all type of problems, as some of them cannot be successfully turned into a computer algorithm [4]. We can use heuristics but than we still have to verify the results manually. In crowdsourcing [5] approach the user is encouraged to perform a task for some type of gratitude. The task can be both algorithmic and non-algorithmic.

It is also worth mentioning that the problems that are difficult for computers are usually quite easy for humans. Example of such problem is image recognition, image tagging, natural language understanding and processing or verification of results obtained by traditional heuristics. The results often very complicated algorithms are quite easy to grasp by an average human. Linking those two areas could prove to be useful for performing laborious tasks without a need of hiring additional workers especially that many research results needs some evaluation and sometimes it is the sole purpose of the research [6].

In this paper we focus on a so called human-based computation (HBC) [7] model. It is using human brain directly to solve a computational problem. The term was defined by Kosorukoff in 2001 in a paper about human enhanced genetic algorithm [8].

HBC can be viewed as similar to crowdsourcing. The later focuses solely on solving the problem by human, while in the former model part of the problem is solved by a computer. Usually the machine performs sub-problem organization, distribution and retrieval of results, sometimes some calculations are done using heuristics. The human part usually contains the verification of computer generated results or performing the calculations itself [9].

In our research we applied HBC-model for verification of mappings. As an example we used mappings between WordNet and Wikipedia [10], [11], [12], [13] that were obtained during Colabmap[1] project and are a result of running heuristics on a computer. Currently we are working on generalization of the proposed solution hoping to provide a general framework suitable for solving different types of problems.

II. Games with a Purpose

In 2006 Luis von Ahn proposed usage of computer games as something more than pure entertainment and thus creating

[1] http://kask.eti.pg.gda.pl/colabmap

978-83-60810-90-3/$25.00

the idea of so called GWAP (Game With A Purpose) [4]. GWAPs are typical games that provide standard entertainment value that users expect but are designed in a way that allows generation of added value by solving a problem requiring intellectual activity. It is worth noticing that GWAPs does not allow financial gratification for the work. The will to continue playing should be treated as the only way of gratifying users [14].

Ahn defined three types of GWAPs:

- output-agreement game,
- inversion-problem game,
- input-agreement game.

In the first type of GWAPs two randomly selected players are presented with identical input data and each produces results only based on the available information. Both players should achieve identical results without any knowledge about the other player - they are awarded only when both will give identical answers. In this case an identical answer provided by both players is treated as highly probable to be correct as it comes from independent sources. Example of such game is The ESP Game [15], where users task was to tag images with keywords. The players were presented with an image and were given 2,5 minute to enter all keywords that are related to the image. The game proved to be very popular. During first few months authors managed to gather around 10 million tags with statistics showing many users playing for over 40 hours a week [4]. In 2006 Google released their own version of the game called Google Image Labeler[2] (it was shut down in 2011) which was used to extend capabilities of Google Graphics.

The second type, the inversion-problem game, also selects players randomly. The players are however divided into two groups - describers and guessers. The describer is presented with input data and is responsible for creating tips allowing the guessing player to correctly point out the input data. The players are awarded points when the output given by the guesser is equal to the input. One of the examples of such game is Phetch [16]. One of the players is presented with a random image from the Internet. His or her task is to describe the image to other players. Other players task is to find an identical image. Other example is the Peekaboom game [17]. The task of the players is to quest words that are describing an image. The "boom" player is presented with an image and its description in a few words. The "peek" player is presented with empty page on which the "boom" player gradually reveals parts of the image. The "peek" player have to guess, based on the revealed fragments, the exact words describing the image.

The third type, input agreement game, also selects players randomly. Both players have to achieve agreement on the input data. More precisely they have to guess whether the other player received the same or different input data. Each player describes what he or she sees on the screen and the other player have to state whether the input is similar to theirs or different. The example of such game is TagATune [18] where players should describe their feelings about a tune that is played. Based on the description the players have to decide whether they heard the same or different tune.

What is common for all above types of games is that the players unknowingly generate added value that is not possible to calculate using computers. The problem behind such games is a way to lure players - only very large user base can provide viable results. During implementation many techniques can be used to enrich the game and encourage more players, like time limits, awards in form of points and achievements, difficulty levels, leader boards or randomness of input data [14].

The quality of target game can be described by two parameters: average lifetime play (the time that average player spent playing the game) and throughput (average number of problems solved per hour of playtime) [4]. Simko [19] also pointed out that GWAP should be characterized also by the total number of players that took part in the game.

III. Wikipedia - WordNet Connections Validation

During the Colabmap project we created a set of mappings between English Wikipedia articles and WordNet synsets. Sample mappings are presented in Table I. Each mapping consists of a WordNet synset, definition of the synset and the title of Wikipedia article with special characters coded using RFC 3986. Such mappings, when proved to be correct, will allow formalization of Wikipedia structure. The obtained set of mappings contained algorithmically created 54475 connections that required verification. Tempted by the results obtained during the Samsung's survey we decided on implementing a GWAP for validation of those connections.

The originally obtained mappings were extended with three additional "next best" mappings with the idea of presenting the user a question (definition of a synset) with 4 possible answers (Wikipedia article titles). At the beginning the 3 other answers were randomly selected from the set of Wikipedia's pages but such approach quickly proved to be incorrect as the "next best" mappings were not related at all to the question. Instead we used Wikipedia search functionality to select alternative answers (according to Wikipedia) following the Algorithm 1.

Algorithm 1 Algorithm for selecting alternative answers

```
for all synonyms of WordNet synset do
    Read the synonym
    Perform a Wikipedia search using the synonym
    Store 3 top elements from search results
end for
```

The example of extended mappings are presented in Table II. For the tests we randomly selected 100 synsets from our database to limit the time needed to gather the results and verify the viability of the game.

IV. TGame

We decided to implement TGame[3] ("Tagger Game") as a 2D platform game following the output-agreement model.

