***Abstract*—This paper presents and evaluates different computational models for review rating prediction. The models rely solely on star ratings from an annotated corpus of customer reviews of mobile apps that were collected from the Google Play Store in a related work. Fine-granular opinions and the classification of their sentiment orientation were already available. The models build upon them to make predictions based on their polarity. Predicting star ratings is of importance to the sentiment analysis community because it can better be understood how customers subjectively rate products. Rating them consistently with corresponding written reviews, however, remains a difficult task for automated predictors. This paper sheds new light in that direction.**

***Index Terms*—Mobile apps, review rating prediction, semantic sentiment analysis.**

I. Introduction

MOBILE app star ratings and reviews drive apps' rankings, downloads, updates, and in-app purchases. That is what a study from Apptentive has found after surveying smartphone owners and after analysing "historical data from delivering over 160 million interactions and ratings prompts" [1]. According to the study, both star ratings and reviews strongly influence not only the success of mobile apps but also the consumers' engagement with them.

The analysis and interpretation of mobile app star ratings and reviews are not straightforward tasks, however. Monitoring star ratings and reviews is expensive, difficult to accomplish, laborious, and error-prone [2]; many of the ratings and reviews are biased (e.g. app users are more likely to leave ratings or reviews after a negative experience with the app [1]); reviews are in general short and often use abbreviations, emoticons, and informal language; and even star ratings are sometimes unrelated to the experiences with the app itself (e.g. [3] analyses how people give poor ratings just because they are asked to rate the app, explicitly).

Star ratings and reviews are extremely important for brands, for example, for improving their products based on customers' feedback. Ratings also matter for marketing purposes and companies' reputation: it is not only crucial that a top app is highly rated but also that it has at least four stars and many ratings. According to Walz [4], 88% of top-100 Android apps (51% of top-100 iOS apps) have a rating greater than four stars, and the average top-100 Android app (top-100 iOS app) has 3.1 million (196 thousand) ratings.[1] But how to predict or to influence users' star ratings?

Star ratings and reviews are also crucial for customers and their future behaviour when using and recommending the apps. If new customers trust an app's ratings and reviews, then they are more willing to download the app and to benefit from its functionality, e.g. to buy products easily, or to connect and communicate instantly with others, or to simplify daily activities at the office, to name a few benefits. If their experiences with the app are positive, then they would recommend it further and even give feedback to the company for improvements to the app: a win-win situation. Although customers and companies value feedback differently [5], it is true that not only star ratings but also the reviews' content play an important role for both parts.

However, could we *teach* users how to rate apps *consistently* with the review they are writing for a mobile app? For example, would it be possible to improve recommendation accuracy by suggesting to users the most adequate star rating they should give to a product depending on the semantic orientation of what they have already written in the review? How does it compare to previously reviewed mobile apps? Would an improvement in the accuracy also mean an improvement of users' engagement and satisfaction with the apps?

The remaining sections of this paper continue as follows: Section II introduces both the task of review rating prediction and related work in this area. A corpus of annotated reviews of mobile apps from different domains that is used for analysis is presented in Section III. Computational models that are proposed to predict star ratings based on the annotated reviews of the corpus are topic of Section IV. These models are analysed and evaluated in several experimental settings that are defined in Section V. Finally, results are discussed before the conclusions of the paper are presented together with some ideas for further work.

II. Related Work

The prediction of star ratings (e.g., ratings ranging from 1 to 5 stars) has been the focus of many academic and business applications to date. In particular, *review rating prediction*,

[1]Figures from June 2015.

also known as *sentiment rating prediction*, is a task that deals with the inference of an author's implied numerical rating, i.e. on the prediction of a rating score, from a given written review [6], [7]. Recommendation systems, for instance, often suggest products based on star ratings of similar products previously rated by other users.

Yet analysing a textual review is a much more difficult task than guessing the rating by only considering other available numerical scores. This is why not only classifying sentiment [8], [9] but also predicting rating scores has captured the attention of the sentiment analysis community in the last few years. For example, Pang and Lee apply classification and regression, supervised learning techniques to rate movie reviews [10], and Goldberg and Zhu extend their approach by applying a graph-based semi-supervised learning algorithm that achieves better performance [11]. Tang and co-authors follow a similar approach [12], and present a neural network-based method that considers not only the review texts but also author information. They claim that their method "performs better than several strong baseline methods which only use textual semantics." Li and co-authors go beyond the review texts and their authors, and add information also about the product that is reviewed, by modelling all three features using a three-dimensional tensor [13]. Then, they apply tensor factorisation techniques and optimise their model using gradient descent. Their results outperform other similar approaches. Furthermore, Qu et al. introduce the *bag-of-opinions* representation for which their method learns rating scores from domain-independent corpora using constrained ridge regression [14].

Zhang and co-authors delve deeper into the polarity[2] of a review by stating that "it might not be appropriate to use overall ratings as ground-truth to label the sentiment orientations of review texts, as users tend to act differently when making overall ratings and expressing their true feelings on detailed product aspects or features" [15]. This means that rating predictors should consider the subtle differences between review texts as a whole, and reviews of individual aspects. [16] and [17] come to the same conclusions, and affirm that textually derived ratings are better predictors than numerical star ratings. In their experiments, Zhang and co-authors first let three annotators manually label the polarity orientation of sample reviews from a restaurant dataset and then compare them against automatically generated annotations using unsupervised review-level sentiment classification [15]. Afterwards, the annotators label not reviews as a whole but their aspects or features individually. Again, the results are compared to those obtained with the methods the authors propose, showing the inconsistency between textual reviews and numerical ratings when the latter do not consider phrase-level sentiment polarity.

Gupta and co-authors also apply supervised learning with a multi-aspect rating prediction for textual reviews of restaurants [18]. They consider numerical ratings for aspects like food, service, and overall experience, inter alia, as well as considering the interdependence of aspects for around eight sentences per review on average. Orimaye and co-authors introduce a sentence-level polarity correction [19]. Their technique identifies sentences with inconsistent polarities that are handled as outliers and, as such, are discarded from the reviews. This approach might not be convenient for mobile app reviews, where the length of subjective phrases might be about two words long on average, and the reviews are not long enough either [20]. Discarding information in the case of mobile apps would introduce an extra bias to the problem.

Sänger [20] introduces an aspect-based opinion mining of mobile apps ratings that extends Klinger and Cimiano's work [21], [22]. According to Sänger, Klinger and Cimiano's approach was chosen because it deals with fine-granular aspect-based opinion mining, its implementation is open-sourced (see https://bitbucket.org/rklinger/jfsa), and it is suitable for mining text written in German, as is the case of the dataset he uses (see next section). Sänger concludes that such a technique is also appropriate for analysing mobile app reviews; he both adapts and validates Klinger and Cimiano's work for such reviews.

Sänger's approach serves as the background to, and the basis for, the work presented here. It is worth mentioning, however, that the goal of the work presented in this paper *is not* to deal with aspect identification nor with sentiment classification; but assuming that these tasks are performed *before* the star ratings are predicted. A complement to Sänger's work, in other words. Thus, *unlike* other approaches that identify aspects or classify sentiment at a fine-granular level, like most of the works reviewed above (e.g. [10]–[12], [17], [21], to cite but a few), the idea of our approach is to provide a method for predicting star ratings based *solely* on available annotated, fine-granular opinions.

The next section introduces the dataset that is used for analysis and validation.

III. Corpus of Annotated Customer Reviews

The annotated corpus used here was initially provided by Sänger as constructed in [20], later named *SCARE* as introduced in [23]. It consists of 1,760 randomly selected, annotated reviews for a total of 130 mobile apps from different domains. The annotations consider fine-granular opinions as well as the app aspects and their relationships. Each textual review includes a customer evaluation of the app, and has an associated rating. All textual reviews are in German. Each evaluation consists of at least one phrase. There is a total of 6,446 phrases from which 3,959 are manually annotated subjective phrases. The corpus contains a total of 2,487 aspects.

Sänger claims that his mobile app dataset is the first of its kind. It comprises a total of 802,860 reviews in German of 148 mobile apps from 11 different categories, the annotated corpus introduced above being a subset of it. The reviews were collected from the Google Play Store (see https://play.google.

[2]See next section for more on polarity.

com/store) using an open-source API for the Android Market (see https://code.google.com/archive/p/android-market-api/).

Specifically, the annotated corpus that is used here contains the following information, which follows the structure presented in [24]:

all.data A list of all reviews as retrieved through the Android Market API, including the app's name, the full review text, and the star rating given by the user.

all.txt A list of all review texts as they were used in the annotation process (the review title and its content are concatenated).

all.csv A list of all annotated subjective phrases and aspects, each subjective phrase with an internal ID, its corresponding ID, and its polarity.

all.rel A list of all annotated relations between the subjective phrases and their aspects.

Figure 1 shows all major steps of the prediction process that makes use of the annotated corpus. It starts by *parsing* the lists introduced above and by creating workspace variables with which to work.

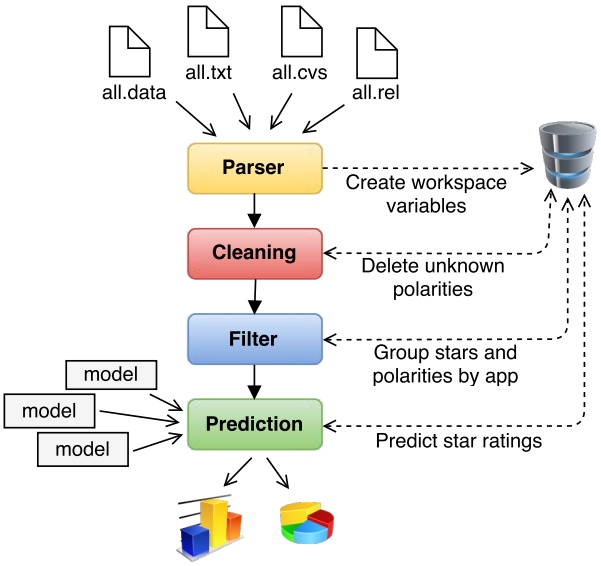

Fig. 1 Prediction process.

The polarity of a phrase depends on the expressed opinion, and thus on the semantic orientation or *sentiment* of the phrase, i.e., whether the expressed opinion of the opinion holder[3] is positive, negative, or neutral [7]. Since a review might have more than one phrase, calculating the polarity of the review would depend on the polarities of its phrases. In particular, mobile app reviews are much shorter than other product reviews, use language constructs that are similar to those used in micro-blogging (e.g., Twitter), have unstructured sentences in general, and often use more concise words [20].

According to Sänger [20], the subjective phrases were annotated and their polarity determined following a rigorous process that comprised the development of annotation guidelines, the explicit training of four annotators on these guidelines, the annotation of random phrases in iterative rounds, as well as a later controlling and improvement of the performed annotations. The final version of the annotations during the training process achieved a substantial inter-annotator agreement with a kappa value $\kappa = 0.72$, computed using the Fleiss' kappa measure (see Chapter 3 in [20] for more). Then, the actual annotations to be considered for the corpus were carried out.

It is worth mentioning that the polarity of type *unknown* was handled as a default value in the tool that was used for annotating the corpus (see http://brat.nlplab.org/). According to Sänger [25], this relates to reviews where the annotators forgot to specify the polarities. Because the phrase polarity was not of further interest in his work, there was no need to correct that issue. Thus, unknown sentiments are not considered for the experiments that will be introduced in succeeding sections: they are deleted from the corpus in a *cleaning* procedure (see Figure 1).

After cleaning the unknown polarities out, the new annotated corpus consists of 1,751 reviews, 130 apps, 6,398 phrases, and 3,927 subjective phrases. Table I shows the distribution of all phrases from the corpus according to their polarity, before and after the cleaning process has taken place. Almost two thirds of the subjective phrases express a positive opinion, and about one-third have a negative polarity.

TABLE I
POLARITY DISTRIBUTION OF ANNOTATED SUBJECTIVE PHRASES.

	Before cleaning		**After cleaning**	
Polarity	Annotated phrases	%	Annotated phrases	%
positive	2,463	62.2	2,458	62.6
negative	1,433	36.2	1,416	36.1
neutral	53	0.01	53	1.3
unknown	10	0.002	–	–

The star ratings associated with the entries from the corpus, i.e., to the annotated mobile apps reviews, after the cleaning process are summarised in Table II.

TABLE II
DISTRIBUTION OF STAR RATINGS.

Star rating	No. of annotated reviews	%
1	295	16.8
2	111	6.3
3	136	7.8
4	299	17.1
5	910	52.0

If reviews with 4-5 stars are considered positive reviews and those with 1-2 stars are considered negative reviews (the *thumbs-up-thumbs-down* approach suggested by Liu in [7]), then over two-thirds of the reviews from the annotated corpus have a positive polarity (69.1%) and only about one out of four reviews is negative (23.1%). Compared to the

[3]The person that holds the opinion [9]. Also, opinion source.

subjective phrases polarities from Table I, these are slightly smaller values (62.6% positive polarity). This means that the expressed opinions from the corpus are in general more positive when they are given as an overall numerical rating than when taking into account their individual subjective phrases (probably aspect-related) polarity. It can be observed in Figure 2 that the line depicting the average of star ratings is above the expected line averaging the subjective phrases polarity. The fine-granular analysis suggested by Klinger and Cimiano [21], [22] and extended by Sänger [20] confirms the findings from other approaches [15]–[17] with respect to the subtle differences between ratings of reviews as a whole and as differentiated subjective phrases.

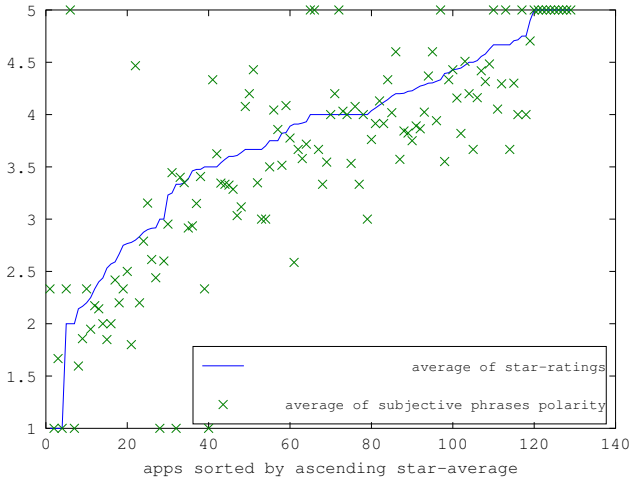

Fig. 2 Average of labelled star ratings versus average of subjective phrases polarity.

Figure 3 shows the number of star ratings and subjective phrases for each app after a *filtering* procedure (see Figure 1) that groups them together according to the reviews associated with that app. There are about twice as many subjective phrases than star ratings per app. They have a strong linear dependency: there is a positive correlation, with the Pearson's correlation coefficient $\rho = 0.8$. This is a good indicator for considering linear regression models that can predict the star ratings without human intervention.

Yet another possibility to plot the data from the corpus is shown in Figure 4. This time, the number of reviews per app is taken into account. Such a visualisation was helpful when analysing apps according to their importance or to the number of reviews that are provided. We do not consider further implications in our experiments but were better aware of the distribution of the ratings when analysing the data.

Not only is a visual analysis of the data concerning the number of reviews and their ratings interesting, but also in which relation stay positive and negative opinions to each other. As can be seen in Figure 5, negative reviews have higher impact than positive reviews. There is a negative correlation between both of them, with Pearson's correlation coefficient $\rho = -0.78$ (apps with no positive subjective phrases were

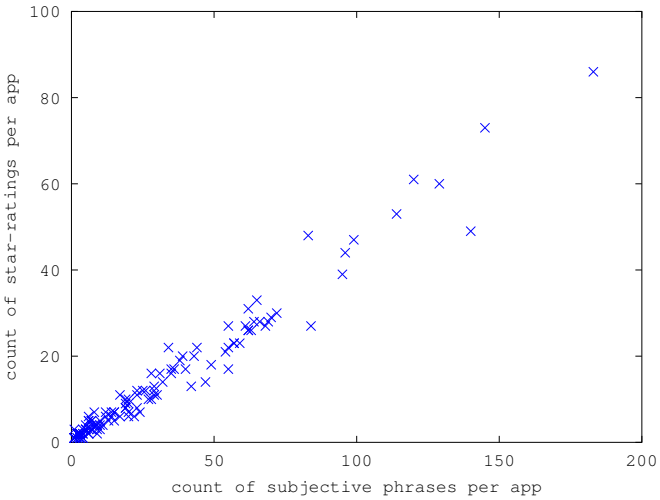

Fig. 3 Number of star ratings and subjective phrases for each app in the annotated corpus.

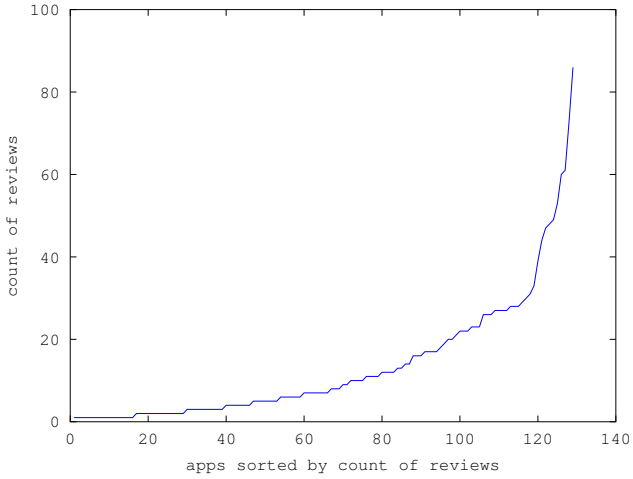

Fig. 4 Count of reviews per app sorted in ascending order.

filtered out to avoid indetermination when considering the negative vs. positive sentiment ratio).

All these observations determined which computational models should be considered in order to predict star ratings. Some of these models will be presented in the next section. In this paper and for the reasons commented above (like the strong linear dependency between subjective phrases and star ratings per app), we place great emphasis on multivariate regression models.

IV. Prediction of Star Ratings

Let $h_\Theta : \mathbb{R}^{n+1} \to \mathbb{R}$ be the hypothesis of a multivariate regression model,

$$h_\Theta(\mathbf{x}) = \theta_0 x_0 + \theta_1 x_1 + \cdots + \theta_n x_n = \Theta^\intercal \mathbf{x}, \qquad (1)$$

with $\Theta \in \mathbb{R}^{n+1}$ being a vector of parameters, $\mathbf{x} \in \mathbb{R}^{n+1}$ being a vector of features or independent variables, $n \in \mathbb{N}$, and $i = 0, \ldots, n$.

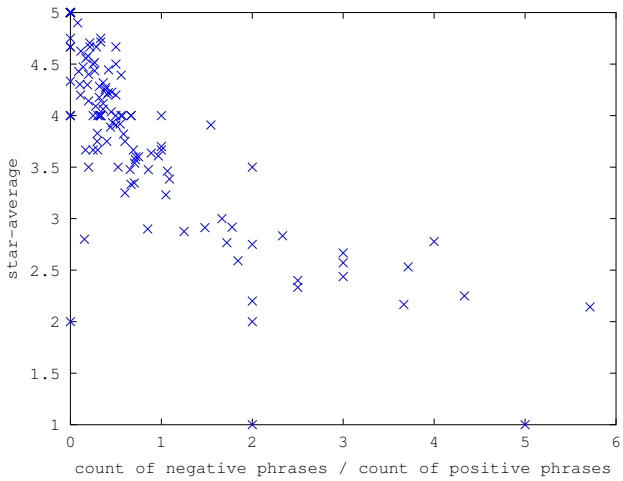

Fig. 5 Star average according to the negative vs. positive sentiment ratio.

The cost function which is to be minimized in order to find the optimal values of the parameters θ_i is the following:

$$c(\Theta) = \frac{1}{2m} \sum_{j=1}^{m} (h_\Theta(\mathbf{x})^{(j)} - y^{(j)})^2, \tag{2}$$

with $m = 1701$ being the number of reviews in the corpus and y being the dependent variable or star rating for each annotated review j.

For predicting star ratings of mobile apps, a model with four variables (or features) could be considered, where

- x_0 is equal to 1 for convenience of notation,
- x_1 is the number of subjective phrases with positive polarity,
- x_2 is the number of subjective phrases with negative polarity, and
- x_3 is the number of subjective phrases with neutral polarity.

Let $h_{1_\Theta} : \mathbb{R}^4 \to \mathbb{R}$ be the corresponding hypothesis:

$$h_{1_\Theta}(\mathbf{x}) = \theta_0 x_0 + \theta_1 x_1 + \theta_2 x_2 + \theta_3 x_3. \tag{3}$$

This is the *baseline model*.

In case the neutral polarities are not considered, as will be discussed in the next section, the above model can be simplified as follows:

$$h_{2_\Theta}(\mathbf{x}) = \theta_0 x_0 + \theta_1 x_1 + \theta_2 x_2, \tag{4}$$

with $h_{2_\Theta} : \mathbb{R}^3 \to \mathbb{R}$.

Since some apps might have many more reviews than others, the values of the features could be normalised using the following scaling:

$$x_i' = \frac{x_i - \mu_i}{\sigma_i}, \tag{5}$$

with μ_i the mean value and σ_i the standard deviation of the feature i in the vector of features $\mathbf{x}$.

An average-based, simpler model could also be considered by taking into account only the average value of the polarities of a review (e.g., average polarity between all positive, negative, and neutral sentiments of the review) in one feature. Let $h_{3_\Theta} : \mathbb{R}^2 \to \mathbb{R}$ be the hypothesis for that case:

$$h_{3_\Theta}(\mathbf{x}) = \theta_0 x_0 + \theta_1 x_1. \tag{6}$$

The average polarity (numerical) value of a review can be calculated by mapping the polarities to the following values: 5 for a positive polarity, 3 for a neutral polarity, and 1 for a negative polarity.

The average polarity value can also be calculated by considering the *review rating score* (RRS) as suggested in [16] and [17]. This would mean that only the positive and negative polarities are taken into account, and are summed up using the following formula:

$$RRS^{(j)} = \left(\frac{P^{(j)}}{P^{(j)} + N^{(j)}} \cdot 4 \right) + 1, \tag{7}$$

where $P^{(j)}$ is the number of positive subjective phrases in review j, $N^{(j)}$ is the number of negative subjective phrases, and $1 \leq j \leq m$. As in [16], the new rating is scaled in the range of the corpus star rating (i.e., one to five stars).

Even a polarity ratio can be computed, too, where only the proportion between negative and positive polarities is taken into account.

Altogether, eight different models will be analysed and evaluated in the experiments that are introduced in the next section. They are summarised in Table III.

TABLE III Overview of prediction models.

Model	Hypothesis	Neutral polarities	Features normalised	Polarity average	RSS average	Polarity ratio
M1	h_{1_Θ}	✓				
M2	h_{1_Θ}	✓	✓			
M3	h_{2_Θ}					
M4	h_{2_Θ}		✓			
M5	h_{3_Θ}	✓		✓		
M6	h_{3_Θ}			✓		
M7	h_{3_Θ}				✓	
M8	h_{3_Θ}					✓

V. Experiments

Two different groups of experiments are considered for predicting the star ratings of mobile apps based on the expressed opinions from each review. All rely only on the polarity of the subjective phrases that are included in the annotated corpus.

The first group of experiments deals with assessing the importance of sentiment in the reviews. For example, whether to filter *neutral* phrases out from the corpus or not is investigated by applying different regression models, as introduced in the section above. Furthermore, filtering reviews

with no sentiment out (i.e., those that do not contain subjective phrases at all) is also analysed.

The second group of experiments makes use of other predictors, as suggested in [16] and [17], after considering the results of the first group of experiments.

Each individual experiment is run 10,000 times. A Monte Carlo cross-validation[4] is applied each time: on each iteration, the annotated reviews dataset is randomly partitioned into a 70% training dataset that is used to train the model in a supervised manner, and into a 30% testing dataset that is used to validate it.

A. Multi-variate linear regression-based predictors

Ganu et al. point out that neutral polarities do not add significant information to their experiments [16]. This could be also the case for the sentiment rating prediction of mobile apps that are used here. In order to investigate this, some of the regression models introduced in Section IV are trained and evaluated both with and without taking into account the neutral sentiments. Furthermore, they are also trained and evaluated with a reduced corpus that does not contain reviews that have no subjective phrases at all, i.e., reviews with no positive, neutral, or negative phrases are filtered out from the corpus. Concretely, a total of 77 reviews are filtered out.

The first experiment, experiment *E1*, considers the polarity count and evaluates the baseline regression model, i.e., hypothesis $h_{1_\Theta}(\mathbf{x})$ from Equation 3 and hypothesis $h_{2_\Theta}(\mathbf{x})$ from Equation 4. In other words, models *M1* and *M3* are evaluated, i.e., with and without neutral polarities.

The second experiment, experiment *E2*, uses the average-based hypothesis $h_{3_\Theta}(\mathbf{x})$ from Equation 6 for the training. Models *M5* and *M6* are evaluated, i.e., with and without neutral polarities.

The third experiment, experiment *E3*, considers the baseline model and the model without neutral polarities, i.e., hypotheses $h_{1_\Theta}(\mathbf{x})$ and $h_{2_\Theta}(\mathbf{x})$, both with normalised features. Models *M2* and *M4* are evaluated.

B. Univariate, average-based predictors

This group of experiments considers the RRS as defined in Equation 7.

First, an experiment *E4* with hypothesis $h_{3_\Theta}(\mathbf{x})$ is considered. In this case, model *M7* is evaluated.

A second experiment, experiment *E5*, also uses hypothesis $h_{3_\Theta}(\mathbf{x})$ but with the negative vs. positive polarities ratio, i.e., model *M8* is evaluated.

A third experiment, experiment *E7*, makes a *metadata-based prediction* (also similar to that proposed in [16]): given a new test review of an app, it predicts the rating by computing the average of all reviews available in the training set. A hypothesis like that from Equation 6 is considered and, with it, a new model *M9* is evaluated.

[4]The Monte Carlo cross-validation is a non-exhaustive cross-validation technique.

VI. Results and Discussion

The results show the averages of the mean squared errors (MSE) and the standard deviation σ for both the training and the test sets for each of the 10,000 iterations from the experiments. Together with these metrics, the value of the maximum error minus the minimum is also given.

Table IV shows the results for the first group of experiments, i.e., for those settings that evaluate not only the importance of neutral sentiment orientation but also whether reviews without subjective phrases should be included in the analysis or not.

The model that best predicts the star ratings is *M6* (see the last column of experiment *E2* in Table IV). This means that filtering both subjective phrases with neutral polarity *and* reviews with no sentiment orientation at all, fits much better the predictor (i.e., hypothesis $h_{3_\Theta}(\mathbf{x})$ from Equation 6) to the observed data.

In a second grade of importance are the best results that were obtained for experiments *E1* and *E3*. These are underlined. For our concrete corpus, it is not a good idea to normalise the model features: this does not improve the accuracy (see the second-last column of experiment *E3* in Table IV). Furthermore, models with more features profit from more data, as expected (see the first column of experiment *E1* in Table IV).

Figure 6 shows a visual comparison between the results of the first two experiments, *E1* and *E2*.

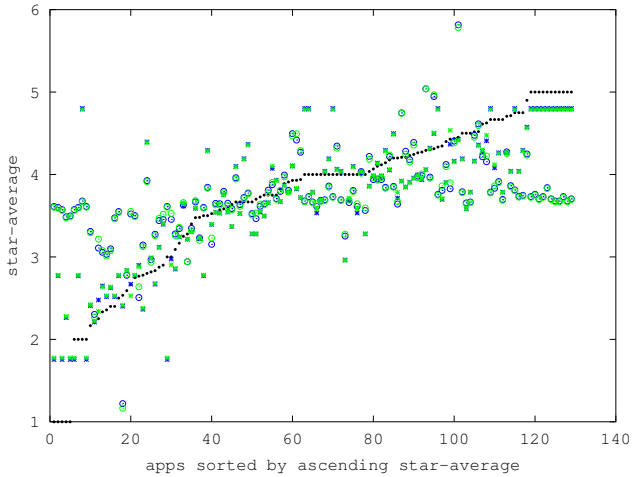

Fig. 6 Rating prediction for experiments *E1* and *E2*. Black asterisks: labels, blue (dark gray) circles: *E1* with neutral phrases, blue (dark gray) asterisks: *E2* with neutral phrases, green (light gray) circles: *E1* without neutral phrases, green (light gray) asterisks: *E2* without neutral phrases.

Since the hypothesis of the best model so far is h_{3_Θ}, then predicting the star rating for a new app given its review[5] would mean evaluating the hypothesis as follows:

$$h_{3_\Theta}(\mathbf{x}) = 1.0814 + 0.73538x_1,$$

[5]And after having classified the sentiment orientation of its subjective phrases.

TABLE IV Mobile apps rating prediction: Importance of sentiment in the reviews.

where x_1 is the average of the positive and negative polarities of the review, and the intercept and the slope are the optimal parameters Θ that were found.

Table V shows the results for the second group of experiments.

TABLE V Mobile apps rating prediction: Other (average-based) predictors.

Experiments	with neutral phrases			without neutral phrases		
	MSE	σ	max-min	MSE	σ	max-min
E4: Linear regression with RRS						
Training	–	–	–	**0.23979**	**0.04484**	**0.21852**
Test	–	–	–	**0.25547**	**0.10604**	**0.50679**
E5: Linear regression with ratio neg/pos polarities						
Training	0.79105	0.08650	0.59050	0.87870	0.09371	0.65414
Test	0.82057	0.20284	1.55290	0.91346	0.21984	1.63780
E6: metadata-based prediction						
Training	–	–	–	–	–	–
Test	–	–	–	2.35960	0.08397	0.63069

If the review rating score is considered, i.e., model *M7*, then its results outperform all other predictions (see the final column of experiment *E4* in Table V).

Figure 7 shows a closer look when comparing the best models of both groups of experiments, i.e., *E2* and *E4*.

The predictions that are computed based on the review rating score are much closer to the star ratings given by the authors of the reviews, as Figure 8 clearly indicates (compared to those of Figure 2).

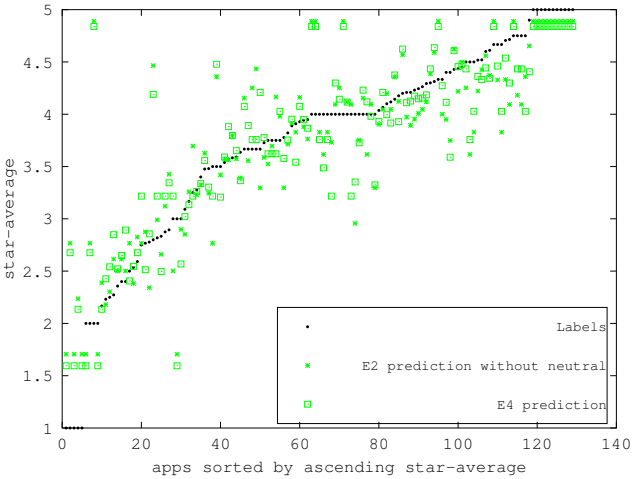

Fig. 7 Rating prediction for experiments *E2* and *E4*. Black dots: labels, green (light gray) asterisks: *E2* without neutral phrases, green (light gray) boxes: *E4* without neutral phrases.

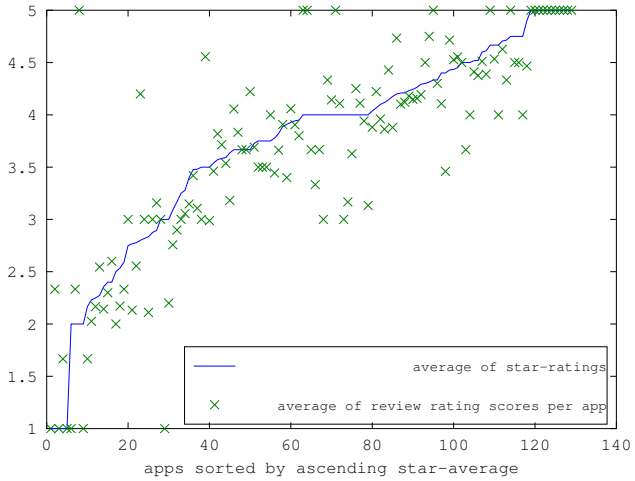

Fig. 8 Review rating scores per app.

VII. Conclusions

Textually-derived rating prediction can be performed well even when only phrase-level sentiment polarity is available. This is what the computational models introduced and evaluated in this paper have shown. Not all fine-granular opinions are of importance, however: filtering out subjective phrases with neutral sentiment and computing the overall sentiment of a review using the review rating score proposed in [16] and [17] provides the best star rating predictions for mobile apps' reviews written in German. Based on these results, new applications could suggest to customers how to

rate apps more consistently with the reviews they write, by considering their expressed opinions at the phrase level. Both customers and companies would benefit alike.

Further work will deal with the ideas that follow. Subjective phrases are aspect-oriented, i.e., the expressed opinions are probably related to features or aspects of a particular app. By extending the model to consider the aspects' relevance, an improvement in performance might be achieved. Furthermore, the phrase polarity is usually given in broad categories (i.e. positive, neutral, and negative). It could be interesting to analyse the *strengths* of the opinions [26], too. Moreover, it is our interest dealing with other types of models different than linear, multivariate regression ones.

ACKNOWLEDGEMENTS

We would like to thank Mario Sänger for insightful discussions and for providing us with the annotated customer mobile apps' reviews dataset.

***Abstract*—Contemporary travel information services are connected to huge amount of travel related data used for improving personalized suggestions. Such suggestions include finding better routes, access to amusement and educational amenities implemented as digital services, as well as the features for people collaboration, and for planning leisure time with respect to existing attractiveness evaluation algorithms under time-budget constraints. Much effort is required for supporting personalized itineraries construction in such a way which would leverage existing cultural and technological user experience. In this paper we analyze the underlying algorithms and major components being an implementation of the proposed model investigated with particular attention to annotated leisure walk route construction, traveler collaboration and travel meeting management. In sum, we make an effort to address a number of complex issues in the area of developing models, interfaces and algorithms required by modern travel services considered as an essential application of a human-centric computing multidisciplinary paradigm.**

I. Introduction

There is no exaggeration in saying that traveling is one of remarkable ways to discover the world. Among different obvious factors (which include journey time planning, accommodation management, equipment preparation, etc.) there are many aspects related to the careful forethought of a journey which would make it coming up well to the traveler's interests and expectations. To a significant extent, present day information services for travelers are about personalization, extending usage scenarios, improving suggestions and recommending journey options on the base of the information retrieved from various warehouses containing huge amount of travel related data.

The idea of our approach is to combine user experience orientation and rich facilities of the present day information retrieval, processing and presentation tools for the benefits of better travel planning, itinerary construction and traveler experience sharing. Indeed, with current level of computer-assisted tools and methods tourists expect more facilities than simply finding a fastest and cheapest way or getting a direction. They expect to be advised how to deal with many competitive factors of route construction, some of them (like sight attractiveness) aren't easily formalizable. The problems of developing better personalized services for travelers are within the scope of the emerging domain of urban computing [1], [2] where suggestion environments are rapidly developing. Thus, leisure could be suggested: we believe that advancing services for travelers is a perfect area to be upgraded by introducing better suggestion facilities.

In this work we don't pretend to cover all possible suggestion use cases supported by a big variety of existing applications. We partially address only a selection of scenarios representing five major aspects of travel planning and management:

1) Journey preparation and planning;
2) Itinerary construction automation and navigation;
3) Multimedia assistance automation;
4) Traveler interaction and collaboration;
5) Post-travel experience.

The listed aspects (which are not exhaustive, nor totally independent) and the corresponding scenarios are described in Section II.

II. Aspects and Use Cases

Let us examine our selection of travel planning and management aspects.

The first aspect is **journey preparation and planning**. Nowadays travelers still use but aren't totally satisfied with traditional paperback editions of numerous travel guides containing plenty of maps and city plan fragments. Voyagers consult different guides implemented as software applications (currently available on many mobile platforms and advertised on the web sites like *Musement*[1], *Izi.travel*[2] or *PocketGuide*[3]), they share their experience via social networks and traveler forums available on relevant web sites (like *TripAdvisor*[4]). Many applications exist for mobile devices supporting GPS-sensors, electronic maps, as well as various multimedia features. In Section III-A we provide a brief survey of existing web resources for travelers.

Instead of taking predefined packages, many people prepare their own itineraries with the help of information available on the web sites for travelers. Thus, the second aspect is **route construction automation and navigation**. While planning

978-83-60810-90-3/$25.00

visiting some area for a certain period of time, tourists are unlikely able to visit each attraction. Effectively, they solve a kind of fuzzy optimization problem in order to select something that would be specifically interesting to them. Tourists select points of interest (POIs) depending on their significance from a certain point of view. Hence, one of possible application of traveler advisory systems is to navigate the selection process by implementing the criteria representing a tourist object attractiveness by some formal schema. In Section III-B we analyze possible approaches for such a formalization.

Creating personalized itineraries requires using rich facilities of **multimedia assistance automation**. This aspect is connected to different issues, including assisting visually impaired pedestrians [3], creating multimedia travel books integrated with electronic maps and accessible from mobile devices [4], creating audio guides for museums and cultural sights [5], [6], designing personalized recommendation systems in order to mitigate information overload [7], and so on.

The next aspect is **traveler interaction and collaboration**. Somehow, many current efforts are about delivering personalized solutions allowing travelers to leverage and to share their experience and/or to follow major scenarios we could learn as a result of travelers' experience study [8], [9].

Personalization and user collaboration is connected strongly to the possibility to leverage **post-travel experience** knowledge. Among existing solutions for travel reporting we can cite a couple of examples like *TripJournal*[5] and *TripCast*[6].

To sum up, we agree with the statement from [10] that the focus of many existing solutions is on creating a technology which wouldn't support only a kind of time-budget optimization problem but would allow travelers to develop their own *memorable experience* (the latter term being borrowed from [11]).

III. State-of-the-Art Approaches

This section contains a brief survey of state-of-the art approaches developed and used in the domain of traveling related information systems.

A. General Information Services for Travelers

Apart from research projects (examined in details in further sections), there are two big classes of present day electronic services for tourists: thematic web sites (which are sometimes linked to special software applications) and a huge variety of mobile applications. Among popular web based solutions there are the following major groups:

- Web sites for hotel, flight, restaurant searching and booking: they are kinds of aggregation bridges to many external services; sometimes they contain traveler forums and features for collecting and displaying user feedback and user impressions. Good examples are *TripAdvisor* and *Expedia*[7].
- Travel guides implemented as a collection of stories and suggestions which are sometimes focused not only on sites and attractions but also on interesting events and on sharing personal experience: particular implementations may contain event calendars, transport and place orientation, integration with electronic maps. Good examples are *Timeout*[8], *I.Know*[9] and *Japan Guide*[10].
- Individual trip planning or collaborative planning: journey agenda and route planning (like in *Travefy*[11] and *Tripomatic*[12]), transportation planning (like in *RouteRank*[13] and *Hyperdia*[14]).
- Journey and transport trackers, including flight trackers (*FlightTrack*[15], *GateGuru*[16]).
- Personalized itineraries construction examined in the subsequent sections of this paper.
- Platforms for sharing user in-travel and post-travel experience: good example is (*TravelDiaries*[17]). Travel diaries are often used by other travelers in time of preparation their future trips.
- Multimedia guides: good examples are audio guides used not only in traditional indoor museum environments but also for outdoor journeys (*Azbo*[18], *Izi.Travel*[19], *PocketGuide*[20]).
- Unusual models: good example is *Explorra*[21], an approach where a collection of attractions is accessed after a user selects a color.

Of course, the above mentioned groups exist rarely in its pure form, many features being shared among different solutions. Currently the focus is being shifted to lightweight (mobile) applications targeting the everyday life stories.

B. Itinerary Construction: Interfaces and Implementations

Among existing solutions for travel itinerary construction we have to mention several projects which are within the scope of our research.

The mobile application TAIS for guiding tourist activity described in [12] is focused on step-by-step itinerary construction in response to user actions and movements. There is an interesting feature of collecting user impressions about the visited POIs. The application generates recommendations collected on the base of other travelers' experience and evaluations. For each POI its detailed information includes a list of images associated with the attraction and its description. As

[21] https://www.explorra.com/labs/travel-by-color

a routing service the authors use *OpenStreetMap* API, while *Yandex.Schedule* API is used for searching available public transportation routes, the latter being a very promising feature.

A tour planning system *Aurigo* combines a recommendation algorithm with interactive visualization for creating and managing personalized itineraries [10]. To a great extent, this project is in the same direction as the project of ours: the authors investigate a possible balance between an automated and purely manual approaches.

TripBuilder framework described in [13] is an implementation of an approach for planning personalized sightseeing tours in cities. The itineraries are being constructed after analysis of the geo-tagged photos collected from *Flickr*[22] and associated with the POIs collected from Wikipedia. The photos are considered as traces revealing the behaviors of tourists and as a source of spatio-temporal information about their sightseeing experience. The itinerary construction is modeled as an instance of the generalized maximum coverage problem with respect to visiting time-budget optimization and to further building of the itinerary as an instance of the traveling salesman problem. The approach was advanced in [14] by applying an algorithm for suggesting contextually relevant POIs on the base of user preferences and interests.

In our previous works (see [15], [16]) we described an approach to design an application which is not limited to obtaining the information about different attractions, it provides the ability of planning and constructing a travel itinerary in advance. That's why tourist guides may use it in their work. We expect that, by using the application, professional experts and amateur guides can prepare their tours both in automatic and manual modes.

In contrast to [17] we couldn't totally agree that "creating an efficient and economic trip plan is the most *annoying* (our emphasis) job for a backpack traveler". We believe that creating a customized itinerary is a very creative stage which is part automatic, part manual: for producing interesting high quality suggestions the contribution of *human* experts is extremely important.

Our application focuses a concept of an annotated travel itinerary. which is not a simple path (for instance, the shortest one) between two points on the map, but a route description which includes a set of POIs representing such attractions as architectural sights, museums, historical places, monuments, view points, etc. In order to create a relevant annotation, one should consider including such entities as texts, images (photos, drawing, replicas, diagrams, etc.), multimedia objects (audio or video clips), web links, notes, citations, dates, timeline connections, information about related people, places or events, to cite a few.

Figure 1 gives an idea of existing complexity of a domain specific ontology by an example of architectural points. Figure 2 follows a pattern proposed in [18] and shows major usage scenarios. The common-sense ontology provides a foundation for the information system architecture.