[2]http://en.wikipedia.org/wiki/Google_Image_Labeler

TABLE I
SAMPLE WORDNET – WIKIPEDIA MAPPINGS

Synset (WordNet)	Definition (WordNet)	Article (Wikipedia)
Sept. 11, September 11, 9-11, 9/11, Sep 11	the day in 2001 when Arab suicide bombers hijacked United States airliners and used them as bombs	September_11
interval, time interval	a definite length of time marked off by two instants	Time
ice age, glacial epoch, glacial period	any period of time during which glaciers covered a large part of the earth's surface	Ice_age Glacial_period
man hour, person hour	a time unit used in industry for measuring work	Man-hour
entity	that which is perceived or known or inferred to have its own distinct existence (living or nonliving)	Entity
French leave	an abrupt and unannounced departure (without saying farewell)	French_leave
hunt, hunting	the pursuit and killing or capture of wild animals regarded as a sport	Huntingdon
blindman's bluff, blindman's buff	a children's game in which a blindfolded player tries to catch and identify other players	Blind_man%27s_bluff
landler	a moderately slow Austrian country dance in triple time	L%C3%A4ndler
coup d'oeil, glimpse, glance	a quick look	Coup_d%27%C5%93il

TABLE II
SAMPLE OF EXTENDED MAPPINGS, THE ORIGINAL MAPPING IS EMPHASIZED

Synset (WordNet)	Articles (Wikipedia)
Sept. 11, September 11, 9-11, 9/11, Sep 11	*September 11*, 9/11 Commission, 9/11 conspiracy theories, United Airlines Flight_93
interval, time interval	*Time*, Interval (music), Interval, Interval (mathematics)
ice age, glacial epoch, glacial period	*Ice age*, Pleistocene, Wisconsin glaciation, Gravettian
man hour, person hour	*Man-hour*, Hourman, Man of the Hour, 24 Hours of Le Mans
entity	*Entity*, Administrative divisions of Mexico, Administrative division
French leave	*French leave*, French leave (disambiguation), Desertion, French Leave (1930 film)
hunt, hunting	*Huntingdon*, Hunting, Fox hunting, Seal hunting

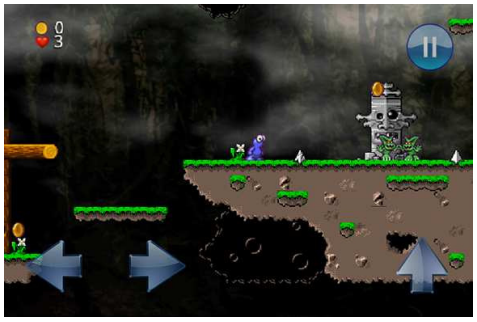

Fig. 1. TGame.

Fig. 2. Checkpoint activation.

We chose Android platform as a test environment due to its popularity and ease of access for users and developers. The game implements standard features like different levels and collectibles (coins, hearts), need of finishing one level before the other one is accessible. The player is encouraged to replay levels by a simple point system that awards the player for killing monster, gathering stars and hearts (Figure 1).

A. Tying questions with the game

One of the biggest challenge is to properly include the mappings (or any type of a general question) into the game. We tried to implement the questions to be as non intrusive as possible but still easy to stumble upon. In TGame the verification of mappings is done when the player wants to activate a checkpoint (a respawn place when player is moved when killed). To activate the checkpoint player needs to answer the question provided by marking the correct mapping (Figure 2). When the answer is identical to the one stored in the database the checkpoint is activated. If the player chose other answer then the checkpoint is not enabled. When the player is certain that he or she selected a correct answer then he or she can report his or her answer using the proper option in the pause menu. The checkpoint is then activated for one use.

From the technical point of view the communication between the client and the server goes as follows. Each client upon first connection downloads pack of configurable number of questions and possible answers so connection to the Internet

is required only at first start of application and later at user chosen intervals. Whenever possible the game sends gathered results with statistical information and downloads new pack of questions (if needed).

B. Answer Verification

The process of reporting wrong answers requires explicit action from the user. It was designed to require some activity but not too much so not to discourage the users. Very easy access to submission would encourage people to skip reading the question and just submitting information about wrong answer. In general the game has to be paused and proper menu have to be selected. Only the last question can be reported.

Furthermore when submitting results also time elapsed between displaying the question and selecting the answer is also submitted. Such extensions allows us to eliminate submissions that i.e. are so short that the user would not be able to read the question. Randomly selected batch of questions required on average 5 seconds to be properly read and understood by players. We decided to discard all answers that took less than 4 seconds (8% of all results).

The answers that the players gave (correct, incorrect and reported) are later compared with the one calculated by Colabmap algorithms. All the selected answers are visible in administrators panel of the server side of the solution and can be exported using csv format to an external tool.

C. Results Analysis

During first two months of tests the game was downloaded by 25 people, mainly students and friends (currently according to Google Play web page there are between 50 and 100 downloads without any additional advertising). The original 25 players gave 626 answers for 100 questions. The game run 10 hours in total on multiple devices. Each player solved 44,42 questions per hour. At this rate, with average playtime of each player at 5 hours, we would need minimum 2500 players to answer each question at least once. Judging by other similar games available on Google Play such number can be achieved with proper advertising of the product given the user base and popularity of mobile games.

During the evaluation of the proposed solution we faced two main type of problems. In some cases the additional answers generated using the Wikipedia search functionality provided very similar pages which introduced difficulty in choosing the correct one. Selection of 100 random questions also introduced problem with high variety of difficulty level among questions. It became obvious that some of them require expert-level knowledge. Examples of questions belonging to those two groups are presented in Table III. The column "Answer 1" contains the correct mapping. Furthermore the type of game implemented (a simple platform game) did not match the questions asked. In future work we will reorganize the questions to Yes/No/Unsure form to lower the difficulty level and implement other type of games to better match the type of mappings that are verified.

TABLE III
SAMPLE QUESTIONS WITH HIGH LEVEL OF DIFFICULTY

The Question	Answer 1	Answer 2	Answer 3	Answer 4
Asiatic nut trees: wing nuts	Pterocarya	Pterocarya fraxinifo-lia	Pterocarya stenoptera	Cyclocarya
a colorless flammable volatile liquid hydrocarbon used as a solvent	Xylene	O-Xylene	P-Xylene	Xylene cyanol
a former large county in northern England	Yorkshire	Yorkshire 6	Yorkshire captaincy affair of 1927	South Yorkshire Fire and Rescue
fine porcelain that contains bone ash	Bone china	Aynsley China	Bisque (pottery)	Porcelain

V. MAPPING UPDATE

We tried three approaches for deciding whether the mapping, based on the answers provided by the players, should be updated or not:

- The mapping was considered correct when 75% of the player answers agreed. This approach however did not give any results as only 50% of original mappings managed to get enough answers, none of the incorrect mappings were marked as correct.
- The mapping was considered correct when at least 50% of player answers agreed. In this case 64% of all mappings were marked as correct which covered 75% of all mappings marked as correct in our database. Unfortunately this method generated some false positives.
- The mapping which gathered the most of the player answers was considered correct. In this case 74% of all mappings were marked as correct witch covered 80% of all mappings originally marked as correct in our database. This method also generates false positives.

Currently in our solution we implemented the third method as it provided the best results. Still this method does not allow us to automatically state whether the given mapping is correct or not. However "problematic" mappings are clearly pointed out by the players (by either majority of wrong answers or reports). Such mappings can than be verified manually by experts. In our further work we plan on extending the procedure with additional parameters like user reputation, level and field of education, history of answers etc. which should improve the level of trust that can be put in user the generated answers.

During the evaluation period the players submitted 17 mappings update requests regarding 12 questions. Sample reports are presented in Table IV. The corrected mappings are emphasized.

TABLE IV
UPDATED MAPPINGS

WordNet Definition	Original mappings	Other available answers
an advanced student or graduate in medicine gaining supervised practical experience ('houseman' is a British term)	Internet Movie Database	Houseman, Julius Houseman, *Internship (medicine)*
large voracious aquatic reptile having a long snout with massive jaws and sharp teeth and a body covered with bony plates	Crocodile tears	*Crocodile*, Crocodylus, Schnappi
(elections) more than half of the votes	Supermajority	*Majority*, Simple majority, Absolute majority

VI. CONCLUSIONS AND FURTHER WORKS

We proposed a platform for verification of the results of heuristic algorithms. Currently verification of mappings is supported. We verified the solution using Wikipedia – WordNet mappings and managed to get some promising results and were able to correct some of the mappings. The problems that still need to be solved include better formulation of the question and the trust that the system can put in answers provided by the users.

We also plan on extending the proposed solution by generalizing it for other type of tasks, inclusion of different clients, not only game based, designed for certain types of questions or with required user knowledge in mind. We are also currently implementing social features like achievements and leader boards that should lure more players and create a wider user base. In case of Wikipedia - WordNet mappings we plan on tagging questions with difficulty levels and include them in a quiz-like game similar to "Fifteen to One"[4] or "1 of 10"[5]). Such type of client could be more suitable for such defined problems. The TGame can be a great application for crowd base image tagging or a client when the questions will be redesigned to a Yes/No format.

Our research shows that popularity of computer games and wide availability of devices that can be used for playing at any time makes GWAPs an approach that has some unexplored potential. Our first implementation, despite its drawback, shows that this potential is relatively easy to unlock. Even for small user base we managed to find some errors in our mappings. Implementation of different client applications more fitting the types of tasks needed to be done (image tagging, sound analysis etc.) and careful question formulation should enable us to fully unlock the possibility of crowdsourcing based task execution. When succeeded such possibility can be of great help to researchers around the world as it reduces resources and time needed to verify the results of designed algorithms and implementations. Furthermore it can be implemented as an alternative to in app purchases or advertisements. This way the users can be provided with content with their work be treated as another means to "pay" for it.

***Abstract*—Context-aware Recommender Systems aim to provide users with the most adequate recommendations for their current situation. However, an exact context obtained from a user could be too specific and may not have enough data for accurate rating prediction. This is known as the data sparsity problem. Moreover, often user preference representation depends on the domain or the specific recommendation approach used. Therefore, a big effort is required to change the method used. In this paper we present a new approach for contextual pre-filtering (i.e. using the current context to select a relevant subset of data). Our approach can be used with existing recommendation algorithms. It is based on two ontologies: Recommender System Context ontology, which represents the context, and Contextual Ontological User Profile ontology, which represents user preferences. We evaluated our approach through an offline study which showed that when used with well-known recommendation algorithms it can significantly improve the accuracy of prediction.**

I. Introduction

RECOMMENDER Systems are software tools and techniques providing suggestions for items to be of use to a user. Various kind of items can be suggested, such as music tracks, movies and news. Context-Aware Recommender Systems (CARS) are a particular category of recommender systems which exploits contextual information to provide more effective recommendations. For example, in a temporal context, vacation recommendations in winter should be very different from those provided in summer. Or a restaurant recommendation for a Saturday evening with your friends should be different from that suggested for a workday lunch with co-workers [1].

We distinguish three forms of context-aware recommendation process: *contextual pre-filtering*, *contextual post-filtering* and *contextual modeling* [2]. *Pre-filtering* approaches use the current context to select a relevant subset of data on which recommendation algorithm is applied. *Post-filtering* approaches exploit contextual information to select only relevant recommendations returned by some algorithm. *Contextual modeling* differs from others techniques as it incorporates the context into recommendation algorithm.

Nowadays context information such as time and location are easy to be obtained with modern devices. However, also other parameters may be considered, such as company (*alone*, *with friends*, *with girlfriend*) which may be relevant when recommending movies or vacations. In addition, the exact context sometimes can be too narrow, as Adomavicius and Tuzhilin [2] exemplified by considering the context of watching a movie with a girlfriend in a movie theater on Saturday. Using this exact context may be problematic for several reasons. First, certain aspects of the overly specific context may not be significant. For example, user's movie watching preferences with a girlfriend in a theater on Saturday may be exactly the same as on Sunday, but different from Wednesday's. Therefore, it may be more appropriate to use a more general context specification, i.e. weekend instead of Saturday. Second, exact context may not have enough data for accurate rating prediction, which is known as the data sparsity problem. Thus it may be useful to refer to a more general context such as watching a movie with a girlfriend in a movie theater on weekend, watching a movie with someone in a movie theater on weekend and so on.

Additionally, often user preferences and items representation depends on the application domain addressed or on the specific recommendation approach used. Thus, a big effort is required to adapt the recommender system to another domain or to change the approach to use.

In this paper, we address the problems previously mentioned and we focus on the following research questions:

- *Is it possible to represent context by combining different dimensions (such as time, location, mood, etc.) and representing different granularities for each dimension (e.g. the precise time moment, the day of the week or the season)?*
- *Is it possible to represent user preferences and items in such a way that can be adapted to different application domains and combined with different recommendation approaches?*

The second author was supported by a fellowship from TIM.

We present a new approach to represent context and user preferences, which is based on two ontologies: Recommender System Context (RSCtx)[1] which represents the context, and another ontology, Contextual Ontological User Profile (COUP), which represents user preferences. RSCtx is an ontology in a classical sense, while COUP is an ontology build according to Structured-Interpretation Model (SIM) [3] and it consists of multiple ontological modules. Moreover, we propose a new ontology-based contextual pre-filtering method which could be used with existing recommendation algorithms.

We evaluated our approach by means of an offline study with a rating prediction task which showed that the usage of proposed ontologies and pre-filtering technique with recommendation algorithms could significantly improve the accuracy of prediction according to the Mean Absolute Error (MAE) measure.

The rest of the paper is organized as follows: Section II presents related work, Section III introduces our ontology to represent the context, while Section IV addresses the overall recommendation approach and the representation of user preferences. We detail the evaluation process and its results in Section V. Conclusions and future work close the paper.

II. Related Work

We distinguish related work in works which addressed representation of context and other ontology based recommender systems proposed. The first is presented in Section II-A while the latter is briefly described in Section II-B.