[22]http://www.flickr.com

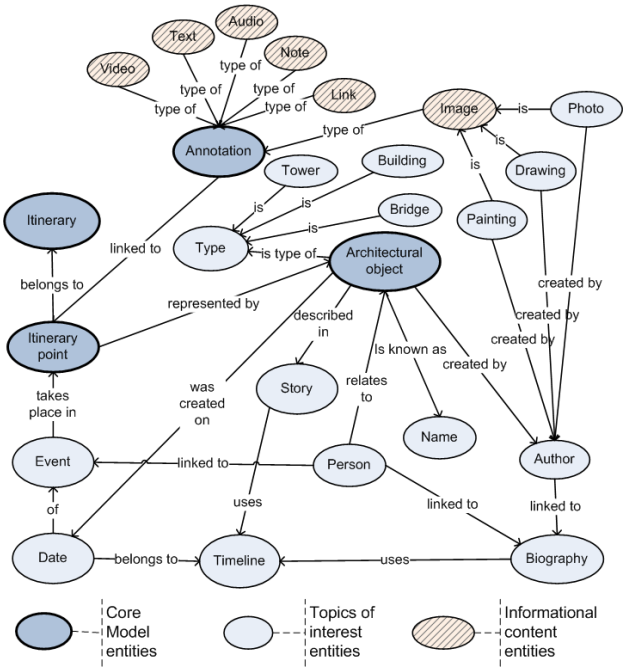

Fig. 1. An example of domain specific ontology fragment

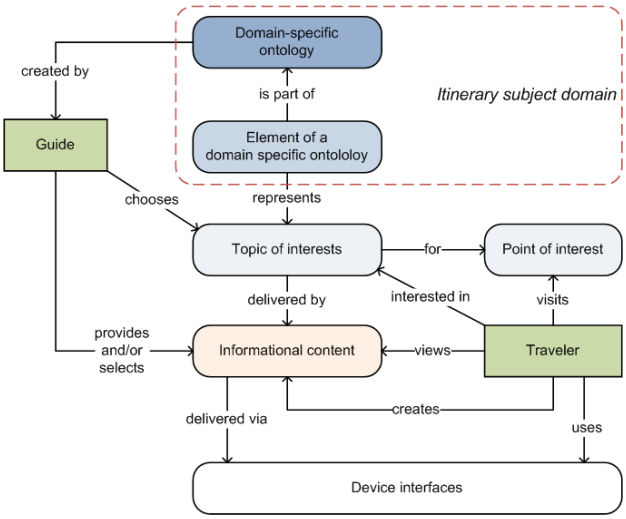

Fig. 2. Common sense ontology

C. Travel Route Automation: Formal Models and Algorithms

Itinerary planning automation is still an important aspect even for local itineraries for leisure walks. An obvious formal model representing the problem of generating an itinerary is finding an optimal way on an undirected or directed weighted graph. However the question is not about finding a shortest path. There are many competing factors that have to be taken into consideration:

- POI opening and closing times (time schedule);
- POI visual characteristics (viewpoints);

- POI purposes and their relation to the journey focus (important for thematically organized itineraries);
- POI importance (in a sense);
- POI types (historical objects, relaxation objects, sanitary facilities, transportation hubs, etc.);
- Dependency on weather, traffic, safety conditions, and similar issues.

Hence, common shortest path algorithms aren't enough. Hereafter we examine possible approaches that could be useful for automatic itinerary construction.

1) Using Genetic Algorithms: An adaptive genetic algorithm described in [19] is based on partitioning the work space by several blocks with unique numbers as Figure 3 shows.

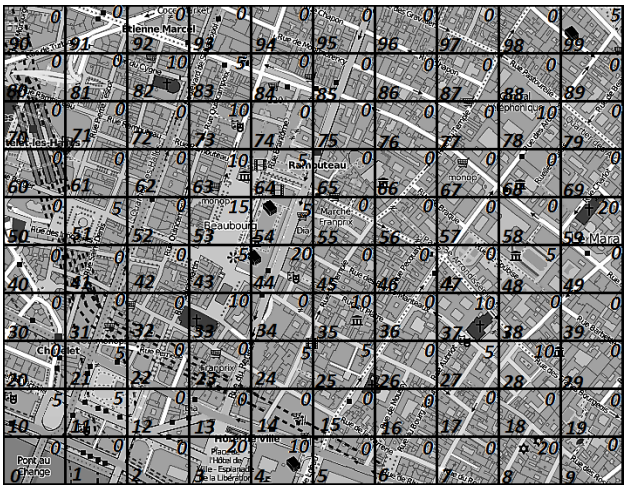

Fig. 3. Division the workspace into blocks

A path is a sequence of "visited" blocks, while a fitness function defined as an adopted version from [19] is as follows:

$$F = (1 + \frac{1}{\sqrt{n-1}}) \cdot D \cdot C \tag{1}$$

In equation (1) n is the number of free cells, D is the sum of linear distances between adjacent individuals, C is is the sum of object scores (shown on the upper right corners of each block in Figure 3) within the selected blocks.

This method allows planning routes quickly: on a grid of 10×10 cells with scale of population equal to 40 and length of each population equal to 20, a stable population is created after 40-th generation. However the fitting function ignores some important factors, for example, it ignores the walk duration.

2) Random Search Algorithms: In [20] the authors used a greedy randomized adaptive search procedure which could be explained as follows. The first step is to find some start solution (for example, we can select several POIs with the highest popularity and a shortest path between them). The second step is to calculate the value of F function that describes the effect of adding a POI to the route:

$$F = \frac{T_{beforeAdding}}{T_{afterAdding}} \cdot S \tag{2}$$

In equation (2) $T_{beforeAdding}$ is a route time before inclusion of current POI, $T_{afterAdding}$ is a time after inclusion of the POI into the best position (i.e. the position corresponding to the time which is as minimal as possible), while S is a score of current object.

The next steps are iterative: the idea is to find several points with the best F value which are not included to the major route, and to select a random point from them, so as to add it into the route. This process is being repeated until we decide to stop. There could be different stop situations: for example, we don't have more time to continue searching, or we don't have any POIs more. Figure 4 gives an illustration for one iteration.

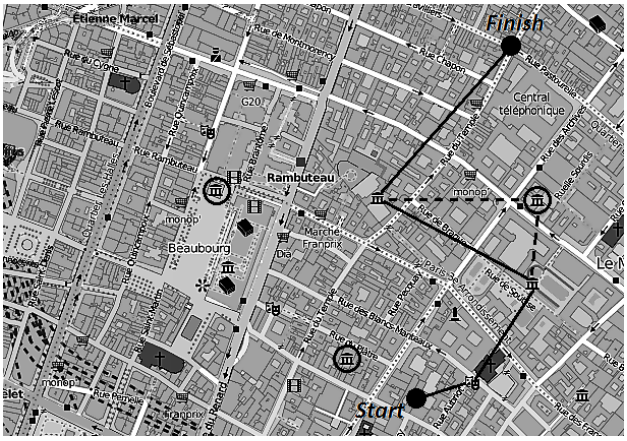

Fig. 4. One iteration of the route generation using GRASP

3) Ant Colony Optimization: The promising way is to use ant colony optimization (ACO) known since 1991 [21] and originally developed for solving a problem of finding an optimal path on a graph. A traditional ant colony algorithm is based on modeling the behavior of the ants dropping pheromones while deciding where to go depending on the intensiveness of pheromone trails. If an independent ant moves rather randomly, an ant discovering a previously laid pheromone trail follows this trail with higher probability. As a "side" effect, an ant following such previously laid trail reinforces the amount of pheromones on its way. There are ACO applications for many areas; in [22] there is a description of ACO application for a traveler salesman problem which is often a part of travel planning algorithms. An interesting ACO modification for tourist route planning was described in [23] as a formal foundation for a food tour recommendation system.

The solution can be enhanced by taking into consideration such important leisure walk properties as walk time, time required to visit a POI, nutrition conditions and other characteristics.

IV. A Prototype Software System

In this section we describe the software components developed to demonstrate the key ideas of our approach, namely: making suggestions, interface simplification, implicit actions preferred, a focus on the above mentioned selected aspects.

A. Component for Interactive Itinerary Construction Integrated with OpenStreetMap

According to an *annotated travel itinerary* concept presented in Section III-B, we developed an interface allowing to deal with a diversity of data to be visualized along the editable itinerary. Figure 5 shows a fragment of a POI description in terms of domain-specific ontology presented in Figure 1.

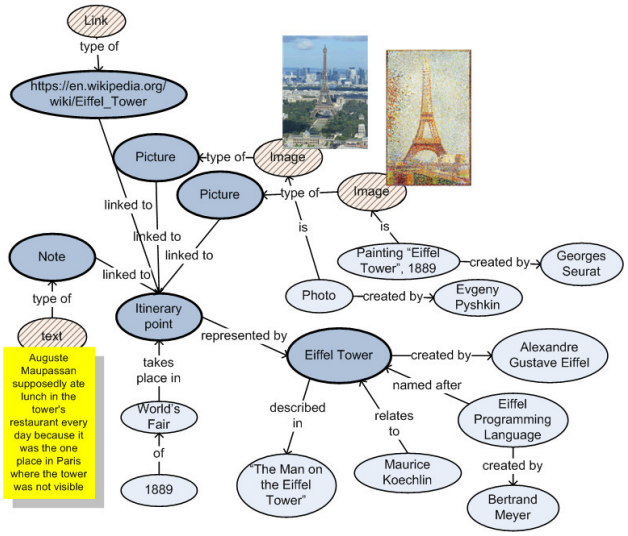

Fig. 5. A POI described in terms of domain-specific ontology (fragment)

Figure 6 shows a main panel of our prototype application for annotated itinerary construction together with some examples of POI annotations. As an electronic map service we use *OpenStreetMap* (OSM)[23] which is a collaborative project for free editable world maps creation. In our implementation a *JMapViewer* component is used.

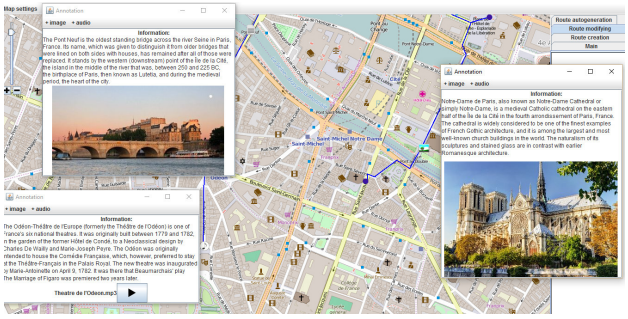

Fig. 6. Main frame window with an example of constructed itinerary

Users are able to select a search area on the map in order to allow suggesting the POIs for further consideration for including them to the itinerary. Figure 7 gives an idea of the adviser component user interface.

In sum, currently the system supports the following features:

[23]http://www.openstreetmap.org

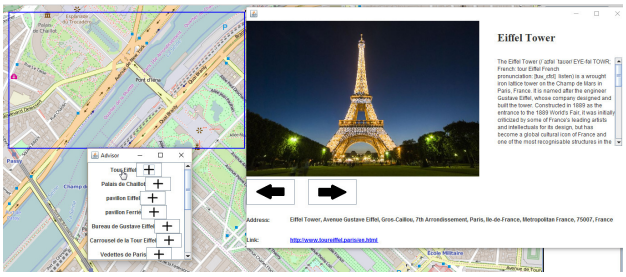

Fig. 7. Interactive adviser: attractions within the selected area

- Ability to create the route itself and to add the annotations containing text information, images, audio, links to web sites, etc.;
- Ability to modify the created tourist route;
- Ability to search POI-related information on the web;
- Automatic tourist route construction.

B. Automatic Itinerary Construction

For the leisure walk itinerary automation we use the following simplified scenario:

1) Define a time slot, select the departure and destination points. Define other constrains if required.
2) Explore potential locally accessible POIs for the current point on the route (initially the current point is set to the departure point).
3) Evaluate the POIs by using some formalized model for taking into account the degree of POI popularity, attractiveness, price to visit, location, etc.
4) Rank the POI and add the best ranked POIs to the part of the route in progress.

Steps 2–4 are repeated until the destination point is reached.

The standard task of tourist route generation is formalized by Souffriau [24] as follows:

Assume there are N POIs. For every POI: $x_{ij} = 1$, if there is a path between the POIs i and j, otherwise $x_{ij} = 0$. S_i is a i-th POI's score, i ranging from 1 (departure) to N (destination). Time t_{ij} corresponds to the shortest path from point i to point j. The total score S_{total} has to be maximized within the limit T_{max} time.

This model sets boundaries of the future route and determines criteria for the best tourist route which is the best selection of the tourist objects and the best path connecting these objects.

Due to the fact that the POI score depends on its place along the route, each potentially accessible POI's score has to be recalculated at each iteration. In order to explore POIs locally we use the geometric model shown in Figure 8.

This geometric model has the following parameters: *Start*, *Finish* – the arrival and departure points within the route area, a – the semi-major axis of the search area, b – the semi-minor axis of the search area, c – half of the focal distance of the search area, $S_{max}/2$ – half of the maximum distance that can be covered for the remaining time, α – search area angle of rotation, γ – semi-minor axis minimization coefficient.

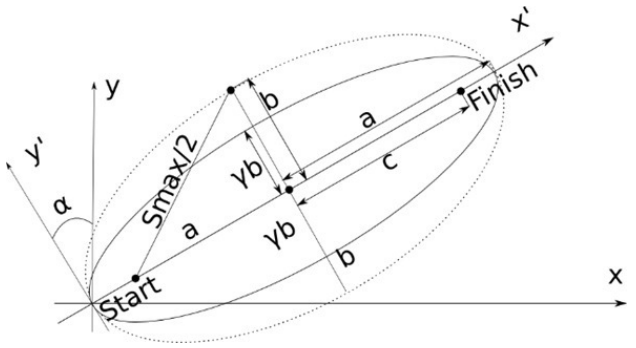

Fig. 8. Exploring local area

Unlike to the model used in the earlier mentioned *Aurigo* project, where the authors introduced a *Pop Radius* for exploring the POIs in the *circled* local area [10] (similar idea is also used in *ATIPS* project [25]), we use an elliptic model for the local POI exploration area. The elliptic form of the local region, where the potential POIs to visit are explored, allows us to use ellipse particularity: the sum of the distances to the two focal points is constant for every point on the curve. It means that if this sum is equal to the distance to the most distant point, a person can theoretically reach it within the given time and speed limits; each point outside the ellipse couldn't be reached. So, too distant POIs must be excluded from the short list used for further analysis. The POIs located close to the border of the ellipse may also be excluded from the search, otherwise it may happen that the resulting route is too sparse: a traveller will spend much time to walk in-between, instead of visiting the selected attractions.

In current implementation, we used an extension of a gradient descent algorithm for searching POIs to be included to the route. The extension is as follows: searching a new POI to be included occurs in the area with a maximum distance between two objects in the buffer route. This modification makes possible to reduce the maximum distance between the tourist objects and to exclude from the consideration hardly reachable objects. Then the selected objects are evaluated in order to find the object with the best score.

C. Implementing A Simplified Scenario for Meetings Halfway

Let us examine one interesting use case for suggestion oriented routing services which is a service targeting not the only user but the joint interests of several independent users.

Even in the case of a simplified scenario of arranging a meeting of two travelers, the task is not trivial: the involved persons have to consider air flight prices, flight schedule, tickets availability, accommodation and living costs. Huge arrays of data are potentially available via existing Internet services, but it is almost impossible to process them manually: an air ticket price and availability might change very quickly and dramatically in time, currency exchange rates are also not stable, there is a huge amount of data on flight connections, to cite a few.

We follow an idea similar to Google maps based *Meetways* application [26] developed since about 2008 [27]. One more example is *Geo Meetpoint* [28]. Probably the closest implementation is provided by *Meet Me in the Middle* application [29]. The latter has an easy-to-use interface and lightweight design fitting well searching for short distance routes, but there is limited support for cross-border points.

Informally, our model scenario could be described as a story of two friends trying to find a suitable meeting point:

Alex lives in St. Petersburg, Russia, while his girlfriend Tina lives in London, UK. They would like to meet each other. However, there are some constrains: they are students (so, they have rather limited funding), currently Alex has no UK visa (and it takes much time to get it), however they are open for any idea about the suitable place.

Saying more formally, assume $City_1$ is a city where Alex flies from, and $City_2$ is one where Tina flies from, while $City_3$ is a possible halfway meeting place. A set R_1 is a set of possible flights departing from the $City_1$ airports, while a set R_2 is a set of possible flight departing from $City_2$. Then an intersection X of R_1 and R_2 provides the selection of flights which correspond to the possible meeting places. In order to find the best choice we have to download the detailed flight information (prices and available dates) for all the flights departing from the $City_1$ and $City_2$ airports. Then we consider the combinations of all the destinations from the set X corresponding to the flights departing from $City_1$ or $City_2$. Such combinations give us an array of one-way flights. Then we add return flights in order to consider the full trip cost. Finally, the selection is sorted so as to discover the best options. Figure 9 illustrates the issue.

We organized the prototype implementation by introducing three components: web data access, data matching analysis and end user interface. First component is responsible for downloading data from available web sites providing access to flight data. Currently we use an *aviasales.ru* [30] open API allowing us to get flight information with dates, prices and possible directions from a selected city. Web data is parsed by a Python component. Data are extracted by using *Requests* library [31]; the response is received in JSON format [32]. Here is an example of such a response:

```
"success":true,
"data":[{
 "show_to_affiliates":true,
  "trip_class":0,
  "origin":"LED",
  "destination":"HKT",
  "depart_date":"2015-10-01",
  "return_date":"",
  "number_of_changes":1,
  "value":29127,
  "found_at":"2015-09-24T00:06:12+04:00",
  "distance":8015,
  "actual":true
}]
```

Figure 10 shows the user interface supporting four options: first departure city selection, second departure city selection, trip duration (in days) and desired departure date. Web-application is implemented by using *Flask* [33].

Fig. 9. A problem of finding a meeting point for two travelers

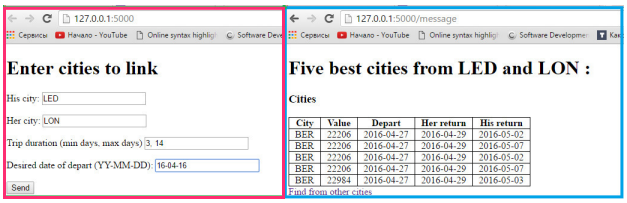

Fig. 10. A selection of flights which fit the user input

As a main result, currently the application yields a suggestion. Before any decision could be made, the application requires much more information than any user is able to handle. Thus, the implementation illustrates a concept of managed suggestion: we analyze plenty of flight related information and suggest the most suitable option. The solution can be extended so as to support many different use cases: meeting in a city, going to a cinema, following a music band in a tour, finding a place for a conference, arranging a business meeting, and many others.

V. Conclusion

In this paper we made an effort to touch a selection of aspects of today's information systems for travelers where there is a convergence of approaches being developed within the framework of human-centric, aware and urban computing. We designed the software components targeting better travel personalization and user collaboration with special emphasis on suggesting better itineraries both in local and global scope. Specifically, the following ongoing projects were presented:

- A visual *OpenStreeMap* based tool for constructing annotated travel itineraries: the tool is useful both for independent travelers and for guides preparing the journey for their clients;
- A tool for automatic of travel itinerary construction integrated with the above mentioned visual guide assistant;
- A *Meeting Point* application suggesting a suitable halfway meeting point for two travelers using air flights for reaching the meeting destination.

We believe that currently the process leading us towards better route and leisure suggestions is being rethought with more attention to the following aspects:

- More orientation on planning by collaboration;
- Deeper integration with external services including electronic maps, navigation systems, knowledge resources, libraries, etc.;
- Resolving usability issues and developing better intelligent user interfaces and HCI solutions for leveraging user experience and taking into account existing features of present day computers and portable smart devices;
- Planning experiments conducted by real users.

With regard to the content related improvements, we believe that automatic tourist route generation algorithms have to be extended in order to support an extremely useful feature like constructing the thematically linked and multi-day journeys. We think about deeper integration with multimedia features used during the suggested sightseeing walks. We also consider investigating the issue of using old maps available as images. A perspective to the ancient views accessible electronically will significantly extend the way to learn history while visiting tourist attractions all around the world.

Appendix

In research works it is rarely shown how information about existing relevant domain-specific solutions are being retrieved. Table I and Table II give a hint how the searching process was organized in our case. We included information about search queries, extended queries and a selection of Google results obtained while using Google Chrome in private view mode so as not to keep any search history information. Results mentioned as "Direct" mean that they are obtained directly as Google web search output. Results discovered after subsequent examination of "direct" resources are mentioned as "Indirect". We also noted the results relevance to the scope of current contribution. Some of explored models, approaches and algorithms provide good foundation for further investigations within the framework of our research.

Acknowledgment

The authors thank Matvei Pyshkin for his valuable contribution to the detailed survey of the solutions, products and services examined in our work.

Semantic Knowledge Extraction from Research Documents

Rishabh Upadhyay, Akihiro Fujii
Department of Applied Informatics,
Hosei University, Tokyo, Japan
Email: uhrishabh@gmail.com, fujii@hosei.ac.jp

***Abstract*—In this paper, we designed a knowledge supporting software system in which sentences and keywords are extracted from large scale document database. This system consists of semantic representation scheme for natural language processing of the document database. Documents originally in a form of PDF are broken into triple-store data after pre-processing. The semantic representation is a hyper-graph which consists of collections of binary relations of 'triples'. According to a certain rule based on user's interests, the system identify sentences and words of interests. The relationship of those extracted sentences is visualized in the form of network graph. A user can introduce new rules to extract additional Knowledge from the Database or paper. For practical example, we choose a set of research papers related IoT for the case study purpose. Applying several rules concerning authors' indicated keywords as well as the system's specified discourse words, significant knowledge are extracted from the papers.**

***Index Terms*—Knowledge extraction; Semantics; Ontology; Discourse; Science and technology foresight**

I. Introduction

KNOWLEDGE extraction can be defined as the creation of information from structured or unstructured data. The general purpose of Knowledge discovery is to "extract implicit, previously unknown, and potentially useful information from data" [1]. Due to continuous growth of electronic articles or documents, automated knowledge extraction techniques become more and more important. The extraction of useful information from unstructured or semi-structured articles is attracting attention [3-7]. Knowledge mining can be characterized as concerned with developing and integrating a wide range of data analysis methods that are able to derive directly or incrementally new knowledge from large or small volumes of data from structured or unstructured sources using relevant prior knowledge [2]. Text mining tools in this context have the capability to analyze large or small quantities of natural language text and detect lexical and linguistic usage patterns [8]. The extracted information also should be machine understandable as well as human understandable in terms of open-data perspective.

This paper proposes a new method for Knowledge extraction or mining based on the integration of Semantics Technology (ST), Natural language processing (NLP) and Information extraction (IE). ST and NLP are significant topics in recent years. Knowledge extraction works in iterative manner, starting with a small set of rules which are tested on the available corpora or dataset and extended until the desired recall value is reached. The process of extracting knowledge is guided by certain rules inputting to the system which will define the knowledge according to the interests of a particular user. Semantic technology is based on RDF model. NLP concerns with the correction of the sentences and text which is obtained after IE phase. In this paper, we explore the benefit and application that can be achieved by the integration of these three areas for knowledge mining.

As we assume, one of the application of this system would be foresight scenario building based on the results where experts are working on writing or discussing technology trend of a certain field of research. Those experts are not necessary knowledgeable about technical issue written in a research paper, so that extracting fragments of knowledge and facts should be provided to the user compactly and easily in a limited time period.

In section 2, we give an introduction and background to Text mining as well as Technology forecasting. In section 3, introduce our model that we have used for knowledge extraction or mining. Details of the application of our system are introduced in section 4. Then in section 5 we examine the result acquired by the proposed model. Related works is presented in section 6. Conclusion and future works are introduced in section 7.

II. Background

A. Text Mining

Research in text mining has been carried out since the mid- 80s when the Prof Don Swanson, realized that, by combining information slice or fragments from seemingly unrelated medical articles, it was possible to deduce new hypotheses [13]. "Text mining" is used to describe the

978-83-60810-90-3/$25.00

application of data mining techniques to automated discovery of useful or interesting knowledge from unstructured text such as email, text documents etc. [9]. Several techniques have been proposed for text mining including association mining [10 and 11], decision tree [12], Machine learning, conceptual structure and rule induction methods. In addition, Information extraction and Natural language processing are the fundamental methods for Text Mining [23].

In Information extraction, natural language texts are mapped into predefine, structured representation, or templates, which, when it is filled, represent an extract of key information from the original text [15]. So the IE task is defined by its input and output. The work of [16] and [17] present text mining using IE. The Application of text mining can be extended to various sectors where text documents exist. For example, Crime detection can profit by the identification of similarities between various crimes. Some of the past researches in the field of Text mining or knowledge extractions are as follows:

Rajman and his colleagues [24] presented an approach for knowledge extraction using Text Mining technique. They have presented two example of information that can be extracted from text collections- probabilistic association of keywords and prototypical document instances. They have given the importance of the Natural language processing tools for such knowledge extraction. So his was the base for our method.

Alani and his team [25] have provided an updated for Artequakt System. This system uses Natural Language processing tools to automatically extract knowledge about artists from documents using predefined ontology. Steps for knowledge extraction are as follows: Document Retrieval, Entity Recognition and Extraction procedure. In knowledge extraction procedure, consists of Syntactical analysis, Semantic Analysis and Relation extraction. They have produced acceptable results.

Peter Clark and Phil Harrison [26] worked on knowledge extraction by making database of "tuples" and thus capturing the simple word knowledge. And then using it in improving parsing and the plausibility assessment of paraphrase rules used in textual entailment.

Parikh [27] proposed an approach to learn a semantic parser for extracting nested event structures with or without annotated text. The idea behind this method is to model the annotations as latent variables and incorporate prior that matched with Semantics parses of the events.

B. Technology Forecasting and foresight:

Technology forecasting is used widely by the private sector and by governments for applications ranging from predicting product development or a competitor's technical capabilities to the creation of scenarios for predicting the impact of future technologies [19]. It is "the prediction of the invention, timing, characteristic, performance, technique or process serving some useful purpose". Detailed account of achievements and failures of the technology forecasting over the four decades is given by Cuhls [19]. Johnston [20] proposed five stages in the chronology of foresight, technology forecasting and futurism leading to technology foresight, which can be used for wide understanding of the economic and social processes that shape technology. Foresight can be referred as systematic process of reflection and vision building on the future among a group of stakeholders. Foresight is nowadays referred as an element in a continuous policy learning process that is contributing to a more effective mode of policy making [21]. In a European research group, foresight is described as "...a systematic, participatory, future intelligence-gathering and medium-term vision-building process aimed at present-day decisions and mobilizing joint actions" [22].

III. RELATED WORKS

Their have been many research in the field of literature mining or extracting knowledge from research documents. But most of them are related to Biomedical or medicinal field. Our approach was related to the field of Technologies. QasemiZadeh [33] have presented an approach for structure mining from Scientific or research papers. He has only processed using Language processing, but we have combined three main fields to extract knowledge. Cimiano et. al. [34] gave a survey of current methods in ontology constructions and also discussed relation between ontology and Natural language processing.

Mima et. al. [35] gave a method for knowledge management using ontology-based similarity calculation. We have also used ontology for extracting knowledge but apart from ontology we have also given emphasis on Natural language processing and a bit of Information extraction (early stage). Mima have also not presented any information regarding evaluation of the system. Hahm et. al. [36] presented an approach for knowledge extraction from web data. Triple store was produced using web data. But in our method we have given more emphasis on research document and producing triple with it and then ontologies is applied on the produced triple datasets of line and sentences.

IV. PROPOSED SYSTEM

Proposed system uses combination of semantics of sentences and natural language processing technique over the sentences. It also provides visualization of the result. We do not expect fully machine processing results from the system. In a sense that after some processing by inference rule and getting sentences which might be significant, user creativity is required to understand what is written in the document. In this sense, our method is hybrid with software processing and expert knowledge in the area. The following Fig.1 describes the proposed model of our system.

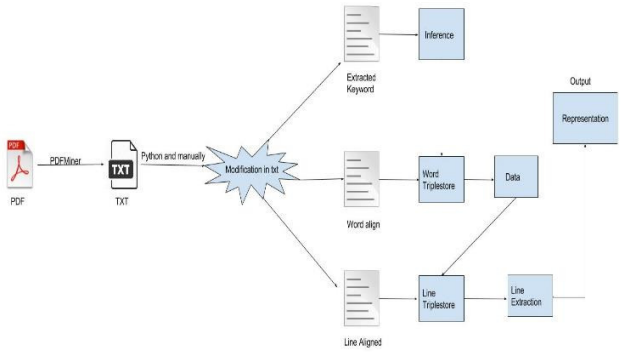

Fig. 1 Pipeline of Proposed System

Our model consists of the following Steps which is given below:

1. Extracting information from PDF file to text file.
2. Pre-processing of data.
3. Extracting the Keywords.
4. Extraction of Discourse words
5. Building a simple Triple-store (Word and Line).
6. Inference Rule.
7. Visualizing the data.

1) Extracting information from PDF file to Text file:

We made a dataset of IOT research papers. We had about 69 research papers dataset. We used some paper out of those papers. The paper were in pdf format. So to work on them we have to extract information from the pdf files. So to extract information we used Python Library "PDFMiner" [29].

2) Pre-processing of data:

After extracting information from *pdf* file into text file pre-processing was done. The extracted documents had problems, as extracted information was on a single line. So to work on them the modification of the extracted information is required. So the modification includes removing the noise (image), make proper alignment of the sentences, checking the extracted data.

So we removed the noise which is caused by extracting the image from the pdf file. As image will contains least information in the form of text so we ignored the text extracted by image. We align each sentence on the separate line and also checked the percent of the extracted data. Most of the file had some errors so we corrected it manually.

3) Extracting the Keywords:

As this system will be extracting the important knowledge from the research papers, rules should be created according to the important Keywords. So, the easiest way was to extract the Keywords from the research papers.

We worked on the research paper with the standard structure such as Title, Abstract, Keywords then Main text. So the extraction of Keywords from the research paper takes places only for specific structure. So we automated the process of extracting the Keyword using python's regular expression. After getting keywords the frequency of the extracted words is obtained. Because those frequent words will be used by the inference rule to create new rules for extracting useful sentences from documents.

4) Extraction using Discourse words:

Discourse words are the words which give "important message" that helps us to understand or comprehend a text. This discourse words ranges from Numbering words to Adding words, linking words to Contrasting words (however) etc. These words are used everywhere from articles to research papers. So we emphasis on these words to represent knowledge or message from the research articles. We went through 5-6 paper to get the list of the discourse words. Those words were used in making new rules for the extraction of the message from the articles. Then after creating the rules for those 5-6 papers we then used those words to create the rules for other research documents to check, if these words can be generalized.

5) Building a simple Triple-store:

Till now we were doing the pre-processing of the data and collecting words for making new rules. In this section we will discuss about the schema to analyze the sentence and word data. We focused on two triple-stores that is, sentence and words separately.

There are many semantics toolkit available. We have referred Python code [28]. We choose this programming language because of its simplicity and flexibility towards various toolkits in the field of semantics and Artificial intelligence.

So from the above toolkit we have produced a dataset of sentences and words. In fact, this dataset is of three type formats that is why single data it is known as "triple". The three type formats are Subject, Predicate and Object.

We have maintained two triple-stores. The format of both the Triple-Store is shown below.

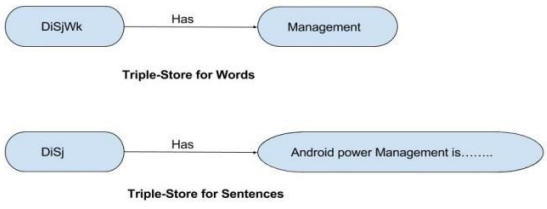

Fig.2 RDF graph example

Above Fig.2 shows a triple syntax called an RDF graph. RDF, an abbreviation for "Resource Description Framework," is a concept adopted in defining knowledge structure. Knowledge fragments are given in a syntax consisting of three elements: the subject, the predicate, and the object.

Let's consider the triple store for words for the above example, the subject is "*DiSjWk*", Predicate is "*Has*" and Object is "Management". So the subject *DiSjWk* stands for *i* th Document, *j* th Sentence and *k* th word. We have chosen the predicate to be "*Has*". The Object will be the extracted word from the paper.

For the sentences triple-Store, We have subject "*DiSj*", Predicate "*Has*" and Object will be the Sentence extracted from the document. Subject *Di* stands for *i*th Document and *Sj* stands for *j*th sentence. This Triple-Store will be base for our Experiments.

So this triple-Store will be used for extracting the knowledge or useful terms from the documents. For extracting the so called "knowledge", we will use Inference rule, which is introduced in next step.

6) Inference Rule:

Inference is the process of deriving new information from the information you already have [28]. So the "information" and which rule to apply to extract the information will vary depending on the context. As we have explained the structure of the Knowledge fragments that are given in a three elements structure. So to describe ontologies, logical expression is configured. So the process to configure the logical expression uses a syntax called predicate. Ontologies are written in OWL. Ontology is defined as the explicit and abstract model representation of already defined finite sets of terms and concepts, involved in knowledge management, knowledge engineering, and intelligent information integration [30]. In simple word, ontology is the collection and classification of terms to recognize their semantic relevance. OWL stands for Web Ontology Writing Language; its standardization has been conducted by W3C. To describe a knowledge structure in a predicate logic, a set of elements that meet a certain condition is constructed, such as "*If A, then B*". After construction, the resulting set is Fundamental to knowledge processing in the semantic data processing. Knowledge processing based on the predicate logic takes the form of generating answers from the collection of the knowledge fragments, such as *"If A is true, then B is satisfied*" and "*If B, then C,*" to queries such as "*Is Z true, if A holds?*". This process is referred to as the reasoning mechanism.

The basic pattern of inference is simply to query the information relevant to the rule and then apply the transformation that turns these bindings into a simple triple data added to the main Triple-Store, with appropriate Subject, predicate and Objects. After getting this new triple data, we use this information to process the knowledge from whole tripe-store, so Fig.3 gives the insight of our Triple data sets.

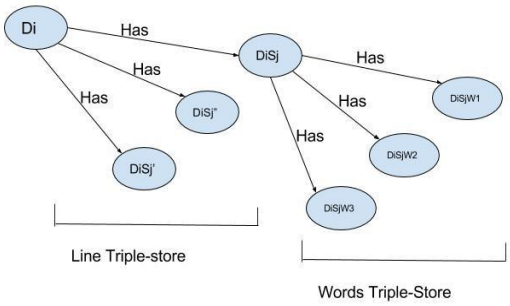

Fig.3 Triple Data Example

We have data sets with line and word Triple store. The knowledge processing or extraction of line data set uses the words triple store. We use the rule on word triple store, added the new triple data using inference rule and then we extract the knowledge from the line data sets. The steps are shown in the Fig.4 below.

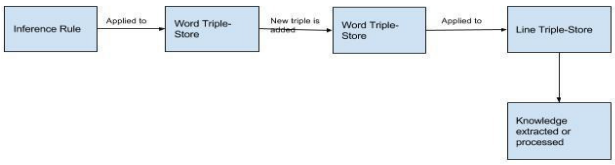

Fig.4 Pipeline of the Inference System

7) Visualization:

So, using the above process we extracted the useful and meaningful line from whole documents. Then we emphasized on visualization of the extracted knowledge. For visualization, we created new triple dataset to make a relationship between words and line. This dataset will show which word is in which line. Subject will be word, Predicate will be "Has" and Object will be sentences. So using this we got a third triple store that will consist of words and sentences together. So we will use this RDF file for visualization of the knowledge.

We used *GraphViz* graph drawing package [31]. This library has support extrinsic data in its graph drawing algorithm. It offers one of the best solution for drawing directed cyclic graphs which is state-of-the-art in graph drawing. *GraphViz* application *neato* [32] is a straightforward method for rapidly visualizing undirected graphs. The graphs are generated by using:

"neato-Teps undirected.gv > undirected.eps",

Where undirected.gv is a file that contains the code of the graph, –Teps specifies an Encapsulated Postscript output format. So using the above given library we visualized our knowledge.

V. APPLICATION

Natural language processing (NLP) is one of main field of artificial intelligence study. Extraction of meaningful information from vast amount of document database is an example of the features that NLP possibly contribute well in performing scenario building practices.

On the other hand, Science and Technology Foresight (STF) is an activity to identify important research areas or directions as well as to search key features and driving forces for those researches. For STF, there are numerous papers and books on methodologies. The scenario development is one of main measures for such future-oriented work. However, even in scenario development alone, there is wide range of possible practices depending on purpose of outcome, participant's knowledge etc.

For the scenario building method in STF, the creativity of those who participating the workshop is the most important. Usually such an activity is held in limited time scale. In order to stimulate the creativity of participant in short period of times at scenario building workshop, for example, quick identification of important sentences of the area of interests from large number of research papers is quite helpful. At the same time results of extractions could be provided with visual imaging with of data processing and graphic visualization software. With the help of such a system, human experts may exercise more efficiently during scenario building workshop.

In this context, we have designed an artificial intelligence support for the scenario building activities in this paper. We applied semantic information about structure of sentences in research papers and support human user quick visualization of extracting of sentences and key words for the purpose.

By using algorithm or method, we have achieved two aspects to a certain extent. Scenario writing is one of the example of such system could support efficiently. In the process, firstly some key driver is necessary. We may use current algorithm to get meaningful sentences that may help understanding scenario drivers. Then our algorithm also could produce different sentences with slightly different angle of interests.

The extracted sentences and words might help the scenario writer to write down case scenario.

VI. EXPERIMENTAL RESULTS.

This section show the example of using Hybrid method. We have a dataset of 69 research papers which we developed using varius sources. This dataset consist of paper which was pubished in IEEE journals and conferences. For results we have given emphasis on two methods, that are:

- Extracting the knowledge using Keywords from the paper.
- Extracting the knowledge using discourse Keywords.

As the dataset consist of the research paper which were in PDF format. So the first step is to extract the information from the PDF document so that it would be easier to work on them. PDFminner was used for this process.Then the prepocessing of the Information takes place. In prerocessing the unwanted extracted information was removed. While using PDFminner, the images in the document was extracted but contains many noise or unwanted characters. So preprocessing emphasis on removing the unwanted characters and also aligning the line using python. Then after the preprocessing we give importance on extarcting the keyword from all the documents and then we can choose the most frequent words from the document. These words were used directly from the word mentioned in the keywords section. As the keyword section consists of the words which are important acording to the context. So all this processing and counting of the word is done automatically using python. The Table1 shown below consists of frequent term in all the 69 documents:

Table 1 Keywords Examples of the 69 papers

Internet of Things	42
Wireless-network sensors	22
RFID	13
Social network	8
System security	8
Energy Efficiency	7
Service Management	7
Enterprise systems	6
Learning technology	5
6lowpan	4

After this the formation of tripe-store takes place. The dataset consists of 69 documents, with about 21K lines and 300K words before filtering. After filtering we got about 200K words and 21K lines. So two triple-store are created one for lines and one for words. Subject is choosen such that it have some relationship between two triple-store. After the making of triple-store and all process now the important step is to extract the knowledge using INFERENCE rule. This consist of the SPARQL type query. So the user makes important rule ,through this rule the knowledge is extracted. The main step in this method is INFERENCE rule. This rule can be created by user according to their preference. So this

rule will help to extract the knowledge from the Huge database rather then reading all the documents. To ease the understanding we also given importance to visualise the knowledge.

The above method was related to our first method that we mentioned in the start of this section.

In next method, we gave attention to the discourse keywords in the documents. Discourse keywords is the keywords which talks and give information about the text. After going through set of papers we came up with some Discourse keywords which are listed in Table2.

Table 2 Examples of Discourse Keywords

consists	become	aimed	Instead
useful	capable	using	Provide
method	propose	enhance	application
future	explore	aspects	Discover
objectives	focused	pedagogy	Crucial
different	various	integration	Import
promote	reflect	classified	Need

So new rule is generated using the discourse term which is mentioned above. We used this words in two form first on training set then on test set. Using training documents we got those words, then we used these words in some other documents to check the effectiveness of the words.

Here, we chose one of the 69 papers as a case study example. Document [37] is a servey paper about IoT applications of RFID(Radio Frequency IDentifier). We extracted some useful sentences which can be considered as significant knowledge descriptions about the application. Some example sentences are given below with the associated discourse term as results from the system.

"aimed" -- "this paper is aimed at drawing a landscape of the current research on rfid sensing from the perspective of iot for personal healthcare

"application" -- "thanks to the recent advantages in biomaterial engineering, a rich variety of tattoo-like thin surface electronic devices have been experimen- ted in the last three years

"based" -- "the body-centric networks investigated so far are mostly based on active devices"

"bring" -- "data processing and human behavior analysis the interactions between people and their habitat bring precious information on behavioral parameters concerning the activity rate during the different phases of the day and of the night"

"useful" -- "air monitoring is also useful in common spaces with the purpose to avoid the inhalation of anesthetic gases"

Althought those are not whole result but only the fragments of whole content of the paper, sentences indicates condenced informations about several issues discussed in the paper. We have evaluated usefulness of extracted sentences over 10 documents out of 69 papers. In each paper, there are around 10 discourse terms, but most of them were same as before and after that the inference rules were introduced based on the network visualization in the process of extraction.

In the Fig.5 we have presented both the methods i.e. Keywords and Discourse words. So first we have extracted Keywords from both the sources and then we have used the semantic analysis on it to extract the knowledge from it. The output is in the form of graph which is easy to understand. One example of the extracted knowledge is given below which is extracted by using keyword "Pedagogy".

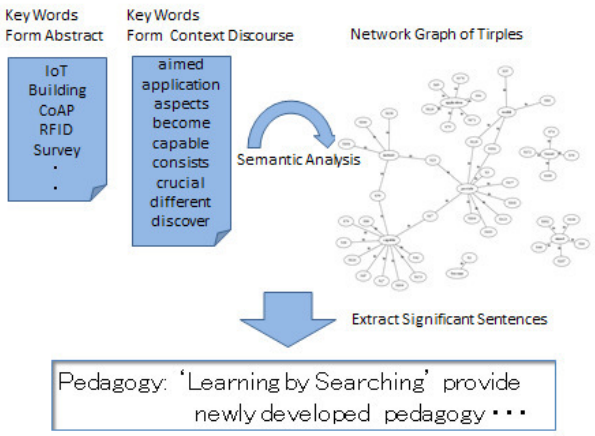

Fig.5 Example Visualization of Konwledge

Apart from this to check the extracted information we calculated the precision of the information. So after using this Hybrid method, which range from Information extraction to Semantics for knowledge extraction, the precision of the model was good.

VII. Conculsion And Future work.

In this article, we have discussed practical sentence extraction procesure and supporting system which we intended to call knowledge extraction system. Since processed data is always stored in a form of triples, resulted dataset is always fully machine readable in every stage of cyclic extraction and cleaning of data. The system assumes human exparts support in selecting so called discourse keywords. Such characteristics is useful and practical in the situations where exparts need to aquire a certain level of knowledge in a research area such as Science and Technology Foresight activities. As we have also shown, that the above introduced or obtainted discourse words can be used in any research documents and on the basis of that words useful information can be obtainted.

There are two directions for enhancing the system. One is to inroduce more sophisticated inference rules over sentences. Purhaps it will come with NLP technique with looking at grammatical structure of sentences. In addition to this, the system can try to extract discourse words from the extracted lines (using Keywords) rather than those words which are mentioned by us. Another direction goes toward practical utilizations. Big data analysis is currently one of the most needed technology in IT related services. The availability of software based data processing is very important aspect of reusing and deepining knowledges obtaind in a stage of processing.

6th International Workshop on Dealing with Spatial and Temporal Uncertainty and Imprecision

MANY fields of research concern data that carry a spatial or temporal component: data related to a location or time, which often are prone to uncertainty and/or imprecision. As both spatial and temporal data tend to be an additional aspect of the data and as both have similar issues with resolution, relative notions and intuitive notions, they are often considered together. The combination of uncertainty and/or imprecision, an increasing amount of data and the need for a higher level of reasoning on the data requires innovative methods.

The first iteration of this event concerns estimating, handling and representing uncertainty within the model, but also new ways of modelling and processing uncertain spatial or temporal data. The main focus is on novel technologies, such as possibilistic and fuzzy methods, to represent, limit or estimate the uncertainty or imprecision; but also on algorithms that involve such methods to process the data accordingly.

TOPICS

- uncertain spatial data
- spatial data analysis
- fuzzy set theory in spatial data
- use of artificial intelligence in spatial data
- fuzzy topology
- natural language in spatial data
- uncertain temporal data
- temporal data analysis
- fuzzy set theory in temporal data
- use of artificial intelligence in temporal data
- uncertainty in time series
- natural language in temporal data

***Abstract*—Consider the problem of allocation of spatially correlated gridded data to finer spatial scale, conditionally on covariate information observable in a fine grid. Spatial dependence of the process can be captured with the conditional autoregressive structure, suitable for gridded (areal level) data. Also geostatistical methods, particularly empirical universal kriging, can be used for this purpose. In this study, we compare prediction results as well as prediction standard errors for two disaggregation procedures, based on the inventory of agricultural ammonia emissions reported in Pomeranian Voivodeship of Poland.**

I. Introduction

IN MANY environmental and epidemiological applications, one has to deal with spatial variables observed at different resolutions. The change of support problem is encountered, for example, in a development of high-resolution inventories of greenhouse gases [1], [2] or ammonia emissions [3].