A. Context Representation

In this section, firstly we address ontology-based context modeling and then we review context representation for recommender systems.

Many context ontologies have been proposed in the context awareness community. There are a number of surveys which review the literature relevant to context modeling in general [4], [5] or focusing on ontology-based models [6], [7]. In addition, Costabello [8] presented and compared a number of ontology-based context models against a set of requirements. This requirements fit also for our purpose therefore in the following we present the requirements and summarize Costabello's comparison, obviously also considering RSCtx.

The relevant context aware and ontology engineering requirements are:

R1. Domain independence. A number of context ontologies have been created to model a given domain-specific scenario. Others adopt a domain-independent approach.

R2. Coverage. The ontology must guarantee a proper level of completeness for what concerns the desired contextual dimensions. In particular, the model must support multiple context dimensions such as device features, user preferences, location and time.

R3. Formality. Some ontology-based context models rely on formal definitions, while others adopt a more intuitive approach.

R4. Variable Context Granularity. Certain ontologies model context dimensions at different level of granularity. For example, location might be expressed in terms of latitude and longitude, or with a label assigned to a place (e.g. office, beach, cinema, etc.).

R5. User Friendliness Evaluation. Context-aware application developers must spend a reasonable amount of effort dealing with the context model, thus the ontology must be sufficiently easy to adopt and well documented. The presence of a user evaluation campaign to assess such feature is assessed by certain context models.

R6. Core ontology approach. The vocabulary must adopt a modular design, thus focusing on modeling core classes and properties that will be extended by third-party domain specialists.

Linked Data[2] is a set of best practice to publish structured data on the Web. The set of data, vocabularies and ontologies which follows these practices made up the Web of Data. Costabello [8] considered also a number of requirements related to the Linked Data principles, which also fit for our purpose:

R7. Open World Assumption. The Web of Data is an open environment, and describing context in this scenario must consider third-party extensions unknown beforehand. Extensibility must be obtained with a low effort, thus add-ons must not impact on the already existing model.

R8. Lightweight Ontology. According to Linked Data best practices [9], the goal is to keep ontologies small and simple.

R9. Reuse of Existing Terms. Linked Data best practices favor the reuse and the combination of classes and properties of existing vocabularies. This is done to prevent the proliferation of terms and reduce the range of choices when modeling data.

R10. Availability on the Web. Web of Data vocabularies are published on the Web, and accessible according to Web of Data best practices. Moreover, they are associated to an HTML page, the "namespace document", whose task is to provide a textual description of the vocabulary rationale, along with classes and properties explanation and examples.

Following these requirements, Costabello [8] compared a number of ontologies which modeled context and proposed PRISSMA[5], a vocabulary designed to model client generated context data. We present in the following the main feature of this vocabulary and other related works showed in Table I. PRISSMA satisfies the most of the aforementioned requirements, although *variable context granularity* only partially. It miss formality and user friendliness evaluation, but none of the other works satisfies these two. On the contrary, all

the works provide coverage and are domain independent, and all but one support (at least partially) the open world assumption. The only other ontology published on the Web is the Delivery Context Ontology (DCO)[6], a modular and fine-grained vocabulary to model mobile platforms. It does not provide linking with other vocabulary, thus it is not considered a lightweight ontology. The SOUPA ontology [10] is an OWL ontology which is extensible, i.e. support the open world assumption, and reuses external ontologies, but it does not comply with Linked Data principles, for example it is not publicly available on the Web. CoOL [11] is a modular OWL ontology, which is grounded on F-Logic and uses features typically avoided in lightweight ontology. CONON [12] is another modular OWL ontologies, which is not published on the Web and does not reuse existing vocabularies. CoDaMos [13] is an extensible OWL ontology that is available on the Web but no namespace vocabulary is present. It is not lightweight and does not reuse other vocabularies. Korpipää et al. [14] present a context model designed for mobile, context-aware applications. It is general, but does not reuse existing terms and it is not extensible. Hervás and Bravo [15] propose a modular context model composed by independent ontologies which support extensions, although they do not reuse already existing linked data ontologies.

Various works addressed context representation for recommender systems. Abowd et al. [16] distinguish among primary and secondary context: the first can be directly measured, while the second not and needs to be derived from other types of contextual information. Kaminskas and Ricci [17] reviewed literature about contextual music retrieval. They distinguish among environmental, user-related and multimedia context: the first refers to information about the location of the user, the current time, weather, temperature, etc.; the second to information about the activity of the user, the user's demographic information, emotional state; and the third to other types of information the user is exposed to besides music, e.g., text and images. In addition to traditional dimensions (time location etc.) the authors suggested traffic, noise and light level. As multimedia context, they mention text and images. They indicated some cases in which it can be useful consider this kind of context, e.g. for adapting music to text context as done by Cai et al. [18]. Baltraunas et al. [19] proposed an approach to assess which contextual factors are important and to which degree they influence user ratings. They conducted a study in which users where asked to judge whether a contextual factor influences the rating given a certain contextual condition. In their survey they focus on tourism domain and consider budget, time availability, transport in addition to traditional dimensions. RSCtx supports most of the addressed dimensions and distinguish among user-related and environmental context. It does not address multimedia context, but it considers the device features.

B. Ontology based Recommender System

It has been proved that ontological user profile improves recommendation accuracy and diversity [20]. More specifically, a number of ontology-based and context-aware recommender system have been proposed. AMAYA allows management of contextual preferences and contextual recommendations [21]. AMAYA also uses an ontology-based content categorization scheme to map user preferences to entities to recommend. News@hand [22] is an hybrid personalized and context aware recommender system, which retrieves news via RSS feed and annotates by using system domain ontologies. User context is represented by a weighted set of classes from the domain ontology. Rodriguez et al. [23] proposed a CARS which recommens Web services. They use a multi-dimensional ontology model to describe Web services, a user context and an application domain. The multi-dimensional ontology model consists of a three independent ontologies: a user context ontology, a Web service ontology and an application domain ontology, which are combined into one ontology by some properties between classes from different ontologies. The recommendation process consists in assigning a weight to the items based on a list of interests in the user ontology. All this works focus on a specific domain and an ad-hoc algorithm, while our approach for representing user preferences is cross-domain and can be applied to different recommendation algorithm.

Hawalah and Fasli [24] suggest that each context dimension should be described by its own taxonomy. Time, date, location and device are considered as default context parameters in the movie domain. It is possible to add other domain specific context variables as long as they have a clear hierarchical

representations. Besides context taxonomies, this approaches uses a reference ontology to build contextual personalized ontological profiles. The key feature of this profile is the possibility of assigning user interests in groups, if these interests are directly associated with each other by a direct relation, sharing the same super-class, or sharing the same property.

Other works uses ontologies and taxonomy to improve the quality of recommendations. Middleton et al. [25] uses an ontological user profile to recommend research papers. Both research papers and user profiles are represented through a taxonomy of topics and the recommendation are generated considering topics of interest for the user and papers classified in those topics. Mobasher et al. [26] proposed a measure which combines semantic knowledge about items and user-item rating, while Anand et al. [27] inferred user preferences from rating data using an item ontology. Their approach recommends the items using the ontology and inferred preferences while computing similarities. A more detailed description of ontology based techniques is available in [28] and [29].

III. The Recommender System Context Ontology

Recommender System Context (RSCtx) extends PRISSMA[7], a vocabulary based on Dey's definition of context [30]. PRISSMA relies on the W3C Model-Based User Interface Incubator Group proposal[8], which describes mobile context as an encompassing term, defined as the sum of three different dimensions: user model and preferences, device features, and the environment in which the action is performed. A graph-based representation of PRISSMA is provided Figure 1.

We designed RSCtx following METHONTOLOGY [31], a well know ontology design method. We assumed there is a predefined set of contextual dimensions in a given application, each with a defined set of attributes and we modeled the contextual information relevant to provide recommendations. We did not focus on any particular domain, on the contrary we aimed at reusing the ontology in different applications. As in PRISSMA, the point of view used to describe the context itself is the application point of view, thus we considered, the user itself as part of the context.

We needed a more detailed representation of the environment, in order to consider other contextual dimensions such as the purpose of the user and the weather. Figure 2 shows how `prissma:Environment` has been extended, by adding a number of properties and related concepts. To represent the weather we integrate `hw:WeatherState` from the Weather Ontology[9]. In this ontology the temperature is represented with respect to the room temperature, thus we defined a new class to represent symbolic values of temperature (such as warm, cold, etc.) and an attribute to represent numeric values, as show in Figure 3.

[9]https://www.auto.tuwien.ac.at/downloads/thinkhome/ontology/WeatherOntology.owl

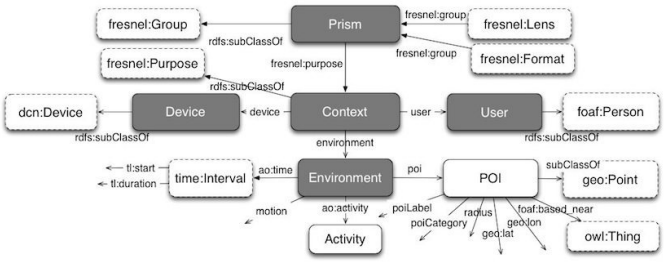

Fig. 1. The PRISSMA vocabulary [8].

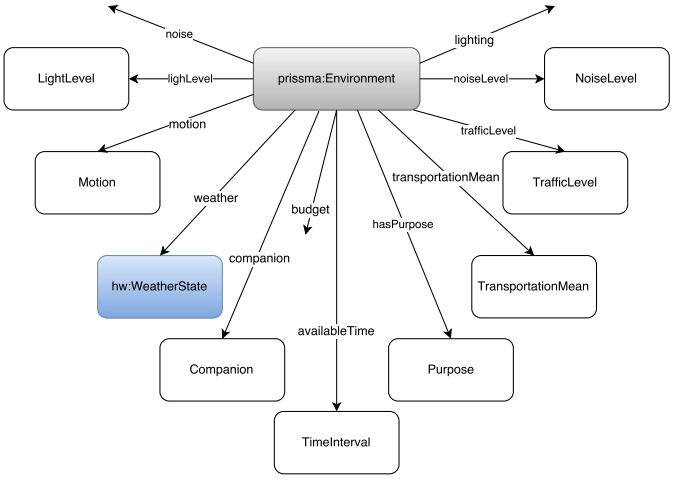

Fig. 2. Relations and concepts which extend `prissma:Environment`

We also extended the time and location representations. We needed a more expressive model of these two dimensions, since asking for recommendations which have the same time stamp and the coordinates of the actual context is too restrictive and the recommender system may not have enough data. On the contrary, by generalizing the context (for example distinguishing among weekend and working day, or considering the city or neighborhood instead of the actual user position) may enable the recommender system to provide recommendations. The concept `prissma:POI` has been extended with various properties to represent the location in the context of a specific site by integrating the Buildings and Rooms vocabulary[10]. Furthermore, other properties related to the hierarchical organization of the location (such as the neighborhood, the city and the province of the current user position) have been added and some concepts from the Juso ontology[11] have been reused. Figure 4 depicts relations and attributes which characterize a location. Yellow rectangles indicate concepts from rooms vocabulary, while blue ones are taken from Juso. The representation of time augments `time:Instant` defined in the Time ontology[12]. Some time intervals have been defined: the hours and the parts of day

[10]http://vocab.deri.ie/rooms

[11]rdfs.co/juso/latest/html

[12]https://www.w3.org/2006/time

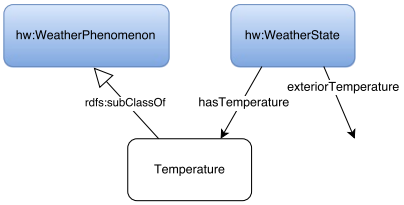

Fig. 3. Temperature representation in our ontology.

(morning, afternoon, etc.). In addition, days of week are classified in weekdays or weekend and seasons are represented. Figure 5 illustrates how time is represented and the relations with PRISSMA and the Time ontology.

Furthermore, we extended the user representation adding some dimensions which may be of interest, as the emotional, mental and physiological state of the user or his fitness. This can be interesting mainly in the medical or fitness domain, but emotional state can affect the user also in taking other kind of decisions, like choosing a movie to watch or music to listen to. Emotional, mental and physiological state concepts are equivalent to emotional, mental and physiological state in the General User Model Ontology (GUMO) [32], an ontology to describe the user which is available on the Web, although it is not compliant with Linked Data principles since it has not a namespace assigned. In addition, the emotional state is an extension of `emoca:Emotion`, which is defined in the Emotion Ontology for Context Awareness (EmOCA)[13]. We added some attributes to the physiological state and also defined an arousal relation which reuse `emoca:Arousal`. Figure 6 depicts the user representation in our ontology.