The choice of a relevant model capturing spatial correlation depends on a type of data, but also it can depend on a size of dataset and computational efficiency. In principle, the model suitable for areal data is based on Markov random fields, in particular the commonly used conditional autoregressive structure. However, the point-referenced data can be aggregated to the area level, and modelled the same way [4]. On the other hand, the geostatistical approach, designed for continuous spatial processes, can be used to model a process over a gridded domain.

In this paper, we aim to explore uncertainty underlying a particular procedure of areal data disaggregation from a coarse to fine grid. The setting assumes knowledge on (i) a variable of interest in a *coarse* grid, and (ii) some related variables (proxy data) in a *fine* grid. The task is accomplished with two alternative approaches to modelling spatial data: the one based on conditional autoregressive model, and the other, using geostatistical methods. These models represent two general classes commonly used in spatial statistics. Within geostatistical approach, empirical universal kriging was applied for a prediction of unknown values in a fine grid. For each model we compare the prediction standard errors against actual residuals (their absolute values), as resulting from an empirical study of ammonia emission inventory. In addition, we analyse the effect of the level of disaggregation.

II. Motivating Data Set

A. Inventory of ammonia emissions

The analysed dataset concerns ammonia (NH_3) emission inventory in a region of Poland. Ammonia is emitted mainly (up to $80-90\%$) by agricultural sources such as livestock production and fertilized fields [5], [6]. High concentrations of ammonia can lead to acidification of soils [7], forest decline, and eutrophication of waterways [6]. All of these lead to loss of plant biodiversity [8]. Moreover, ammonia emissions are recognized for their importance in contributing to fine particulate matter [9], hence their spatial distribution is of great importance.

However, agricultural emission sources cannot be measured directly, and spatial emission patterns need to be assessed otherwise. This issue was addressed, for instance in [3], where agricultural and land cover data were used to disaggregate the national NH_3 emission totals across Great Britain. This was accomplished employing a spatially weighted redistribution of emission sources, with weights based on respective landcover classes. It was demonstrated in [10] that this type of straightforward, linear approaches to spatial allocation can be substantially improved by introducing a spatial random effect modelled with a conditional autoregressive structure.

B. Data description

The dataset comprises the gridded inventory of ammonia emissions from fertilization (in tonnes per year), reported in Pomeranian Voivodeship of Poland. The inventory grid cells are of regular 5km×5km size, and the whole of cadastral survey compiles $n = 800$ cells, denoted $\boldsymbol{y} = (y_1, \ldots, y_n)^T$; see Fig. 1.

It should be noted, that the considered variable y of ammonia refers to a total amount of emissions over a grid cell; it is called an *extensive* variable [11]. This should be distinguished from *intensive* variables, e.g. emission concentrations or proportions over a geographic region.

978-83-60810-90-3/$25.00

For explanatory information we use the CORINE Land Cover Map for this region, available from the European Environment Agency [12]. Specifically, for each single grid cell we calculate area (in m^2) of those land use classes that are related to ammonia emissions. The following CORINE classes were considered (for reference, the CORINE class numbers are given in brackets):

- Non-irrigated arable land (211), denoted $\boldsymbol{x}_1$;
- Fruit tree and berry plantations (222), denoted $\boldsymbol{x}_2$;
- Pastures (231), denoted $\boldsymbol{x}_3$;
- Complex cultivation patterns (242), denoted $\boldsymbol{x}_4$;
- Principally agriculture, with natural vegetation (243), denoted $\boldsymbol{x}_5$.

Only land use data are used as explanatory information. Also, it should be pointed out that our modelling approach includes both a regression component as well as a spatial correlation component, and the resulting regression coefficients are not the same as typical emission coefficients, specific for the listed land use classes.

Performance of a disaggregation framework depends on various factors. Among others, it highly depends on the extent of disaggregation; note, that this is connected with a preservation of the correlation across spatial scales. An impact of this feature is evaluated in the study. We test the disaggregation from 10km×10km and 15km×15km (coarse) grids to a 5km×5km (fine) grid. To examine performance of the disaggregation procedure, first we aggregate the original fine grid emissions into respective coarse grid cells. Next, we fit respective model and predict ammonia emissions for a 5km fine grid. Finally, we check obtained results with the original inventory emissions of a 5km grid. Thus, our simulation study tests the cases of a fourfold and ninefold disaggregation. The aggregated values of the two coarse grids as well as the actual inventory data in the fine grid are shown in Fig. 1.

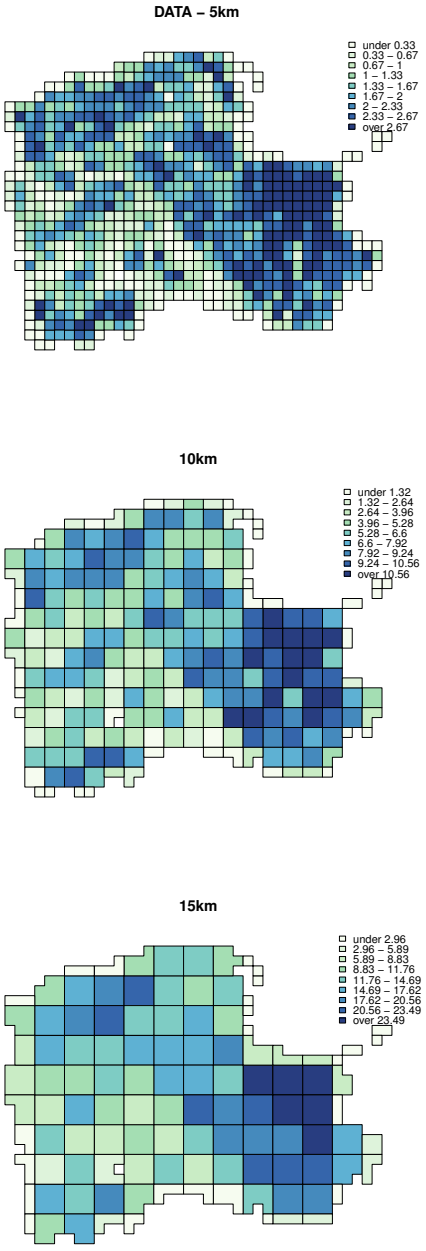

Fig. 1. Ammonia emissions (in tonnes/year): inventory data in 5km grid, and aggregated values in 10km and 15km grids

III. Disaggregation Model Based on Conditional Autoregressive Structure

In this section we present an approach for areal to areal data realignment, where the residual covariance structure is modelled with the conditional autoregressive (CAR) specification [13], [14]. This class of models is used in the case of areal data, and it introduces spatial association through a neighbourhood structure.

A. The model

1) Fine grid: We begin with the model specification in a fine grid. Let $\boldsymbol{Y} = \{Y_i\}_{i=1}^n$ denote random variables associated with missing values of interest $\boldsymbol{y} = \{y_i\}_{i=1}^n$ defined at each cell i, $i = 1, ..., n$ of a fine grid. Assume that random variables Y_i follow a Gaussian distribution with respective mean and variance, $Y_i|\mu_i, \sigma_Y^2 \sim \mathcal{N}\left(\mu_i, \sigma_Y^2\right)$. Given the values μ_i and σ_Y^2, the random variables Y_i are independent.

The values $\boldsymbol{\mu} = \{\mu_i\}_{i=1}^n$ represent the underlying mean process, and the (missing) observations in a fine grid are related to this process through a measurement error of variance σ_Y^2. The model for the underlying mean process is formulated as a sum of regression component with available covariates, and a spatially varying random effect.

The approach to modeling μ_i expresses an assumption that available covariates explain part of the spatial pattern, and the remaining part is captured through a spatial dependence, introduced as the conditional autoregressive CAR model. The CAR scheme follows an assumption of similar random effects in adjacent cells, and it is given through the specification of

full conditional distribution functions of μ_i for $i = 1, \ldots, n$ [15], [16]

$$\mu_i|\mu_{j,j\neq i} \sim \mathcal{N}\left(\boldsymbol{x}_i^T\boldsymbol{\beta} + \rho\sum_{\substack{j=1\\ j\neq i}}^{n}\frac{w_{ij}}{w_{i+}}\left(\mu_j - \boldsymbol{x}_j^T\boldsymbol{\beta}\right), \frac{\tau^2}{w_{i+}}\right), \tag{1}$$

where $\boldsymbol{\mu}_{-i}$ denotes all elements in $\boldsymbol{\mu}$ but μ_i; w_{ij} are the adjacency weights ($w_{ij} = 1$ if j is a neighbour of i and 0 otherwise, also $w_{ii} = 0$); w_{i+} is the number of neighbours of area i; $\boldsymbol{x}_i^T\boldsymbol{\beta}$ is a regression component with explanatory covariates for area i and a respective vector of regression coefficients.; and τ^2 is a variance parameter.

The conditionals (1) yield the following joint distribution of the process $\boldsymbol{\mu}$, see e.g. [15]

$$\boldsymbol{\mu} \sim \mathcal{N}_n\left(\boldsymbol{X}\boldsymbol{\beta}, \tau^2\left(\boldsymbol{D} - \rho\boldsymbol{W}\right)^{-1}\right), \tag{2}$$

where $\boldsymbol{X}$ is a design matrix with vectors $\boldsymbol{x}_i$; $\boldsymbol{D}$ is an $n \times n$ diagonal matrix with w_{i+} on the diagonal; and $\boldsymbol{W}$ is an $n \times n$ matrix with adjacency weights w_{ij} . Equivalently, we can write (2) as

$$\boldsymbol{\mu} = \boldsymbol{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}, \quad \boldsymbol{\epsilon} \sim \mathcal{N}_n\left(\boldsymbol{0}, \boldsymbol{N}\right), \tag{3}$$

denoting also $\boldsymbol{N} = \tau^2\left(\boldsymbol{D} - \rho\boldsymbol{W}\right)^{-1}$.

2) Coarse grid: The model for a coarse grid (aggregated) observed data is obtained by multiplication of the mean process (3) with an $N \times n$ *aggregation matrix* $\boldsymbol{C}$, where N is a number of observations in a coarse grid

$$\boldsymbol{C}\boldsymbol{\mu} = \boldsymbol{C}\boldsymbol{X}\boldsymbol{\beta} + \boldsymbol{C}\boldsymbol{\epsilon}, \quad \boldsymbol{C}\boldsymbol{\epsilon} \sim \mathcal{N}_N\left(\boldsymbol{0}, \boldsymbol{C}\boldsymbol{N}\boldsymbol{C}^T\right). \tag{4}$$

The matrix $\boldsymbol{C}$ consists of 0's and 1's, indicating which cells have to be aligned together. The random variable $\boldsymbol{\lambda} = \boldsymbol{C}\boldsymbol{\mu}$ is treated as the mean process for variables $\boldsymbol{Z} = \{Z_i\}_{i=1}^N$ associated with observations $\boldsymbol{z} = \{z_i\}_{i=1}^N$ of the aggregated model

$$\boldsymbol{Z}|\boldsymbol{\lambda} \sim \mathcal{N}_N\left(\boldsymbol{\lambda}, \sigma_Z^2\boldsymbol{I}_N\right), \tag{5}$$

where $\boldsymbol{I}_N$ is the $N \times N$ identity matrix. Also at this level, the underlying process $\boldsymbol{\lambda}$ is related to $\boldsymbol{Z}$ through a measurement error with variance σ_Z^2.

B. Maximum likelihood estimation

The parameters $\boldsymbol{\beta}, \sigma_Z^2, \tau^2$ and ρ are estimated with the maximum likelihood method based on the joint unconditional distribution of $\boldsymbol{Z}$

$$\boldsymbol{Z} \sim \mathcal{N}_N\left(\boldsymbol{C}\boldsymbol{X}\boldsymbol{\beta}, \boldsymbol{M} + \boldsymbol{C}\boldsymbol{N}\boldsymbol{C}^T\right), \tag{6}$$

where $\boldsymbol{M} = \sigma_Z^2\boldsymbol{I}_N$. Next, the log likelihood function associated with (6) is formulated

$$L(\cdot) = -\frac{1}{2}\log\left|\boldsymbol{M} + \boldsymbol{C}\boldsymbol{N}\boldsymbol{C}^T\right| - \frac{N}{2}\log\left(2\pi\right)$$
$$-\frac{1}{2}\left(\boldsymbol{z} - \boldsymbol{C}\boldsymbol{X}\boldsymbol{\beta}\right)^T\left(\boldsymbol{M} + \boldsymbol{C}\boldsymbol{N}\boldsymbol{C}^T\right)^{-1}\left(\boldsymbol{z} - \boldsymbol{C}\boldsymbol{X}\boldsymbol{\beta}\right),$$

where $|\cdot|$ denotes the determinant. The analytical derivation is limited to the regression coefficients $\boldsymbol{\beta}$, and further maximisation of the profile log likelihood is performed numerically. The standard errors of parameter estimators for this model have been developed by means of the expected and observed Fisher information matrices, details of which are provided in [17].

C. Prediction in a fine grid

Regarding the missing values in a fine grid, the underlying mean process is of our primary interest. The predictors optimal in terms of the minimum mean squared error are given by $E\left(\boldsymbol{\mu}|\boldsymbol{z}\right)$. The joint distribution of $\left(\boldsymbol{\mu}, \boldsymbol{Z}\right)$ is

$$\begin{bmatrix}\boldsymbol{\mu}\\ \boldsymbol{Z}\end{bmatrix} \sim \mathcal{N}_{n+N}\left(\begin{bmatrix}\boldsymbol{X}\boldsymbol{\beta}\\ \boldsymbol{C}\boldsymbol{X}\boldsymbol{\beta}\end{bmatrix}, \begin{bmatrix}\boldsymbol{N} & \boldsymbol{N}\boldsymbol{C}^T\\ \boldsymbol{C}\boldsymbol{N} & \boldsymbol{M} + \boldsymbol{C}\boldsymbol{N}\boldsymbol{C}^T\end{bmatrix}\right).$$

The above distribution allows for full inference, yielding both the predictor

$$\widehat{E\left(\boldsymbol{\mu}|\boldsymbol{z}\right)} = \boldsymbol{X}\widehat{\boldsymbol{\beta}} + \widehat{\boldsymbol{N}}\boldsymbol{C}^T\left(\widehat{\boldsymbol{M}} + \boldsymbol{C}\widehat{\boldsymbol{N}}\boldsymbol{C}^T\right)^{-1}\left[\boldsymbol{z} - \boldsymbol{C}\boldsymbol{X}\widehat{\boldsymbol{\beta}}\right] \tag{7}$$

and its variance

$$\widehat{Var\left(\boldsymbol{\mu}|\boldsymbol{z}\right)} = \widehat{\boldsymbol{N}} - \widehat{\boldsymbol{N}}\boldsymbol{C}^T\left(\widehat{\boldsymbol{M}} + \boldsymbol{C}\widehat{\boldsymbol{N}}\boldsymbol{C}^T\right)^{-1}\boldsymbol{C}\widehat{\boldsymbol{N}}. \tag{8}$$

IV. Geostatistical Approach

In this section, we briefly review geostatistical approach, which is dedicated to modelling point-referenced data over a continuous domain. It specifies the process through a covariance function.

In the application considered, ammonia emission $Y(\boldsymbol{s})$ is the variable of area type. The point level data are obtained by dividing this variable by area (in km^2) of respective grid cell. This is a kind of approximation which expresses emissions over a unit area, or (roughly) *emission intensity*. Thus, a geostatistical model is applied to the modified process $Y_A\left(\boldsymbol{s}\right) = Y(\boldsymbol{s})/A$, where A stands for area of a 5km grid cell. We observe $\boldsymbol{Y}_A = \left(Y_A(\boldsymbol{s}_1), \ldots, Y_A(\boldsymbol{s}_n)\right)^T$ in a fine grid, and we wish to predict the variable $Y_A(\boldsymbol{s}_0)$ at a location $\boldsymbol{s}_0 \in D$ where it has not been observed, i.e. in centroids of a coarse grid.

Gaussian geostatistical models are based on two assumptions: second order stationarity and isotropy. Second order stationarity means that the process mean is constant and its covariance function depends only on the difference between locations. The process is isotropic if, additionally, the covariance depends only on distance (not direction) between two locations. Once these assumptions are met, spatial process can be modelled with parametric covariance functions. The exponential covariance function, applied in this study, is defined as,

$$cov\left(h\right) = \begin{cases}\sigma^2\exp\left(-\phi h\right) & \text{if } h > 0\\ \tau_{nug}^2 + \sigma^2 & \text{if } h = 0,\end{cases} \tag{9}$$

where h denotes the Euclidean distance between two points, τ_{nug}^2 represents the nugget effect, σ^2 is the partial sill, and ϕ denotes the effective range of the covariance. Furthermore, denote $\boldsymbol{K} = cov\left(\boldsymbol{Y}_A, \boldsymbol{Y}_A^T\right)$, $\boldsymbol{k} = cov\left\{\boldsymbol{Y}_A, Y_A(\boldsymbol{s}_0)\right\}$, and $k_0 = cov\left\{Y_A(\boldsymbol{s}_0), Y_A(\boldsymbol{s}_0)\right\}$.

With land use information available as covariates denoted $\boldsymbol{X} = (\boldsymbol{x}(\boldsymbol{s}_1), \ldots, \boldsymbol{x}(\boldsymbol{s}_n))^T$ and $\boldsymbol{x}(\boldsymbol{s}_0)$, universal kriging [18] was applied for a prediction in a fine grid. The model for a random field $Y_A(\boldsymbol{s})$ has a linear mean function and the error process $\epsilon(\boldsymbol{s})$

$$Y_A(\boldsymbol{s}) = \boldsymbol{x}(\boldsymbol{s})^T\boldsymbol{\beta} + \epsilon(\boldsymbol{s}), \tag{10}$$

where $\boldsymbol{\beta} = (\beta_1, \beta_2, \ldots, \beta_p)^T$ is a vector of p unknown coefficients, and $\epsilon(\boldsymbol{s})$ is a zero-mean Gaussian process with the exponential covariance function given by (9).

The geostatistical prediction problem is formulated as follows. We seek a predictor $\hat{Y}_A(\boldsymbol{s}_0)$ that minimises the mean squared prediction error among the predictors satisfying two properties:

1) linearity: $\hat{Y}_A(\boldsymbol{s}_0) = \boldsymbol{\lambda}^T\boldsymbol{Y}_A$
2) unbiasedness: $E\hat{Y}_A(\boldsymbol{s}_0) = E\left(\boldsymbol{\lambda}^T\boldsymbol{Y}_A\right) = EY_A(\boldsymbol{s}_0)$ for all $\boldsymbol{\beta} \in \mathbb{R}^p$

We obtain minimisation of $E\left\{Y_A(\boldsymbol{s}_0) - \boldsymbol{\lambda}^T\boldsymbol{Y}_A\right\}^2$ subject to

$$\boldsymbol{X}^T\boldsymbol{\lambda} = \boldsymbol{x}(\boldsymbol{s}_0). \tag{11}$$

This constraint optimisation task can be solved with the method of Lagrange multipliers, see e.g. [19], [15]. Provided that matrices $\boldsymbol{K}$ and $\boldsymbol{X}^T\boldsymbol{K}^{-1}\boldsymbol{X}$ are invertible, it yields

$$\begin{aligned}\boldsymbol{\lambda} = &\left\{\boldsymbol{K}^{-1} - \boldsymbol{K}^{-1}\boldsymbol{X}\left(\boldsymbol{X}^T\boldsymbol{K}^{-1}\boldsymbol{X}\right)^{-1}\boldsymbol{X}^T\boldsymbol{K}^{-1}\right\}\boldsymbol{k} \\ &+ \boldsymbol{K}^{-1}\boldsymbol{X}\left(\boldsymbol{X}^T\boldsymbol{K}^{-1}\boldsymbol{X}\right)^{-1}\boldsymbol{x}\left(\boldsymbol{s}_0\right)\end{aligned} \tag{12}$$

and the best linear unbiased predictor (BLUP) of $Y_A(\boldsymbol{s}_0)$ becomes

$$\begin{aligned}\hat{Y}_A(\boldsymbol{s}_0) =& \boldsymbol{\lambda}^T\boldsymbol{Y}_A \\ =& \left\{\boldsymbol{k} + \boldsymbol{X}\left(\boldsymbol{X}^T\boldsymbol{K}^{-1}\boldsymbol{X}\right)^{-1}\left[\boldsymbol{x}\left(\boldsymbol{s}_0\right) - \boldsymbol{X}^T\boldsymbol{K}^{-1}\boldsymbol{k}\right]\right\}^T \\ &\times \boldsymbol{K}^{-1}\boldsymbol{Y}_A.\end{aligned} \tag{13}$$

The resulting mean squared error of the BLUP, called also the kriging variance, is given by

$$k_0 - \boldsymbol{k}^T\boldsymbol{K}^{-1}\boldsymbol{k} + \boldsymbol{\gamma}^T\left(\boldsymbol{X}^T\boldsymbol{K}^{-1}\boldsymbol{X}\right)^{-1}\boldsymbol{\gamma}, \tag{14}$$

where $\boldsymbol{\gamma} = \boldsymbol{x}(\boldsymbol{s}_0) - \boldsymbol{X}^T\boldsymbol{K}^{-1}\boldsymbol{k}$.

Estimation of parameters has been performed using the `geoR` package from the `R` software [20].

V. Results

A. Fourfold disaggregation

This subsection presents the model testing results for disaggregation from a 10km grid.

Table I displays the maximum likelihood estimates and standard errors for all parameters. Also the statistical significance of regression coefficients is reported with the t-statistic and respective *p*-values. It should be stressed, that estimation of parameters has been performed for *emission values* in the case of CAR models, and for *emission intensity* in the case of geostatistical models (denoted GEOST). Therefore, parameter estimates are comparable only within the same class of models. As regards GEOST models, due to an optimisation procedure [20], the standard errors are available only for the ratio τ^2_{nug}/σ^2_Z.

From a visual comparison of the 5km maps with predicted values of ammonia emissions (not shown), the differences with respect to the original data cannot be easily distinguished. Instead, Fig. 2 presents scatterplots of predicted values y_i^* against observations y_i. This suggests that CAR model gives better results than GEOST. In general, CAR model provides very accurate predictions, although it tends to overestimate significantly some of small values.

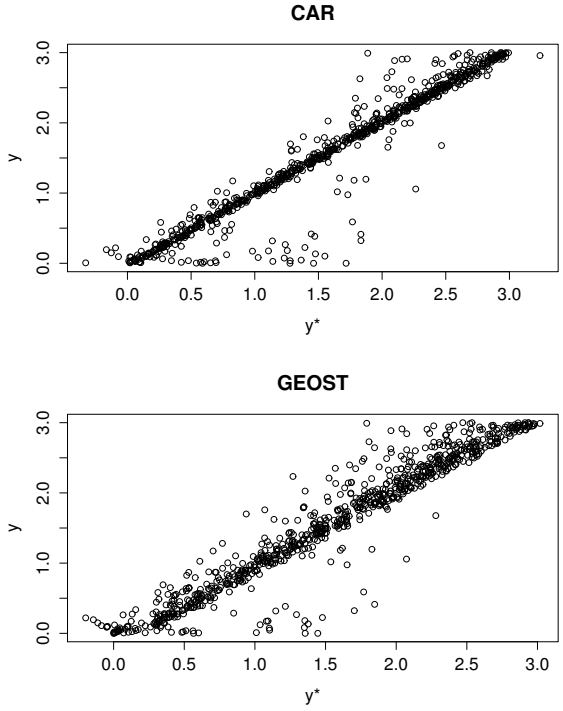

Fig. 2. Predicted (y^*) versus observed (y) values (in tonnes/year); disaggregation from 10km grid

Model residuals $(d_i = y_i - y_i^*)$ are further summarised in Table II (the upper panel). The quantitative comparison confirms that CAR model outperforms the geostatistical one, both in terms of the mean squared error (*mse*) as well as the sample correlation coefficient (*r*). Still, the highest overestimate, i.e. min(d_i) = -1.717, is reported for CAR model.

Next, the prediction standard error was calculated following the formula (8) for CAR model, and the formula (14) for geostatistical model. Since in the present case study the correct values of emissions predicted in 5km grid are known, we are in a position to compare the prediction error with actual residuals (more precisely, with their absolute values). In Fig. 3 these values are presented on maps for both disaggregation procedures. For CAR model, it is noticeable that the prediction error does not reflect diversification of actual residuals very ac-

GEOST	0.144	-1.914	1.519	0.913

curately, and the highest values of residuals are underestimated (compare the scales of both maps). Otherwise, the prediction standard errors seem to provide a reasonable assessment. On the other hand, the prediction standard error for GEOST model is significantly underestimated, as seen from the map scales. Note, that for both disaggregation methods, the highest residuals are reported on the border of the domain; this fact is known in spatial statistics as the *edge effect*.

In addition, Fig. 4(a) presents the differences between the prediction standard errors of the models and absolute values of actual residuals. The empirical cumulative distributions of these differences confirm that the geostatistical model underestimates the prediction standard errors, much more than the CAR model does.

B. Ninefold disaggregation

Next, the results of disaggregation from a 15km grid are presented. In Table I we can see, for respective models, the increase of variances σ_Z^2 when turning from a 10km to 15km disaggregation.

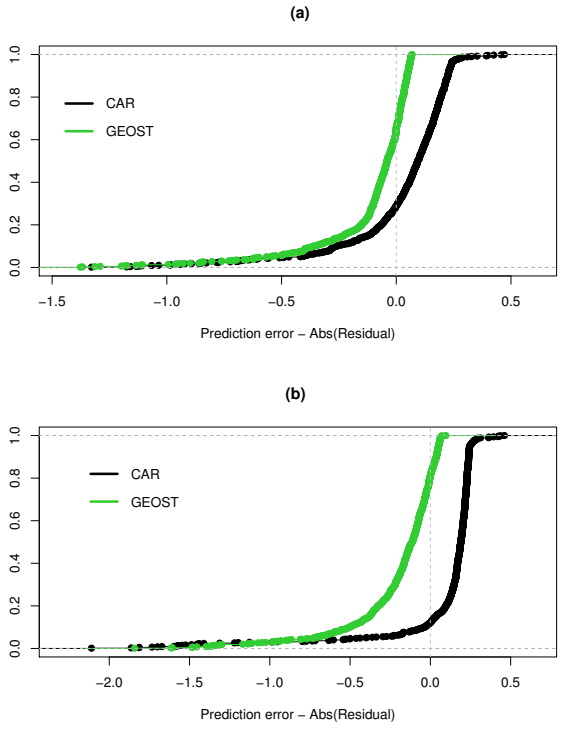

Fig. 4. Empirical cumulative distributions of the differences between the prediction standard errors and absolute values of residuals (in tonnes/year) for (a) 10km and (b) 15km disaggregation

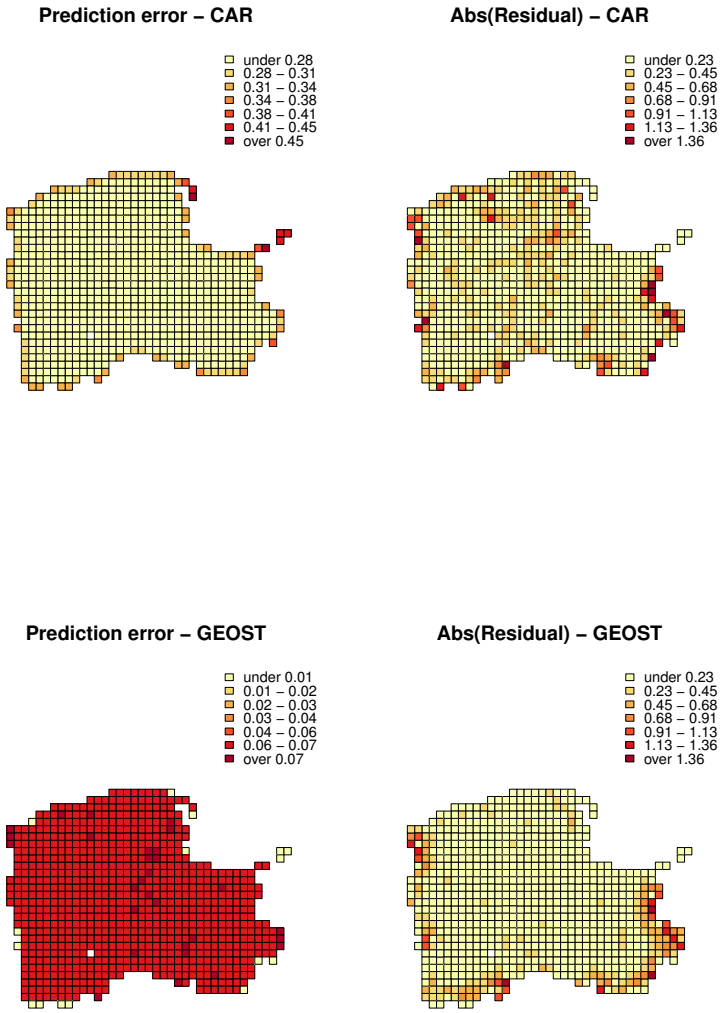

Fig. 3. Prediction standard errors and absolute values of residuals (in tonnes/year) for CAR (upper panel) and GEOST (lower panel) models; disaggregation from 10km grid. Note that the maps are drawn in different scales.

The scatterplot in Fig. 5 reveals important differences between the two methods. CAR model generally provides more accurate predictions but heavily overestimates numerous values. Predictions from GEOST are less accurate, and the model also tends to overestimate low values and underestimate high ones. Overall, Table II shows that both approaches provide comparable quality of predictions, as summarised by the mean squared error and correlation coefficient. Again, the highest overestimate, i.e. $\min(d_i)$ = -2.428, is noted for CAR model.

For the case of ninefold disaggregation, the prediction standard errors and absolute values of residuals are depicted in Fig. 6. For CAR model, this comparison provides quite good picture, although the highest values of residuals are still underestimated. Apart from this, the model uncertainty is reflected rather well. This is not the case for GEOST model. Firstly, a regular pattern on the map of prediction standard error is completely different from the actual residuals. It can be attributed to inherent features of the geostatistical method which provides the lowest prediction error at observed locations. Secondly, the prediction error for this procedure is evidently underestimated, similarly as for the case of 10km disaggregation.

Respective cumulative distributions of the differences be-

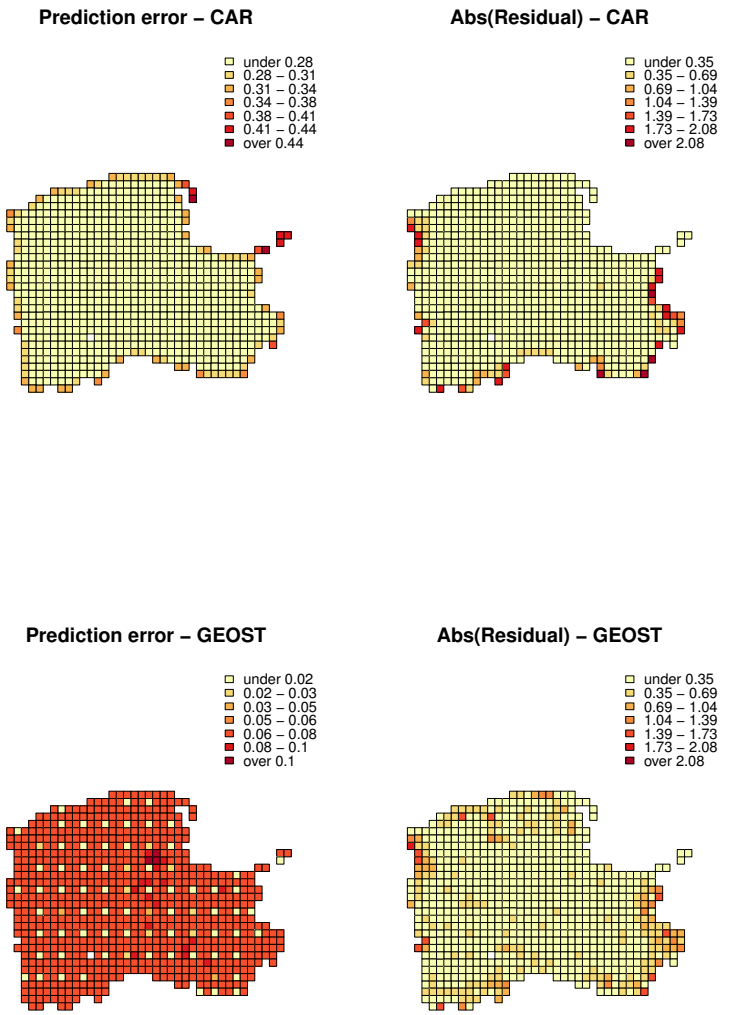

Fig. 6. Prediction standard errors and absolute values of residuals (in tonnes/year) for CAR (upper panel) and GEOST (lower panel) models; disaggregation from 15km grid. Note that the maps are drawn in different scales.

tween the prediction standard errors and absolute values of residuals, presented in Fig. 4(b), illustrate that CAR model provides rather higher estimates of error than the actual residuals, while GEOST underestimates the model error. Compared with the results for 10km disaggregation, we note that accuracy of uncertainty assessment improved for CAR model, and it declined for GEOST.

VI. Concluding Remarks

The major objective of this paper was to study uncertainty of two procedures for spatial allocation from a coarse to fine grid. For a particular disaggregation setting with proxy data available in a fine grid, we analysed the approach based on the conditional autoregressive structure, and the one based on the geostatistical methods.

For disaggregations from 10km and 15km grids to a 5km grid, both methods provided very good predictions, with r = 0.96 and 0.91, respectively. The mean squared error of predictions was approximately 20% lower for CAR model in the case of fourfold disaggregation, and 5% in the case of ninefold disaggregation.

As regards the geostatistical method, despite its good predictive performance, this disaggregation procedure failed to properly assess uncertainty of the model. It should be noted

TABLE III
PROS AND CONS OF THE DISAGGREGATION METHODS

CAR model	GEOST model
ADVANTAGES	
- Very good predictive performance - Reliable assessment of prediction error - Accuracy of uncertainty assessment remains high also when increasing a degree of disaggregation. - The method is well suited for areal data.	- Very good predictive performance - Prediction with universal kriging is a well known, popular method, and thus easy to implement for practitioners. - Wide availability of dedicated software
DISADVANTAGES	
- CAR structure is less popular among practitioners, and usually one needs to develop their own codes.	- Poor assessment of model uncertainty - The method is dedicated to point-referenced data, and application for areal data requires some additional manipulations.

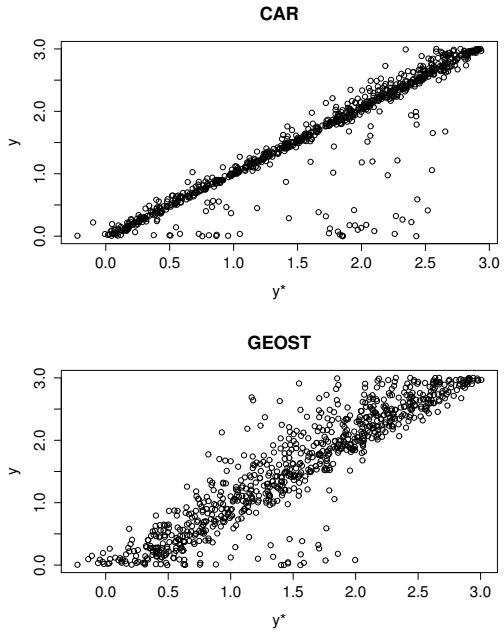

Fig. 5. Predicted (y^*) versus observed (y) values (in tonnes/year); disaggregation from 15km grid

that in our study the covariance function was unknown and respective parameters were estimated, which resulted in *empirical* universal kriging procedure. In such a case, the predictor is no longer a linear function of the data. In [16] the authors note that empirical kriging variance tends to underestimate the actual prediction error variance of the empirical universal kriging predictor because it does not account for additional error due to parameter estimation. CAR model provided a reliable assessment of prediction error. In this particular case study, this might result also from the fact that CAR structure is dedicated to areal data, like the analysed dataset of ammonia emissions.

When increasing a degree of disaggregation, obviously the quality of predictions decreases, but the accuracy of uncertainty assessment improved for CAR model. For the geostatistical approach presented, it is generally poor. Nevertheless, universal kriging is a popular, widespread technique, built into numerous software tools, which facilitates application of this disaggregation approach.

To summarise, Table III lists advantages and disadvantages of both methods for the considered case of areal data disaggregation.

ACKNOWLEDGMENT

The authors greatefully acknowledge the staff of *Ekometria sp. z o.o.*, in particular Wojciech Trapp and Małgorzata Paciorek, for provision of data.

***Abstract*—The paper addresses the problem of uncertainty in the greenhouse gas emission inventories, by proposing an alternative method for assessing uncertainty and its evolution over time. To estimate the inventory accuracy, the revisions published in consecutive years are used. These revisions are considered nonstationary time series. We describe evolution by time-dependent models, used to analyze data from the National Inventory Reports published annually up to 2015, for selected EU countries. We present a parametric model and a procedure for estimating parameters, along with the results obtained.**

I. Introduction

ACCORDING to the United Nations Framework Convention on Climate Change (UNFCCC) and its Kyoto Protocol, each of the cosignatories is obliged to provide annual data on greenhouse gas (GHG) inventory. These data are given in the National Inventory Reports (NIR), prepared either according to the 2000 IPCC report 'Good Practice Guidance and Uncertainty Management in National Greenhouse Inventories'[1], or later to the 2006 'IPCC Guidelines for National Greenhouse Gas Inventories' [2], describing in detail how uncertainty analysis should be conducted. Each NIR report contains data from a given year and revisions of past data. Data for previous years are revised given more precise information. This means that, revisions made in different years use different knowledge, and hence uncertainties in different revisions change.

In general, uncertainty associated with GHG inventory can be classified as scientific uncertainty (when the the actual emission and/or removal process is insufficiently understood) and estimation uncertainty (mostly structural, connected with activity data, emission factors, and other parameters), present whether GHG emissions are quantified. Three tier's are described for categorizing both emissions factors and activity data. A tier represents a level of methodological complexity. Tier 1 is the basic method, while Tier's 2 and 3 are each more demanding in terms of complexity and data requirements. Two of these approaches i.e. the error propagation (Tier 1) and the Monte Carlo approach (Tier 2) are recommended to assess uncertainty. The first one is much easier to calculate, while the second is considered more accurate. Since the use of the given approach is only suggested, most countries use only one of these approaches, or change the method of uncertainty assessment in consecutive reports, which makes it difficult to compare the estimates and its changes over time. In particular, it may happen that the alleged reduction in uncertainty is in fact connected with the different method of its assessment. The goal of this paper is to present an alternative, data-driven method of uncertainty assessment.

The problem of uncertainty analysis from the report data is not new, and has been dealt with for several years. Various databases were analyzed, including the IPCC data from the National Inventory Reports, but in most papers, all revision data were studied independently, e.g. in [3]. The question of how to analyze temporal evolution of the accuracy of emission inventories from several revisions was first formulated in [5], where uncertainty estimates were calculated for Austria using an algebraic approach, based on available data from different revisions year by year. Some conclusions from the results obtained there, were also presented in [4]. A similar year by year approach was presented in [8], using the Austrian NIR data as well.

This paper presents a different, revisions oriented analysis. We are interested in all consecutive yearly revisions, and differences between them, rather than in examining each of them separately. Intuitively this means that, by analyzing consecutive revisions and therefore errors and inaccuracies associated with them, which are different for each revision, we want to capture the structure of the uncertainty and its evolution over time. The method proposed combines a nonparametric regression technique using smoothing splines, as presented in [3], with a parametric model. This two-step semiparametric approach enables prior preparation of the data to which the model is fitted. Using the spline, is aimed at smoothing the data, i.e. at de-trending of the time series reported, and this in turn results in much better modelling.

978-83-60810-90-3/$25.00

This paper continues considerations outlined in [6] and carried out in [7], where we discussed some parametric model, applied to the NIR data published up to the year 2007. With the analysis carried out on longer samples, i.e. based on the NIR data published up to 2015, we managed to significantly improve the model, and get more representative results.

In Section II we present the idea of interpreting the data and propose a parametric model, that describes the uncertainty structure. Section III contains the results of fitting the model to the data on CO_2 emission from the National Inventory Reports for selected EU countries, along with the uncertainty assessment. Conclusions are given in Section IV.

II. Data and Model

We analyze data from the National Inventory Reports for selected EU countries. To consider a model, the data must first be interpreted in a manner which allows the extraction of uncertainty.

A. Data interpretation

Let $E^n_{y_j,i}$ denote the inventory data for the country i, in the year n, $n = 1, \ldots, N_j$, revised in the year y_j, $j = 1, \ldots, J$, where y_J is the last year, when the last revision was made. The index j enumerates the revisions. For a given country i, all the inventory data form a table (Table I), in which each row contains revision data reported in the year y_j i.e. a time series indexed by n, and each column contains emission inventory for the year n, recalculated in consecutive yearly revisions up to n, (a time series indexed by y_j). The analysis will be conducted for rows of that table, i.e. investigating emission inventories from consecutive yearly revisions.

For a given country i, we model any revision data to be composed of the 'real' emission, which we call the 'deterministic' fraction and the 'stochastic' fraction, related to our lack of knowledge and imprecision of observation of the real emission. We assume that the uncertainty is related to the stochastic part of the model.

For the most recently revised data, there is

$$E^n_{y_J,i} = D^n_{y_J,i} + S^n_{y_J,i}, \qquad S^n_{y_J,i} \sim \mathcal{N}(0, \sigma_{y_J,i}),$$

where E stands for the emission inventory, D for its deterministic fraction, S for the stochastic fraction, and n is the year, for which the revised data were recalculated.

Now, the data revised in the year y_j, where $j = 1, \ldots, J-1$ are modeled as having the same deterministic fraction. Thus they follow the same type of decomposition

$$E^n_{y_j,i} = D^n_{y_J,i} + S^n_{y_j,i}, \quad \text{with} \quad S^n_{y_j,i} \sim \mathcal{N}\big(0, \sigma^n_{y_j,i}\big), \quad (1)$$

where the standard deviations $\sigma^n_{y_j,i}$ are of the form

$$\sigma^n_{y_j,i} = \sqrt{\sigma^2_{y_J,i} + \alpha_{j,i}\,(y_J - y_j)^2}, \quad \alpha_{j,i} > 0. \quad (2)$$

Parameters $\alpha_{j,i}$, associated with the stochastic fraction $S^n_{y_j,i}$, can be estimated from the data together with $\sigma^2_{y_J,i}$. They describe a shift of the precision level and depend on the difference between the revision year y_j, $j = 1, \ldots, J-1$ and the most recent revision year y_J, due to the learning. The deterministic fraction $D^n_{y_J,i}$ is found, using smoothing spline, as presented in [3]. Applying this nonparametric approach to the most recently revised data $E^n_{y_J,i}$, gives not only the estimate of the deterministic fraction, but also an estimate of the variance $\sigma^2_{y_J,i}$. Considering dependence of the obtained results on spline determination, all results given in the paper are conditioned on the splines, though it is not additionally stressed in the sequel.