The emotion in EmOCA are represented according to Russel's model [33]. We extended `emoca:Emotion`, in particular we added pleasure and dominance as subclasses of `emoca:Component` in order to represent emotions according to the Pleasure Arousal Dominance (PAD) model [34] as well, as it is showed in Figure 7. In this way, we can indicate that the emotion is defined by valence and arousal by means of `emoca:isDefinedBy` to refer to Russel's model, while we can indicate that the emotion is defined by pleasure, arousal and dominance to refer to the PAD model. Furthermore, in psychology it is possible to refer to emotion just by indicating its category (such as joy, anger, disgust, etc.). In EmOCA, six categories have been already defined, which can be used also in RSCtx since the emotional state is a subclass of `emoca:Emotion`. We can add more categories in our ontology if it will be needed, although at the moment it has not been done.

IV. Recommendation Approach

A. Contextual User Profile Ontology

To model user profiles we used the Structured-Interpretation Model (SIM) [35], [36], which consists of two types of ontological modules, i.e. *context types* and *context instances*. Context types describe the terminological part of an ontology (TBox) and are arranged in hierarchy of inheritance. Context instances describe assertional part of an ontology (ABox) and are connected with corresponding context types through a relation of instantiation. There is another kind of relation, i.e. aggregation, which links context instances of more specific context types to a context instance of a more general context type. In the class hierarchy in a classical ontology there always exists a top concept, i.e. `Thing`. In SIM ontology there is a top context type and a top context instance connected by instantiation. It is possible to add multiple context instances to one context type and aggregate multiple context instances into one context instance. The idea of SIM is shown in Figure 8.

The idea of adaptation SIM ontology as a user profile was proposed by Karpus and Goczyła [37]. They modeled contextual user profiles using only three context variables, i.e. location, time and mood, which influences a split of terminology into ontological modules. Our approach is different in some crucial aspects. First of all, we allow storage of many user profiles in one SIM ontology. We also support a storage of preferences from multiple domains by adding context types related to different domains. Another difference is the number of context variables permitted. We add context types and context instances related to contextual parameters in a dynamic way. As a consequence, we can use as many variables as needed in our approach. An example of contextual profile for one user is shown in Figure 9.

Only three modules in the example illustrated in Figure 9 are fixed: `topContextType`, `topContextInstance` and `UserType`. All others are configurable or can be added in a dynamic way. In `topContextType` we defined the concept `Rating` and its corresponding roles, e.g. `isRatedWith` and `hasValue`. `UserType` is artificial and is present in the SIM ontology because it enable to add many user profiles to the ontology. In the next level of the hierarchy, there are context types that describe domains of interests related to a recommender system which will use the profile. In the next levels, all context types and instances are added to the contextual user profile during the learning phase or later, when a new context situation occurs.

The general process of learning the user profile is as follows. At the beginning there is just the RSCtx ontology and an empty contextual ontology, i.e. with terminological part only. For a given user, an item is taken with the rating and the situation in which it was consumed from the user's history. The level of granularity of the context is checked with the RSCtx ontology and is changed if needed, e.g. shifting from *time = 2 p.m.* to *time = afternoon*. A context instance is created for this context, if it is not already available. Finally, an item with its rating is added to the identified context instance. Each item is represented as a set of individuals of appropriate concepts defined in a domain context type.

B. Recommendation

We use the ontologies previously presented for pre-filtering in the recommendation process. The aim is to provide a

[13]http://ns.inria.fr/emoca/

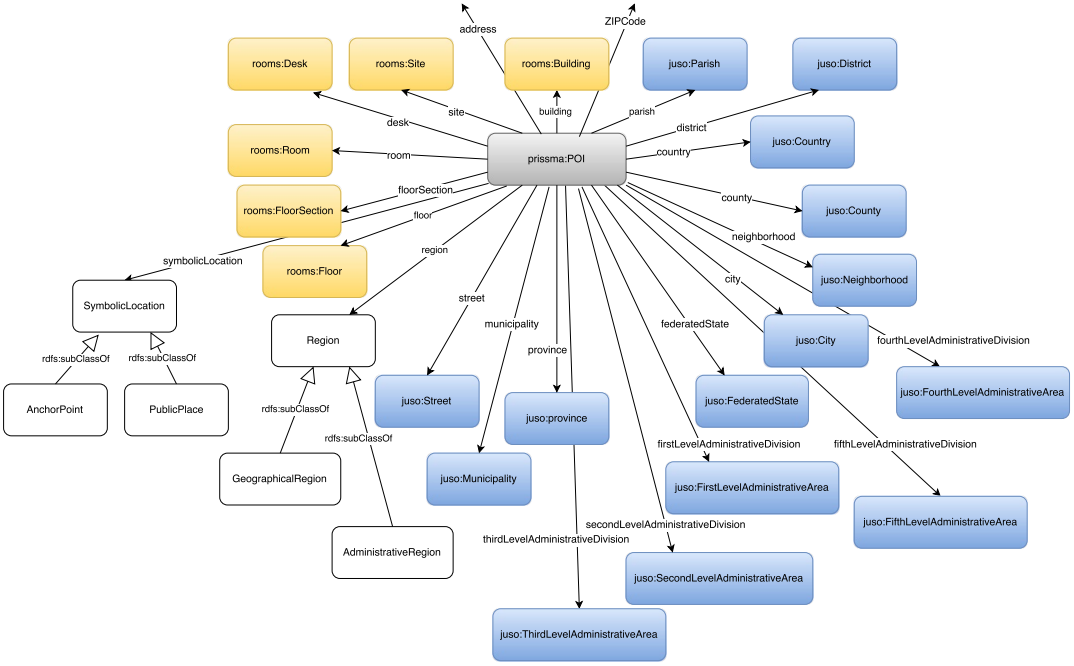

Fig. 4. Concepts and relations of RSCtx representing the location dimension.

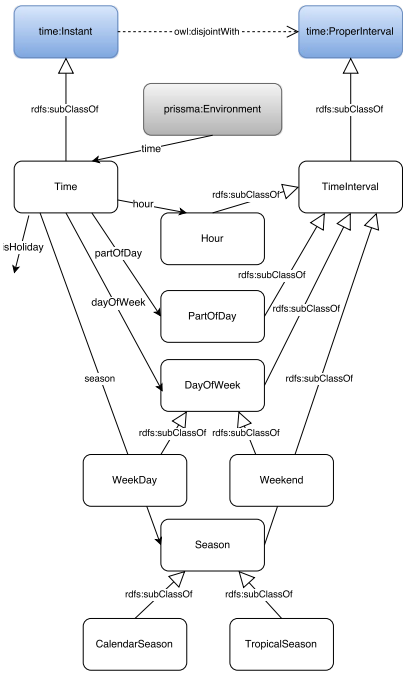

Fig. 5. Time representation in RSCtx ontology as extension of Time and PRISSMA ontologies

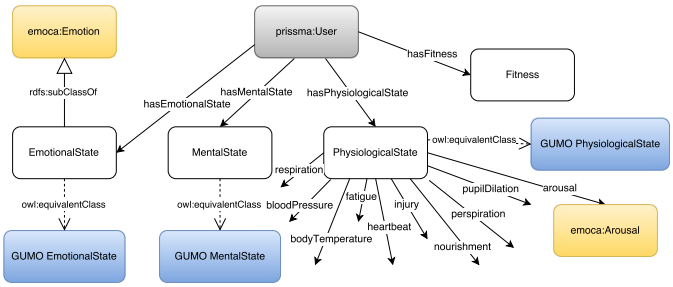

Fig. 6. User representation in RSCtx ontology.