TABLE I
Indexing the data

$$\begin{array}{cccccccc}
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
\cdots & E^n_{y_j,i} & E^{n+1}_{y_j,i} & \cdots & E^{y_j}_{y_j,i} & 0 & \cdots & 0 \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
\cdots & E^n_{y_J,i} & E^{n+1}_{y_J,i} & \cdots & E^{y_j}_{y_J,i} & E^{y_j+1}_{y_J,i} & \cdots & E^{y_J}_{y_J,i}
\end{array}$$

B. Model and Parameters

Given the smoothing spline $\mathrm{Sp}_{y_J,i}$, we consider it the estimate of $D^n_{y_J,i}$ and use it, along with the emission data $E^n_{y_j,i}$, for $j = 1, \ldots, J-1$ to estimate uncertainty described by $S^n_{y_J,i}$. The method is based on analysis of the differences between the revisions $E^n_{y_j,i}$, and the smoothing spline $\mathrm{Sp}_{y_J,i}$

$$v^n_{y_j,i} = E^n_{y_j,i} - \mathrm{Sp}_{y_J,i},$$

where $j = 1, \ldots, J-1$, $n = 1, \ldots, N_j$. Following (1) – (2), we assume that, for a fixed country i

$$v^n_{y_j} \sim \mathcal{N}\Big(0, \sigma^n_{y_j}\Big), \quad (3)$$

where differences $v^n_{y_j}$ are independent and

$$\sigma^n_{y_j} = \sqrt{\sigma^2_{y_J} + \alpha_j (y_J - y_j)^2} \quad (4)$$

Parameters α_j in (4) can be obtained as Maximum Likelihood estimators. Due to (3) the log-likelihood function, with parameter $\sigma^n_{y_j}$ is of the form

$$\ln L(\sigma^n_{y_j}) = -N_j \ln\sqrt{2\pi} - \frac{1}{2} N_j \ln(\sigma^n_{y_j}) - \frac{1}{2(\sigma^n_{y_j})^2} \sum (v^n_{y_j})^2$$

Substituting (4), gives

$$\ln L(\alpha_j) = -N_j \ln\sqrt{2\pi} - \frac{1}{2} N_j \ln((\sigma^n_{y_J})^2 + \alpha_j (y_J - y_j)^2) - \frac{\sum (v^n_{y_j})^2}{2((\sigma^n_{y_J})^2 + \alpha_j (y_J - y_j)^2)}$$

Then

$$\frac{d \ln L(\alpha_j)}{d\alpha_j} = -\frac{N_j (y_J - y_j)^2}{2((\sigma^n_{y_J})^2 + \alpha_j (y_J - y_j)^2)} + \frac{1}{2} \sum (v^n_{y_j})^2 \frac{(y_J - y_j)^2}{((\sigma^n_{y_J})^2 + \alpha_j (y_J - y_j)^2)^2}$$

Applying the necessary condition of extreme, we get the ML estimator of α_j, $j = 1, \ldots, J-1$

$$\widehat{\alpha}_j = \frac{1}{(y_J - y_j)^2} \left(\frac{1}{N_J} \sum (v^n_{y_j})^2 - (\sigma^n_{y_J})^2 \right). \tag{5}$$

Having obtained (5), we take

$$\alpha_j = \beta (y_J - y_j)^\gamma, \text{ where } \alpha_j > 0 \tag{6}$$

which leads us to the following **model**

$$v^n_{y_j} \sim \mathcal{N}\Big(0, \sigma^n_{y_j}\Big), \text{ where } \sigma^n_{y_j} = \sqrt{\sigma^2_{y_J} + \beta (y_J - y_j)^{\gamma+2}}. \tag{7}$$

Parameters β and γ in (7) are to be estimated by the Least Squares method, fitting (6) to the sequence $\widehat{\alpha}_j$. We put $\widetilde{\alpha}_j = \ln \widehat{\alpha}_j$, and $\widetilde{\beta} = \ln \beta$, which brings (6) to the following regression model

$$\widetilde{\alpha}_j = \widetilde{\beta} + \gamma \ln (y_J - y_j). \tag{8}$$

Parameters $\sigma^n_{y_j}$, $j = 1, \ldots, J-1$ are now obtained from (7). Dividing $\sigma^n_{y_j}$ by the smoothing spline Sp_{y_J} gives the relative uncertainty estimates of the form

$$\widehat{u}_j = \frac{\sigma^n_{y_j}}{\mathrm{Sp}_{y_J}}, \quad j = 1, \ldots, J-1. \tag{9}$$

The procedure for a fixed country i, consists of two steps.

Procedure 2.1: Assessing uncertainty.

Step 1 For the most recently revised data $E^n_{y_J}$

- find the smoothing spline Sp_{y_J}
- estimate the variance $\sigma^2_{y_J}$
- calculate the differences $v^n_{y_j} = E^n_{y_j} - \mathrm{Sp}_{y_J}, \quad j = 1, \ldots, J-1.$

Step 2 To fit the parameters in model (3) – (4)

- find $\widehat{\alpha}_j$, $j = 1, \ldots, J-1$, using (5)
- estimate $\widetilde{\beta}$ and γ in regression model (8)
- find $\sigma^n_{y_j}$, $j = 1, \ldots, J-1$, due to (7)
- find relative uncertainty estimates $\widehat{u}_j$, $j = 1, \ldots, J-1$, using (9).

III. Uncertainty assessment

We analyze UNFCCC data on CO_2 emission (in Gg) without land-use, land-use change and forestry (LULUCF), published yearly in the National Inventory Reports up to the year 2015 [9]. Calculation of emission estimates based on the measurements collected takes approximately two years, so the data reported in 2015 originate from the year 2013.

To illustrate various features of uncertainty structure we consider the data for six EU countries: Austria, Belgium, UK, Denmark, Ireland, and Finland. Each of them started to report data on GHG emission before the agreed year 2003 (on y_J=2001), conducting a test phase and providing data on emission since 1999 (Austria, UK, Ireland, and Finland) and since 2000 (Belgium and Denmark). This means we analyze the data on CO_2 emission excluding LULUCF for the year $y_J = 2013$, and all the earlier revisions, down to 1999 or 2000.

The smoothing splines Sp_{y_J}, built for the most recently revised data, i.e. a time series $E^n_{y_J}$, where $n = 1990, \ldots, 2013$, for each of the countries considered are depicted in Fig. 1. They clearly evidence sudden year-to-year changes in the inventories that are interpreted as results of errors with respect to the curves obtained by smoothing.

One can notice that, the spline fit is not the same for all countries. It seems to be much better for countries whose emissions are depicted in figures in the left-hand column of Fig. 1. Since the purpose of the spline was to extract data on the 'real' emission, this can be explained by different levels of uncertainty, reported by these countries for the year 2013. Total uncertainty, reported for 2013 in the Austrian NIR was equal 4.27%, the one for the UK 4%, and 3.45% for Ireland. In the case of Belgium and Denmark the spline obtained significantly smooths the data reported, which can be interpreted in terms of higher uncertainty – the total uncertainty reported for 2013 was equal 5.53% and 5.2% for Belgium and Denmark respectively. Fig. 1(d) can be considered a good example illustrating the problem of uncertainty assessment. Finnish total uncertainty reported for 2013 is the highest of them, estimated for 6%, although the fit may suggest much lower value. This is connected with the fact, that the uncertainty assessment in the Finnish NIR was obtained using Tier 2 (Monte Carlo approach), while the remaining ones are calculated using Tier 1. Just like in this case, the results obtained through different approaches are often difficult to compare.

Fig. 1 demonstrates also some similarities in the monotonic behaviour of emissions for the countries analyzed. It's easy to see a decreasing trend starting from 2005 (it is visible even in the case of oscillating Belgian and Danish emissions, heavily smoothed by the spline). More interesting, however, is a significant drop in emissions in 2009, associated with the economic crisis.

The estimates for variances $\sigma^2_{y_J}$, where $y_J = 2013$, calculated when building the smoothing spline are equal 2715127.62, 8091277.78, 121449538.0, 15182144.8, 650202.035, and 5940914.85 for Austria, Belgium, UK, Denmark, Ireland, and Finland respectively.

Having built the smoothing spline for $y_J = 2013$, we subtracted it from all the earlier revisions $E^n_{y_j}$, where $y_j = 1999, \ldots, 2012$ in the case of Austria, the UK, Ireland, and Finland, and $y_j = 2000, \ldots, 2012$ for Belgium and Denmark. In each case, the revision data represented a time series $E^n_{y_j}$, for $n = 1990, \ldots, y_j$.

The assumptions in model (7) were checked, by performing statistical tests. The differences obtained, were tested for normality using the Shapiro-Wilk test (considered the most reliable normality test). Since in some cases we had to deal with small samples, the results were confirmed by the Lilliefors test (modification of the Kolmogorov-Smirnov test with unknown parameters). Moreover the differences were tested for significance of true population mean, using two-sided t-test, and taking significance level 0.05.

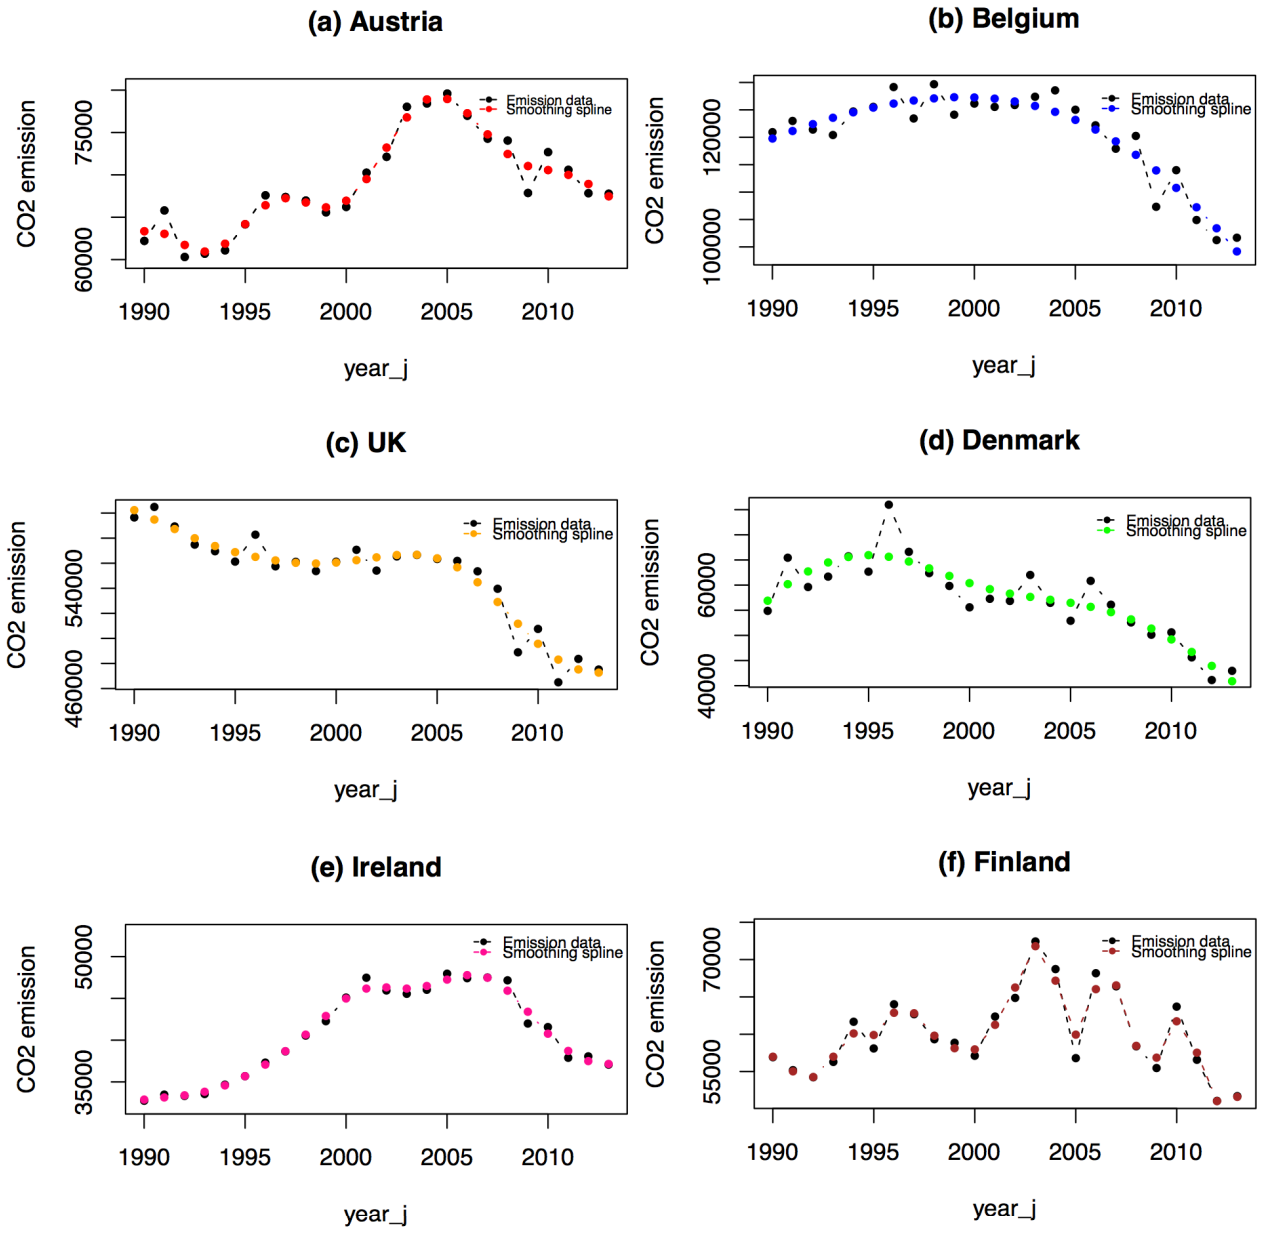

Fig. 1. Smoothing spline built for the most recent NIR data ($y_J = 2013$) on CO_2 emission [Gg CO_2], published in 2015

.

In most cases, there was no statistical evidence against the null hypothesis on normality of the data analyzed, and hence the alternative hypothesis was clearly rejected. The test failed in the case of the most initial revisions, in particular those provided in the test phase, i.e. concerning emission data on the years 1999 – 2000, which can partly be explained by the fact that the method of calculating emission revisions was being developed at that time. The t-tests performed on these differences, for which the normality assumption was met, showed that in most cases true population mean, is statistically insignificant and can be assumed zero. This means that, the assumptions taken in the model considered, were reasonable.

Following procedure 2.1, we found coefficients α_j, as ML estimators (5) and fitted parameters in regression model (8). The model fitted has been verified. All the parameters estimated turned out to be significant – the null hypotheses considering them insignificant were rejected, since p-values in the case of $\widetilde{\beta}$ ranged from $\exp(-7)$ to $\exp(-13)$ and for γ from $\exp(-4)$ to $\exp(-8)$, the same as p-values in the F-test.

Coefficient of determination R^2, indicating the goodness of fit of the model considered, was equal 84% for Austria, 77% for Belgium, 86% for the UK, 94% for Denmark, 81% for Ireland, and 97% for Finland.

The estimates of $\gamma + 2$ and $\widetilde{\beta}$ are given in Table II, along

with the results of model (8) validation.

The main result of the paper – relative uncertainties u_j, calculated due to (9) based on $\sigma^n_{y_j}$, $j = 1, \ldots, J-1$ in (7) for each of the six countries considered, are given in Table III and depicted in Fig. 3.

The temporal evolution of standard deviations $\sigma^n_{y_j}$, $j = 1, \ldots, J-1$ in (7), for all countries analyzed is shown in Fig. 2. It can be observed that, they are decreasing rather slowly in time. In turn, the corresponding relative uncertainty estimates $\widehat{u}_j$, $j = 1, \ldots, J-1$, presented in Fig. 3, for some countries, like Austria, Uk, and Ireland decrease, some others, like those for Denmark or Belgium increase slowly until 2004 – 2005. An exception is Finland, for which nonmonotonic and slightly oscillating values of u_j are shown. However, it can be observed that the uncertatinty estimates for all of the countries analyzed in the paper grow quite rapidly in later years (in particular those for Denmark and Ireland). This is connected with noticeable decrease of emissions for all countries in the years 2005 – 2012, much quicker than the slow decrease of standard deviations $\sigma^n_{y_j}$. Note that the values of $\sigma^n_{y_j}$ estimated for the UK, are much higher than for other countries, due to much higher emissions. This did not prevent us, however, in getting a good uncertainty assessment, also for that country.

It is worth stressing that, the uncertainty estimates obtained due to (9) agree quite well with the official uncertainty assessments provided in the National Inventory Reports (see Fig.4). Uncertainty assessments have become part of the 2000 IPCC Good Practice Guidance [1]. Next to the emission data, parties are expected to provide assessment of total uncertainty level of reported emission and trend uncertainty, using Tier 1 analysis (error propagation), along with the uncertainty assessment for each greenhouse gas, and each of the key IPCC categories. It is also suggested to give the results at the Tier 2 level (Monte Carlo simulation), if available. The advantage of using Tier 2 methodology is that uncertainties are taken into account and the ranking shows where uncertainties can be reduced. In the 2006 IPCC guidelines [2] it is suggested that, good practice reporting should include analysis of both Tier 1 and Tier 2.

Since applying given approach is only suggested, most countries use only one of them, i.e. Tier 1, which is easier to calculate, although considered to be less accurate. Tier 2 approach is used by Austria (starting with 2005), for Finland (for the years 2001-2005 Tier 1 analysis was not conducted, the uncertainty assessments published in the National Inventory Reports was based on Tier 2), and the UK (2003), while Belgium provides the uncertainty assessments obtained using Monte Carlo approach only for Flanders.

We compared the resulting uncertainty estimates $\widehat{u}_j$, with the reported Tier 1 trend uncertainty, and the uncertainty of CO_2 (Fig. 4). In the case of Finland, the trend uncertainty reported for 2001-2005 and 2011-2012 was calculated using Tier 2 approach, therefore in Fig. 4 both methods are considered. For the convenience of the reader, we set the same range on the vertical axis for all figures in Fig. 4, which allows for better comparison of the estimated uncertainties.

It can be seen that, the proposed uncertainty estimates correspond to those reported in the National Inventory Reports. In the case of Austria and the UK, they almost coincide with the official CO_2 uncertainty assessments, but after 2006, you may notice a slight difference in both ratings – the relative uncertainties u_j are then slightly higher than the reported ones. For Belgium and Denmark the values of u_j are pretty close to the uncertainty assessments for CO_2 and show similar monotonic behaviour. The estimates obtained for Ireland and Finland agree rather with the CO_2 uncertainty assessment, however the general monotonic behaviour is comparable with the trend uncertainty reported.

Assessments of trend uncertainty, reported since 2003 and 2004, are somewhat higher than the determined values of u_j, which may be partly explained by the fact that, they relate to total GHG emission.

The results obtained using the method proposed can therefore be considered independent confirmation of the official uncertainty estimates calculated according to [1] and [2].

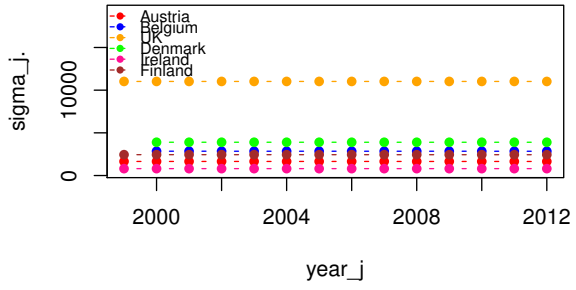

Fig. 2. Estimates of standard deviations $\sigma^n_{y_j}$ in model (7), for Austria, Belgium, UK, Denmark, Ireland, and Finland.

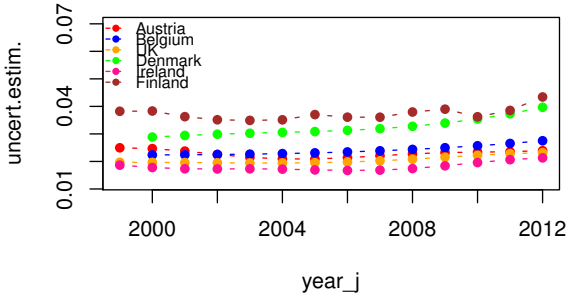

Fig. 3. Uncertainty assessment by means of $\widehat{u}_j$, for Austria, Belgium, UK, Denmark, Ireland, and Finland.

TABLE II
ESTIMATES OF $\gamma + 2$ AND $\widetilde{\beta}$ IN (8).

Model	Austria	Belgium	UK	Denmark	Ireland	Finland
$\gamma + 2$	0.60	0.91	0.59	0.62	0.48	1.02

IV. CONCLUSIONS

The paper deals with estimating uncertainty of the GHG inventory prepared by the countries within the Kyoto Protocol from the reported data. As opposed to conventional way of calculation of inventory error variance by processing the estimates of the activity and emission coefficients of all atom emission sources, recommended in the guidelines, the method presented uses solely official inventory data, submitted by parties to IPCC, according to common inventory protocol. The uncertainty estimates are obtained under very mild assumptions on smoothness of consecutive in time emission values for a given party. A simple model of uncertainty evolution in time is assumed. The statistical methods are used to estimate model parameters and then to calculate the uncertainty estimates. Hence, the results are obtained regardless of estimates given by parties and confirm independently the values calculated according to the methods recommended by IPCC.

The method gives quite smooth temporary curves for uncertainty estimates evolution. This effect can be induced by a model structure which was designed to catch the main directions of uncertainty evolution rather than very accurate estimation of local changes. An advantage of such model is, that the estimates obtained from our statistical estimation resemble the uncertainty estimates reported by countries as to the similar smoothness of both kinds of curves. They are also close in values to the estimates reported by countries.

The method presented is general enough to be applied to inventory data provided by other countries. Being a statistical method, its accuracy depends a lot on the number of available data points. The six countries analyzed in this paper were chosen due to their relatively long inventory sequences. It is intended to extend the calculation for other countries. Studying common properties of these models hopefully enables obtaining reliable results also for countries with shorter reported samples.

***Abstract*—Underwater acoustic communication (UAC) system designers tend to transmit as much information as possible, per unit of time, at as low as possible error rate. However, the bit rate achieved in UAC systems is much lower than for wire or radio-communication systems. This is due to disadvantageous properties of the UAC channels, namely the sea and inland waters. Estimation of UAC channel transmission properties is possible within a limited bandwidth and temporal resolution. Thus, the UAC physical layer of data transmission is designed on the basis of roughly estimated channel parameters, or assuming the worst possible conditions. The paper presents the methodology of adapting UAC signaling schemes to tough underwater propagation conditions, through an example of two communication systems designed and developed at the Gdansk University of Technology.**

I. Introduction

THE Department of Marine Electronic Systems, the Faculty of Electronics, Telecommunications and Informatics Gdańsk University of Technology has a long and rich tradition in the processing of acoustic signals used in underwater systems. The main areas of interest are hydrolocation systems, namely sonar systems [1-6], and UAC systems [7-9]. The latter are particularly vulnerable to interference, due to tough propagation conditions, causing a time dispersion and time variability in the acoustic signals transmitting the information.

Due to a wide range in the transmission properties of UAC channels, there are, in the world, only few standards used to define very slow communication. In deep-water channels, transmission rates of up to 100 kbps can be achieved, while the same research centers offer much slower standards in shallow water channels, where reliable communication at a speed of 40-80 bps is a significant achievement. Such differences in UAC systems performances is due, *inter alia,* to the large temporal uncertainty of underwater channel transmission characteristics [10].

Furthermore, depending on the communications system in question, there are different requirements for speed and the dependability of transmissions in acoustic links. It may be a case of: a) slow but reliable transmission with autonomous underwater vehicle's (AUV) control signals, b) slightly faster but still generally reliable measurement of data transmission from an underwater monitoring system or, c) maximum speed video transmissions from underwater cameras. Therefore, there is no one, single, typical, UAC problem. The physical layer of the data transmission should be adapted to the specific propagation conditions of the particular channel.

II. Transmission properties of the UAC channel

A. Propagation conditions

The range of the UAC system is determined mainly by the absolute value of absorption attenuation, and varies in proportion to the square of the frequency of the system (except for the band between 0.5 to 5 kHz and 200 to 1000 kHz, in which it grows more slowly). Excessive differences of attenuation, due to growth in range has a limiting effect on the bandwidth of the system and reduces its throughput.

Phenomenon which strongly impacts transmission properties of the UAC channel consists of reflections from the sea-bottom and the water's surface, as well as other objects present in water. This causes multipath propagation, and, in consequence, reception of both direct and delayed signals. This phenomenon also goes hand-in-hand with strong refraction, which is caused by a significant change in sound velocity as a function of depth. Both multipath propagation as well as refraction produce time dispersion in the transmitted signal, that can be measured as a parameter, known as multipath delay spread τ_M. Moreover, due to multipath propagation phenomenon, selective fading of transmitted signal spectrum is observed. A maximum bandwidth not affected with selective fading is expressed as coherence bandwidth B_C.

The movement of the UAC system's transmitter and receiver causes the Doppler Effect, resulting in the time-domain scaling of a natural broadband communication signal. This phenomenon also has a significant impact on the communication system's performance. Because of the relatively low velocity of propagation of acoustic waves in water, which is approximately 1500 m/s, the relative Doppler shift is approx. 200,000 times higher than in case of radio-communication systems. The impact of the Doppler Effect on the received signal in UAC channels is expressed as a scal-

ing factor or – for narrowband signals – a maximum Doppler spread ν_M.

UAC channel propagation conditions can change over-time. Depending on the phenomena under consideration, the variability of transmission properties can be of a range of several months (i.e. seasons), several days and hours (i.e. tides, times of day), minutes (i.e. internal waves), a few seconds (i.e. surface waves) as well as the order of milliseconds (that is to say: reflections, scattering) [7]. In designing the UAC physical layer it is essential to determine the time and frequency ranges over which the channel can be considered as stationary. This is defined by coherence time T_C parameter [11].

B. UAC channel transmission properties measurement

The time-varying impulse response (TV-IR) $h(t,\tau)$ of the UAC channel is modeled as tapped delay line (Fig. 1). It is defined in the domain of two time variables: observation time t and delay τ. The values of t indicate the moments of subsequent IR measurements while τ denotes the position on the time axis of successive samples of the IR in a single observation.

TV-IR is the basis for computation of transmission characteristics. If TV-IR fulfills the wide sense stationary uncorrelated scattering (WSSUS) assumption, it can describe the channel statistically, providing information on transmission parameters: multipath delay spread τ_M, Doppler spread ν_M, coherence time T_C and coherence bandwidth B_C [11]. The accuracy of instantaneous transmission parameters depends on the accuracy of channel impulse response estimation [12].

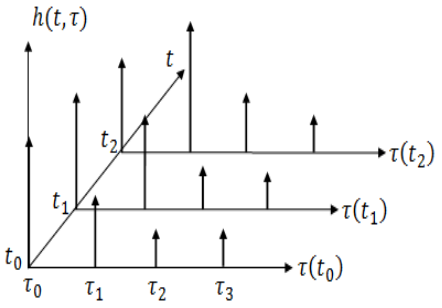

Fig 1. Tapped-delay line model of time-varying impulse response.

The measurement of impulse response is performed using the correlation method. As the probe signals, pseudorandom binary sequences (PRBSs) and linear frequency-modulated (LFM) chirps are used. A PRBS is the repetition of the maximal-length binary sequence $c_m \in \{-1,1\}$, modulated onto a binary phase-shift keyed waveform. Maximal-length binary sequences (known also as m-sequences) are widely used for communication synchronization, and transmissions of signals below the noise level [13-14]. A single "ping" of the passband PRBS of the center frequency f_C, bandwidth B, time duration T, m-sequence length M, and bit pulse shape $u(t)$ is given by:

$$p(t)=\sin(2\pi f_c t)\sum_{m=0}^{M-1} c_m u\left(t-\frac{m}{M}T\right) \quad , \qquad (1)$$

where $0\le t\le T$ and $0\le m\le M$, while a single "ping" of an LFM chirp signal is given by:

$$p(t)=\sin\left(2\pi\left[\left(f_c-\frac{B}{2}\right)t+\frac{B}{2T}t^2\right]\right) \qquad (2)$$

The channel probe signal is constructed as a concatenation of N pings:

$$s(t)=\sum_{n=0}^{N-1} p(t-nT) \qquad (3)$$

As a result of correlative measurement, time-varying impulse response $h(t,\tau)$ is obtained. The duration T and resolution T/M of a single "ping" determines range and resolution of variable τ. Moreover, the resolution of t is equal to $1/T$, while its range depends on number of "pings" and is equal to NT.

The uncertainty in time (and frequency) of probe signals is characterized by their ambiguity functions $A(\tau,\nu)$. It shows correlation filter response for a single ping as being a function of the time delay τ from the beginning of signal and frequency (Doppler) shift ν quantified for the center frequency:

$$A(\tau,\nu)=\int_{-\infty}^{\infty} p(t)\,p^*(t-\tau)\,e^{2\pi i\nu t}\,dt, \qquad (4)$$

where $0\le\tau\le T$ and $-1/(2T)<\nu<1/(2T)$. Fig. 2. shows ambiguity functions of PRBS and LFM signals of duration of $T=256\,ms$. At zero frequency shift, the ambiguity functions are the same as for PRBS and LFM, but in other areas they are very different. The PRBS offers high resolution in both delay and Doppler, but experiences clutter at frequency shift $\nu\neq 0$ [15].

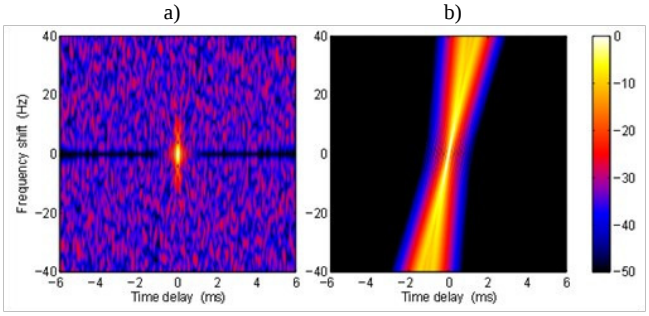

Fig 2. Ambiguity functions of PRBS (a) and LFM chirp signal (b) [15].

The chirp has a much stronger response than the PRBS for Doppler-shifted signals, but this Doppler insensitivity comes with a delay shift of $\Delta\tau=\nu\times T/B$. The LFM also shows some broadening in large frequency shifts [15].

C. The UAC impulse response

As a result of correlation measurement an estimate of TV-IR $h(t,\tau)$ is obtained. A single TV-IR estimate can be acquired but amounting to no more than the duration T of the probe sequence, which should be adapted to the geome-

try and the time variability of the channel. The channel should be sampled as often as possible to obtain a TV-IR estimate with a satisfactory time resolution. However, T is limited by the coherence time T_C of the channel. This limitation stems from the assumption that channel characteristics should remain unchanged for the duration of a single measurement in order to obtain a single estimate of the impulse response. At the same time, T should be greater than the time dispersion of the channel expressed as multipath delay spread τ_M .

Depending on the reciprocal of product of the coherence time T_C and the coherence bandwidth B_C , known as the spreading factor $SF = 1/B_C T_C$, the UAC channel can be classified as being "underspread" or "overspread".

If , the $SF < 1$ channel is assumed to be underspread. Such a channel can have a long impulse response which varies gradually, and this can be measured through the use of sufficiently long m-sequence or LMF signals. Underspread channels are also channels that change rapidly, but who possess a short TV-IR. A series of measurements through the use of short testing signals allows us to obtain knowledge on the nature of the variation in such channels.

If $SF > 1$, the channel is called overspread. In this case, the channel has a long and rapidly varying impulse response. Measurement of the TV-IR of an overspread channel is extremely difficult and gives unreliable results, if not totally impossible [12]. Measurement with the use of a short sequence allows to examine variability in the channel, but the IR will be that of visible time-aliasing [15]. On the other hand, measurement with a long testing signal will result in the collection of true information on the distribution of subsequent multipath components along the time line. However, information on channel variability will be lost.

D. WSSUS assumption

Time-varying impulse response $h(t,\tau)$ is a starting point for the construction the UAC channel model. Due to the complexity of acoustic waves' propagation mechanism, building a deterministic description is a complex task. Therefore, a statistical approach is applied, assuming (as in the radiocommunications [11]) that the channel can be described with Rayleigh distribution, making the set of the time-varying channel impulse response $h(t,\tau)$ a two-dimensional Gaussian processes with a mean of zero. With this supposition, the characteristics of the channel will be a specification of second-order statistics and the autocorrelation function of the impulse response, in addition to the IR itself, will be a subject for further analysis.

The autocorrelation of two-dimensional impulse response $h(t,\tau)$ is a four-dimensional function:

$$R_h(t,t+\Delta t,\tau,\tau+\Delta\tau) = E\left[h^*(t,\tau)h(t+\Delta t,\tau+\Delta\tau)\right] \quad (5)$$

where $-T < \Delta\tau < T$ and $-NT < \Delta t < NT$. A channel is called wide-sense stationary (WSS) if the mean value of $h(t,\tau)$ is constant and $R_h(t,t+\Delta t,\tau,\tau+\Delta\tau)$ is stationary process in t domain. Thus it can be reduce to a three-dimensional function:

$$R_h(t,t+\Delta t,\tau,\tau+\Delta\tau) \overset{WSS}{=} R_h(\Delta t,\tau,\tau+\Delta\tau) \quad (6)$$

Additionally the uncorrelated scattering (US) assumption is fulfilled, when there is no correlation between the fading coming from different signal scatters. Thus the impulse response $h(t,\tau)$ is uncorrelated in τ domain and the autocorrelation function can be denoted as:

$$R_h(t,t+\Delta t,\tau,\tau+\Delta\tau) \overset{US}{=} R_h(t,t+\Delta t,\Delta\tau) \quad (7)$$

The transfer function $H(t,f)$ of US impulse response has an autocorrelation function that is "stationary" in frequency domain f .

Under WSSUS assumption the autocorrelation function can be reduced to a two-dimensional function [16]:

$$R_h(t,t+\Delta t,\tau,\tau+\Delta\tau) \overset{WSSUS}{=} R_h(\Delta t,\Delta\tau) \quad (8)$$

The second order statistics are thus presumed to be time-invariant, and signal reflections reaching the receiver are treated as mutually uncorrelated.

In practical systems TV-IR is measured with with bandpass modulated signal, and than down-sampled into baseband. Thus, the resulting $h(t,\tau) = h_I(t,\tau) + h_Q(t,\tau)$ is complex time process, represented with real (in-phase) $h_I(t,\tau)$ and imaginary (quadrature) $h_Q(t,\tau)$ components. According to [17], for a WSS bandpass process, the in-phase and quadrature components are balanced in the sense that they have the same autocorrelation function. Also, the cross correlation of the in-phase and quadrature components must be an odd function for any pair of WSS processes. This property can be used to test whether $h(t,\tau)$ is WSS [18]. Testing US condition requires the calculation of the complex transfer function $H(t,f)$ as the Fourier transform of $h(t,\tau)$. Analysis of in-phase and quadrature components of $H(t,f)$, analogous to WSS test, is than performed.

E. Transmission Characteristics

Under the WSSUS assumption the scattering function $S(\nu,\tau)$ can be calculated as the Fourier transform in t domain. It characterizes the mean amplitude of signal reflections reaching the receiver with the delay τ and Doppler Shift ν :

$$S(\nu,\tau) = \int_{-\infty}^{\infty} h(t,\tau)e^{-j2\pi\Delta\nu\Delta t}\,d\Delta t \quad (9)$$

where $-1/2T < \nu < 1/2T$.

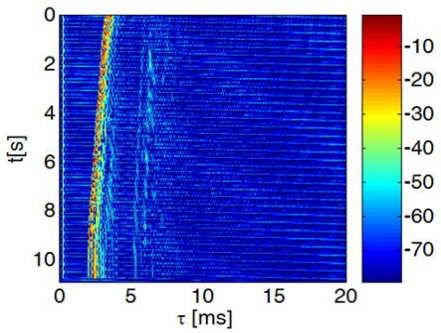

Fig 3. Time-varying Impulse response of UAC channel.

Fig. 3 and Fig. 4 show the impulse response and the scattering function of the UAC channel measured over the course of an experiment in a lake. The receiving hydrophone was placed 0.5m below the surface of the water and the speaker – 0.5m deeper. The hydrophone was moved slowly with a velocity of 15 cm/s.

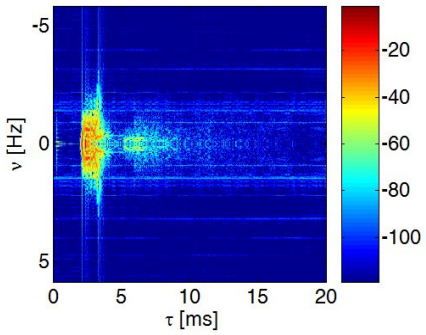

Fig 4. Scattering function of UAC channel.

As a result of integration $S(\nu,\tau)$ for the Doppler shift ν or delay τ, one of two transmission characteristics is obtained. The first is the multipath intensity profile $P(\tau)$, describing the average received power variation as a function of time delay τ (τ represents the signal's propagation delay that exceeds the delay of the first signal arrival at the receiver) [11]. For a shallow water channel, the received signal usually consists of numerous discrete multipath components (Fig. 5a). For deep water channels, due to strong refraction phenomenon, received signals are often seen as a continuum of multipath components.

For a single transmitted impulse, the time between the first and last received component represents the multipath delay spread τ_M, during which the signal power falls to some threshold level below that of the strongest component.

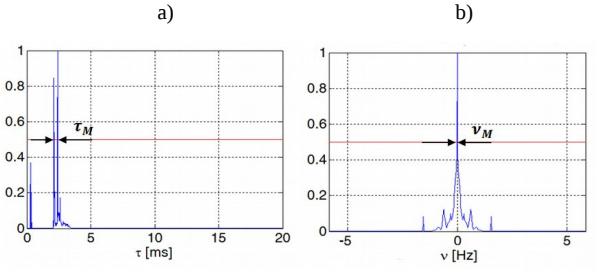

Fig 5. Multipath intensity profile (a) and Doppler power spectrum (b).

The second characteristic is the Doppler power spectral density $P(\nu)$, describing the time-variant nature of the channel. If the time-variation is random, it is seen as spectral broadening of $P(\nu)$, while a signal variation due to the transmitter or receiver movement with constant velocity reveals as a shift of $P(\nu)$ in ν domain. In case of UAC channel that fulfills the WSS assumption, $P(\nu)$ is a symmetrical function of ν. However, measurement experiments have shown, that for non-WSS channels the Doppler power spectral density can have asymmetrical shape [18]. The width of $P(\nu)$ is referred to as maximum Doppler spread, denoted by ν_M (Fig. 5b).

On the basis of autocorrelation function $R_h(\Delta t,\Delta\tau)$, the autocorrelation of the channel transfer function is calculated as:

$$R_H(\Delta t,\Delta f)=\int_{-\infty}^{\infty} R_h(\Delta t,\Delta\tau)e^{-j2\pi\Delta f\Delta\tau}d\Delta\tau \qquad (10)$$

where $-B/2<\Delta f<B/2$. It is a basis for calculating another two transmission characteristics of the communication channel. For $\Delta f=0$, the time correlation function $R_h(\Delta t)$ is obtained. Its width represents the coherence time T_C (Fig. 6a). For $\Delta t=0$ the frequency correlation function $R_h(\Delta f)$ is obtained. It represents the correlation between the channel's response to two signals as a function of the frequency difference between the two signals. It allows to determine the coherence bandwidth B_C as its width (Fig. 6b).

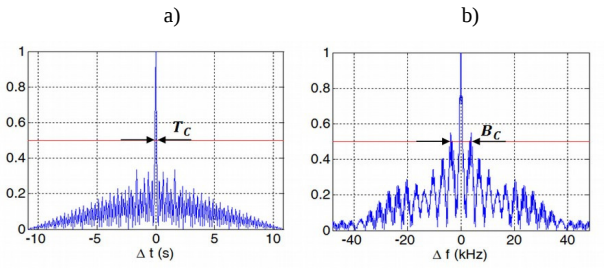

Fig 6. Time (a) and frequency (b) correlation functions.

The levels of transmission characteristics at which transmission parameters are determined depend on, amongst other factors, the technical capabilities of the particular UAC system and these are determined experimentally [11].

A set of four parameters $\{\tau_M,\nu_M,T_C,B_C\}$ is used for the designing a physical layer of the UAC system to minimize the influence of the time dispersion and time variability of the channel on the transmitted signal. The methodology is presented in the next section, in the examples of two UAC systems using different frequency diversity techniques.

F. Limitations of WSSUS assumption

In case of many underwater communication channels, especially when system terminals are in movement, the WSSUS model is of limited value. As it was shown in [18], UAC channels hardly ever fulfill the WSS and US assumptions, also in quasi-stationary conditions. But for a restricted period of time and a limited frequency range the assumptions can be satisfied. This approach is called local-sense stationary uncorrelated scattering (LSSUS) [19]. It allows to use two other transmission parameters, namely stationary time T_D and stationary bandwidth B_D, determining period of time and frequency range in which the WSSUS assumption is locally satisfied. They can extend the set of transmission parameters $\{\tau_M,\nu_M,T_C,B_C,T_D,B_D,\}$ used for the designing a physical layer of the adaptive UAC system [19].

III. Case study – OFDM System

The orthogonal frequency division multiplexing (OFDM) method is based on splitting the available transmission bandwidth into many narrow-band channels with center frequencies known as sub-carriers. The data is split into several parallel data streams, one for each sub-carrier, modulated with the use of a conventional modulation scheme (such as QAM, PSK or DPSK techniques) at a low symbol rate [11].

To adapt the OFDM signaling scheme to underwater channel conditions, the sub-carrier spacing B_{OFDM} in the frequency domain is chosen, so as to satisfy the rule:

$$B_C > B_{OFDM} \gg \nu_M \tag{11}$$

The sub-carrier spacing should be smaller than the coherence bandwidth, wherein the transfer function remains constant. It should also be much greater than the maximum Doppler spread in order to avoid interference between neighboring sub-carriers due to the Doppler shift.

In the time domain, a single OFDM symbol duration T_{OFDM} should satisfy the rule:

$$\tau_M < T_{OFDM} \ll T_C \tag{12}$$

The OFDM transmission symbol should be shorter than the coherence time T_C in which the channel's statistics can be assumed to be stationary. On the other hand, the transmission symbol should last at least as long as the corresponding signal reflections take to reach the receiver. This prevents overlapping consecutive symbols, known as inter-symbol interferences. Moreover, each OFDM symbol is preceded by a cyclic prefix, i.e. a redundant repetition of the last segment of itself. The cyclic prefix of duration T_G additionally protects the OFDM signal against inter-symbol interference [11].

Numerous sea and oceanic experimental trials of OFDM underwater communication systems have been reported [20-27]. The data transmission rate of a few kbps is achieved in shallow water channels with a depth of several hundred meters. [23]. In case of a channel with a depth of less than 100 m (and thus with much stronger multipath propagation phenomenon), only few hundred kbps are obtained [20-21]. However, there is a lack of reported results for very shallow water channels with a depth of ca. 10m.

The OFDM technique is being implemented in a laboratory model of an acoustic data transmission system, designed at the Department of Marine Electronics Systems, Faculty of Electronics, Telecommunications and Informatics, Gdansk University of Technology [28-29]. Using this model, the underwater experiments were carried out in a lake. The underwater channel was ca. 4 m deep, and experiments were performed at distances from 1 to 30 m. The speaker was placed 1 or 2 m below the surface and the hydrophone was placed 0.5, 1 or 2 m below the surface. In mobile scenarios, the hydrophone was moved slowly with a velocity of 15 cm/s. The analysis of the impulse response, measured using PRBS signal, has shown that the multipath delay spread, measured at a -10 dB threshold level of the multipath intensity profile, was ca. $\tau_M = 5\,ms$ and the maximum Doppler spread was ca. $\nu_M = 1\,Hz$. The coherence bandwidth B_C was measured as being the width of the frequency correlation function at level 0.7 of the maximum value, as well as the coherence time T_C, on the basis of the time correlation function. The results were: $B_C = 23\,Hz$ and $T_C = 1\,s$.

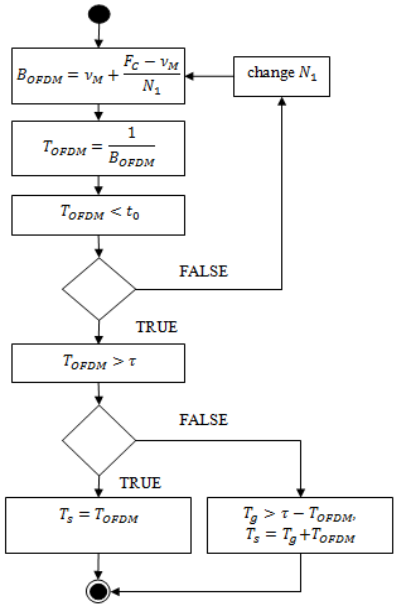

Fig 7. Procedure of calculating OFDM signaling scheme parameters.

The bandwidth of tested UAC system was 3 kHz, with a centre frequency of 5 kHz. With such fixed band and transmission parameters in the measured channel, the OFDM signaling scheme was determined as shown in Fig. 7. The sub-carrier spacing B_{OFDM} was randomly chosen from a range of (ν_M, B_C). Next, the condition was checked, that is to say, if $T_{OFDM} < T_C$, $T_{OFDM} = 1/B_{OFDM}$. If this was not the case, another B_{OFDM} value was randomly chosen. After adjusting the value of B_{OFDM} ,the following condition was checked: $T_{OFDM} > \tau_M$. If this was not the case, a cyclic prefix of the duration $T_G = T_{OFDM}/5$ was attached, lengthening the OFDM symbol duration.

With this procedure, a sub-carrier spacing of $B_{OFDM} = 5.86\,Hz$ was calculated that corresponds to symbol duration $T_{OFDM} = 0.2\,s$. Binary data, coded with a BPSK digital scheme, modulated each of the sub-carriers [18]. No channel coding was implemented. The maximum data transmission rate achieved during the underwater experiment in quasi-static scenario was 22 bps with bit error rate $BER < 10^{-3}$, and 880 bps with $BER < 10^{-1}$. In case of receiver moving in a uniform manner at a speed of about 15 cm/s, transmission rate of 615 bps was achieved with $BER < 10^{-1}$, however to perform any data transmission (<20 bps) with $BER < 10^{-3}$, it was necessary to expand a sub-carrier spacing to $B_{OFDM} = 11.72\,Hz$. This confirms the strong influence of Doppler effect on UAC system performance.

IV. Case Study – FHSS System

The second considered communication system is based on the use of spread spectrum techniques [11]. These techniques create expedient conditions for the implementation of data transmission in occurrences of harsh multipaths. Where multipath delay spread of tens of milliseconds are encountered, this excludes the use of equalization. Spread spectrum techniques were originally developed for use in military systems on account of their low probabilities of interception (LPI) and decent resistance to different types of jamming signals.

The conception of spread spectrum systems is due to the well-known Shannon equation (13), to channel capacity C, with the specified bandwidth B, and the power signal to noise ratio SNR:

$$C = B\log_2(1+SNR) \tag{13}$$

By transforming the above equations to the following form (14) we can concluded that the greater the noise that dominates the signal, the greater the possibility that it will require a wider bandwidth signal in order to receive it correctly.

$$\frac{C}{B} \simeq 1.44\,SNR \tag{14}$$

Therefore, by greatly increasing the operating bandwidth, this at the same time, allows the use of a much lower signal to noise ratio.

In general, the work of the spread spectrum system is as follows. On the transmitter's side, this is carried out by transforming an information signal into a transmission signal with a much wider bandwidth. When this is the case, this is achieved by spreading the data signal with a pseudorandom code. On the receiver's side, there must be instated a despreading operation in order to restore the transmission signal to its original bandwidth. It is important to mention the same pseudorandom code in both the receiver and in the transmitter.

There are many types of spread spectrum techniques, of which the most common are: Frequency Hopping Spread Spectrum (FHSS), Direct Sequence Spread Spectrum (DSSS), Time Hopping Spread Spectrum (THSS) and Chirp Spread Spectrum (CSS). The first of them will be briefly discussed and analyzed.

Communication systems with frequency hopping spread spectrum techniques commonly use binary frequency shift keying. In this technique, all available channel bandwidth is divided into adjacent sub-channels. The carrier among subchannels is switched by using a pseudorandom sequence. Pseudorandom sequence controls the frequency synthesizer in every signaling interval. In this technique, MFSK modulation with non-coherent demodulation is usually employed. Because of this, the use of coherent modulations is difficult to retain phase coherence during the generating process of the signal, in accordance with the hopping pattern.

In transmitters, the data signal is subjected to channel encoding and interleaving. Then goes to the input of MFSK modulator. The modulator assigns a corresponding frequency in baseband to value of sending bit with duration T_B. The produced signal is then placed in the appropriate sub-channel (frequency slot) for the time T_C - termed as "dwell time". After the amplification, the signal passes on to the channel by using the transducer.

In the receiver, the amplified signal is firstly subjected to dehopping by mixing the synthesizer output with the received signal. Then the resulting signal is demodulated into an MFSK demodulator. A synchronization signal for keeping adequate synchronism in the pseudorandom generator with frequency hopping, a received signal is extracted from a received signal. A synchronization signal between each transmitted bit is placed in the signal frame. "Coarse" synchronization is carried out based on the signal of the frame synchronization which is usually a couple of LFM signals. This signal is also used in the estimation of channel impulse response functions. Hyperbolic frequency modulation (HFM) can be used because it is more resistant to the Doppler Effect.

For the sake of the simplicity in the receiving process, and by using the fast Fourier transform (FFT), non-coherent reception is performed. Similarly, the transform is the discrete-time implementation of the corresponding matched filters. In the next step, this is subjected to an analysis of the entire operating band, in which dehopping is carried out by selecting an appropriate sub-channel.

This technique has no impact on performance in an AWGN channel. The characteristic parameter for this type of spread spectrum system is *gain processing*, which expresses the bandwidth expansion factor:

$$G_p = \frac{T_B}{T_C} \tag{15}$$

In cases in which changes of the carrier frequency are used many times during particular data bit T_B, then we are dealing with a fast frequency hopping system (FFH). The figure below shows an example of an FFH system with the frequency hopping pattern $T_B=3T_C$.

Parameters such as coherence bandwidth and coherence time are included in the following manner. The FFH technique uses frequency and time diversity to effectively counteract the effects of the multipath. Due to the fact that this system commonly works for worst-case conditions in the channel, it is necessary to determine the requirements for the resistance to the maximum multipath delay spread. The cause of this, as shown in the figure above - i.e. channel clearing time - is the length of time long enough to allow the disappearance of multipath arrivals and in correspondence with the used pseudorandom time sequence during the transmission of a single bit. Although the extension of an applied pseudorandom sequence allows for more effective counteraction in the effects of the multipath, yet this will reduce the transmission rate and requires a broadening of the operating band. However, it should be noted that an important purpose of frequency diversity is the protection of each bit against spectral nulls due to frequency-selective fading.

The employed frequencies are spaced in order to take into account the limits of the frequency change caused due to the presence of the Doppler Effect in the entirety of the available operating band. They also satisfy the condition of or-

thogonality by determining the minimum frequency separation Δf for the herein employed length of tones.

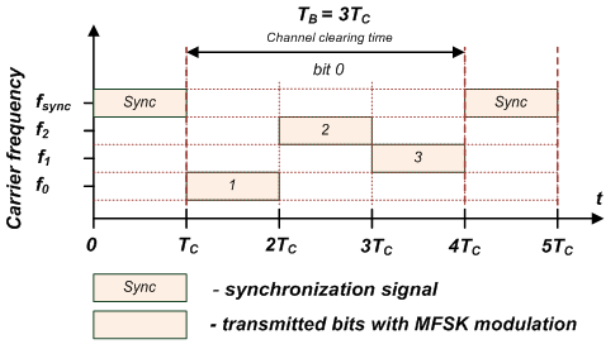

Fig 8. FFH system

The assumption concerning a communication system with this technique presented here can potentially reach maximum transmission of tens of bits per second. When the communication system takes into account the maximum value of a multipath delay spread of 30ms, then the system functioning according to the scheme shown in Fig. 8. has a value of a channel clearing time of 37.5ms, at a length Tc = 12.5ms. This yields a maximum transmission rate of 20bps for BFSK modulation, and 40bps for 4-FSK modulation, with no use of any channel coding.

Generally, a suppression mechanism in an interfering signal results from the fact that the useful signal is only transmitted at the specific moment in time, in a single narrowband channel. When the system works with the FFH technique, the interfering signal will coincide with the spectrum of the useful signal only to a small overall with its duration. The frequency hopping technique is simple to implement and is suitable in battery-powered solutions.

V. Conclusions

Due to the low propagation velocity of acoustic wave compared to electromagnetic wave, and thus greater influence of the Doppler effect, UAC systems provide transmission rates of tens or hundreds bps. The same modulation and coding techniques, applied in radiocommunication systems, allow to achieve transmission rate of Mbps and Gbps [30].

UAC channels are characterized by a large variety of propagation conditions. Designing reliable communication system requires knowledge of transmission parameters of the channel, namely multipath delay spread, Doppler spread, coherence time and coherence bandwidth. However, the possibilities of the measurement of transmission characteristics are limited, specially in case of overspread channels. New methods are needed to improve the estimation of time-varying dispersive underwater channels [12][18].

In shallow underwater channels with strong time-varying multipath propagation conditions the physical layer of data transmission is selected for the worst-case multipath delay spread and Doppler spread. The adaptation of the signaling scheme into the instantaneous transmission properties is possible only in selected well-tested channels. New modulation and coding techniques should be developed to perform reliable data transmission in time-varying propagation conditions [31].

1st International Workshop on Language Technologies and Applications

DEVELOPMENT of new technologies and various intelligent systems creates new possibilities for intelligent data processing. Natural Language Processing (NLP) addresses problems of automated understanding, processing and generation of natural human languages. LTA workshop provides a venue for presenting innovative research in NLP related, but not restricted, to: computational and mathematical modeling, analysis and processing of any forms (spoken, handwritten or text) of human language and various applications in decision support systems. The LTA workshop will provide an opportunity for researchers and professionals working in the domain of NLP to discuss present and future challenges as well as potential collaboration for future progress in the field of NLP.

TOPICS

The submitted papers shall cover research and developments in all NLP aspects, such as (however this list is not exhaustive):

- computational intelligence methods applied to language & text processing
- text analysis
- language networks
- text classification
- document clustering
- various forms of text recognition
- machine translation
- intelligent text-to-speech (TTS) and speech-to-text (STT) methods
- authorship identification and verification
- author profiling
- plagiarism detection
- knowledge extraction and retrieval from text and natural language structures
- multi-modal and natural language interfaces
- sentiment analysis
- language-oriented applications and tools
- NLP applications in education
- language networks, resources and corpora

***Abstract*—This paper reports our efforts toward an ASR system for a new under-resourced language (Fongbe). The aim of this work is to build acoustic models and language models for continuous speech decoding in Fongbe. The problem encountered with Fongbe (an African language spoken especially in Benin, Togo, and Nigeria) is that it does not have any language resources for an ASR system. As part of this work, we have first collected Fongbe text and speech corpora that are described in the following sections. Acoustic modeling has been worked out at a graphemic level and language modeling has provided two language models for performance comparison purposes. We also performed a vowel simplification by removing tones diacritics in order to investigate their impact on the language models.**

I. Introduction

AUTOMATIC Speech Recognition (ASR) is a technology that allows a computer to identify the words spoken by a person in microphone. Speech recognition technology is changing the way information is accessed, tasks are accomplished and business is done. The growth of speech applications over the past years has been remarkable [1]. ASR applications have been successfully achieved for most western languages such as English, French, Italian etc., for Asian languages such as Chinese, Japanese, Indian etc, because of the large quantity and the availability of linguistic resources of these languages [2]. This technology is less prevalent in Africa despite its 2,000 languages because of lack or unavailability of these resources for most African languages (vernacular for most). Also, for the most of the time, these are not written languages (no formal grammar, limited number of dictionaries, few linguists). Despite the shortcomings, some have been investigated and now have the linguistic resources to build a speech recognition systems. For example, in the context of a project entitled ALFFA[1], the authors in [3] developed ASR systems for 4 sub-saharan african languages (Swahili, Hausa, Amharic and Wolof). Another language of West Africa (Yoruba) spoken mainly in Nigeria, in Benin and neighboring countries has been also investigated for an ASR system. [4] provides a brief review of research progress on Yorúbà Automatic Speech Recognition.

Our main objective in this paper is to introduce a first ASR system for an under-resourced language, Fongbe. Fongbe is a vernacular language spoken primarily in Benin, by more than 50% of the population, in Togo and in Nigeria. It's an under-resourced because it lacks linguistics resources (speech corpus and text data) and very few websites provide textual data. Building these resources, acoustic models and language models for Fongbe ASR becomes a challenging task. For this, we used Kaldi toolkit[2] that has allowed us to train our acoustic models on speech data that we have collected ourselves. For the language modeling, we used SRILM toolkit[3] to built trigram language models that we trained on collected text data. To enhance performance of our ASR, we subsequently transformed the vowels by normalizing different tones of Fongbe. Experiments have shown a significant improvement in the results given by the world error rates (WER).

The remainder of this paper is organized as follows. The next section describes the target under-resourced language that is Fongbe. Section 3 describes how text and speech corpora have been collected. Section 4 and 5 focus respectively on language modeling and acoustic modeling. Section 6 presents

[2]kaldi.sourceforge.net/
[3]www.speech.sri.com/projects/srilm/

978-83-60810-90-3/$25.00

and comments the experimental results of WER that we obtained. Section 7 concludes this paper and presents future work.

II. Description of Fongbe language

Fongbe language is the majority language of Benin, which is spoken by more than 50% of Benin's population, including 8 million speakers and also spoken in Nigeria and Togo. The Fongbe people are the largest ethnic group in Benin. Fongbe is part of the Gbe dialect cluster and is spoken mainly in Benin [6]. It is quite widespread in the media and is used in schools, including adult literacy. The Fongbe group is one of the five Gbe dialect. J. Greenberg classifies Fongbe in the Kwa languages group in the Niger-Congo branch of the large family Niger-Kordofan [5]. It is written officially in Benin with an alphabet derived from the Latin writting since 1975. It has a complex tonal system, with two lexical tones, high and low, which may be modified by means of tonal processes to drive three further phonetic tones: rising low-high, falling high-low and mid [6]. The use of diacritical marks to transcribe the different tones of the language is essential even if they are not always marked since Fongbe is originally a spoken language. The Fongbe's vowel system is well suited to the vocalic timbre as it was designed by the first Phoneticians. It includes twelve timbres: 7 oral vowels with 4 degrees of aperture and 5 nasal vowels with 3 degrees of aperture. Its consonant system includes 22 phonemes.

Scientific studies on the Fongbe started in 1963 with the publication of Fongbe-French dictionary [7]. Since 1976, several linguists have worked on the language and many papers were published on the linguistic aspects of Fongbe. Unlike most of the western languages (English, French, Spanish, etc) and some Asian languages (Chinese, Japanese, etc) and African (Wolof, Swahili, shrugged, etc.) the Fongbe language suffers from a very significant lack of linguistic resources in digital form (text corpus and speech) despite the many linguistic works (phonology, lexicon and syntax).

III. Collection of language resources

The development of automatic continuous speech recognition system is made from a large amount of data which must contain both speech signals (for the acoustic modeling of the system) and also text data (for the language model of the system). It becomes a challenge and very difficult when it is an under-resourced language that still doesn't possess these digital resources. In this section we describe the methodology used to collect texts and audio signals of Fongbe language for building of the recognition system.

A. Speech corpus

As an audio corpus is not available for Fongbe, we proceeded to the speech signals collection to build the audio data for the system. We thus conducted the tedious task of recording the texts pronounced by native speakers (including 8 women and 20 men) of Fongbe in a noiseless environment. We have recorded at 16Khz 28 native speakers who have spoken around 1500 phrases (from daily living) grouped into 3 categories. A category is read by several speakers and contains texts that are different from contents of other categories. These recordings were made with an android application referred to as LigAikuma [8] which is developed by GETALP group of Grenoble's Computer Science Laboratory. Overall, there are around 10 hours of speech data that have been collected. First, we split the data by categories leading to a first configuration FC1: 2 categories for training (8 hours) and 1 category for testing (2 hours). Next, we split the data by speakers leading to a second configuration FC2: 20 speakers (8 hours) for training and 8 speakers (2 hours) for testing. We split the data this way firstly to make sure that category appear in test data will not appear in training and secondly, to reduce the chance of having speakers overlapping between training and testing.

TABLE I
Contents of Fongbe speech corpus.

	Speech segments	Phrases	Duration	Categories	Speakers
FC1 - config					
Train data	8,234	879	7h 35mn	C2 & C3	25
Test data	2,168	542	1h 45mn	C1	4
FC2 - config					
Train data	8,651	1,421	8h	C1, C2 & C3	21
Test data	1,751	1,410	2h	C1, C2 & C3	7

B. Text corpus

To build a language model we need to have a text corpus containing thousands of words of the given language. The standard way most commonly used to build a text corpus is the collection of texts from websites. As we have shown in previous sections, Fongbe is an under-resourced language and thus has a very limited number of websites compared to languages such as Wolof, Hausa, and above all Arabic, French and English that have a very large wide coverage on the internet and do not suffer from lack of textual data. So, based on the few websites that provide texts in Fongbe, we used RLAT [9] to crawl text from these websites covering few texts from everyday life and many texts of the Bible translated into Fongbe. RLAT enables us to crawl text from a given webpage with different link depths. For improving the quantity of texts obtained from HTML links of websites, we have added to our corpus some texts obtained from PDF files that cover many of Fongbe citations, songs and the Universal Declaration of Human Rights. After extracting all text content in web pages and pdf file, we conducted to a cleaning and normalization of the texts:

1) remove all HTML tags and codes,
2) remove empty lines and punctuations,
3) conversion of texts to Unicode,
4) remove pages and lines from other languages than Fongbe,

5) transcription of special characters and numbers,
6) delete duplicate lines.

In total, we obtained nearly 10,130 words to build our vocabulary dictionary and a corpus which contains 34,653 sentences collected from the few documents written in Fongbe that are actually available. In table II, we list the websites used to extract text for two language models (LM1 and LM2) and from which we selected 1,500 utterances (source 1) for recording speech data for the training and testing set.

TABLE II

IV. LANGUAGE MODELING

Statistical language models (LM) are employed in various natural language processing applications, such as machine translation, information retrieval or automatic speech recognition. they describe relations between words (or other tokens), thus enabling to choose most probable sequences. This proves to be especially useful in speech recognition, where acoustical models usually produce a number of hypotheses, and re-ranking them according to a language model can substantially improve recognition rates [10] To compare the performance of our Fongbe recognition system, we built two language models (LM) using the same text corpus. The first language model (LM1) is built with the original texts after normalization and contain different tonal vowels. The use of tonal vowels implies that the system has to handle 26 vowels (with accented characters) considered as different tones instead of the 12 initial vowels. The second language model is built with the original texts that we modified by performing a second normalization on different tonal vowels from text corpus. The normalization was made by removing the tones from vowels and replacing accented characters by single characters. The result is that we have new entries with their transcriptions in our vocabulary dictionary. For example, the original word *axɔ́sú*, which means *king* will become in the dictionary *axɔsu*. Table III summarizes the various changes made to the vowels.

We used SRILM toolkit to train the two languages models. LM1 and LM2 were trained on 995,338 words (10,095 unigrams) by using the training data from text corpus (1,054,724 words, 33,153 sentences) without utterances used for the speech corpus (5,490 words and 1,500 sentences removed). LM1 was trained with the original texts while LM2 was trained with the modified texts by vowel normalization. To represent the uncertainty of our language models, we calculate the perplexity values of all the utterance transcriptions from speech corpus that are not contained in the various text corpus and which represents our test data to evaluate the performance of the two language models. Table V shows the perplexity values. The vowel normalization after the original text modification has positive impact on the quality of the language model by reducing in the OOV from 9.1% to 4.96%. This leads to observe a significant perplexity improvement with LM2 compared to LM1. Final system has been built using a lexicon which contains 10,130 unique grapheme words. As in [12], [11], we used grapheme as modeling unit to create our own lexicon because. An example of its content obtained after text pre-processing is shown in Table IV.

V. ACOUSTIC MODELING

In this section, we describe the methods that we used for training and testing our 2 configurations (FC1 and FC2) and

present in the next section the obtained results. The recordings and their transcriptions are used for acoustic modeling. The Acoustics models (AMs) are trained and tested on acoustic data from both FC1 and FC2 by using Kaldi acoustic modeling scripts that we have adapted to produce Kaldi scripts for Fongbe. We not only explored AM training methods but also experimented the impact of presence of tones in the utterances transcription from speech corpus by using LM1 (with tones) or LM2 (no tones). Thus, FC1 and FC2 training are performed not only with the same scripts but also by using both pronunciation dictionary. The pronunciation dictionary based grapheme that is used with LM1 contains 49 graphemes while the dictionary used with LM2 contains 28 graphemes.

The models are trained with 13 MFCC (Mel-Frequency Cesptral Coefficients) features whose coefficients are tripled with the $\Delta+\Delta\Delta$ by computing the first and second derivatives from MFCC coefficients. We also computed other feature transformation techniques such as LDA (Linear Discriminant Analysis) and MLLT (Maximum Likelihood Linear Transform) which gain substantial improvement over $\Delta+\Delta\Delta$ transformation. Subsequently, we also applied speaker Adaptation with feature-space Maximum Likelihood Linear Regression (fMLLR). Refer to the papers [13] and [14] for details on the theory of these transformation techniques implemented in Kaldi ASR. Figure 1 and Table VI show the hierarchy of the acoustics models that we trained in our experiments. In this hierarchy, we started by training monophone model using the MFCC features and we ended up training of SGMM using fMMI transformed features. The intermediate triphone models are also trained as shown in Figure 1. For decoding, we used the different trained acoustics models with the utterances from the test data. For each trained acoustic model we used the same speech parametrization and feature transformation method as was used for the given acoustic model at training time.

VI. EXPERIMENTAL RESULTS

The experiments focus on comparing the quality of ASR hypothesis measured by WER on AMs trained by different methods. To obtain the best path, we followed the standard KALDI procedures and report the best WER. The experiments were performed first on LM1 built with the original texts and using both speech data configurations. Then we conducted experiments based on the same procedures on LM2 including texts without diacritics. The interest is to measure the impact of using diacritics in language modelling from the results given by the WER. We also showed how the data speech configuration influence the quality of AMs measured by WER.

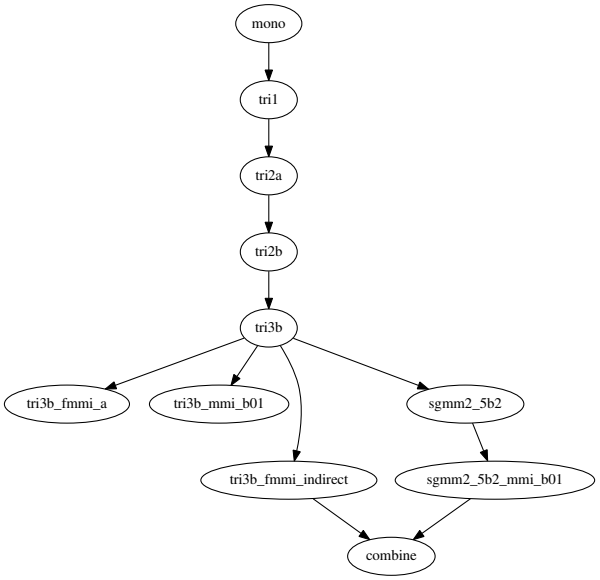

Fig. 1. Hierarchy of trained 2coustics models

A. Results before vowel normalization

In this subsection we present the results of different acoustic training methods according to data speech configuration. Table VII presents AMs results for LM1.

From the results in table VII, we can see that the monophone AM has the worst WER while the best performances are achieved with the sgmm2_5b2 AM for FC1-config and the sgmm2_5b2_mmi for FC2-config. We can thus notice that the monophone AM is typically used for the initialization of triphone models. The quality of speech recognition varies according to the used discriminative training method. The LDA+MLLT is more effective feature transformation than using $\Delta + \Delta\Delta$ features. There are subtle performance differences among the discriminatively trained acoustic model. The WER on both speech data configuration for fixed LM1 is around 44%. This can be explained by the complexity of Fongbe language for modelling the diacritics and the quality of language model used (LM1). The perplexity reported in table V justifies this assertion. Figure VI-A shows the curve performances of the acoustic training methods for both speech data configuration.

B. Results after vowel normalization

Table VIII presents two WERs of different acoustic training methods according to data speech configuration. In the second

column (LM2-Based ASR), we have included the WER results of ASR performed after vowel normalization (without diacritics).

Colunm of LM2-Based ASR in Table VIII also shows that triphone models significantly improve the monophone model performance. The tri2b+SAT+FMLLR acoustic model adapted to speaker from feature-space Maximum Likelihood Linear Regression reduced the WER by 6% absolute for both speech data configuration. The WER on FC1-config is lower than 20% for discriminative methods based on tri3b. For FC2-config, these acoustic training methods reduced the WER by 20%. The best results are coming from the training for Subspace Gaussian Mixture Models (SGMM), with an overall WER of 14.83% for FC1-config and 28.93% for FC2-config. The speech data divided by speakers helps us to obtain a relative gain of 14% with the best final WER of 14.83%. This leads us to choose AM training methods using SGMM for performance

TABLE VIII
WER OF LM2-BASED ASR (WITHOUT DIACRITICS) AND LM1'-BASED ASR (REMOVING OF DIACRITICS FROM HYPOTHESES AND REFERENCES OF LM1-BASED ASR).

Speech data config/ method	LM2-Based ASR	LM1'-Based ASR
FC1-config		
Monophone (a)	36.36	59.05

LDA + MLLT + SAT + FMLLR + fMMI (f)	35.36	37.46
LDA + MLLT + SAT + FMLLR + MMI (g)	32.38	36.19
LDA + MLLT + SAT + FMLLR + fMMI + MMI (h)	32.94	37.52
LDA + MLLT + SGMM (i)	31.64	**31.58**
LDA + MLLT + SGMM + MMI (j)	31.36	32.75
LDA + MLLT + SGMM + fMMI + MMI (k)	**28.93**	32.02

comparison among FC1-config and FC2-config. Figure VI-B shows the evolution of WER depending on acoustic models with LM2.

It is therefore remarkable that the language model LM2 gives very satisfactory decoding results compared to LM1 standard (with diacritics). Adding diacritics in text corpus before language modelling maked the speech recognition system less efficient by increasing the WER by 44.04% compared to 15.23% (performance without diacritics). While diacritics add information, which should help the recognition system, it also increases OOV rate and perplexity of the language model (see table V).

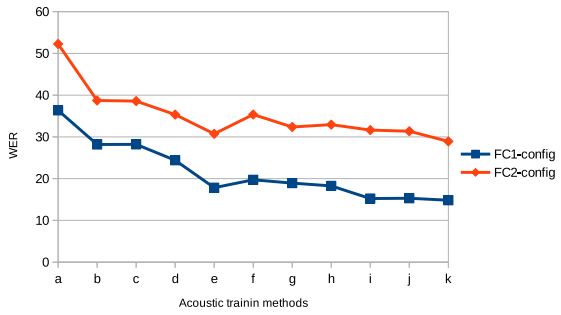

Fig. 3. Influence of speech data configuration on speech recognition quality. LM2 is fixed and only speech data and acoustic models vary. The letter in abscissa represent acoustic training methods labelled in table VI-B

For further, we performed an effective comparison of ASR performance without diacritics. To do this, we removed the

diacritics from the outputs (hypotheses) and references of ASR system built with LM1 (LM1'-Based ASR). The obtained results for this evaluation are included in the third column of Table VIII. These results can be compared to results obtained with LM2-Based ASR system (second column). This comparison leads us to assert that the removing of diacritics for different models is more effective and provides an efficient ASR system.

VII. Conclusion

In this work we introduced the first system of Fongbe continuous speech recognition by training different acoustic models using Kaldi scripts and different language models using SRILM toolkit. We also demonstrated the effect of tones on the quality of the recognition system. This leads us to conclude that with the current state of our system, the language modelling without diacritics improves significantly the recognition performances by decreasing the WER by 15.23% for speech data divided by speakers and 28.93% for speech data divided by category. Using the Kaldi recipe and the language resources we provide, researcher can build a Fongbe recognition system with the same WER obtained in this paper. For future work, firstly we will enhance the speech and text data and introduce other training techniques to further improve the performance of this first system of Fongbe recognition. Secondly, we will investigate the Fongbe re-diacritization in the context of Speech recognition.

***Abstract*—This paper presents the experimental study of multi-stage classification based recognition of Lithuanian speech emotions. Three different criteria for feature selection were compared for this purpose: Maximal Efficiency, Minimal Cross-Correlation feature criterions, and the Sequential Feature Selection. A large database of spoken emotional Lithuanian language was used in this experiment – each of 5 emotions was represented by 1000 utterances. The results of the speaker-independent emotion recognition experiment show the superiority of multi-stage classification using the SFS technique by 0.7-8 %. This classification scheme gave the highest recognition accuracy and the smallest feature set.**

I. Introduction

SPEECH emotion recognition is a classical task of pattern classification including feature extraction, training and classification (decision making). The feature extraction step is a crucial for the successful speech emotion identification process: appropriate and relevant feature set is a key component of any valid and efficient recognition system.

Various feature sets have been proposed for speech emotion recognition [1]-[5]. In straightforward manner composed feature sets often contain a few hundred or even thousand features and this can become problematic in case of limited datasets. Thus various feature selection or transformation techniques are applied for reduction purposes [2], [3], [6], [7]. Various parallel, serial, and hierarchical classification schemes have been proposed and proved to be more effective for speech emotion recognition [2], [4], [8], [9] also.

In this paper we present multi-stage classification based recognition of Lithuanian speech emotions. Section II contains the review of multi-stage classification of speech emotions. The multi-stage classification scheme using three different feature selection criteria is presented in next section. The results of the experimental study are given in Section IV and concluded in Section V.

II. Multi-stage Classification of Speech Emotions

The classification of speech emotion can be implemented in two ways. The simplest is to classify emotions in one step using one general feature set for all emotions. Usually this means a very large but not optimal feature set.

The interest in sophisticated classification schemes has been noticeable in last few years. Variations of classification scheme include multi-stage classification (when the whole recognition process is implemented in a few steps), multiple classifier schemes (different classifiers are dedicated to separate emotions or emotion groups), pair-wise classification and others. All these classification schemes can be arranged into three groups: serial, parallel, and hierarchical (Table I).

The serial combination of classifiers considers the speech emotion classification process as the consecutive identification of one or more separate emotions during one classification step. *N-1* separate classifiers will therefore be needed to identify *N* emotions [2]. The parallel scheme is based on the concurrent identification of separate emotions – all the emotions are analyzed by a set of classifiers during one step [2], [9]. The third and the biggest group of multiple classifier systems is based on the hierarchical organization of the classification process according to some criterion.

The speaker's gender, three dimensional emotion model based groups and other criteria are used for hierarchical organization of the classification process. In general, the hierarchical group contains attributes of both the serial and parallel schemes [1]-[9].

As we can see, multi-stage organization of the speech emotion classification process results in a complicated process and the accuracy obtained varies from 50 % up to 88 %. Nevertheless, the above-mentioned multi-stage classification schemes outperform single-step schemes and provide an opportunity to modify the feature set for a particular emotion or emotion group without affecting another. This should be considered as the main advantage of multi-stage classification of speech emotion.

III. Feature Selection Based Multi-stage Classification

Considering the above-mentioned advantages, we proposed a multi-stage classification scheme for speech emotion recognition [10]. The main idea of the proposed scheme is the grouping of emotions for different classification stages. All groups of emotional speech

11.	A. Milton and S. Tamil Selvi [9]	Class-specific multiple classifiers scheme	7	German	80.6%

utterances are labeled in several stages. During the first stage all utterances are classified into predefined groups. During successive stages, these groups are divided into subgroups or separate emotions. This classification scheme enables us to use different (more effective, we suppose) feature sets per classification node, thereby improving the overall recognition rate. The feature set for every node (we will call this set as subset) is formed individually according to performance on the emotional group analyzed.

Three feature selection techniques were applied for the multi-stage classification scheme: Maximal Efficiency criterion (ME), the criterion of the Minimal Cross-Correlation of features (MC), and the Sequential Forward Selection (SFS) based technique.

A. Maximal Efficiency Feature Selection Criterion

This criterion is applied by making an assumption about the aggregate efficiency of features with maximal individual efficiency i.e. of features giving the lowest classification error. The formation of a feature subset using the ME selection criterion is carried out

$$f_m^{(l)} = \arg\min_j E(f_j^{(l)}), j = 1,...,J. \qquad (1)$$

Here $E(f_j^{(l)})$ is a classification error of the j-th feature in the l-th level $f_j^{(l)}$. J is a total number of features in the l-th classification level.

The feature subset is initialized once and repeatedly extended with the most effective features $f_j^{(l)}$. The evaluation of every subset case is carried out and the extension process is stopped when the overall efficiency of the subset is not improved. Thus the selection procedure of J features from M feature set will require analysis of J+M-1 feature subsets.

B. Minimal Cross-Correlation Criterion

In this case an assumption is made as to the efficiency of linearly independent features. Independent features make the set more effective than strongly correlated ones. Thus by selecting linearly independent features we seek for a more effective subset.

MC criterion based feature selection is initiated with the most efficient feature thus ensuring the discriminative power of the subset. The analyzed feature subset is expanded by adding features with the minimal cross-correlation value

$$f_m^{(l)} = \arg\min_j \left| R\left(f_0^{(l)}, f_j^{(l)}\right)\right|, j = 1,...,J. \qquad (2)$$

Here $f_0^{(l)}$ is the feature with highest classification accuracy for analyzed emotion group. $R(f_0^{(l)}, f_j^{(l)})$ is the cross-correlation of the $f_0^{(l)}$ and the new feature $f_j^{(l)}$.

Again, the expansion of the feature subset is stopped when the efficiency of the feature subset begins to diminish. Similar to ME criterion the selection procedure of J features from M feature set using MC criterion will result in analysis of J+M-1 subsets.

Considering the unknown distribution of emotion feature values, the Spearman coefficient was selected to evaluate the correlation of the features. Moreover, the Spearman correlation is hypothesized as being more robust to data outliers, an aspect we find important in the case of speech emotion features.

C. Sequential Forward Selection

The SFS technique is one of the acquisitive search algorithms aiming to find the most significant subset of the features, and the aggregate efficiency of the feature subset is considered rather than individual properties of the features.

The selection of features starts from initialization of the empty feature subset F_0. The subset is extended with a feature $f_j^{(l)}$ making the new subset F_{i+1} more effective

$$f_m^{(l)} = \arg\max_j \left[E\left(F_i + f_j^{(l)}\right) - E\left(F_i\right) \right], j = 1,...,J. \quad (3)$$

The feature set extension step is repeated until the efficiency of newly obtained feature set F_{i+1} increases or while $j \le J$. $J \times M$ different feature subsets should be analyzed to select J-th order feature subset using this procedure. Therefore, the SFS will require number analyzed feature subsets grows significantly in comparison with aforementioned criteria.

The applied Maximal Efficiency and Minimal Cross-Correlation feature selection criteria, and the Sequential Forward Selection Technique make locally optimal choices and will thus give suboptimal feature subsets.

IV. Experimental Study

In this study we decided to perform a thorough comparison of the aforementioned feature selection criteria for the recognition of Lithuanian speech emotions. Three versions of the multi-stage classification scheme were implemented using different feature selection criteria and applied to the Lithuanian speech emotion identification task.

We have chosen recognition tasks for 3 emotions (anger, joy, neutral), 4 emotions (anger, joy, neutral, sadness), and 5 emotions (anger, joy, neutral, sadness, and fear). 1000 examples of each emotion (recorded by 5 females and 5 males) were analyzed during the experiment [11].

The initial full set consisted of 6552 different speech emotion features including time and frequency domain features, mel scale features, probabilities of voicing in speech, and their various derivatives (first and second order differentials, statistics, distribution data) [12].

A non-parametric K-Nearest Neighbor classifier was chosen for experimental testing. The value $K = 5$ was selected considering the large size of the data sets.

A two-stage classification scheme was designed assuming low-pitch and high-pitch emotion classes in the first classification stage. These two groups are classified into separate emotions during the second stage using a group-specific feature subset.

Considering the number of examples for each emotion, a 10-fold cross-validation scheme was selected to obtain more robust results. As every speaker pronounced 100 emotional sentences, the speech emotion recognition experiment was performed in speaker-independent mode.

The average recognition results are given in Fig. 1, detailed results for every emotion are given in Table II (the Maximal Efficiency criterion is denoted as *ME*, Minimal Cross-Correlation criterion denoted as *MC*, and the SFS technique denoted as *SFS*).

As we can see in Fig. 1, the SFS based multi-stage recognition of speech emotions showed the highest accuracy in all cases. Its superiority over other selection criteria based schemes was 0.7-8 %. Two things should be pointed about these results. To begin with, the average results are much lower than our previously obtained results. In the case of 5 emotions, the recognition rate was 50 % approximately (not impressive in comparison with results from other studies). Besides, the superiority of the SFS based multi-stage scheme is much smaller in comparison with previous results. There are two possible reasons for the lower results:

- Non-professional actors: the valence of the emotions is much lower in comparison with emotions expressed by professional actors. Consequently, the classification of these patterns is a more challenging task.
- The size of the database: the much larger set of emotional utterances contains more different verbal expressions, thus the variability of the utterances is much wider and more confusing.

The MC criterion produced the lowest recognition rates for emotional cases. In case of 5 emotions, the recognition rate was 41.6 %. Nevertheless, the single-stage recognition of 5 emotions (using the entire set of features) has shown an accuracy of 28.4 % only. Thus multi-stage classification has obvious superiority over single-stage classification.

Analysis of the recognition results for particular emotions reveals that anger and the neutral state are the most difficult emotions to recognize among the others.

Figure 2 shows the dependence of the obtained feature set size (order) on the number of recognized emotions. Again, the SFS based multi-stage scheme demonstrated the highest efficiency. The size of the feature sets was 2.5-4 times smaller in comparison with the cases of ME and MC selection criteria. The highest order was obtained for the MC criterion; the total size of the feature set was 90-110. In general, the order of the feature set increases with the number of analyzed emotions. This could be caused by suboptimal feature selection techniques.

Analyzing individual results from every speaker, we have noticed a fluctuation in recognition rate amongst speakers. For example, the average recognition results of speaker #9

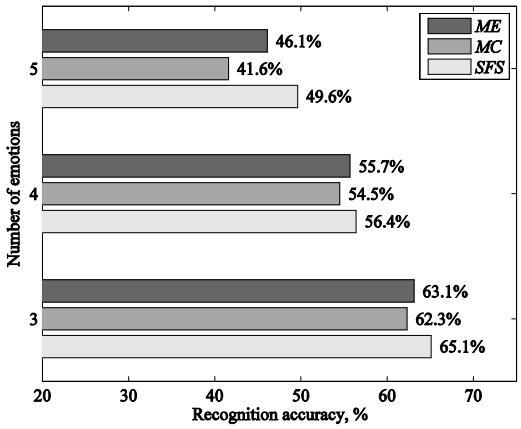

Fig 1. Average emotion recognition results

TABLE II
RECOGNITION RATES FOR PARTICULAR EMOTIONS

Criterion	Number of emotions	Recognition accuracy, %				
		Anger	Joy	Neutral	Sadness	Fear
ME	3	56.6	67.3	65.5	–	–
	4	53.5	62.2	50.1	56.8	–
	5	42.7	48.1	45.1	49.3	45.2
MC	3	54	62.6	70.3	–	–
	4	49.6	58.3	46.4	63.8	–
	5	42.4	38.1	40.3	52.8	34.6
SFS	3	57.6	71.7	66	–	–
	4	52	67.6	48	57.8	–
	5	49.4	60.6	41.2	50.3	46.7

were 1.5-2.5 times lower than average. The results of speaker #10 were 1.2-1.3 times higher than the average results. The reason is the suboptimal feature selection aiming for the highest average recognition rate not for the individual one.

V. CONCLUSIONS

In this paper the results of a comparative study of a multi-stage classification scheme for Lithuanian speech emotion recognition are presented. Three different feature selection criteria were applied for recognition purposes: Maximal Efficiency, Minimal Cross-Correlation of features and Sequential Forward Selection. The following conclusions can be drawn from the results:

- The average recognition rate was 62-65 % for the 3 emotion set (anger, joy, and neutral), 55-57 % for the 4 emotion set (anger, joy, sadness, and neutral), and 42-50 % for the 5 emotion set (anger, joy, sadness, fear, and neutral). The results are not impressive in comparison with results from other studies, but the large set of emotional utterances should be considered as the main factor for the accuracy obtained.
- Sequential Forward Selection based scheme shows higher performance in comparison with individual feature properties based selection criteria (Maximal Efficiency and Minimal Cross-Correlation in our case). The superiority was 0.7-8 %.
- The recognition of a large number of emotional utterances requires large feature sets. Increasing the number of recognized emotions also expands the size of the required feature set. Consequently, speaker and text-independent speech emotion recognition would require for huge feature sets.

***Abstract*—Protection of private data, signing electronic documents are selective use of identity verification. In this work, the problem of voice verification has been discussed. The method of verifying the voice based on the methods of artificial intelligence was presented. Numerous tests were performed to demonstrate the effectiveness of the presented solution - research results are shown and discussed in terms of advantages and disadvantages.**

I. Introduction

THE digitization of today's world has started some time ago. At almost every step we associate with the technology in one form or another. Each one of us carries a cell phone or laptop and therefore has continuous access to the Internet. On the Internet, people handle all the daily issues - buy goods, pay bills or store images and a variety of data. These are the times in which it is hard to remain anonymous what requires continuous improvements in data transmission and data protection.

One of the most advanced trends in computing today is artificial intelligence, which finds its use in almost any application. One of the first approaches of this trend were neural networks, which are mainly used as classifiers, i.e. classification of signatures [1], surface structures [2] and multimedia applications [3]. Modern methods of mathematics and artificial intelligence are increasingly finding application in medicine and other aspects. In [4] and [5], the authors presented an interesting approach to the processing of EEG signals. A very important achievement is also fuzzy logic, which is often combined with neural networks in order to not only increase precision, but allow the classification of other measures such as linguistics [6] and [7]. Similarly we can use voice recognition in AAL environments to help users [8] and improve data acquisition [9]. These aspects of artificial intelligence methods are also widely used in verification of people. On a daily basis, we meet with the problem of verification in banks, stores (e.g. when signing checks), companies or in different institutions for which a signature, voice, or even features of the iris are a confirmation of our identity. Voice verification is one of the least expensive in implementation of solutions of this type – just a microphone and expert application are needed. Different approaches are analyzed in order to maximize the precision of the voice classification. In [10], the authors presented the statistical approach, again in [11] used hidden Markov models for the same purpose. In this work, I would like to introduce an innovative way of extracting features of the voice sample using heuristic and neural classifier.

II. Audio signal processing

For the purposes of analysis of digital sound samples, sound file must be represented by a numerical value, or a function that enables analysis. One of the best known methods is the Discrete Fourier Transform (DFT) presented in [12]. Transform is called transformation of vector that represents the numerical values of the signal $\vec{x} = [x_0, x_1, \ldots, x_{N-1}]$ into $\vec{z} = [z_0, z_1, \ldots, z_{N-1}]$, where the value of $z_i \in \mathbb{C}$. DFT is performed according to the following formula

$$z_k = \frac{1}{N} \sum_{n=0}^{N-1} x_n \exp(\frac{-2kni\pi}{N}), \tag{1}$$

where k is harmonic number, n is number of signal samples and N is total number of samples.

One way to display the audio signal is to use a spectrogram [13] which is a graph of amplitude spectrum signal over time. The construction of the spectrogram operates on the principle of dividing the signal (obtained by the use of short-time fast Fourier transform with Hamming function) on parts for which the amplitude of harmonic components are calculated. During the analysis of this graph, we assume that

- the power at a given frequency is based on the color - the value is higher if the color is warmer;
- the frequency increases with the height of the point on the chart.