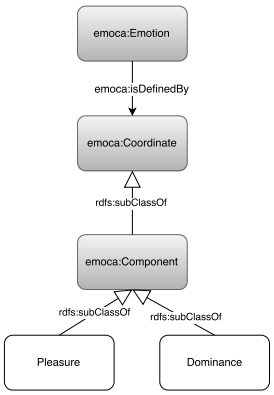

Fig. 7. Emotion representation in RSCtx ontology.

universal context-aware improvement for existing algorithms.

The system consists of three main functional parts: context detection and generalization, user profile and pre-filtering, and recommendation. In the first part, we used the RSCtx ontology to identify the user context from raw data and generalize it in the desired granularity level . The second part is responsible for building user profile, finding a context instance that fits the actual user context, and returning only relevant user

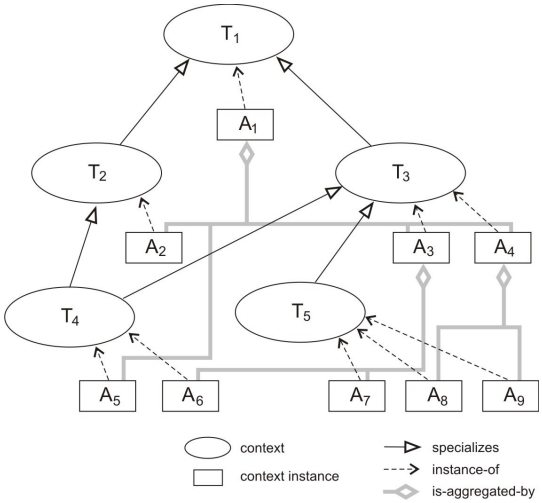

Fig. 8. Structured-Interpretation Model [3]

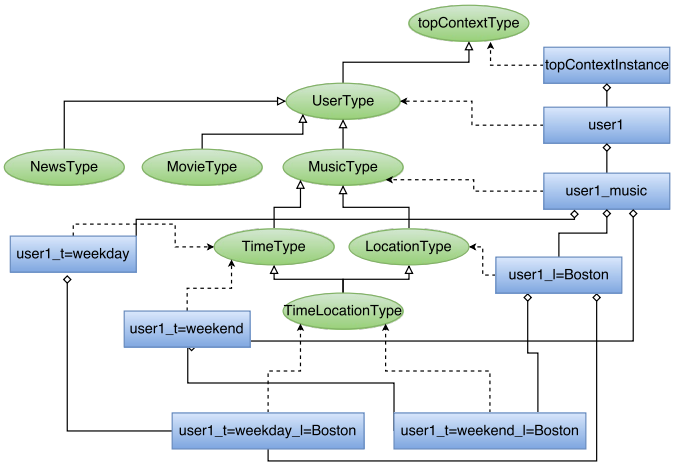

Fig. 9. An example of COUP

preferences. The last part uses well-know algorithms, e.g. Item kNN, User Average, SVD++, for providing recommendations. For this task we exploit implementations from the LibRec[14] library.

The general recommendation process is as follows. Given a user and his current situation, a proper generalization of his context is generated by using the RSCtx ontology. Then, an appropriate context instance from COUP is identified by using the generalized context. If a context instance is not found in the user profile, the generalization step is repeated to search for a module that corresponds to the new context. If it is found, user preferences are prepared to be used with a recommendation algorithm.

V. Evaluation

We conducted an offline study in order to evaluate the RSCtx ontology and the COUP ontology. We selected a number of algorithms and we compared the accuracy of each algorithm when used as is and when combined with proposed ontologies. We aimed to answer the following question: *does our context and user preferences representation improve accuracy of recommendation algorithms?*

We relied on ConcertTweets dataset [38], which combines implicit and explicit user ratings with rich content as well as spatio-temporal contextual dimensions and social network data. It contains ratings that refer to musical shows and concerts of various artists and bands. Since the dataset was generated automatically, there were some duplicated events, for example the same concert was occurring twice, once with country *United Kingdom* and once *UK*. We fixed this kind of situations. Another problem with the dataset is the usage of two rating scales: one numerical scale with ratings in the range [0.0, 5.0] and one descriptive scale with possible values equal to *yes*, *maybe* and *no*, although *no* never occurred. We decided to split the dataset into two separate sets according to the scale type and we mapped the descriptive values *yes*, *maybe* and *no* with the numerical values 2, 1 and 0. Table II presents some statistics about the data by considering the whole dataset and each of the sets generated when splitting by scale type. We prepared two pairs (one for each scale) of training and test sets for hold-out validation. In the test set we put 20% of the newest ratings of each user. All other ratings were placed in the training set. The split was performed based on rating timestamp value.

Because of the dataset domain, we needed to add to contextual user profile a new *context type*, `MusicType`. For this purpose we reused two existing ontologies related to music, i.e. `musicbrainz`[15] and `music vocabulary`[16]. We used their terminological parts only. Any item can be represented as a pair of individuals of type `mb:Artist` and `m:Musical_Event` and with their corresponding properties.

Our approach is a pre-filtering approach and can be used with existing recommendation methods. We evaluated the ontologies with five algorithms: Random Guess, Item kNN, User Average, SVD++ and Time SVD++. We compared the results of first four algorithms without pre-filtering and with pre-filtering, while the fifth was executed without pre-filtering only, because it already contains the *time* as a contextual factor [39]. We used it as a baseline for comparing our contextual pre-filtering technique combined with SVD++ algorithm.