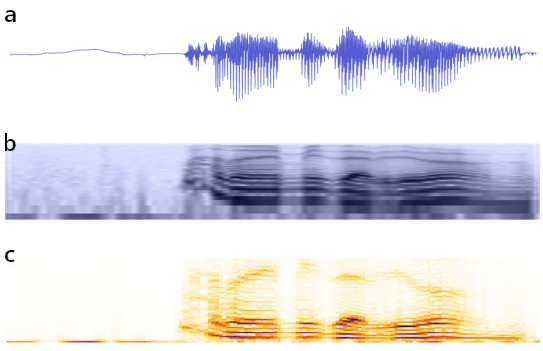

Fig. 1: Graphical representation of sound samples with the sentence "My name is Han Solo": (a) the DFT of the signal (b) spectrogram of the recorded sound with noise (c) spectrogram of the clear signal.

978-83-60810-90-3/$25.00

Recorded sound is exposed to register all types of noise - in the case of voice verification in a large company, people standing in a queue already make noise as well as any other voices. Noise is clearly visible on spectrograms interiors as a plurality of light color. In order to correct analysis of sound, noise should be removed to leave only the desired recording. Noise reduction can be achieved by a multi-band spectral subtraction described in [14]. The algorithm assumes that speech spectrum will be divided into N bands and the estimate of the clean speech spectrum can be obtained by performing the following formula for each band i for k value

$$|\hat{S}_i(k)|^2 = |Y_i(k)|^2 - \alpha_i \delta_i |\hat{D}_i(k)|^2 \qquad l_i \leq k \leq h_i, \quad (2)$$

where $\hat{S}$ means the magnitude spectra of the clean speech and $\hat{D}$ of the noise, Y is the magnitude spectra of the incoming signal, l_i is the beginning frequency of the ith band and similarly h_i is the ending frequency, δ_i is a tweaking parameter which is set by empirical way. The parameter α_i can be calculated by

$$\alpha_i = \begin{cases} 5 & \psi_i < -5 \\ 4 - 0.15 * \psi_i & -5 \leq \psi_i \leq 20 \\ 1 & \psi_i > 20 \end{cases}, \quad (3)$$

where

$$\psi_i = 10 \log_{10} \left[\left(\sum_{k=l_i}^{h_i} |Y_i(k)|^2 \right) / \left(\sum_{k=l_i}^{h_i} |\hat{D}_i(k)|^2 \right) \right]. \quad (4)$$

The samples of this methods to process audio file are shown in Fig. 1. Another way to present the audio signal is a periodogram, which for the first time was shown by Arthur Schuster [15]. It is obtained by the modulus squared of the DFT and presents the Power Spectral Density (PSD) estimate, as shown in Fig. 3.

III. Preprocessing for Neural Network

Creating samples is an important part for the pattern recognition problem. Each sample must not only represent input data but save as much information about the sample using the fewest number of values. For that purpose, a model of the general pattern based method on a large number of input samples is proposed. All samples representing the specific person will be created using general pattern.

A. Preparation of the aggregate sample

In the first step of processing sound samples, spectrograms are created. Each spectrogram is subjected to noise removal. On the basis of all samples, the aggregated sample is prepared. This process is about creating one sample spectrogram, which retain repeating features in all processed ones. At the beginning of the method, the $w \times h$ array is created, where w is the width and h the height of all samples - each point (x, y) on spectrogram is corresponding to one cell in the array. Initially, each cell is set to 0. For each point (x, y) color pixel on each bitmap is verified. In the case where the pixel is not white, the value on this position (x, y) is increased by 1 in the array. Color $[R_{old}, G_{old}, B_{old}]$ is selected and the new sample is created. For each pixel, the color is calculated using a value of m from an array and the following formula

$$C_{new} = C_{old} * (1 - m\varsigma), \quad (5)$$

where C is one of the color components (R, G or B) and ς means the color shade and it is calculated as

$$\varsigma = \frac{2}{\max\limits_{0 \leq i < w \wedge 0 \leq j < h} m_{ij}}. \quad (6)$$

In the next section of this paper, created spectrogram will be called a *general spectrogram*. The process of creating a *general spectrogram* is shown in Fig. 2.

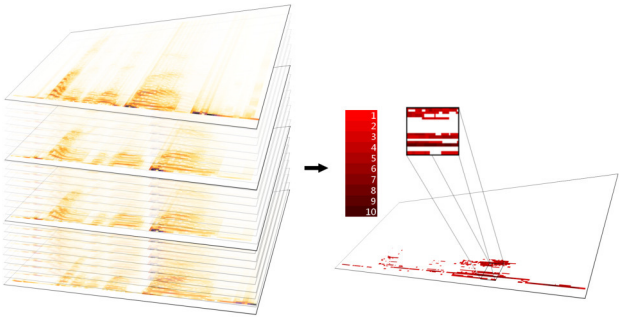

Fig. 2: Visualization of creating a *general spectrogram* based on input spectrograms with attached legend of colors - the darker shade of red, the point often occurs on the input samples.

B. Heuristic detection of key-points

Using the so-created *general spectrogram*, heuristic algorithm will be used to find the key points of the image. The coordinates of key points will allow to create the mask of the features by which we will be able in a quick and effective way to retrieve specific values from the spectrogram to perform training using verification vectors.

As a heuristic algorithm, Flower Pollination Algorithm (FPA) [16] was selected, which is a mathematical model of a natural phenomenon pollination of flowers in the spring. The original algorithm assumes some basic rules aimed at simplifying some dependence

- Global pollination (e.g.: biotic phenomenon) is represented as Levy flights,
- Local pollination is interpreted as abiotic and self-pollination,
- Pollen is carried by the wind what is modeled by a random factor $p \in [0, 1]$.

FPA is used to find the important points in the image. Population of flowers is placed in random places on *general spectrogram*. Then, the simulations of global and local pollination are performed in order to find the best points. Point

selection is done according to the fitness function, which is defined as

$$F(x_i) = \begin{cases} \min\limits_{0 \le j < N} 0.2 * B(x_j) & \text{if } x_{best} = 0 \\ \sqrt{B^2(x_i) - B^2(x_{best})} & \text{for others} \end{cases}, \quad (7)$$

where x_i is a point representing a pollen, x_{best} is a point with the best fitness value in actual iteration, and the function $B(\cdot)$ is the brightness of a pixel that takes values of $[0, 1]$, N is the size of population.

In each iteration, two operations are performed – global and local pollination. Global pollination moves pollen x_i over the spectrogram image according to

$$x_i^{t+1} = x_i^t + L(x_i^t - x_{neighboring}), \quad (8)$$

where t is the number of iteration, $x_{neighboring}$ is the nearest point to x_i and $L(\cdot)$ is a function of Levy flight understood as

$$L(x, \kappa, \mu) = \sqrt{\frac{\kappa}{2\pi}} \frac{e^{-\kappa/(2(x-\mu))}}{(x-\mu)^{3/2}}, \quad (9)$$

where κ and μ are specified parameters.

The second operation is a local pollination which takes place over the neighborhood pixels for a given point x_i and it is defined as

$$x_i^{t+1} = x_i^t + \epsilon(x_j^t - x_k^t), \quad (10)$$

where x_j and x_k are neighboring pollens.

The algorithm returns the best adapted solution with its motion path. From a mathematical point of view, the trajectory is a closed consisting of two-dimensional coordinates of key points found on the spectrogram. Created set will allow to get the appropriate features based on the spectrogram in a very short time. Moreover, for every person, FPA will find a different trajectory, and therefore the possibility of fraud during the verification respectively decreases.

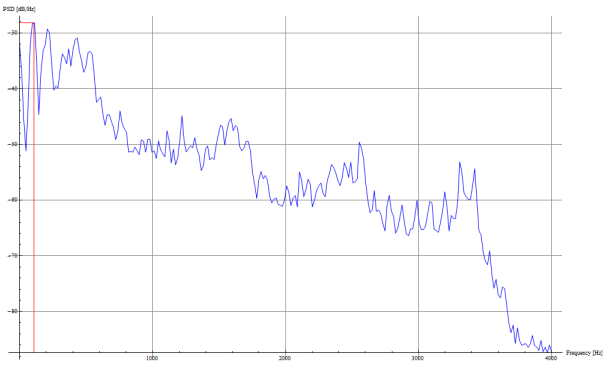

Fig. 3: Periodogram of the sentence "Han Solo" with the selected maximum value of PSD.

C. A general vector for identification

In order to analyze every sound, a file should be saved as a vector of numbers representing as much as possible features. In addition, the vector should contain the minimum number of values, because then a learning process occurs much more efficient. The proposed model in the general formula for a vector in this work is the combination of the features extracted from the spectrogram and the periodogram using the method described in Sec. III.

The proposed model of the sample can be defined as follows

$$[B(x_0), B(x_1), \ldots, B(x_n), f_{max}, id], \quad (11)$$

where $B(x_i)$ is brightness value of pixel at the key-point x_i obtained from FPA, f_{max} is the maximum value of the PSD determined from periodogram (see Fig. 3) and id is the designation of the owner of the sample.

IV. Neural Network

The beginning of the history of neural network models is dated to the first half of the twentieth century [17]. Until today, new and modified models of the network, or even learning algorithms of this type of networks are created. A neural network is understood as a complex object composed of many layers. The simplest models contain only two - input and output layer. In this type of layers, learning vector is inserted into input layer and the calculation result is forwarded to the next layer. In more complex structures the hidden layers are added between input and output. Their number depends on the size of the problem, for which a structure has been created. Each layer is made of neurons through which the layers are connected – each neuron of one layer is connected to each neuron in the next one. Neurons use activation function, whereby the value is calculated. In [18], different activation functions were proposed, but the most common is a unipolar sigmoid function. Moreover, each connection between two neurons is burdened with a certain weight in the range of $[0, 1]$ and this contributed to a number of learning methods for improving received results.

One method of learning neural network is the back-propagation algorithm for the first time mentioned in [19]. To this day, it is one of the most commonly used training algorithms for neural networks. It is a type of supervised learning which is based on minimizing the error function of the output layer up to the achievements of the first hidden layer. The error calculated in this way is used to modify the weights on the connections between neurons. The formula for calculating an error for the neuron k is defined as follows

$$\delta_k = \begin{cases} out_k(1 - out_k)(ex_k - out_k) & \text{the output layer} \\ out_k(1 - out_k) \sum\limits_{o \in out} w_{ok}\delta_k & \text{the hidden layer} \end{cases}, \quad (12)$$

where out means the output values from neuron k, ex is the expected value at the output of the neuron. The calculated error values are used in updating the weights by

$$w_i = w_i + \delta w_i. \quad (13)$$

V. Experiments

Using the method of pre-processing sound samples described in Sec. II and III are processed. In experimental research 100 different sound files belonging to four people

were used. During the processing, the following parameters were used

- FPA – 100 flowers, 15 iterations, $\kappa = 0.4$, $\mu = 0.35$,

After creating samples, obtained vectors have been placed in a database and used for training the network until the error value was smaller than 0.1 with the proportion of mixed samples – 80% to train and 20% to verify. Subsequently, using all samples for examined network an accurate measurements were calculated in Tab. I.

TABLE I: Average accuracy for the identification

Id	Correctly classified	Incorrectly classified	Accuracy
1	14	11	56%
2	20	5	80%
3	23	2	92%
4	18	7	72%

The results allow to calculate the effectiveness of the verification network, which reaches 75% with 25 samples of voice for one person. The results in the table indicate that for a person no. 1 efficacy haughty only 56% accuracy, again for a person no. 3 it was 92%. Such a large discrepancy between the results can be an effect of a bad sound recording or different voice tones. Another problem that might be a big obstacle in good verification is possible jitters or hoarseness. This can be accomplished by recording the samples for a few days—not only by one day.

VI. Final Remarks

In times where almost everything revolves in the digital world, any method of data security become an important area of IT. Newer and more complex algorithms can increase the security not only of information in computer networks, but many companies, where the entrance is authorized.

The innovative idea of the features extraction from the processed audio samples is presented in this work. Experiments based on artificial intelligence methods have been performed and discussed. The proposed method of voice verification due to the 75% effectiveness is a good alternative to existing methods. Moreover, the use of heuristics to find a sequence of points can efficiently assist in verification of possibility of fraud - each sequence of points is different because of the basic assumption of randomness for heuristics. Therefore proposed solution seems to be right development to increase security in man-machine interactions.

***Abstract*—In this paper, we describe the process by which web services ontologies are populated from a web services collection. The general approach relies on a global ontology model that is used to represent automatically web services. The model is enriched with web service instances classified into a taxonomy. The main idea is to extract taxonomic relations (*isTypeOf*) from web services using a supervised classifier of textual descriptions attached to web services. The entire process for ontology population involves the following tasks: text extraction from web service descriptions, classification of text descriptions and extraction of taxonomic relations (instances of classified web services). An experimentation was carried out with a collection of web service, which shows promising results and the feasibility of our approach.**

***Index Terms*—web services classification; ontology population; web services ontology population; text classification.**

I. Introduction

WEB services are reusable software components through which it is possible to build and integrate new applications without having to implement all elements of a system. Nowadays, Web services have become more popular due to their proliferation for offering storage services and resource management in the cloud. Web services are available in both public and private repositories using descriptions in XML and natural language, such as: English, Spanish or German. There are several public repositories of Web services, for example: SOAP Web service directory supported by Membrane[1]; Repository of Visual Web Service[2]; ProgrammableWeb[3]; OWLS-TC[4].

Web services are described using the standard WSDL and OWL-S. Both consist of an XML file, in which necessary elements to achieve a detailed description of web services is defined.

Programmers and application developers can use web services like software components, but they need search them into a large volume of web service published in repositories. This task is commonly known as web services discovery. However, web services discovery remains a difficult and error-prone task, since web services repositories offer keywords-based search mechanisms. In addition, web service repositories are organized in static structures that do not allow a flexible and dynamic organization of services. As a solution to this problem, ontologies can organize web services repositories with semantic relations and taxonomic relations in order to offer a semantic organization of them. In addition, this structure can help to discover and test web services in the work presented in [1].

In this paper, we present an approach for web services classification based on the frequency of *1-grams* (words), in order to populate a web services ontology. The main aim of this paper is to improve the structure repositories in order to facilitate web services discovery by providing an ontology-based semantic structure.

The rest of the paper is organized as follows. In Section II, we report the state of the art related with classification and ontology population in web services. Section III describes Web Services Descriptions Language (WSDL) and an ontology-base service description language (OWL-S). Section IV presents the global ontology model used for populate web services. Section V presents our approach for web services ontology population. Experiments and results are presented in Section VI. Finally, conclusions and future work are shown in Section VII.

II. Related Works

Web services are described using parameters (input and output) names, data type names and operation names. These elements have been exploited for several purposes. As in [2] and [3] that have used text processing with parameters and operations names in order to obtain the similarity between web services; content-based approaches for web services classification have been proposed in [4], [5], [6], [7], [8] and [9], which are described below. Web services clustering from WSDL documents in order to facilitate web services discovery proposed in [10] and [11], also in [12] a clustering-based approach to web service categorization in order to form a hierarchy of service taxonomy is presented.

In this paper, we rely on text classification to enable web services ontology population. Text classification is a task widely used, as in [13]. Moreover, web services classification is a task that has been addressed in different ways. Regarding with web services ontology population using text descriptions

[1]http://www.service-repository.com/
[2]http://www.visualwebservice.com
[3]http://www.programmableweb.com
[4]http://projects.semwebcentral.org/projects/owls-tc/

classification of web services, poor works have been propounded. However, web services classification is close to web service ontology population since it needs a class name to be instantiated. Thus, we have conducted our research of related works in two aspects: approaches for supervised classification of web services; and works for ontology population.

Using OWLS-TC collection, we have the following works: [4] uses web services textual descriptions, such as: operations, inputs/outputs textual descriptions. They classify web services with a *Naive-Bayes* classifier. In [5], the classification of web services is based on support vector machine algorithm and it is achieved by calculating a similarity between words using *WordNet* and a domain taxonomy in order to reach an efficient classification of web services in the collection. A similar web services classification has been proposed in [6], in this case it is based on sets, they propose a representation of web service descriptions with vector space model and an entropy-based weighting of all terms.

There are works that not use the public collection mentioned above. They use private collections of web services. [7] showed that using quality attributes (reliability, documentation, performance, and response time), it is possible to classify and predict the quality of a web service; they have used a private collection of 364 web services. Unsupervised classification is applied in [8], where an automatic classifier is presented based on tags embedded in WSLD documents for each web service, its method was tested with 951 web services distributed in 19 categories. In addition, other relevant work is presented in [9], they expose a text mining approach to web services classification by identifying key concepts in textual documentation services, but only in a specific domain.

Another field for this paper is web services ontology population. Some works that have presented ontology learning methods includes ontology population for web services domain. As in [14] that enhances an existing ontology with similarity relations between operation of web services. An ontology learning mechanism is proposed in [15] in order to enable *RESTful* semantic web services using syntactic and semantic descriptions. And [16] propose an automatic extraction method that learns domain ontologies from textual documentations attached to Web services.

III. Web Services Description

The recommended SDL for the Web Service implementation is named Web Service Description Language (WSDL), which is currently a well-established W3C standard. WSDL defines an XML grammar for describing networked services as collections of communication endpoints capable of exchanging messages. In this work, we consider WSDL 2.0, that is the latest version, which incorporated important changes in the description of a service. WSDL 2.0 changes the *definitions* tag with the *description* tag. The main difference between WSDL 2.0 and previous versions are: the *targetNamesSpace* is a required attribute of the definitions element in WSDL 2.0; message constructs are removed in WSDL 2.0; operator overloading is not supported in WSDL 2.0; *PortType* is renamed as Interface; Interface inheritance is supported by using the extends attribute; and Port is renamed as Endpoint.

Also, OLW-S is an ontology-based service description language, which provides a semantic description of web services. OWL-S is based on *Service* class that presents a *Profile* class in order to describe the service functionality, which is described by *Service Model* class. OWL-S contains descriptions in natural language focused on the understanding by humans. A challenge is faced when this user-focused description need to be processed.

IV. Global Ontology Model

This section presents a global ontology model exposed in [17], which is used to populate web services from text descriptions in our approach. It is also widely explained here.

We use Manchester Syntax for OWL 1.1 [18] in order to present the global ontology due to it is a user-friendly syntax. Thus, the ontology model created in [17] represents the following relevant classes for our approach.

```
Class: GeneralService
Class: GeneralOperation
Class: GeneralEffect
Class: GeneralPrecondition
Class: GeneralParameter
Class: InputParameter
     SubClassOf: GeneralParameter
Class: OutputParameter
     SubClassOf: GeneralParameter
```

The ontology model also includes object properties, relation between classes, as follows:

```
ObjectProperty: hasOperation
     Domain: GeneralService
     Range: GeneralOperation
ObjectProperty: hasEffect
     Domain: GeneralOperation
     Range: GeneralEffect
ObjectProperty: hasPrecondition
     Domain: GeneralOperation
     Range: GeneralPrecondition
ObjectProperty: hasInput
     Domain: GeneralOperation
     Range: InputParameter
ObjectProperty: hasOutput
     Domain: GeneralOperation
     Range: OutputParameter
```

The idea of this paper is that the web service instances are created and classified into subclasses of *GeneralService* class and thus, we have an extended ontology model from presented in [17]. Under this assumption, Figure 1 shows nine subclasses that we have proposed to be populated.

V. Web Service Ontology Population

Web Service Ontology Population is carried out by text classification of each Web service description in WSDL tags and natural language. Text classification associates predefined

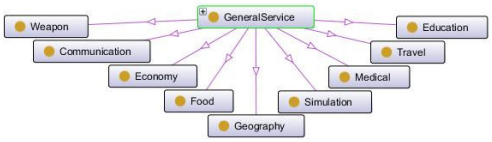

Fig. 1. Our taxonomy proposed from GeneralService class

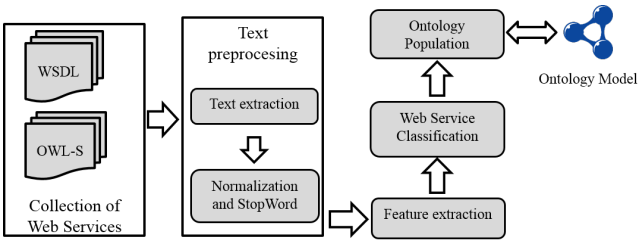

Fig. 2. Architecture of Web service ontology population

categories to a Web service from text analysis. Figure 2 shows our architecture for web service ontology population from web service descriptions through text classification. From a general ontology model, our process of ontology population is able to discover taxonomic relations to enhance our initial model and thereby achieve the classification of web services.

Web service ontology population uses a collection of public web services that are classified in any of nine proposed categories. Each web service in our collection has associated a WSDL description and an ontology-based extension of this description in OWL-S. We have proposed four phases in order to populate a web service ontology, which are described below.

A. Text preprocessing

WSDL files and OWL-S files that describes web service functionality are analyzed in order to identify and extract the text descriptions, which is useful for achieve content-based classification. Thus, the content of *serviceName* and *textDescription* labels from *Profile* class is extracted, such labels contain natural language text. From WSDL file, the service name (*wsdl: service name*), names of operations (*wsdl: operation name*) and the data type names of messages, both simple or complex (*xsd: simpleType name* and *xsd: complexType name*). This natural language text and full names of elements are used to characterize, classify and represent the web service instances into the corresponding class in our extended ontology model.

Text extracted is segmented into canonical words. In web services domain is common to find complex names of services, operations and data type names, which are formed by two or three complex words. They are segmented into lexical words by considering the switching from lowercase to uppercase and the use of subscripts as separator of lexical words. As an example: *getAddressLocation* or *get_address_location* is separated into the following lexical words: [*get*] [*address*] [*location*].

In addition, the texts are normalized by applying a conversion to lowercase, removing punctuation and stop words, which they not add meaning to the services and therefore are considered non-functional for classification based on service content.

B. Features extraction and selection

Lexical words of each web service were normalized and selected in order to represent a space model to have a formal representation of each web service. This model uses the lexical words (*1-gram*) like features. From our collection of web services 1801 words are extracted and represented in vectors.

Features are weighted using the *Bag-of-Word(BoW)* model, which consists of a collection of texts and their vocabulary that is considered features in our research. Each web service is expressed like a vector $S_j = (w_{1j}, w_{2j} w_{nj})$, where w_{ij} expresses the relevance that produces a feature i in a text j. In our case, a lexical word (*1-gram*) of vocabulary represents a feature i and web service descriptions represent a text j.

The approach used to obtain the relevance of a feature (*1-gram*) in the text of a web service is based on applying Term Frequency Inverse Document Frequency (*TF-IDF*) in order to determine what lexical word in the collection of texts might be more important for a text description of a Web service. This weighting uses the Term Frequency (*TF*) of our vocabulary in a text (1) and Inverse Document Frequency (*IDF*) that determines whether the term is common in the text collection (2), then the final equation to calculate a *TF-IDF* of a *1-gram* is shown in (3).

$$TF(t_i, S_j) \tag{1}$$

In order to determine the value of *Term Frequency (TF)*, we use the number of times that the term t occurs in a web services description *S*.

$$IDF(t_i, S_j) = \log \frac{|S|}{1 + |sS : t_i s|} \tag{2}$$

Inverse Document Frequency (*IDF*)is obtained by dividing the total number of web service descriptions by the number of web service descriptions that contain the term, and then, logarithm of such quotient is taken.

$$w_{ij} = TF(t_i, S_j) \times IDF(t_i, S_j) \tag{3}$$

A feature selection process was carried out in order to reduce our vector space. The aim of features selection is to reject irrelevant features to obtain the best subset to improve the accuracy in web services classification. For this process, we apply an analysis of attribute correlation and wrapping scheme based on decision trees, widely used as the features selection algorithm, in order to select relevant features. Such process has obtained a subset of 69 lexical words (*1-gram*) like relevant features.

C. Web service classification

Web services classification is based on features extracted from web service descriptions in WSDL and OWL-S and weighted with *TF-IDF*. The features are represented in vectors, which are used by a supervised classifier, widely used in machine learning to estimate the predictive function of each class of a collection.

As a supervised classifier is used to obtain the category of a web service, we have divided our collection in two sets: a training and test set. The main aim of this phase is to build a classifier of web services using their text description. Nine categories are considered by the classifier to be built: *Communication, Economy, Education, Food, Geography, Medical, Simulation, Travel and Weapon*. They are automatically assigned to each web service.

A rule-based classifier was built under machine learning schema using the *1-gram* words like features. C4.5 [19] was used like classification model for web services. This classifier builds decision trees from a set of training data by a selection of the best attributes that obtain effectively partitions from training set, then, the rules of the decision tree are applied to the test set in order to evaluate the results.

C4.5 classifier was trained with 899 web service descriptions, adjustments in the trees are applied for obtaining the corresponding rules, which are used with the test data for obtaining the similar output. The difference in the output determines the performance of our web services classifier. We have implemented the C4.5 for web services classification using WEKA tool [20].

D. Ontology population

This section presents the process of automatic population of Web services ontology. This task uses the assigned categories in the previous phase, they are used to create class instances in order to populate the global ontology model used for the representation of Web services.

Ontology population is the process of adding class instances and relation instances between individuals of the ontology into an existing ontology [21]. Thus, ontology population takes the category assigned to each Web service and it creates an ontological instance into the corresponding class from global ontology model. A *isTypeOf* relation is created between the instance of the Web service and the corresponding class.

Our ontology population process is illustrated with an example. Given a pre-processed text of the web service identified like *ActivityDestination*, as shown below, we determine his class in order to be populated.

Web service description: *name: activity destination service; operation name: get destination; input name: activity name; output name: destination name; description: this web service provides the destinations where an activity is available.*

The following code represents the population of class *Travel* service with the *ActivityDestination* service.

```
Individual: ActivityDestination
    Types: Travel
    Facts: hasOperation GetDestination
    Facts: hasName "Activity destination
service"
```

And the *GetDestination* operation has an input and an output, which are described as follows:

```
Individual: GetDestination
    Types: GeneralOperations
    Facts: hasInput ActivityName
           hasOutput DestinationName
```

VI. Experimentation and Results

The main idea of our experiments is to evaluate the classification task, which was carried out with *C4.5* classifier. Thus, with the evaluation of our classification task, we are evaluating the correct population of global ontology model used to represent Web Services. It is because that the population of web services ontology corresponds to create instances in the class discovered by *C4.5* classifier.

According to the assessment presented above, we carried out our experiments. We use selected word of the vocabulary like features.

Our evaluation was carried out with version 3.0 of OLWS-TC collection, which consist of 1129 web services described using WSDL and OWL-S. As this collection is considered to test, their web services are pre-classified into the following classes:*Communication, Economy, Education, Food, Geography, Medical, Simulation, Travel and Weapon*. It was divided into two groups: 899 web services for training web services classifier and 230 web services for testing our approach.

The experimentation was performed with 899 web services in order to obtain the classification model and then, it was applied to 230 web services to be tested. Also, they used the vector of *1-grams* like features weighted with *TF-IDF* for each web service and the *C4.5* classifier with the following parameters: *confidence factor used for pruning the tree = 0.25* and *the minimum number of instances per leaf = 2*.

We evaluate the results in terms of *Precision(P)*, *Recall(R)* and *F-measure(F1)*. Metrics widely used in classification tasks. In our case, these metrics compare the results to be evaluated with external values of trust (web services previously classified).

Table I shows the results of our evaluation, which consists of testing *C4.5* classifier with features extracted (*1-grams*) and weigh them using *TF-IDF*.

The results showed in Table I emphasize that the use of selected features (words) present promising results reaching 92.1 % of correctly classified web services.

We have used OLWS-TC collection for our experiments. This collection has been used as a benchmark for works that have proposed web services classification. Therefore, it is possible to compare our results with previously proposed approaches, such as Zhang and Pan [4], Wang et al. [5], Chen et al. [6] and Yuan and Jian [8]. In Table II a comparison of proposed approaches with our approach is presented in terms

TABLE I
RESULTS OF THE WEB SERVICES CLASSIFICATION

Class	Precision	Recall	F1
Communication	0.927	0.879	0.903
Economy	0.955	0.953	0.954
Education	0.843	0.944	0.891
Food	0.857	0.706	0.774
Geography	0.982	0.900	0.939
Medical	0.955	0.863	0.906
Simulation	0.933	0.875	0.903
Travel	0.961	0.909	0.934
Weapon	0.974	0.925	0.949
Average	**0.924**	**0.921**	**0.921**

of accuracy, representing the number of correctly identified true or false classifications of web services.

TABLE II
RESULTS WITH OWL-TC COLLECTION

Approach	Accuracy
Zhang and Pan	0.41
Wang et al.	0.89
Chen et al.	0.85
Yuan and Jian	0.87
Our approach	**0.921**

The results show the effectiveness of our approach compared with other approaches under the same Web services collection and the same evaluation criteria. Although the results are not so encouraging for *Food* class as for other classes, our solution can help developers to recovery Web services and reuse existing software components in a disorganized repository of web services.

VII. CONCLUSIONS AND FUTURE WORK

This paper has presented an approach for web service ontology population through a text classification technique. We have employed *C4.5* classifier with *1-grams* using the weighting *TF-IDF* like features to represent a web service using the vector space model. A selection of features was carried out in order to reduce the space of representation, obtaining 69 words like relevant features.

The main contributions of this paper are as follows: (a) we present an approach to classify web services using their descriptions and a text classification technique; (b) we populated a web service ontology; (c) and we have used a benchmark collection for testing called OWLS-TC, in which we have demonstrated that our solution outperforms other approaches in terms of average resulting classification.

As future work, we plan to discover non-taxonomic relations or concepts [22] between web services and functionalities, input/output descriptions to enhance web service ontology in order to facilitate discovery and composition of web services.

In addition, semantic similarity between operations and between classified web services is relevant to extract for helping to software developers in web service discovery.

***Abstract*—With the development of telecommunication technology over the last decades, the request for digital information compression has increased dramatically. In many applications, such as high quality audio transmission and storage, the target is to achieve audio and speech signal codings at the lowest possible data rates, in order to offer cheaper costs in terms of transmission and storage. Recently, compression techniques using wavelet transform have received great attention because of their promising compression ratio, signal to noise ratio, and flexibility in representing speech signals. In this paper we examine a new technique for analysing and compressing speech signals using biorthogonal wavelet filters. In particular, we compare this innovative compression method with a typical VoIP encoding of human voice, underlining how using wavelet filters may be convenient, mainly in terms of compression rate, without introducing a significant impairment in signal quality for listeners.**

***Index Terms*—Wavelet Analysis; Audio Compression; Digital Filters; VoIP; SIP, Quality of Services.**

I. Introduction

SPEECH is a very basic way for people to convey information to each other by means of human voice, within a bandwidth of around 4 KHz. The growth of the computer industry has invariably led to the demand for quality audio data. Analogue audio signals, such as voice speeches, or music, are often represented digitally by repeatedly sampling the waveform and representing it by the resulting quantized samples. This technique is known as *Pulse Code Modulation (PCM)*. PCM is typically used without compression in high-bandwidth audio devices (e.g., in CD players), but compression is essential where the digital audio signal has to be transmitted by means of a communication medium, such as a computer or telephone network [1]. In order to send real-time audio data over a communication link, data compression has be used due to the mismatch with the available link bandwidth [2].

Compression of signals is based on redundancy removal between neighbouring samples or between the adjacent cycles [3]. In data compression, it is desired to represent data by as small as possible number of coefficients within an acceptable loss of quality. Therefore, compression methods rely on the fact that information, by its very nature, is not random but exhibits an intrinsic order and pattern, so that the essence of the information can often be represented and transmitted using less data than would be required for the original signal [2].

Compression techniques can be classified into one of two main categories: *lossless* and *lossy*. Lossless compression works by removing the redundant information present in an audio signal, but preserving its quality and the complete integrity of the data. However, it offers small compression ratios, hence it can be used if we have no stringent requirements; furthermore, it does not guarantee a constant output data rate, since the compression ratio is highly dependent on the input data. On the other hand, one advantage of lossless compression is that it can be applied to any data stream. In lossy coding, the compressed data does not preserve bit-wise equivalence with the original data. The goal of this kind of compression is to maximize the compression ratio or the bit rate reduction, with reduced cost in terms of loss in quality [2].

Compression methods can be classified into three functional categories: *direct methods*, when the samples of the signal are directly handled to provide compression; *parameter extraction methods*, if a preprocessor is employed to extract some features that are later used to reconstruct the signal; *transformation methods*, such as Fourier transform, wavelet transform, and discrete cosine transform. In this latter, the wavelet transform is computed separately for different segments of the time-domain signal at different frequencies. This makes wavelet filtering good for signals having high frequency components for short duration and low frequency components for long duration, such as images, video frames and speech signals [3].

In this paper we show an innovative technique to process and compress an audio signal using a 3.7 biorthogonal wavelet filter, by using thresholding techniques in order to eliminate some insignificant details of the signal, then obtaining a lossy compression that allows us to significantly reduce audio bit-stream length, without compromising the sound quality. While such a technique has been selected because of its remarkable performances, due to the intrinsic nature of the implemented wavelet transforms and filters, it is also possible to implement the coding and decoding pipeline directly on hardware. Therefore, the proposed system not only constitutes an outperforming compression software, but also a possible hardware interface. The latter can be thought both as a consumer-side phone-box or as a provider-side switchboard integrated system.

II. VoIP Encodings

Nowadays, modern telecommunication is mainly based on the following steps: voice information is digitalised (by sampling), then encoded, and then transmitted as a packets stream [4].

A. Encoding

The encoding process starts by producing digital "rough" results during the sampling phase, then normally reducing the bit rate (so, the bandwidth) of the sampled data through a suitable compression. There may be many coding techniques and among these we can mention:

- *Differences encodes*: if the next sample differs not much from the previous one, then we transmit the difference (which requires a lower number of bits) with respect to the original sample; a typical example is video encoding used in MPEG, which adopts a differential coding both regarding the previous frame and the next one [5].
- *Weighted encodes*: if certain samples are often present within the voice stream, we adopt a convention which codifies them through a smaller number of bits in order to save bandwidth (used e.g. in compression techniques such as ZIP) [5].
- *Loss encodes*: it is based on the principle that, for human ear, certain audio signals are practically ignored. This type of encoding causes such parts of signals to be erased, and the resulting encoding becomes leaner because there are less data to send (this technique is used in MP3 audio compression) [6].

With these techniques we can obtain significant signal compressions. Due to the various application fields, different types of codecs, characterised by different complexity, have been developed. In order to determine which of these should be used in a VoIP service, it is important to take into account the features in terms of bandwidth, encoding delay, and the voice quality reproduced on the receiving part. The main encoding used for the telephony transport on digital lines is the PCM, described in ITU-T G.711 recommendation, which produces a flow of 64 kbps [5]. This encoding is very simple and widespread (for the reasons mentioned above) particularly among telcos. The standard which offers the highest compression, maintaining good voice quality, is the DR SCS (Dual Rate Speech Coding Standard) or G.723. It can go up to speeds of 5.3 kbps, and is commonly adopted on videoconferencing systems over analog lines [5], [7].

Other popular voice coding standards for telephony and packet voice include [5]:

- G.711 - Describes the 64 Kbps PCM voice coding technique outlined earlier; G.711-encoded voice is already in the correct format for digital voice delivery in the public phone network or through Private Branch eXchanges (PBXs);
- G.728 - Describes a 16 Kbps low-delay variation of CELP voice compression;
- G.729 - Describes CELP compression that enables voice to be coded into 8 Kbps streams; two variations of this standard (G.729 and G.729 Annex A) differ largely in computational complexity, and both generally provide speech quality as good as that of 32 Kbps ADPCM.

B. Packets encoding

While the previous steps (sampling and coding) can be partially used even on a digital telephone network, the packaging operation is peculiar to packet networks. A package, by its nature, is composed by a series of headers so that the package can reach properly the destination. These headers can not be eliminated; this fact implies they must be present independently from the number of packets sent and their size. In voice over IP, the typical header has a size of 58 bytes (18 bytes Ethernet, 20 bytes IP, UDP 8 bytes, 12 bytes RTP): if each package carried only one data byte, the efficiency would become equal to approximately 1.7%, as a voice stream at 64kbps would generate a traffic of 3.7Mbps. Unfortunately, it is not possible to use packages of arbitrary size, because by decreasing the package encoding time, the delay would increase. A reasonable packaging delay values are in the order of 20-40 ms [5].

Compression efficiency is possible, in this scenario, to work around the problems as well as with respect to the used bandwidth, if the compression is achieved by other coding techniques, such as wavelet compression.

III. Wavelets

In recent years, wavelet theory has been developed as a unifying framework for a large number of techniques for wave signal processing applications, such as multiresolution analysis, sub-band coding and wavelet series expansions [8]. The idea of analysing a signal at various time frequency scales with different resolutions has emerged independently in many mathematics, physics and engineering fields. In fact wavelet analysis is capable of revealing aspects of data that other signal analysis techniques cannot take into account, especially when breakdown points, discontinuities in higher derivatives, and other self-similarity occur. Furthermore, because it let us obtain a different representation of data than those offered by traditional techniques, it can help us to efficiently compress or de-noise a signal without any appreciable degradation [9], [10], [11]. A significant advantage of using wavelets for speech coding is that the compression ratio can easily be optimised, while most other techniques have fixed compression ratios keeping all the other parameters constant.

Wavelet analysis is the breaking up of a signal into a set of scaled and translated versions of an original wavelet. The wavelet transform of a signal decomposes the original signal into wavelets coefficients at different scales and positions.

A. Wavelets in continuos domain

Wavelets are continuos "basis" functions constructed in order to satisfy certain mathematical properties. A wavelet

is defined as a function $\psi(x)$ which must be subject to the following constrains:

1) $\int_{-\infty}^{+\infty} \psi(x)\, dx = 0$

2) $\| \psi(x) \|^2 = \int_{-\infty}^{+\infty} \psi(x)\psi^*(x)\, dx = 1$

Moreover, a whole family of wavelet functions can be obtained by just shifting and scaling as:

$$\psi_{j,k} = \sqrt{2^j}\ \psi(2^j t - k), \quad i, j \in \mathbb{N} \tag{1}$$

The idea behind wavelets is that by stretching and translating one such wavelet function $\psi(t)$ (also called mother wavelet), we can represent a signal $f(t) \in L^2(\mathbb{R})$ as:

$$f(t) = \sum_{j,k} b_{j,k}\ \psi_{j,k}(t) \tag{2}$$

where $b_{j,k}$ are called *wavelet coefficients* of the signal f in the wavelet basis given by the inner product of $\psi_{j,k}$ [12]. The wavelet coefficients represent the original signal in the wavelet domain [10]. An advantage of wavelet transforms is that the windows vary.

B. Discrete Time Case

In the discrete time case, two methods have been developed independently, namely *sub-band coding* (widely used in voice compression) and *multiresolution signal analysis*.

1) Multiresolution analysis: With this method we can derive a lower resolution signal by lowpass filtering with a half-band low-pass filtering having impulse response $g(n)$. This results in a signal $y(n)$ where

$$y(n) = \sum_{k=-\infty}^{k=+\infty} h(k) * f(2n - k) \tag{3}$$

Now based on subsampled version of $f(n)$ we want to find an approximation, $a(n)$, of the original signal $f(n)$: this is done by inserting a zero between every sample, because we need a signal at the original scale for comparison. Therefore, there is some redundancy in the number of samples, which will be proven useful for compression.

2) Sub-band coding schemes: The idea behind this technique is based on the following methodology: a pair of filters are used, i.e. a low pass and a high pass filter; we decompose a sequence $X(n)$ into two subsequences at half rate, or half resolution, and this by means of an orthogonal filter. This process can be iterated on either or both subsequences. In particular to obtain finer frequency resolution at lower frequencies, we iterate the scheme on the lower band only (see Figure 1). Thus, applying wavelet transform on a speech signal helps in compressing it to meet the stringent demands of bandwidth consumption while maintaining the quality and integrity of a signal [10].

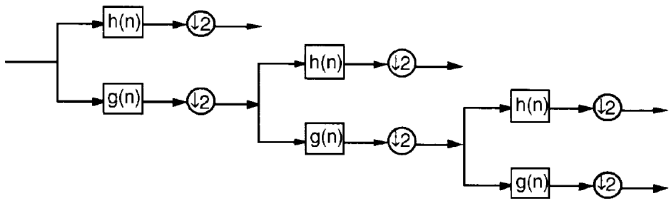

Fig. 1: Filter bank tree of discrete wavelet transform implemented with two discrete time filters (low-pass and high-pass filter, respectively)

C. Biorthogonality

The wavelet filter used in this work for audio signal compression is the 3.7 biorthogonal wavelet transform. A biorthogonal wavelet is a wavelet where the associated wavelet transform is invertible but not necessarily orthogonal; the first number indicates the order of the synthesis filter, while the second number refers to the order of the analysis filter. Even if frequency responses from biorthogonal filters may now not show any symmetry and the energy of the decomposed signal may also not equal the energy of the original signal, there are some reasons behind using biorthogonal wavelets, such as their compact support: this means we do not require IIR filters to approximate the signal. This fact is good because IIR filters are more difficult to treat and they also require extra computing power [12].

IV. GPU Parallel Computing with CUDA

The advent of multicore CPUs and many core GPUs have allowed the development of applications that transparently scale to take advantage of the increasing number of processor cores. Recently, the parallel programming field has seen an increasing success with the development of a novel technology, called Common Unified Device Architecture (CUDA).

A. GPU architecture

A CUDA-enabled GPU is composed of several MIMD (multiple instruction multiple data) multiprocessors that contain a set of SIMD (single instruction single data) processors. Each multiprocessor has a shared memory that can be accessed from each of its processors, and also shares a bigger global memory. Shared memory buffers reside physically on the GPU as opposed to residing in off-chip DRAM, so because of this, the latency to access shared memory tends to be far lower than typical buffers [13].

In CUDA programming model, an application consists of a *host* program that executes on the CPU and other parallel *kernel* programs executing on the GPU. A kernel program is executed by a set of parallel threads, where a thread is a subdivision of a process in two or more sub-processes, which are executed concurrently by a single processor. The host program can dynamically allocate device global memory to the GPU and copy data to/from such a memory from/to the memory on the CPU. Moreover, the host program determines

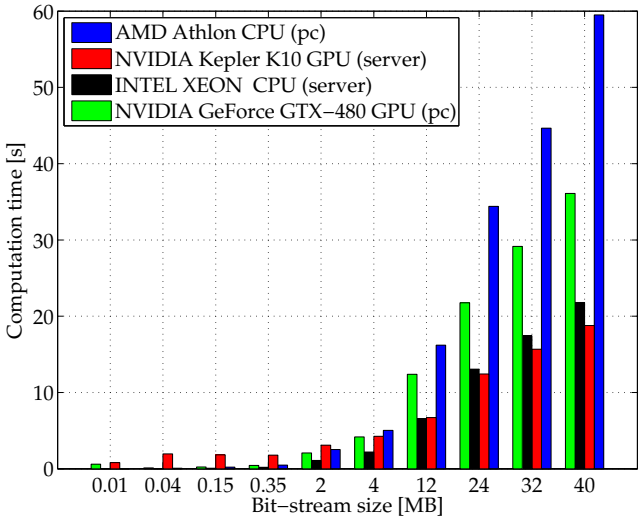

Fig. 2: Comparison among parallel and sequential programs on PC and Server

the number of threads used to execute kernel. Set of threads are grouped in blocks, and each block shares its own memory. It follows also that interactions between CPU and GPU should be minimised in order to avoid communication bottlenecks and delays due to data transfers [14], [15], [16].

B. Performing wavelet transforms on GPU

Classical wavelet transform implementations can be too computationally costly to cater for real time systems, hence we have investigated a parallel and fast approach to the problem at hand. As we have shown in [12], it is possible to adopt a fast GPU-oriented processing system to obtain the wavelet decomposition within the speed requirements of a VoIP service.

Figure 2 shows CPUs and GPUs timing performances for a conventional host, named PC, and for a Server. PC has been equipped with an AMD Athlon 64X2 having CPU clock frequency up to 2.9 GHz and a NVIDIA GeForce GTX 480 GPU; in Server, instead, has been equipped with an Intel Xeon CPU having a clock frequency up to 3.4 GHz, and a NVIDIA Tesla Kepler K10 GPU with 1536 cores.

V. Wavelet Compression

The goal of this work is to show the potential in terms of audio signals compression processed by wavelet filters. In particular, here we used a 3.7 biorthogonal wavelet filter. We will evaluate the wavelet compression efficiency and we will compare it with encoded audio trace through the typical PCM-16-bit VoIP standard at frequency of 8KHz. This analysis looks at both the quantitative aspects of encoding (the *compression factor*), and the audio quality perceived by listeners.

A. Experimental Setup

Initially an audio signal has been imported as a simple numerical array, whose size and the sampling frequency are fixed. In our setup, the audio signal has a duration of about 8 seconds and is sampled at a frequency of 22050 Hz. As explained in Section III, we know that, when we consider details with increasingly sample rate, the wavelet filter selects audio signal components which are at higher frequencies and which are characterised by a short time decay. These characteristics are typical of noise and background, therefore removable from the audio signal. It is then convenient to intervene more strongly on this portion of the information when coming to lossy compression. This result is achieved by appropriately setting thresholds. The detailed coefficients are removed from the last two sub-bands.

The result of superimposition between original and compressed signal is shown in Figure 3b. Once the two last sub-bands are removed, the coefficients set is compressed, taking also advantage of the zero-coefficients redundancy. As explained in Section III-B2, the sub-band coding process performs a dyadic signal processing. In other words, by the first subsampling cycle, we get a details vector, called *d1*, whose size is equal to half of original signal's size; for the second scale, a details vector *d2* is achieved, whose size will be equal to half of *d1* vector's size, i.e. one quarter (25 %) of the original signal size. Moreover, since we have suppressed the last two bands of the original signal, we take into account only the first quarter of the coefficient vector, because all other elements are consecutive zeros that were generated during the compression phase. Furthermore, the existence of other non-consecutive zeros inside the coefficient vector helps the compression further. Finally, we have compressed the coefficients using a gzip compressor. This final result is then transmitted by the VoIP client.

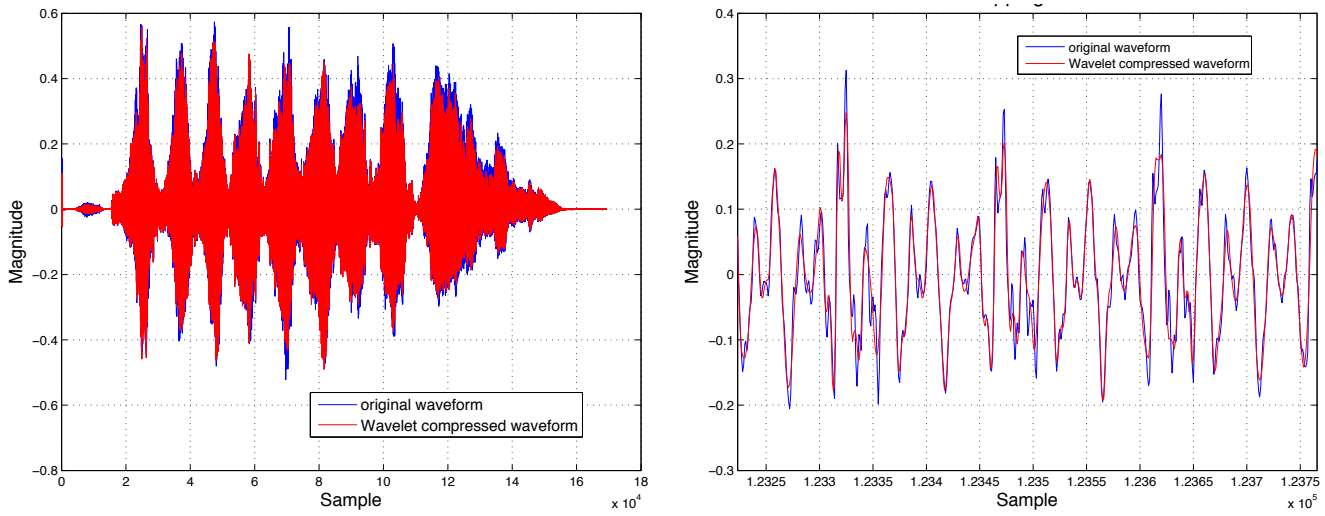
The reconstruction phase proceeds reversely to the compression stage: the starting point is the compressed data; the data stream is then decompressed with gzip. The decompressed data are initially incomplete, because we have to add zeros in order to reach the original size of the coefficients vector. In this way we can reconstruct the original digital signal.

B. Streams

The presented procedure is recursively applied for audio results. In this paper, we have analysed audio tracks that have a minimum duration of 8 seconds and a maximum of 10 minutes. For each of them, we have taken into account:

- the size of starting file, saved in .wav format and sampled at 22050 Hz;
- the size of file encoded using the 16-bit PCM to 8 KHz VoIP standard;
- the size of gzip-compressed file after wavelet filtering.

From the comparison among these three quantities, for different audio traces durations, the final result is shown in Figure 4. By observing Figure 4, it is possible to note a marked difference in the occupied bandwidth between the first two audio signals, namely the original and the VoIP one, compared to the proposed results obtained by wavelet compression. We have determined that the VoIP standard can give a compression factor of about 4, while the wavelet filtering allows us to obtain



(a) Global view of superimposition between original and compressed signal

(b) Superimposition between original and compressed signal in detail

Fig. 3: Superimposition between original and wavelet compressed signal

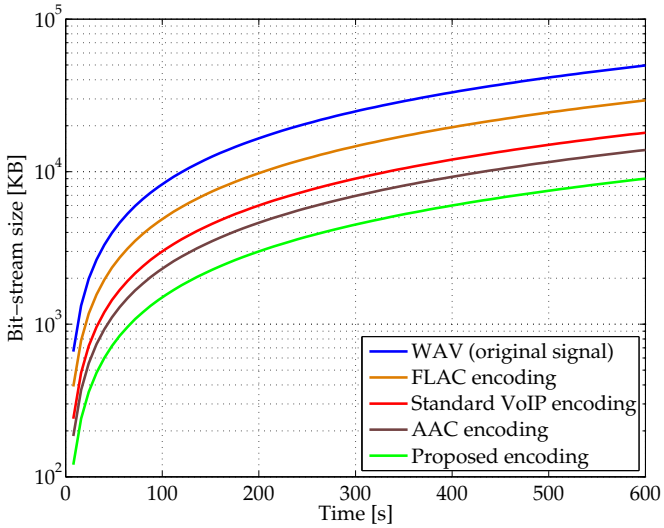


Fig. 4: Comparison among different standard audio data encodings with respect to our proposed wavelet compressed format

a compressed file approximately 10 times smaller than the original one. Therefore, our approach can improve the standard VoIP protocol compression.

VI. Related Works

Some works in the literature have analysed similar problems regarding audio compression techniques, and the relative loss of quality as well as regarding the delivery of content with limited network resources[17]. In [18] the authors use optimal adaptive wavelet selection and wavelet coefficients quantization procedures together with a dynamic dictionary approach. It takes advantages of the masking effect in human hearing. They minimise the number of hits required to represent each frame of audio material at a fixed distortion level. In [19], the authors show that the WP decomposition provides sufficient resolution to extract the time-frequency characteristics of the input signal and the WP based audio compressor provides transparent sound quality at compression rates comparable to the MPEG compressor with less than one third of the computational effort.

In [20], the authors have proposed a novel filter bank scheme which switches between a MDCT and a wavelet filter bank based on signal characteristics. A tree structured wavelet filter bank with properly designed filters offers natural advantages for the representation of non-stationary segments, such as attacks.

Interesting results are usually achieved when using a neural network approach to retain the relevant information on huge amount of sparse data [21], [22], [23], and some experiments have been performed on the compression of images [24]. Moreover, several solutions have been proposed for separating the components representing neural networks and the logic using them [25], [26], [27], [28]. In [29], the authors have proposed to apply wavelet analysis and audio compress technology in audio watermarking. Their approach performs a wavelet transform to determine the local audio properties. In [30] the authors have provided a novel scheme to join the wavelet packets and perceptual coding to construct an algorithm that is well suited to high-quality audio transfer for internet and storage applications. Finally, in [31] the authors examined how a compression method employs an approximation of a psychoacoustic model for wavelet packet decomposition. It has a bit rate control feedback loop particularly well suited to matching the output bit rate of the data compressor to the bandwidth capacity of a communication channel.

VII. Conclusion

In this paper we have investigated the compression potential of a 3.7 biorthogonal wavelet filter based technique for VoIP telecommunication. We have seen how, by using this compression technique, it is possible to obtain a greater compression factor than that obtainable with other traditional encodings. This fact is advantageous because the obtained audio stream is more efficiently compressed and requires less bandwidth for transmission.

The wavelet filtering is also interesting because makes it possible to implement it in a physical device. In fact, the proposed approach can be realised in hardware, basing on digital signals processing and compressing through wavelet filters. Furthermore we have to consider that nowadays modern 3G technology, widely used in mobile telephony, provides users with a quite limited data transmission bandwidth. For this reason wavelet compression approach, featured by a compression factor greater than ones used in other codings, meets practical needs of people who want to exchange data in a wireless medium.

***Abstract*—Grammars might be used for various other aspects, than just to represent a language. Grammar inference is a large field which main goal is the construction of grammars from various sources. Written text might be analysed indirectly with the use of such inferred grammars. Grammars acquired from processed text might grow into large structures as the inference process could be continuous. We present a method to decompose and store grammars into a non-redundant set of lambda calculus supercombinators. Grammars decomposition is based on their structure and each distinct element is stored only once in such a structure. We present a method that can create such a set from any context-free grammar. To prove this and to show the possible applications in the field of natural language processing we present a case study performed on samples from two books. Those samples are the entire Book of Genesis from The King James Bible and the first 24 chapters of War and peace by Tolstoy. We obtain context-free grammars with the Sequitur algorithm and then we process them with our method. The results show significant decline in the number of grammar elements in all cases.**

I. Introduction

REPRESENTATION of extracted information from text is a question that correlates with cognitive science as researchers try to emulate the processes that runs in our head [1]. Natural languages might differ from their formal counterparts, but they can be described with the same formal theory as Chomsky [2] pointed out almost 60 years ago.

From a more pragmatic stand point of view, extracted information may be represented in a grammar form. This is usually the goal of the grammar inference (or grammar induction) field. As Gold in [3] stated, only superfinite grammars can be inferred from a text. By text Gold means a set of positive samples, i.e. samples that belong to the language that inferred grammar is representing. Yet recent advances in this field has shown, that although in a strict formal way Gold theorem still holds, by using heuristic, statistical or evolutionary methods, we are able to infer more complex grammars, like context-free grammars (CFG). De la Higuera presents a review of possible inference methods in [4]. And not only formal languages can be inferred. We are able to perform inference on natural languages as well, as Onnis, Waterfall and Edelman point out [5].

As we infer grammars of large quantities of text, we may indeed obtain large grammars. If those texts are similar, for example we are processing books written in the same language by the same author, then the resulting grammars are in a risk of having a large number of rules and lots of similar information stored separately. This phenomena is called structural explosion. Where structurally similar, but symbolically different rules of grammar are inferred and then stored each separately. In this paper we present a way how to represent any CFG grammar in a non-redundant form. This form is a single structure composed of lambda calculus supercombinators. In the section II we reason why such a form is useful and how it relates to the field of natural language processing.

The main contributions of this paper are:

- We present the entire process of supercombinator set construction from any CFG grammar. The theoretical background is presented in the section III and the detailed description itself is in the section IV. It is a multi step process, each step is explained in a separate section accompanied with appropriate examples.
- Our approach has been tested on larger scale experiments that we present in the section V. We used Sequitur algorithm [6] to create context-free grammars from book samples and then we run our process on them. We present the results, that show significant reduction of grammar elements. This indicates the prevention of structural explosion.
- In the section VI we discuss the possibilities of text analysis that results from the usage of Sequitur algorithm and our supercombinator set acquisition process. We point out that even from the simple grammars, that are the result of Sequitur algorithm, we can extract useful structures contained in a natural language text.

II. Motivation

The basic idea behind this work stems from the engineering discipline of grammarware [7]. Simply put, we can use grammars for other purposes, than just for the representation of a language. With our approach we can decompose and store a CFG into a non-redundant form. In this section we explain, what good that process brings and how it relates to the field of natural language processing.

Why do we need to store a grammar inside a non-redundant structure? If we were given a small, predefined, static CFG, that we use only as a base for a parser for example, than our process could indeed be redundant itself. However, we can

This work was supported by project KEGA 031TUKE-4/2016 "Integrating software processes into the teaching of programming".

obtain a CFG from previously unknown or rather unprocessed text. And we might want to process lots of such texts for purposes like information extraction, language learning, text analysis, grammar inference or others. And consider that we would want to obtain one structure from all of those texts. If we were to keep those grammars stored in a basic CFG form, we could find ourselves buried under structurally same, yet semantically different rules. This is so especially if we are to process grammars that are large yet their rules are rather simple, as we show in the section V. Such rules might differ only in symbols but all grammar operations are the same. So instead of having a sequence of two different symbols stored for each pair of symbols separately, we can store one structural representation of two symbol sequence and link it with its respective symbols. Those symbols are also stored non-redundantly, so in case we have large terminal symbols (like words), having links to them is more memory efficient.

Our approach is based on the lambda calculus principle. The idea of the application and abstraction that is inherent to the lambda calculus offers a way to represent grammar rules that are separated from their terminal symbols. Therefore the entire structure is represented as one big set of supercombinators. The applications of those supercombinators on other supercombinators might be perceived as links. In that case we may view such a set as some network like structure. We explain this principle in further detail in [8] and [9], but also here, in the section III.

Now, how our work relates to the natural language processing? Well, the supercombinator form has few advantages. The non-redundancy has already been mentioned. The second advantage is that it describes and decomposes the structure of grammar rules. This for example opens the possibility to a form of text structure analysis. By searching for similar structures of text, combined with appropriate grammar inference mechanism, we might obtain information that may be used for various forms of analysis, like author or style identification. However, this possibility is out of scope of this paper.

Our process strongly relates to the field of grammar inference. Should we apply our process on a finite string of symbols, we would obtain just two supercombinators, out of which one would be long and would represent entire sequence of words. And that is not what we want, since we want to capture structure. So we need to start from a grammar form.

In this paper we are processing simple (in the structure, not in the size) CFGs obtained by Sequitur algorithm application (see section V) on a text written in a natural language, in our case the English language. We do not need to use Sequitur algorithm only. There are many ways to infer (or induce) a grammar from any text, see section VII. Therefore we can use any CFG grammar in our process.

III. Background

First of all, we need to explain how the entire process of supercombinator form acquisition works. The first version of this process has already been explained in [9]. There we have used only regular languages to create our supercombinator set. And thus the process was left in the theoretical space, i.e. we have not used real world case study. Our other work [8] presented an introduction to context-free languages application via higher order principle. In this section we build up on this principle towards building complete set of supercombinators from any CFG.

A. Enriched Lambda Calculus

Ordinary lambda expression e is defined by the rule (1).

$$e \to a \mid x \mid e\ e \mid \lambda x.e \tag{1}$$

Where a represent any constant, x a lambda variable, $e\ e$ is lambda application and $\lambda x.e$ is lambda abstraction. We can enrich this simple definition with grammar operations, thus the result of lambda expression reduction would not be a single value but the grammar expression, either regular or, as we later show, even context-free. As an example for regular-language-enriched lambda calculus have an expression (2).

$$L = \lambda x_1.\ \lambda x_2.\ x_1 \mid x_2 \tag{2}$$

This expression takes two variables as arguments and results into a regular expression, that consists of the alternative operation applied on both arguments. Therefore lambda application $L\ a\ b$, where a and b are terminal symbols, yields a regular expression $a \mid b$. We may notice, that we have used an infix notation for the alternative operation. This is only a syntactic sugar however.

To enrich our basic lambda calculus definition (2) we just add a regular expression option as another alternative. The formal definition of that regular expression is shown in (3).

$$r \to a \mid r_1 \mathbf{+} \ldots \mathbf{+} r_n \mid r_1 \mid \ldots \mid r_n \mid (r)^{\mathbf{*}} \mid (r) \tag{3}$$

The first element represents terminal symbol. Then the structures of concatenation, alternative and Kleene closure meta-operations are defined. The final element represents ordinary bracketing. Note, that the operators of regular expression themselves are depicted in a bold font, so we can distinguish them from the meta-operators. Concatenation is usually depicted without its operator or with $'.'$ operator. We have used the $'+'$ operator as the dot is already used in the lambda abstraction. Also, the expression $r_1 + r_2$ is equal to the expression $r_1\, r_2$. Should we use operator-less notation in our extended lambda calculus notation however, it could cause a confusion between a lambda application and the concatenation itself. Therefore we are going to stick with the plus operator should we use the concatenation inside of a lambda expression.

The fact, that we may define lots of different and specialized operations for regular expressions is accounted for in this paper. We are not restricting our algorithm for supercombinator form construction with predefined static regular expression operations (i.e. only those three defined in (3)). We use an abstract function that acts as a placeholder for any operation. This idea is further explained in the section IV-A.

We show in Tab I a supercombinator set obtained from the expression $a\,b\,|\,(c)^*$. This expression serves as a good example, since it contains the alternative, concatenation and

TABLE I
SUPERCOMBINATOR SET FOR GRAMMAR $ab|(c)^*$.

Supercombinators			Arguments
L^0	=	$\lambda x_1.\ x_1$	$\{\ a,\ b,\ c\ \}$
L^1	=	$\lambda x_1.\ L^0\ x_1$	$\{\ a\ \}$
L^2	=	$\lambda x_1.\ \lambda x_2.\ L^1\ x_1 + L^0\ x_2$	$\{\ a\ b\ \}$
L^3	=	$\lambda x_1.\ (L^0\ x_1)^*$	$\{\ c\ \}$
L^4	=	$\lambda x_1.\ \lambda x_2.\ \lambda x_3.\ L^2\ x_1\ x_2 \mid L^3\ x_3$	$\{\ a\ b\ c\ \}$

closure operations. The set itself was obtained with the use of process defined in [9]. The process in this paper is slightly different, but any actual difference is pointed out.

The important accompanying part of any supercombinator is its permissible argument string set. There may be more than one permissible argument string for each supercombinator as we can see in the case of L^0. Al three terminal symbols are possible arguments in this case. Only one argument string is allowed for any other supercombinator. We obtain the original expression $ab|(c)^*$ by β-reduction of the supercombinator L^4 with its argument string abc. The original expression would not be the result, if we allow any other argument strings to accompany that supercombinator. Note, that the permissible arguments are represented in the memory only once. They are connected with their supercombinators with the use of links. Argument strings are necessary for the reconstruction of original expression, any other argument string would lead to different expressions being created.

Supercombinators in Table I represent a structurally decomposed form of regular expression $ab|(c)^*$. Some of those supercombinators are applied more than once, like L^0. This is the solution to the structural explosion, since no multiple occurrences of equal supercombinators exist. There exists one top supercombinator for every expression It's the one by which β-reduction we obtain the original expression. In this case it's the L^4. The supercombinator form is reusable. So if we were to process more expressions, all already existing supercombinators would be reused. Only new arguments links would be added in that case. A simple example: if we were to add expression consisting of one symbol, say d, the supercombinators L^0 argument set would be enriched by the d symbol and at the same time it would become top supercombinator for that expression (but only if used with the d symbol).

Each supercombinator represents a part of the entire expression structure. As we see in Table I, the identity function is represented by L^0, a sequence of two variables by L^2 or a closure over one variable by L^3.

B. Higher Order Regular Expressions

We have published a paper under this name [10] where we noted that the difference between regular and context-free expressions is not really that significant. And that we may view context-free expressions as higher order regular expressions, i.e. expressions that may take another expression as an argument.

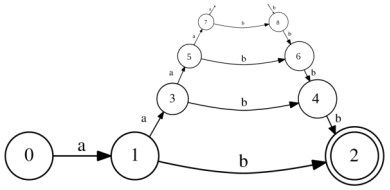

Fig. 1. The infinite state automaton obtained from higher order expression $A \rightarrow aAb \mid ab$.

The simple example is shown in the expression (4).

$$A \rightarrow aAb \mid ab \tag{4}$$

This expression represents the language $a^n\, b^n$, standard example of a nonregular language. The expression (4) is in BNF form, but we may view it as an expression, where we have an alternative of two subexpressions. The first one is a sequence of three symbols. The middle symbol represents a jump inside another iteration of expression evaluation. Expression 4 is represented by the automaton depicted in Fig. 1. It's an infinite state automaton. The important fact here is the idea that there is not that big of a gap between regular and context-free grammars.

This idea of higher order expression translates into our enriched lambda calculus easily. The higher order jump is nothing else but an ordinary lambda application. The first element in the alternative of expression (4) can be translated into the following lambda expression:

$$L^{aAb} = \lambda x_1.\lambda x_2.\ x_1\ +\ (L^A\ x_1\ x_2)\ +\ x_2 \tag{5}$$

Where L^A is the top supercombinator for the expression (4), from which the supercombinator L^{aAb} is being applied. In this scenario, both supercombinators have the same arguments, so there is no need to extend the possible argument set for supercombinators in the lower levels of hierarchy.

It's important to note, that supercombinator (5) is not in the final, complete form, since it applies directly its arguments to the result. In the final form, argument applications are always translated into the identity supercombinator $L^0 = \lambda x.\ x$.

C. Basic Idea

We have presented the idea of regular-language-enriched lambda calculus and the way to view CFGs as context-free expressions or higher order regular expressions. Now we are going to show the outline of our process, where we translate those expressions into a supercombinator set.

Every context-free expression is based on a set of context-free grammar rules. Under the BNF definition (or EBNF if were tu use closure and option operations), these rules have form of $A \rightarrow r$, where A designates the nonterminal and r an expression into which the nonterminal is transformed. The expression has a form as defined in (3) with the addition of nonterminal symbol as a possible element.

Any nonterminal symbol may have more rules that define its expansion. But those rules can be merged together with

the alternative operation without any consequences. , process in (6). Our approach requires all such expressions to be merged together.

$$\left.\begin{array}{l} A \ \rightarrow ab \\ A \ \rightarrow (c)^* \end{array}\right\} \Rightarrow \ A \rightarrow ab \mid (c)^* \qquad (6)$$

There exist one top supercombinator for every expression. This is the supercombinator from which we are able to reconstruct the original expression by applying it to its permissible argument string. We may extract that string even before we start to transform the expressions. This is an important property for implementing higher order jumps.

Simple outline of our transformation process is:

1) First step is to transform the input into the internal expression tree form. Each rule is transformed into separate tree, thus we obtain a set of trees, precisely one tree per nonterminal. Each tree is named after the nonterminal, that it represents.
2) Then we obtain the list of permissible arguments for every tree in the set. These lists do not only include arguments obtained by searching the tree for terminal symbols, but also include all terminals inside each nonterminal accessible from the current expression tree. Each terminal symbol occurs in every final argument string precisely once. No duplicates are allowed.
3) Each expression tree is transformed into separate, independent set of supercombinators. Each supercombinator of that set has exactly one argument string, since they haven't been merged yet. Every occurrence of nonterminal in expression is replaced by temporary supercombinator that points to that nonterminal. We have already acquired their permissible argument strings in the previous step.
4) Equal supercombinators are merged for each expression separately. Supercombinators now may contain more than one argument string in their permissible argument set. This process is done for each expression independently, thus may be performed in parallel.
5) Temporary supercombinators representing other nonterminals are now replaced by top supercombinators of expression represented by those nonterminals.
6) Equal supercombinators from all expressions are new merged together. The result of this is a single supercombinator set that represents a structurally decomposed original grammar.

IV. Supercombinator Set Acquisition from Context-free Grammar

We present the details of the transformation process in this section. All the steps of transformation are illustrated with appropriate examples.

A. Tree Creation

We start our process in the similar fashion as in our previous work, by expression transformation into a tree form. However, the trees used in the current process are different.

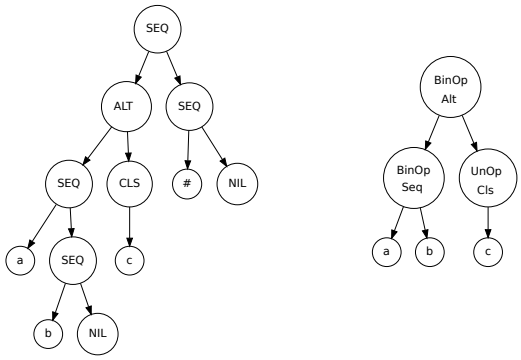

Fig. 2. The old and the new type of expression tree for $a\,b \mid (c)^*$.

Listing 1. Type of a context-free expression tree.

```
data Tree = Leaf Term | Jump NTerm
   | UnOp OpName Tree | BinOp OpName Tree Tree
   | MultiOp OpName [Tree]
```

As mentioned earlier, we tried to separate the operations from the basic structure. While in our previous work, the operations themselves were part of a tree as nodes, now they have been abstracted away.

We have selected $A \rightarrow a\,b \mid (c)^*$ as an example expression. Its depiction on Fig. 2 shows the old and the new type of tree. This figure immediately shows the difference in node amounts. The current tree form, the one on the right, is much more space efficient.

The formal definition of this new tree form is depicted in Listing 1. Constructors `Term` and `NTerm` represent terminals and nonterminals respectively. We can see that instead of a direct use of an operator as a node, we use abstract nodes. They are `UnOp` for unary operations, `BinOp` for binary operations and `MultiOp` for n-ary operations. `OpName` holds the name of that operation, which semantic is not defined here, since for now we only care about the structure. The semantics needs to be supplied for each intended operation for the lambda calculus to work, but it's presented independently from a tree.

We have implemented two different ways of processing operations. One is by constructing the tree only with the use of `MultiOp` nodes, that hold the entire subtree in a list. And the second is by using a combination of `BinOp` and `UnOp` nodes. This difference is crucial, since it produces different supercombinators, as we show in the section IV-C and further expose by the experiment in the section V-A. The list structure can hold any operation arity, therefore may be used exclusively. The other two operations should be used in tandem to achieve currying in application of supercombinators.

Currying is a well known phenomenon, where we may perceive any n-ary function as a sequence of unary high order functions that are applied to the arguments. We may view the sequence $abcd$ as either being transformed to the node $MultiOp(a, b, c, d)$ or as currying like tree $BinOp(a,\ BinOp(b,\ BinOp(c,\ d)))$.

Both tree approaches can be combined, as we did in our

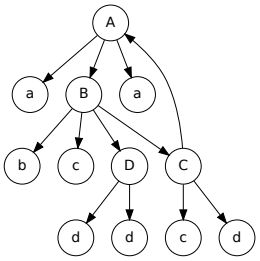

Fig. 3. Graph of elements from the context-free expression (7).

previous work. We have used `MultOp` like nodes for an alternative operation, `BinOp` type for a sequence and `UnOp` for a closure. We have also used special `Nil` node to sign the termination of a whole expression or a sequence. This special node is the reason, why there is L^1 supercombinator in Table I. However, it's equivalent to the L^0 supercombinator and therefore redundant.

The `Jump` node presents an actual jump to the nonterminal designated by the name in this node. This basically turns the set of trees into a directed, possibly cyclic, graph.

B. Argument Lists Extraction from Nonterminals

This step is essential for our process, since we are using jumps to other expressions. And each jump brings a new possibility of permissible terminal symbols at the input of their top lambda expression. Take expressions (7) as an example.

$$\begin{aligned} A &\rightarrow a\ B\ a \\ B &\rightarrow b\ c\ D \mid C \\ C &\rightarrow c\ d \mid A \\ D &\rightarrow d\ d \end{aligned} \tag{7}$$

The only terminal symbol actually inside of the expression A is the symbol a. But others, namely b, c and d are accessible. As they are accessible from the B and the C expressions. The expression D has only the symbol d as accessible.

From a set of terminals and nonrerminals of all expressions, a single directed cyclic graph is constructed. Each nonterminal forms a node which links to its body, and terminals represent leaves. The graph of expression (7) is depicted in Fig. 3.

Afterwards, a depth first search is performed for every nonterminal node in order to find all possible symbols from it. If we omit nonterminals from such a path, only a string of terminals remains. The final step is the removal of all duplicates, so the symbol strings contain each symbol at most once. This process is shown in (8) for nonterminal A. Thus symbol string for expression A is $abcd$, $bcda$ for B and $cdab$ for C. D has only one symbol, d, as a permissible symbol.

$$\begin{aligned} A \Rightarrow A\ a\ B\ b\ c\ D\ d\ d\ C\ c\ d\ a \Rightarrow \\ \Rightarrow a\ b\ c\ d\ d\ c\ d\ a \Rightarrow a\ b\ c\ d \end{aligned} \tag{8}$$

C. Construction of Supercombinator Sets

The process described in this section is performed on all expressions separately, therefore can be executed in parallel.

Listing 2. Definition of a supercombinator data type.

```
data Lambda = LeafLambda LambdaId
 | JumpLambda LambdaId Nterm
 | UnLambda LambdaId OpName SubLambda
 | BinLambda LambdaId OpName SubLambda SubLambda
 | MultiLambda LambdaId OpName [SubLambda]
```

Every single expression yields independent supercombinator set. We used to perform this process with the use of a direct tree transformation in our previous work. We have chosen to do it differently this time.

The basic idea behind obtaining supercombinators is that every operation node of a tree yields exactly one supercombinator. Therefore we have defined a data type for them, shown in Listing 2. All constructors are named after the nodes of a tree they represent. Each of them has its own *id*. All *id*s are unique, since we haven't performed merge yet. The *id* references allow us to use linear form instead of interconnected tree form, hence we may perceive them as pointers.

Each supercombinator has its own permissible argument string. We have separated that string from the underlying data type in order to keep its core aspects tidy and in order. It's functionally irrelevant whether the argument string is represented directly within the data type or as an accompanying list of arguments within a tuple.

The `LeafLambda` constructor represents already mentioned supercombinator $L^0 = \lambda x\ .\ x$, specified only by its *id*. Its argument string consists only from the original symbol of a `Leaf` node. `JumpLambda` is temporary supercombinator that serves as a place-holder for expression name and hold permissible argument strings of that expression. We have already obtained them during the previous step. Other three forms of supercombinators are functionally similar since they represent operations. `SubLambda` represents a supercombinator that is being applied to that operation. It holds only a pointer to the real supercombinator and references to arguments inside the argument string.

The direct mapping between supercombinators and our internal form is shown on the example (9). The ids are upper indices of the L symbol. The arity of a lambda expression is obtained from the length of its argument string. The lists in `SubLambda` tuple refer to the index of an argument inside the argument string. Such an argument string has the length of 2 in this case.

$$\begin{aligned} &BinLambda\ 1\ Sum\ (2,\ [0,1])\ (0,\ [0]) \iff \\ &\iff L^1 = \lambda x_0.\lambda x_1.L^2\ x_0\ x_1 \mid L^0\ x_0 \end{aligned} \tag{9}$$

The permissible argument string for any supercombinator is obtained as a merge of their children arguments. Therefore it is really important to perform step 2, as the jump supercombinators now have an entire argument string of an expression they are referring to.

Using `MultOp` nodes exclusively in a tree yields different supercombinators as an equivalent tree composed of `BinOp` and `UnOp` nodes. The former results into n-ary operation

lambda expressions, where one operation is applied over multiple sub expressions. The latter method usually yields more supercombinators, but each has at most two sub expressions applications in its body, i.e. its underlying operation is at most binary.

D. Merge within Expression Supercombinator Set

The previous step may yield supercombinators that are equal, only their argument strings may be different. All such supercominators are merged, so no duplicates are present inside each set. This step, as the previous one, can be performed in parallel over all expression sets.

The equality of supercombinators, formally described in [9], means, that in order for supercombinators to be equal, they need to have the same arity and need to contain same `SubLambda` elements. In terms of definition in Listing 2 that means equality of all elements excluding the *id*. All equal supercombinators need to be merged. Even some supercombinators which contain references that initially lead to different supercombinators might be equal, since the sub-supercombinators may have been merged in the previous iteration of the merge step. Example of a merger is presented in Table II, where we see the initial and merged supercombinator set of the expression $ab \mid cd$.

We start the merge process with the identification of all equal supercombinators within a set. Then we group them together. We now have some groups of equal supercombinators and the rest of the set. Those groups can now be merged, even in parallel. Well, only their argument strings are merged into a single set and only one supercombinator comes out of this process. Its *id* now needs to be updated in the entire set, replacing the old, now unused *id*s. After this update, new equal supercombinators may be present, so we need to repeat this process until no new equal supercombinators are found. The process depicted in Table II had two merge iterations. Argument sets always consist of strings with the same length, since the arity of equal supercombinators needs to be the same. The resulting set of supercombinators is now duplicate free.

E. Removal of Jump Supercombinators and the Merge of All Sets

At this moment, we possess numerous sets of supercombinators that we need to connect together and then merge them to a single set. Each temporary jump supercombinator is now replaced by a top supercombinator of an expression it points to. It is important to keep the *id*s in between the sets from clashing, i.e. each set needs to have different *id*s. After this step, another merge is applied that joins all the sets to a single, duplicate free set.

For a simple grammar (10) we obtain the final supercombinator set in lambda calculus form, depicted in table III. If we consider the nonterminal A to be the starting symbol, then the top supercombinator is in our case L^2.

$$\begin{aligned} A &\rightarrow a\,B \mid a \\ B &\rightarrow b \mid A\,b \end{aligned} \tag{10}$$

TABLE III
SUPERCOMBINATOR SET OF GRAMMAR (10).

Supercombinators	Arguments
$L^0 = \lambda x_0.\ x_0$	$\{\{a\},\{b\}\}$
$L^1 = \lambda x_0.\ \lambda x_1.\ L^0\ x_0 + L^4\ x_1\ x_0$	$\{\{a\ b\}\}$
$L^2 = \lambda x_0.\ \lambda x_1.\ L^1\ x_0\ x_1 \mid L^0\ x_0$	$\{\{a\ b\}\}$
$L^3 = \lambda x_0.\ \lambda x_1.\ L^2\ x_0\ x_1 + L^0\ x_1$	$\{\{a\ b\}\}$
$L^4 = \lambda x_0.\ \lambda x_1.\ L^0\ x_0 \mid L^3\ x_1\ x_0$	$\{\{b\ a\}\}$

If we use a special form of β-reduction, we obtain the grammar (10) back. By special form we mean replacing all top supercombinators in the body of expression by their nonterminal representation. This is an important step, since it prevents the infinite loop. Already mentioned L^2 supercombinator is the top for A and the L^4 supercombinator is the top for B. But should we use in the β-reduction only on the top supercombinator of an entire grammar, the A, we get a transformed version of a grammar, as shown bellow in (11). We can conclude, that we may use the supercombinator form to transform a form of grammar.

$$A \rightarrow\ L^2\ a\ b \rightarrow^*\ a\ (b \mid A\ b\ ) \mid a \tag{11}$$

V. EXPERIMENTAL RESULTS

We have been using only abstract grammar symbols so far. Those abstract symbols, like a for terminals and A for nonterminals are useful for the explaining purposes, but they do not represent anything we can find in the real world directly. Thus we have performed experiments on the book samples. As mentioned before, we obtain a supercombinator set that represents the structure of elements. But we cannot just use our process over a fixed sequence of words, since that would result into one big supercombinator (and one L^0 supercombinator of course). We need a grammar first. And for that reason we have chosen Sequitur algorithm.

Sequitur algorithm, created by Nevill-Manning and Witten [6], creates context-free grammar from a linear sequence of discrete symbols. The words of English language in our case. The resulting grammar generates only the input text, therefore it's possible to use our supercombinators for text analysis of that text, since no other text is possible to generate either from the Sequitur grammar or our supercombinator set.

We use *the Book of Genesis* from the King James Bible and chapters from Leo Tolstoy novel *War and Peace*[1]. We have chosen these books because they are written in different styles and the former has many unknown authors while the latter was written by a single well known author, therefore may be less schematic and fragmented. We use various samples from these two books, all of which are listed in Table IV. We also list abbreviations, by which we are going to reference them, and we list the total word count of each section as well.

[1]The books were obtained from Project Gutenberg, located at http://www.gutenberg.org, where they are distributed under GNU Free Documentation license 1.2.

TABLE IV
LIST OF BOOKS AND THEIR SECTIONS USED IN THE EXPERIMENTS.

Book Name	Used Sections	Abbreviation	Words
Book of Genesis	Sections 1 - 3	*Gen3*	1429
Book of Genesis	Sections 1 - 6	*Gen6*	3840
Book of Genesis	Sections 1 - 12	*Gen12*	7306
Book of Genesis	All	*Gen*	39797
War and Peace	Chapter 1	*WP1*	2015
War and Peace	Chapter 2	*WP2*	1378
War and Peace	Chapter 3	*WP3*	1469
War and Peace	Chapter 4	*WP4*	1417
War and Peace	Chapters 1 - 4	*WP1-4*	6279
War and Peace	Chapters 1 - 12	*WP12*	17755
War and Peace	Chapters 1 - 24	*WP24*	37538

TABLE V
SEQUITUR GRAMMAR SAMPLE OBTAINED FROM THE BOOK OF GENESIS.

Rule		Rule body
78	→	`have dominion over the fish` **29** `sea` **79 96**
79	→	**56** `the`
80	→	`all` **61**
81	→	**56** `every`

The resulting Sequitur grammar uses only concatenation operation. Using Sequitur to decompose text of literature, i.e. text without rigorous structure, inevitably leads to the state, where the first rule consists of a long sequence of terminals and nonterminals, while the rest of the rules have rather low arity. Despite this fact, we still might obtain interesting results by performing our process, as the portion of lower arity rules might be represented by a single supercombinator. To imagine how Sequitur grammar looks, see Tab V, where we show a sample of the grammar obtained from *Gen*. We see that nonterminals are represented by numbers and terminals by actual words.

What do we expect from our experiments? Since our process captures the structure of rules, we expect the processed Sequitur grammar to have less elements, represented by supercombinators, than is the count of the rules. We show in Table VI the count of Sequitur rules, each column represents different arity. The last column represent the actual arity of the first rule, it does not represent the amount of rules. The Book of Genesis contains more, and larger, repetitive patterns than War and Peace as we can see in Table VI.

Note, that in Table VI we have 9-ary rule for *Gen3* and *Gen6*, but no such a rule is present in *Gen12*. This is not an error, but a result of the text amount *Gen12* contains. The rule in question here is: `have dominion over the fish` **29** `sea` **79 96**. It generates the phrase `have dominion over the fish of the sea and over the fowl of the air`. In case of *Gen12*, the rule for this phrase is different: `have dominion` **531** `fish` **574 86 111**. More sub-phrase rules have been created, since they are reused elsewhere in *Gen12* text. Two 9-ary rules in *Gen* sample are unrelated, since they generate different phrases.

A. *Difference between Binary and N-ary Trees.*

The first experiment is going to show us, whether we should use binary[2] or n-ary trees. As we mentioned in Section IV-C, n-ary trees might result into a smaller set of supercombinators. On the other hand, a binary tree always results in supercombinators with the underlying operation having arity of maximum two. Without the merge operation in mind, the decomposition of an n-ary operation with the use of an n-ary trees would yield one supercombinator with its underlying operation having arity of n. But with the binary trees, we would get maximum of $n-1$ supercombinators with at most binary operations. The actual arity of those $n-1$ supercombinators would gradually drop from maximum of n to 2 in case that every terminal symbol is different for that particular operation. We expect larger set of supercombinators obtained from binary trees than from n-ary based on those mentioned facts.

The difference between those two approaches is illustrated in Table VII for unary and Table VIII for n-ary tree approach. The fields represent the total number of supercombinators described by their operation arity shown in the second row. As mentioned earlier, binary trees yield always supercombinators with at most binary operations. Since only the concatenation operation was used, no supercombinator with unary operation was created in both cases. Supercombinator with nullary operation is the $L^0 = \lambda x.x$. We see, that in all cases it's present only once in each set, so our merge works.

The total amount of supercombinators is dramatically different for binary and n-ary strategies. That's a direct result of the fact mentioned at the beginning of this section. Although

[2]Those trees aren't actually binary, since unary nodes are possible via $UnOp$ constructor. They are called binary for brevity.

TABLE VI
THE AMOUNT OF SEQUITUR GRAMMAR RULES DIVIDED BY THEIR ARITY.

Sample	2-ary	3-ary	4-ary	5-ary	6-ary	7-ary	8-ary	9-ary	11-ary	1st rule
Gen3	122	18	2	5	-	-	-	1	-	762
Gen6	339	35	7	5	-	-	-	1	-	2116
Gen12	660	61	13	5	3	1	-	-	-	3906
Gen	3363	206	56	22	6	1	2	2	1	19512
WP1	120	6	2	-	-	-	-	-	-	1678

Sum	4	5292	5296
Merged	1	5272	5273
WP1-4	1	4825	4826

TABLE VIII
SUPERCOMBINATOR SETS OBTAINED FROM n-ARY TREE APPROACH.

Sample	0-ary	2-ary	3-ary	4-ary	5-ary	1st rule	Total
WP1	1	4	3	1	-	1 (1678)	10
WP2	1	3	2	1	1	1 (1173)	9
WP3	1	4	2	-	-	1 (1244)	8
WP4	1	3	2	-	-	1 (1189)	7
Sum	4	14	9	2	1	4	34
Merged	1	5	5	1	1	4	17
WP1-4	1	8	6	2	1	1 (4812)	19

all supercombinators in the binary section have at most binary operations, the real arity of them can vary. In case of the *WP1* sample, the maximum arity was 728. That is a smaller number than the actual arity of the first rule of Sequitur grammar, which is 1678. This is because the supercombinator form is non-redundant, i.e. the words (the actual arguments of supercombinators from which the total arity is calculated) do not repeat themselves.

If we compare the sum of supercombinators obtained from four different War and Peace chapters and the number of supercombinators obtained after the merge (on supercombinator level) we see no significant difference in the case of Binary trees (5296 compared to 5273). In the n-ary tree case however, the difference is an exact half (34 to 17).

In comparison with the processed grammar of four chapters together, the sample *WP1-4*, we see the difference in case of binary trees (5273 for merged against 4826 for *WP1-4* sample). In the other case however, the difference is insignificant (17 compared to 19). In case of other arities in n-ary tree case, the merged has unified mostly supercombinators with lower arity operations. The difference between merge and *WP1-4* strategy is rather insignificant.

We can thus conclude, that in the case of Sequitur generated grammars, the n-ary tree approach seems to yield significantly smaller set of supercombinators, therefore we are going to use this approach further on in this paper.

B. Constructing Supercombinator Set from a Sequitur Grammar

Straightening out the issue of what tree forms to use we can now proceed to the evaluation of larger book parts. The results are shown in Table IX.

Supercombinators are again divided by their operation arity. This is an especially useful feature for comparison with the arity of Sequitur grammars. We can see that for every arity of the original Sequitur rules (see Table VI) there exists at least one supercombinator with the same operation arity. This result was expected, since we have used n-ary trees. And the actual number of supercombinators is always lower or equal to the number of rules. We can say, that our process does not create any unexpected supercombinators that might introduce different structure into the original text. The arity of the first rule is the same as the arity of the operation within the top supercombinator, which is again the result of the n-ary tree usage.