We performed an experiment for rating prediction task and measured accuracy with MAE. Results are presented in Table III and Figures 10 and 11. It should be noticed that without pre-filtering, the User Average algorithm outperforms SVD++. This may be due to the way in which users rate musical events: it may be possible that they do not use the whole rating scale but just a part of it, e.g. a user evaluates only those events that he likes (his ratings are always greater that 3.0). As it can be seen in Figure 10 and Table III, when our ontological pre-filtering approach is applied, results on the *numerical scale*

Number of ratings	250000	219967	30033
Maximum number of ratings per user	1423	1419	92
Minimum number of ratings per user	1	1	1
Average number of ratings per user	4.045	3.892	1.823
Maximum number of ratings per item	218	216	38
Minimum number of ratings per item	1	1	1
Average number of ratings per item	2.149	1.996	1.406
Number of users who ranked at least 5 items	13241	11548	962
Number of users who ranked at least 10 items	5369	4639	190
Number of users who ranked at least 50 items	289	244	4
Number of users who ranked at least 100 items	66	54	0
Sparsity	0.999971	0.999970	0.999922

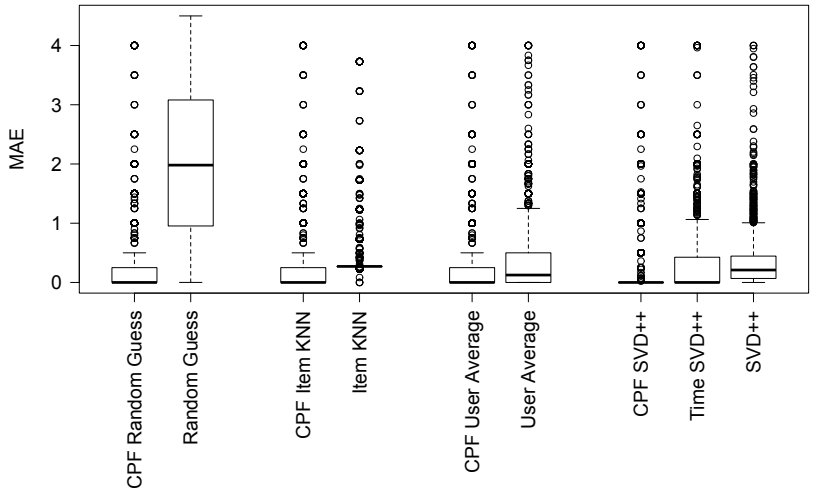

Fig. 10. Boxplots of MAE values of different algorithms computed per user on subset with numeric ratings

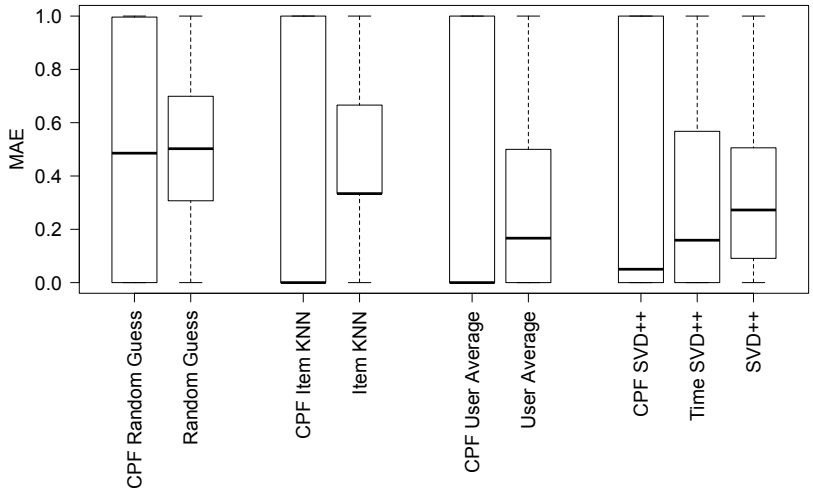

Fig. 11. Boxplots of MAE values of different algorithms computed per user on subset with descriptive ratings

TABLE III
MAE VALUES COMPUTED FOR WHOLE TEST SETS

	Numeric ratings		Descriptive Ratings	
Contextual pre-filtering	**YES**	**NO**	**YES**	**NO**
Random Guess	0.2315	2.0998	0.4694	0.4989
User Average	0.2312	0.3026	0.3624	0.2570
Item kNN	0.2312	0.3976	0.3624	0.4374
SVD++	0.2514	0.3511	0.3621	0.3101
Time SVD++	NA	0.2693	NA	0.2975

subset are better. Our contextual pre-filtering combined with classical SVD++ performs better than Time SVD++. There could be two reasons for this behavior. First, the usage of more contextual parameters than just one, the time, gives more improvement to prediction accuracy. Second, our approach (even if used with time parameter only) with SVD++ is truly better than Time SVD++ algorithm. This should be addressed in further work.

From Figure 11 we see that a median value for our approach is improved for all algorithms but the overall MAE value for *descriptive scale* subset is worst for all of the cases. This suggest that in the case of binary scale (*yes*/*maybe*) contextual pre-filtering may increase the sparsity and noisiness of the data. Thus, the recommendation algorithm may not always predict the rating. However, the difference between results for two subsets could be caused not by wrong pre-filtering method but by psychological differences between *a priori* and *a posteriori* evaluation by a user. It is more reliable when a user evaluates an item after he consumed it than when he declares what he would do or prefer. This could lead us to conclusion that this approach could be successfully applied in recommender systems where numeric scale is used to rate items in *a posteriori* way. Currently, we have not identified any other limitations for applying proposed contextual pre-filtering approach.

To check the statistical significance of the results, we applied Wilcoxon test with *p-value* 0.01. We chose this statistical test because we cannot guarantee the normal distribution of obtained results. The test confirmed the statistical significance of our results.

VI. CONCLUSIONS AND FUTURE WORK

In this paper we presented a new approach for contextual pre-filtering in Recommender Systems. It is based on two ontologies: Recommender System Context (RSCtx), which represents the context, and Contextual Ontological User Profile (COUP), which represents user preferences. RSCtx extends PRISSMA and represents different context dimensions on different granularity levels. COUP was modeled according to SIM approach for modularization. Different users' parts of profile are represented in different ontological module. This allows us to: (I) store multiple users in one ontology, (II) clearly distinguishing user preferences from different domains, but keeping all the user preferences together, and (III) split user interests from one domain into "micro profiles" related to some contextual situation without loosing the possibility to reason on different level of context granularity.

We successfully applied RSCtx for context identification and generalization tasks, showing that it is possible to represent context by combining different dimensions and representing different granularities for each dimension. We used COUP for representing user preferences in different context in the domain of musical events and for obtaining user data relevant to his current context for rating prediction task with baseline algorithms. This offline study showed that the usage of proposed ontologies with recommendation algorithms could significantly improve the accuracy of prediction according to MAE measure. This confirmed part of the second research question, i.e. that it is possible to represent user preferences and items in such a way that can be combined with different recommendation approaches. The next step in our research is proving that we can adapt our user representation for different domains.

As future work, we plan to extend our experiment to ranking task as well as to investigate on the influence of the proposed approach on diversity and novelty of recommendations.