Another interesting result is the comparison of the difference between binary rules and their respective supercombinators. Since the Book of Genesis seems to have more equal parts, as concluded in Section V, it has more supercombinators with larger arity operation. This also means that the sets of lower arities are larger than in the case of War and Peace. We see that difference in *Gen* and *WP24*, where the former has dropped from 3363 to 126 and the latter from 2963 to 33 for binary operations. This is due to the fact, that supercombinators with lower arity operations may contain sub-supercombinators with

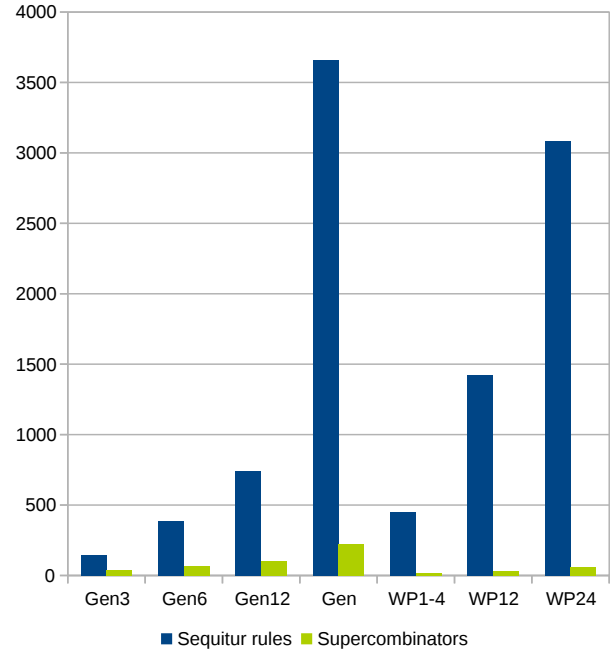

Fig. 4. Total number of Sequitur rules compared with their resulting supercombinator count.

any other operation arities. We see that *Gen* has more larger arity operations than *WP24*.

Figure 4 represents the total difference between the number of Sequitur rules and supercombinators obtained from them. The difference is rather significant. This shows, that our process is capable of data reduction. Different grammar rules with the same structure are merged into a single supercombinator, and as we can see, this has a significant impact in the case of Sequitur generated grammars.

VI. Discussion

Presented results show that our approach can prevent the structural explosion. Although this has already been pointed out in our previous work, we have performed small experiments on a simple regular grammar examples. This paper presents larger scale experiments performed on context-free grammars that support these claims.

We may conclude from the results in Table IX that if the final supercombinator set contains supercombinators with higher operation arities, the total number of supercombinators with the lower ones rises with them as is the case of *Gen* sample. We do not observe this for the *WP24* sample in such a scale, since it has less supercombinators with higher arities.

The different tree approaches that we have defined result into different supercombinator sets. Should we use only binary like trees, the resulting set of supercombinators in the case of Sequitur generated grammars would be larger and thus the promised reduction of size would be impossible. The other, list oriented approach does not suffer from that drawback and delivers the promised results.

Another interesting discovery lies with the analysis of the text itself. Although Sequitur algorithm may be useful for analysis, for example if we want to find out most occurring phrase or longest occurring repeating phrase (like the rule 78 one in Table V), our approach takes this notion one step further. By one step further we mean the analysis of the abstract structures, that supercombinators are. One of those is the argument string length of L^0 supercombinators, that presents absolute count of all words occurring in the text. This number obviously differs from the word count in Table IV, since we do not store duplicates in our structure.

The comparison of arities signifies the difference between The Book of Genesis and War and Piece, but that discovery can be inferred from pure Sequitur results, that we show in Table VI. But should we want to find out, what structure is most used, our supercombinator form is probably better suited for that question. But this is not so visible from the current results, since we have used Sequitur, and thus produced only supercombinators with the concatenation operation. Thus further research with better grammar inference method is necessary.

VII. Related Work

Our work relates with the field of grammar inference. As already mentioned in the Introduction, not only formal inference but the induction of natural languages grammar can be incorporated with our supercombinator set construction mechanism. The induction of grammar can be achieved with the use of various different methods. Onnis, Waterfall and Edelman use cognitive graphs in their model ADIOS to infer CFG in [5]. Adriaans and Van Zaanen created the model EMILE [11], where they use probabilistic methods. Klein and Manning developed model based on constituency [12] that is also capable to induce CFG from text. As our background is in the computer languages field, Stevenson and Cordy presented concise review of the state of the art in [13], where they present various methods of grammar inference.

Our supercombinator form might be practically used in tandem with ontology extraction methods as our supercombinator form of a grammar might be used to identify concepts of a certain kind. In the work of Carvalho, Almeida, Pereira and Henriques [14] we see the use of ontologies that help the concept identification. Other uses of ontologies might be for information retrieval [15], detection of concept similarity across different information media [16] or even for the detection of mental illness from written text [17].

Related methods for concept extractions include rule based approach, as Szwed used in [18]. There we can see extraction of concepts from written text. The rules used are based on Petri nets. Other related method for text analysis is summarization. Example of this method is presented by Jassem and Pawluczuk in [19]. Those methods focus on semantic side of a text, where our supercombinator approach focuses primarily on the structure. The actual meaning is treated separately, therefore we can concentrate more clearly on those separate aspects.

TABLE IX
RESULT COUNT OF SUPERCOMBINATORS DIVIDED BY THEIR OPERATION ARITY.

	0	2	3	4	5	6	7	8	9	11	Last	Total
Gen3	1	25	7	2	4	-	-	-	1	-	1 (762)	41
Gen6	1	40	14	5	5	-	-	-	1	-	1 (2116)	67
Gen12	1	53	25	12	5	3	1	-	-	-	1 (3906)	101
Gen	1	107	71	43	20	6	1	2	2	1	1 (19512)	255
WP1-4	1	8	6	2	1	-	-	-	-	-	1 (4812)	19
WP12	1	15	15	3	-	-	-	-	-	-	1 (12582)	35
WP24	1	29	20	9	2	-	-	-	-	-	1 (24901)	62

VIII. CONCLUSION

We have presented a way to represent any CFG nor-redundantly in a single set of supercombinators. The process has been described in detail, where we show it in separate steps. Many of those steps might be performed in parallel, so better computation time is achievable.

Applications of our supercombinator structure have been presented on the samples taken from literature. The Book of Genesis and War and Piece by Tolstoy were used. Since our process works only on grammars, we needed to process those samples first with Sequitur algorithm. This algorithm constructs CFG from a finite string of symbols, in our case words. We show , that our representation significantly reduces the size of entire structure, since it is non-redundant. Further on, we have discussed the possibilities of a structure analysis, that is possible to perform on our supercombinator structure.

In our future work, we would like to extract more information with the use of better inference mechanism that Sequitur algorithm brings. In the section VII we show various possible ways to induce a grammar from text samples so we would like to actually use them in our experiments to further prove the abilities of our supercombinator form construction method.

***Abstract*—Recognizing textual entailment is typically considered as a binary decision task – whether a text T entails a hypothesis H. Thus, in case of a negative answer, it is not possible to express that H is "almost entailed" by T. Partial textual entailment provides one possible approach to this issue.**

This paper presents an attempt to use word2vec model for recognizing partial (faceted) textual entailment. The proposed approach does not rely on language dependent NLP tools and other linguistic resources, therefore it can be easily implemented in different language environments where word2vec models are available.

I. Introduction and Preliminaries

NOWADAYS, textual entailment belongs to intensively and deeply studied notions in NLP, with potentially many practical applications including paraphrase detection, multi-document summarization, machine translation evaluation, plagiarism detection, etc. In this section we provide a brief description of textual entailment, partial textual entailment, we mention word2vec model and present the main aim of this work.

A. Textual Entailment

Different definitions of textual entailment (abbr. as TE) and a systematic overview of this area can be found in an older but comprehensive paper [1]. *Recognizing textual entailment* (RTE for short) is a corresponding decision problem whether a given (coherent) text T entails a given text H (in this context often called a hypothesis). Currently, there exist several systems for RTE problem: an up-to-date list of them can be found at ACLwikiWeb[1]. Some of them were created in order to participate SemEval challenges.

Since RTE is a binary decision problem, in case of a negative result of RTE, i. e., when T does not entail H, it is not possible to state "how distant" is H from another hypothesis H', such that H' is entailed by T. From a different point of view, it is not possible to express that H is "almost entailed" by T in this setting. Partial textual entailment is one possible approach to this issue. The key elements of the idea of partial textual entailment were introduced in [2], although the notion of partial textual entailment was not explicitly mentioned in the paper. The motivation for partial textual entailment has naturally arised from the problem of (automatic) analysis of student responses in educational process.

[1] http://aclweb.org/aclwiki

B. Partial and Faceted Textual Entailment

According to [3], we say that an ordered pair $(T; H)$ forms a partial textual entailment (abbr. as PTE) if *a fragment* of the hypothesis H is entailed by T. In this definition, the notion of a fragment of the hypothesis is no more specified. Hence, the key question is how to decompose the hypothesis into fragments.

In [2], facets were introduced as special fragments: a facet is an ordered pair of words (f_1, f_2) that are contained in the hypothesis – accompanied by a semantic relation binding these words together. A simplified version of this approach – used in SemEval 2013 challenge – deals only with a pair of words *without* explicitly metioned semantic relation.

For example, if the hypothesis has the form of a sentence "The water was evaporated, leaving the salt.", one of corresponding facets is: (evaporated, water). Starting now, we are going to use only this simplified model.

The problem of recognizing faceted entailment can be stated as follows: *"Does the given text T express the same semantic relationship between the words f_1 and f_2 exhibited in H?"*

II. Note on a Related Work – Existing System for Faceted Entailment

Currently, there are only a very few systems for recognizing faceted entailment. In SemEval 2013 Task 7, only one system was submitted – a system of Levy et al. [3].

It consists of three components: *Exact Match, Lexical Inference, Syntactic Inference*. Exact match checks whether lemmas of words contained in the facet appear both in the text. The Lexical Inference is based on Resnik similarity [4] over WordNet [5]. The idea behind this module is to find out whether words semantically related (semantically similar) to those contained in the facet, occur also in then text.

The Syntactic Inference module is based on BIUTEE entailment engine that deals with dependence trees. The dependency

978-83-60810-90-3/$25.00

tree corresponding to a given facet is obtained from the dependency tree of the whole hypothesis using lowest common ancestor (LCA) of facet-nodes: it is just the path from one facet node to the second one via LCA node. This inference component has no paralel in our approach.

The best results of Levy et al. system were achieved in "Majority" configuration (Exact $\vee$ (Lexical $\wedge$ Syntactic)). In terms of F_1-measure, the scores vary from 0.765 to 0.816 depending on different scenarios.[2]

A. Main Aim of the Work

In this paper we present a novel system for recognizing partial/faceted textual entailment that is based on word2vec representations of the words contained in the text T and words contained in the facets.

The results of this monolingual setting can provide rough estimations of overall accuracy and other measures for intended cross-lingual modification that is briefly described in the last section of this text, thus this work can also be viewed as a prerequisite to cross-lingual faceted entailment.

B. Word2vec Model

Word2vec model belong to a class of distributed representations of words. The main attribute of distributed representations (proposed relatively long time ago, in the second half of 80th in [6]) is, that the representations of (semantically) similar words are close in the vector space.

Word2vec model arises from the idea of predicting the neighbours of a word using a neural network. There are two possible modes of predicting: distributed Skip-gram or Continuous Bag-of-Words (CBOW), see [7]. The CBOW idea is to predict the word "in the middle" from the surrounding words, whereas in Skip-gram model the training objective is to learn predicting its context in the same sentence. The (real number) vector representations of words correspond with the weights between input and first hidden layer in used deep feedforward network. The dimension of the target word2vec space is a parameter of the model.

III. Task Definition, Algorithm Description and Used Data

Recognizing faceted entailment is a binary classification task. The inputs are the text T and the hypothesis H along with the facet (f_1, f_2) of words contained in H. The output classes are *Expressed* and *Unaddressed*[3] (which means the semantic relationship between f_1 and f_2 is expressed explicitly or implicitly in T, or not, respectively).

Let us assume we have a word2vec model, i. e. for (almost) each word w we have its vector representation $r(w)$ in word2vec space of a given dimension, a text T an a facet (f_1, f_2). Parameters of our algorithm is a threshold α from the $(0, 1)$ interval.

[2]The comparison of our proposed system with this one was not provided due to missing information about the data used in each scenario.

[3]In the context of faceted entailment, "Expressed" and "Unaddressed" labels are used instead of "Entailed" and "Not entailed".

A. Algorithm Description

The decision algorithm for faceted textual entailment (abbreviated as W2V in the following text) works in the following steps:

1) Split the text T into tokens $t_1, \ldots, t_n$.
2) Get the word2vec representations
$$r(t_1), \ldots, r(t_n), r(f_1), r(f_2)$$
whenever possible.
3) For f_1 select the word t_p such that $d(r(f_1), r(t_p))$ is equal to
$$\min\{d(r(f_1), r(t_k)) \mid 1 \leq k \leq n\},$$
where d is the standard cosine distance. For f_2 select analogously t_q. Roughly said, select two words in T that have the lowest distances to the facets in the sense of word2vec space.
4) If
$$\frac{d(r(f_1), r(t_p)) + d(r(f_2), r(t_q))}{2} \leq \alpha$$
than (f_1, f_2) is *Expressed* in T, otherwise (f_1, f_2) is *Unaddressed* by T. If some word of the facet is missing in the word2vec model, the result class is set to *Unaddressed*.

If the facet consists of more than two words (tokens), use this algorithm analogously for all of them.

The optimal value of α is obtained after experiments on training data – the selected value provides the best results of this algorithm in terms of overall accuracy. We will refer to this algorihtm as "W2V".

In addition, we will employ the trivial algorithm (that will be refered as "EXACTMATCH"): it returns *Expressed* in case that both words of the facet are contained in the text T, otherwise it returns *Unaddressed*. No lemmatization is taken into account since we are preparing a maximally language independent solution – in EXACTMATCH we deal only with word forms. This trival algorithm is used in order to treat with situations when a facet uses the same words as those contained in the text – but that are not contained in the word2vec model (for instance, correct words with a very low frequency).

B. Used Data and Word2vec Model

The evaluation was performed using a dataset derived from SciEntsBank corpus [8] that was used in the Joint Student Response Analysis and 8th Recognizing Textual Entailment Challenge at SemEval-2013 Task 7. This corpus is focused on previously mentioned domain of student response analysis. It contains scholar questions, reference answers and student responses. From the "practice point of view", the aim is to recognize whether the student's answer is at least partially correct. Transforming this issue to recognizing (partial) textual entailment environment models this situation: the role of the hypothesis H plays the reference answer and the role of the

text T is played by the student's answer. If H is (partially) entailed by T, than student's answer is (partially) correct.

Let us illustrate it on the example.

QUESTION: *You used several methods to separate and identify the substances in mock rocks. How did you separate the salt from the water?*

STUDENT ANSWER: *Let the water evaporate and the salt is left behind.*

REFERENCE ANSWER: *The water was evaporated, leaving the salt.*

FACET: *(evaporated, water)*

As already mentioned, T is the student answer and the task is to decide whether the semantic relationship between "evaporated" and "water" is expressed in T. In this case, the relationship is "Expressed", thus the student answer can be regarded as partially correct.

In contrast, when student answers "I don't know." the facet *(evaporated, water)* is obviously not expressed.

The advantage of using this corpus is that facet extraction was already done and the faceted entailments were manually annotated. The SemEval-2013 Task 7 corpus is divided in two parts, training and test collections. The training collection contains 13145 pairs, the test collection contains 16263 pairs text-hypothesis (i. e. facets). As the texts T, we have considered just the student answers in all cases, no other texts (like parts of questions) were taken into the account.

While in case of "standard" recognizing textual entailment there are several training/test sets, for faceted/partial textual entailment, annotated corpora are very rare.

Word2vec model was built using the original implementation[4] over the TC Wikipedia[5]. Standard preprocessing issues were performed (e. g. lowercasing, punctuation removal). The model was obtained with the following basic parameters: the dimension was set to 200, the window was set to 5, the mode was CBOW.

IV. Results

Since recognizing faceted textual entailment is a binary classification task, the performance is measured in a standard way – obtaining precision, recall and F_1-measure scores over the test collection of SciEntsBank corpus. F_1-measure was chosen in order to compare our results with [3]. The threshold α in W2V algorithm was set to 0.555 – this value of the parameter maximizes the overall accuracy over the training collection.

The results are summarized in Table I, Table II and Table III. They were obtained by "official SemEval scripts"[6].

EXACTMATCH achieves relatively high precision at positive class, nevertheless it provides low recall – these characteristics correspond with "common sense" expectations. The combination of these two approaches leads to better results in F_1-measure than the W2V approach used separately.

TABLE I
W2V ∨ EXACTMATCH RESULTS

	Precision	**Recall**	F_1**-measure**
Expressed	0.661	0.811	0.729
Unaddressed	0.875	0.761	0.814

TABLE II
W2V RESULTS

	Precision	**Recall**	F_1**-measure**
Expressed	0.652	0.774	0.707
Unaddressed	0.854	0.761	0.805

V. Conclusion

We have presented a simple system for recognizing faceted textual entailment that is based on word embeddings: word2vec model in particular – other embeddings with similar characteristics (like GloVe) can be treatened in an analogous way.

Despite of its simplicity it provides reasonable results in terms of F_1-measure. The key features of this system are no need of other language resources in except of a relevant word2vec model and no usage of NLP tools. Thus it can be quickly implemented in any language where word2vec models can be created. The preparation of word2vec models requires only a collection of texts of a sufficient volume like Wikipedia in the corresponding language and/or a relevant web corpus (without any annotations).

Using word2vec model and our approach "simulates" the use of lemmatization in morphologically rich languages (since the cosine distance of a given word form and its lemma is usually very low – observed during experiments with Czech language), thus our approach would most likely achieve relatively comparable results also in other languages.

It can be straightforwardly implemented in different programming languages and environments – in our case, in `R` environment (enriched by `lsa` and `tm` packages) was used. Word2vec representations were stored in CSV format and were loaded into `R`.

Comparing to the mentioned approach of Levy et al. [3], our approach provides a comparable results in terms of overall accuracy – but it can be easily implemented also in "under-resourced" languages (where syntactic tools – as well as WordNet – are not available). Our proposed system approximately corresponds with the first two components of their system (Exact Match and Semantic Inference). The differences are summarized as follows: in [3], Exact Match contains lemmatization, in our approach lemmatization is not used.

TABLE III
EXACTMATCH RESULTS

	Precision	**Recall**	F_1**-measure**
Expressed	0.970	0.366	0.531
Unaddressed	0.731	0.993	0.842

Semantic Inference module is in our setting "replaced" by low distances in word2vec space.

VI. Further Work

Our proposed system can serve as a baseline for further experiments.

Since word2vec models are able to capture many linguistic regularities [9], it is intended to employ rule based transformations on facet representations and subsequently determining whether transformed representations are contained in representation of T (for example, dealing with representations of hyper/hyponyms of words that forms the given facet, similarly as in [10]). These extension can be viewed as a paralel of Syntactic inference module of previously mentioned system.

In our presented approach, the threshold α stays constant in all cases and the distances $d(f_1, t_p)$ and $d(f_2, t_q)$ were simply combined into the mean, which was followingly tested against α. Other way of improving our system will be based on employing more features, e.g.:

- raw distances $d(f_1, t_p)$ and $d(f_2, t_q)$,
- the number of words in text between t_p and t_q,
- the angle between vectors $r(f_1) - r(f_2)$ and $r(t_p) - r(t_q)$,
- features obtained from hypernymy/hyponymy, synonymy and other attributes derived from WordNet data.
- ...

and using ML methods like SVM etc. We suppose that employing features (especially those arising from semantic resources like WordNet will help to improve both precision and recall).

Another part of further work is application-oriented: we are going to employ recognizig faceted entailment system in text summarization task (like that described in [11]) etc.

Note on the Cross-lingual Approach

As already mentioned, the proposed approach will be extended for using in a cross-lingual environment. It has been demonstrated in [12], paralel word2vec models can be used for of generating and extending dictionaries and phrase tables. The underlying idea is simple (with little assumptions about the languages involved): unknown word translations can be obtained by learning language structures over large monolingual data and mapping between languages on a small domain (in terms of the mapping).

More formally, let us have n word pairs and their vector representation $(x_i, z_i)_{i=1}^n$, where $x \in R^{d_1}$ is a vector representation of i-th word in the source language and $z \in R^{d_2}$ a vector representation of its translation. The goal is to find a matrix W such that Wx_i approximates z_i. The matrix W is obtained as a solution of an optimization problem:

$$\min_W \sum_{i=1}^{n} \|Wx_i - z_i\|^2.$$

In [12], this problem is solved with stochastic gradient descent.

At this moment, the modification of our algorithm for cross-lingual faceted entailment is straightforward: Having a facet (f_1, f_2) in the source language and the text T in the target language, then we take the vector representations (x_1, x_2) in source word2vec space, compute $(z_1, z_2) = (Wx_1, Wx_2)$ and determine representations of words that are the closest to z_1 and z_2 in the sense of cosine similarity in the target language word2vec model. The rest will be identical to the monolingual case.

***Abstract*—In contemporary world, translation becomes a critical need of the time. Parallel dictionaries have now become a most accessible source by humans, but confines are there as they do not offer good quality translation function, because of neologisms and words that are out of vocabulary. To overcome this problem in the usage of statistical translation systems is becoming more and more important in maintaining the eminence and quantity of the training data. But due to the limitations in these systems they have very limited availability for few languages and very limited narrow text areas. The purpose of this research is to bring calculation time up gradation via GPU acceleration, tuning script introduction and the enhancement and improvements in the methodologies of the contemporary comparable corpora mining through re-implementation of analogous algorithms through Needleman-Wunch algorithm. Experiments have been conducted on multiple language data which were extracted on numerous domains from Wikipedia. For the sake of Wikipedia, multiple cross-lingual contrasts and comparison were established. Optimistic impact on the both quantity and quality of mined data was observed due to such changes and adaptation. The solution is language independent and highly practical especially for under-resourced languages.**

I. Introduction

THE purpose of the research is to organize the language models and parallel and comparable corpora. This process advances the quality of SMT through riddling of parallel corpora and it also works through extraction of supplementary parallel data via the resulting corpora. In order to improve the language spring of the SMT systems, alteration measures and interpolation methods are applied to the obtainable prepared data. For this, various experiments were led by using wide domain (TED presentations on variety of topics).

SMT system's assessment was functioned on random samples of analogous data by utilizing automated algorithms (BLEU metric) in order to assess the possible usage and standard of the SMT systems' output. In addition, human evaluation was conducted in order to measure the impact of newly obtained corpora on translation error reduction. [1]

While experiments are discussed, the utilization of the software Moses Statistical Machine Translation Toolkit [2] is done. Further, the symmetrisation is done using Berkeley Aligner [3] and translation models training is done using multi-threaded application the GIZA++ tool. Only from single language data base, the statistical models are shaped well by utilizing SRILM (SRI Language Modelling toolkit). Furthermore, the data from external domain is adapted. In the situation of parallel modelling, in-domain data collection is found using, Moore-Lewis Filtering [4] while single-language models are linearly interpolated [5].

Finally, methods recommended in the Yalign [6] parallel data mining tool are upgraded and critically evaluated. By using the tool in a multi-threaded way and by employing graphics processing units (GPUs), its speed was also amplified. Furthermore, by utilizing Needleman-Wunch [7] algorithm and by developing a tuning script that is used to regulate mining parameters to fix domain supplies, its quality is improved as well.

In the tests, the resultant SMT systems out-performed the baseline systems in terms of BLEU metric and error reduction.

II. Corpora Types

A corpus includes a large collection of texts stored up on a computer. These text compilations are known as corpora. Usually in linguistic fields, parallel corpus as a term is used with the reference to texts which are the source of translation of each other. In order to deal with the statistical machine translation, we are significantly considerate about parallel corpora. These are paired with text through another language. For the preparation of parallel texts for the call for statistical machine translation, it may require removing the text from HTML, web crawling and sentence structure [5] and performing document alignment.

Two major kinds of parallel corpora exist in two different languages. One is comparable corpus in which common texts are present and their content is also the same. Polish and English newspaper's articles are best example of comparable corpora. The second one is the translation corpus, in this type of corpus the text of first language (e) is the translation of text in second language (f). It is significant to recognize that the word "comparable corpora" signifies the texts in two different languages, they are common in the content but they are not common translations of one another. [5]

In order to assess a parallel text, pattern arrangement is used which mentions common texting sections (approximately, sentences), that is a significant requirement for examination.

Within first and second language machine translation algorithms for translation are often trained, using common fragments. This includes a first and second language corpus that is an element for element translation of the first language corpus. In such kind of training it may involve huge training sets which can be removed from huge corpora of common sources, like databases of the news articles written in the first and second languages while describing common events [5]. Due to this complicatedness, it is problematic to obtain high quality parallel data, significantly for uncommon languages. Comparable corpora are the key to the solution of problem of absence of data for rare language pairs that are under-resourced languages and other subject domains. It is easier and conceivable to use comparable corpora to achieve straight knowledge for the purposes of translations. This data is considered to be a precious foundation of knowledge for other information dependent and cross-lingual tasks. This data is not as rare as parallel, even for Polish-* languages. On the flip side, single language data is accessible in huge qualities [5].

While concluding, there are four key corpora kinds which are notable. Parallel corpora that are also very uncommon, can be explained as corpora which have the translations of the common file into two and more than two languages. For that such kind of data it is needed for it to be aligned, at the level of sentence as a minimum. Noisy-parallel corpus that contains bilingual structure sentences that are not excellently arranged and they can also have translations with bad quality. Yet, in most cases, bilingual translations of a precise document are present in it. A comparable corpus is structured from unstructured sentences and with un-translated bilingual documents, but the text or the documents need to be about the same topic. Seemingly quasi-comparable corpus also has very non-parallel bilingual and very mixed documents, they may or may not be structured according to the topic [8].

III. State of the art

If comparable corpora are concerned, numerous efforts (as for Wikipedia) have been observed in order to evaluate parallel data samples. Two core methods for building comparable corpora can be easily separated or illustrated. The most common method is founded on the notion of recovery of cross-lingual knowledge. Second approach is based on the fact that source texts or documents should be interrelated by using random translation systems. After that the translated documents can be compared with the texts that are written in the most targeted language and the basic purpose is to find out the pairs of common pairs within the documents.

An exciting idea for searching for parallel data inside the Wikipedia was mentioned and explained in [9]. Firstly, the idea is to utilize an online machine translation (MT) system to decode the language, using translating techniques to translate Dutch language into English language on Wiki pages, and after that try to compare original EN pages with translated ones. This idea, though seems computationally impractical, is interesting but perplexed problem. Their second method uses a dictionary generated from the hyperlinks and Wikipedia titles that are shared between documents. Inappropriately, the second method involves the generation of Wikipedia titles by using dictionary and the hyperlinks that are being shared between texts. The second method was improved in [9] by a range of spare confines of the communication between the portions of the concern document and with the help of the introduction of added measure on the bases of similarity. They report that in [9] the accuracy (number of correct translation pairs over total strength of the applicants) is approximately 21% and at this stage in the recommended method [10], the accuracy is around 43%.

Yasuda and Sumita [12] projected a MT bootstrapping structure on the basis of figures that helps to create a sentence-structured corpus. Sentence structure and alignment is accomplished by utilizing a bilingual lexicon which is spontaneously upgraded by the structured sentences automatically. They use corpus that has previously been structured for the early training session. Their recommendations showed that 10% of Japanese Wikipedia sentences have an equivalent on the English Wikipedia.

Tyers and Pienaar in [10] gave the idea to give lead to internal Wiki links. A bilingual dictionary is removed and evaluated on the bases of Wikipedia link structure. In the work of these authors, they actually calculated the normal disparity for numerous languages that are linked between Wikipedia pages. Results showed that 69-92% depends on the specific language according to the precision of the method.

The authors in [13] attempt to raise the best skill in parallel data mining with the help of modelling of document-level arrangement by utilizing the observational technique, so that parallel sentences can greatly and most commonly be found in propinquity. Authors also use explanation that is available on Wikipedia and a mechanically injected lexicon model. For that authors report 80% precision and 90% recall.

In [14] author introduces an instinctive arrangement methodology for parallel textual documentation fragments which utilizes a phrase-based SMT system and textual entailment method. The author mentions that important up gradation in SMT quality were adopted (BLEU increased by 1.73) by utilizing this arranged data between French and German languages.

M. Volk and M. Plamada also explained another method for discovering Wikipedia which was explained in [14]. Previously explained methods differ from their solutions. In these methods parallel data was restricted to the monotonically control of the arrange algorithms that were used in order to match the candidate sentences. Their algorithm pays no heed to the position of a candidate in the text and, instead, ranks candidates by means of modified measurements that combine contradictory similarity criteria [15]. Additionally, the authors limit the process of mining towards a specific domain and examine the semantic equality of took out pairs. Mining accuracy is 39% in the work of M. Plamada and M. Volk, while 26% are for loud parallel sentences, with other remained sentences misaligned. Reportedly they say that an up gradation of 0.5 points happened in the BLEU metric out of domain data, but no prominent improvement took place in-domain data.

In [16] the authors suggested to use titles and few meta-information only, like time for specific document and publication data, neglecting its full-fledged contents, to lessen the cost of development of the comparable corpora. The similarity of cosine of the title terminology as frequency vectors was utilized to match the contents and the contents of the matched pairs. In the research explained in [17], the two authors came up with a document of resemblance of measure which is based on the occasions. In order to count the values of this metric, they present documents as sets of occasions and events. These occasions are time based and are based on the geographical terms that are found in the texts. Documents that are targeted ranked and based on geographical orders. The writers in [18] also recommend a programmed method in order to build a similar corpus from the website by utilizing news web pages like Twitter and Wikipedia. They mine things, URLs of web pages, filtering within time limitations and the specified lengths of the documents as features for the congregation and the categorization of the similar data.

In the current research, a methodology that was inspired by the Yalign is being used. The method originally was far from perfect, but after the up gradation and improvements during research, it actually has provided us with excellent mining results.

IV. Parallel data mining

This study aims at developing new methodologies for obtaining parallel corpora from the sources that are not aligned likewise comparable corpora, quasi-comparable or noisy parallel. We have selected Wikipedia as a base of the data because of the huge number of texts it provides (4,524,017 on EN wiki approximately). Moreover, Wikipedia comprises not only similar documents, but it also includes some text documents which are the translations of one another. This approach can be qualified by the use of measurements in the translations systems of MT.

In data mining, TED corpora, ready for the IWSLT 2015 assessment by FBK, were selected. This domain is very wide and protects numerous subject areas. Data contains nearly 2.5M un-accessible words [19]. The tests were shown on PL-*.

Our idea can be separated and divided into three key steps. Firstly, comparable data is selected, then it is arranged at the article level, and lastly for parallel, the arranged results are mined. The last two steps are important; the reason is that there are huge numbers of differences between documents of Wikipedia. Sentences in the Wiki corpus are mainly not arranged, with translation lines whose assignment does not agree to any textual information in the foreign language. Furthermore, some sentences have no consistent translations within corpus at all. The alignment is very difficult for the correctness. For that sentence alignment should also be practicable with competency that is of practical use in variety of applications. Earlier, a mining tool precedes the data and the text should be ready. Initially, entire data is preserve in a relational database. In the second phase, our tool organizes article pairs and eradicates the articles that seem to be present in only one of the two languages. All these arranged articles at topic-level are checked in order to get rid of XML tags, HTML tags or other noisy data (figures, references, tables, etc.). Lastly, fluent documents are marked with a single ID as an aligned topic, similar corpus. In order to separate the parallel pair's sentence, a decision was taken in an attempt to develop strategy that was designed to program the parallel text mining process after finding the sentences that are near to the translation matches from comparable corpora. This offers chances for finding parallel corpora from bases, as not translated textual documents including the web, which are not limited to any specific language pair.

Though, alignment models for two languages that are of two designated languages particularly the first one is to be created as priority. By using a comparative sentence metric gave an unbalance estimate (a number that is somehow between 0 and 1). This approximation shows that how there is a possibility of being a translation of the two sentences. It also applies pattern alignment, which gave a sequence that increases the quantity of the unique thread (per sentence pair) that is same between the two texts [6]. In order to maintain order alignment, we at first used error friendly and very slow Yalign that used an A* search method [20] to find an ideal alignment between multiple sentences in two particular documents. The algorithm has a polynomial worst time complication. It cannot control alignments that cancel each other or such that form from two

sentences a single sentence [20]. After the sequence alignment, only sentences which have top probability of being translated are placed in the results. The output is checked to deliver top quality corpus. To accomplish this, an action is used: if the sentence has the similar score that is less than the threshold, at that stage pair will not be included. For similarity of sentence metric, the algorithm uses statistical techniques. The classifier must be skilled to find if the sentence pairs are translations between each other. In this research Support Vector Machine (SVM) classifier is used. SVM can give a distant outlook to the parting hyper plane during labelling. This distance can be simply adapted by utilizing a Sigmoid Function to return a value that is similar to similarity between 0 and 1 [21]. Usage of classifier means that the excellence of the rearrangement depends not just on the input but it also depends on the quality of the classifier. For the training of the classifier, high quality parallel data is necessary. For this, we utilized the TED talks [8] corpora. To get a dictionary, we used a phrase table and took 1-grams from it [22].

V. Development of the Mining Process

Much to our distress, the local Yalign instrument was not practical enough for matters related to calculation in terms of comprehensive and real life parallel data mining. Typical execution required input in simple text or web links and the RAM memory was re-loaded with classifier for every text pair. Moreover, the Yalign software is uniquely stranded. In an effort to speed up the process, this unique solution was developed to supply articles to the tool and load classifier only once per session. The newly developed system also used the multithreading and minimized the mining time by factor of 6.1x, utilizing the four cores and eight thread i7 CPU. The alignment algorithm was replaced to improve accuracy and to make best use of the strengths of the GPUs to fulfil the supplementary requirements of the computations.

A. Needleman-Wunsch algorithm (NW)

Major purpose of this algorithm is to line up two sequences together. At first, it is necessary to define the correspondence among the two elements. It can be explained by using the similarity matrix S in which N represents the number of elements in the first sequence and M represents the number of elements in the second sequence. The algorithm was designed to analyse the matters related to bio-informatics for the assessment of RNA and DNA. However, it can be modified to deal with assessment of textual data. In other words, the given algorithm combines real number and a pair of each element together in the matrix. As the similarity index rises, so is the similarity of the elements concern. For instance, if we have a similarity matrix S which is equal to the numbers between 0 and 1 than by 0 for the two expressions mean that their similarity index is zero whereas 1 means that the two given

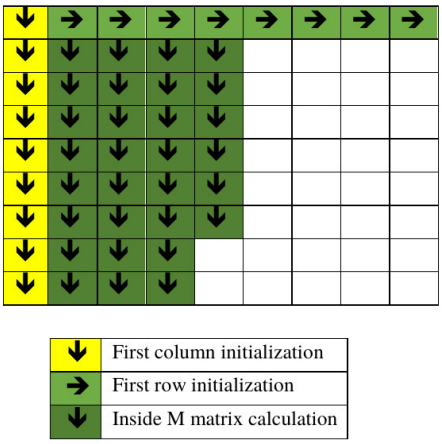

Fig. 1 Needleman-Wunsch S-matrix calculation

words are perfect translations of each other. The significance of similarity matrix index for the consequences of the algorithm is undeniable [20]. After that we will identify the consequences of gap penalty. It is essential particularly when one of the elements of the sequence is connected with the gap in another sequence.

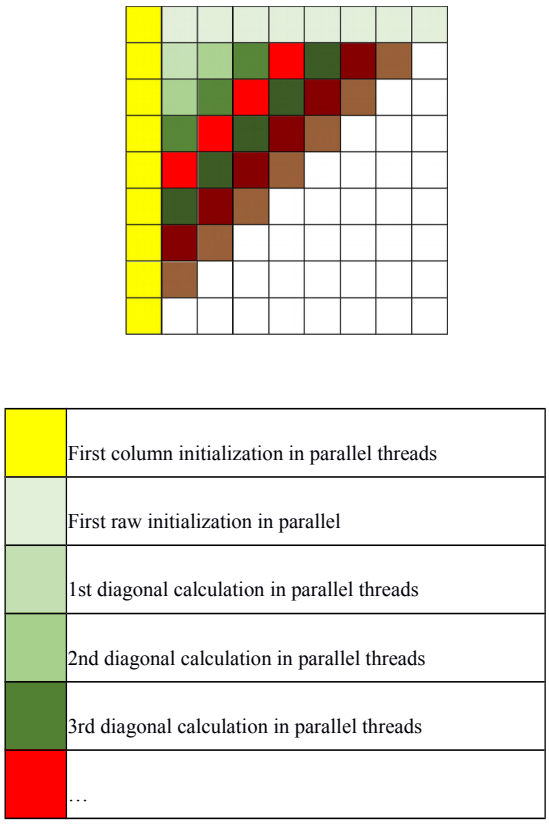

Fig. 2 Needleman-Wunsch S-matrix calculation with parallel threads

Though, such a stride will lead to a penalty (p). The calculation of the S matrix will be executed right from the start of S (0, 0) element which by definition is equal to 0. Once the process of initializing first and second row is started, the algorithm moves to the other elements of the S matrix, taking the cue from the upper left side, leading up to the bottom right side. All of these steps are illustrated in the Fig. 1.

The two (CPU and GPU) NW algorithms are theoretically same but the GPU has a leverage of better performance due to its hardware handicap up to max(n,m) times.

Though, this process is different when it comes to the calculation of the elements of S matrix. At this step forward, we will apply the multiple strands to an optimized level. These processes are so small so that that they can be processed easily by a huge number of Graphics Processing Units (ex. CUDA cores). The major purpose behind this is that we will calculate all the elements in predefined diagonals in parallel way which always starts from upper left and ends at the bottom right, as presented in the Fig. 2 [23].

In an attempt to explain the value of a cell of S(m,n), for all pairs of m and n, the values to its top S(m-1,n) , left S(m,n-1) and top left S(m-1,n-1) must be known in advance and filled with tokenized documents that are to be compared. Where, S(m,n) can be calculated with the help of following equation: [24]

$$S(m,n) = max\{S(m-1) \pm 1, \\ S(m-1,n)-2, S(m,n-1)-2\}$$

Regardless of the results of the A* algorithm, if the coherence between calculation and the gap penalty are defined on the similar patterns as they are defined in the NW algorithm, they will have similar results just if there are supplementary restraints on the way, these ways cannot be led to uphill or left-side in the matrix. Yalign does not compel such terms and conditions, therefore in some cases, expressions can be repeated more than once or misaligned. Most of the cases the algorithm keeps on moving backward and forward to the first two sequences in line. S matrix has been exemplified without any barriers in the Fig. 3.

	a	d	e	g	f
a	X				
d		X			
c	X				
d		X			
e			X	X	X

Fig. 3 S matrix pass-through without constraints

The alignment result in this scenario is:

a, d, a, d, e, g, f

a, d, c, d, e, −, −

In the same problem, the NW would react as presented in Fig. 4:

	a	d	e	g	f
a	X				
d		X			
c		X			
d		X			
e			X	X	X

Fig. 4 S matrix pass through with NW

The alignment result using NW would be:

a, d, −, −, e, g, f

a, d, c, d, e, −, −

For second example, we will assume that the very first sequence in a row is “Tablets make children very addicted” and second one says that “Tablets make people spoil children”. Fig. 5 given below presents a solution to this problem by the help of A* algorithm and Fig. 6 shows it with NW, without any restrains.

	Tablets	make	children	very	Addicted
tablets	X	-	-	-	-
make	-	X	-	-	-
people	X	-	-	-	-
spoil	-	-	-	-	-
children	-	-	X	X	X

Fig. 5 A* alignment without constraints

Due to lack of any restrains, repetitions and bad alignments are most likely to be made by envisaging the blemish A* algorithm, which is applicable in the Yalign program. However, some of the sentences can be easily passed over during the checking of the alignment. That is why NW with GPU optimization is the most preferred algorithm.

	Tablets	make	children	very	addicted
tablets	X	-	-	-	-
make	-	X	-	-	-
people	-	-	-	-	-
spoil	-	-	-	-	-
children	-	-	X	-	-

Fig. 6 NW alignment with constraints

B. Other improvements to data mining methodology

The SVM classifier is used to define the quality of the alignment; it creates a trade-off between the recall and the precision. Two configurable variables can be found in the classifier.

- Threshold: the acceptance of an alignment is 'Good' if the confidence threshold if high. For less recall and more precision, the value should be lowered. The probability estimated through the support vector machine is the 'confidence' that classifies it as 'is a translation' or 'is not a translation' [25].
- Penalty: the alignment allows control of the amount of 'slipping ahead' [6] if you are aligning subtitles. There would then be no extra or fewer paragraphs, and the alignment would be one-to-one while the penalty would be high. The penalty would be lower if the translations of the alignments are similar and there are no extra paragraphs.

These parameters are automatically selected during the training; however, they can be manually changed if necessary. A tuning algorithm is also introduced in our implementation of the solution[1] used. In this research, it allows adjustments for better accuracy. Random articles of the corpus must be extracted to perform the tuning; humans can manually align these random articles. Given the information provided, the tuning mechanism finds the classifier value through randomly selected parameters; it tries to find the output that would be as humanly similar as possible.

The improvements that were debated earlier, deal entirely with heuristics utilized in the mining tool and they can be implemented to any fluent textual data. Though, Wikipedia has huge extra sources of cross-lingual information that need to be utilized. Firstly, the theme domain of Wikipedia cannot be enclosed into a particular domain; this page covers approximately any topic in question. Due to the fact that these articles frequently contain complex vocabulary, and that is why approaches of statistical mining can skip many of the parallel sentences. The answer to this query can be extracted dictionary by utilizing the article titles from Wikipedia (Fig. 7) and moreover it can be implemented into web crawler tool.

Fig. 7 Sample of bi-lingual Wikipedia page title

In [11] authors say that the precision of this dictionary can be attained at 92%. For that this dictionary can be utilized not only for the delay of the parallel corpora but in the classifier phase of exercise as well.

Secondly, figures contain best quality parallel sentences and explanations. It is likely to attain pictures and graphics with the help of hyperlinks and analysis the pictures. Similarly, same is for any figures, maps, tables, videos, audio or even compound media on Wikipedia. Tactlessly not whole knowledge can be removed from Wikipedia dumps and it is essential to utilize a web crawler that is right for this assignment (Fig. 8). It also can be predicted that simply only cross-language knowledge which are marked with simple links can be removed.

Fig. 8 Specimen of bi-lingual character caption

On Wikipedia it is very likely for the sentences to be equal linguistically, if they are referenced with the similar publication. Such an analytical approach, combined with other comparative tactics, can move us forward to better accuracy in a parallel text sequence discovery task (Fig. 9).

Fig. 9 Sample of bilingually referenced sentence

[1]https://github.com/krzwolk/yalign

VI. Assessment of obtained parallel corpora and conclusions

By the help of techniques explained earlier we were capable of creating comparable corpora for many PL-* language pairs and later, probe them for parallel phrases. We paired Polish (PL) with Arabic (AR), Czech (CS), German (DE), Greek (EL), English (EN), Spanish (ES), Persian (FA), French (FR), Hebrew (HE), Hungarian (HU), Italian (IT), Dutch (NL), Portuguese (PT), Romanian (RO), Russian (RU), Slovene (SL), Turkish (TR), Vietnamese (VI). Statistics of the resulting corpora are presented in Table I.

In order to assess the corpora quality and usefulness, we trained the baseline SMT systems by utilizing the WIT[2] data (BASE). We also augmented them with resulting mined corpora both as parallel data as well as the language models (EXT). The additional corpora were domain adapted through the linear interpolation and Modified Moore-Lewis filtering [26]. Tuning of the system was not executed during experiments due to the volatility of the MERT [27]. However, usage of the MERT would have an overall positive impact on MT system in general [27]. The results are showed in Table II.

The assessment was based on sets of official test sets from IWSLT 2013[3] conference. Bilingual Evaluation Understudy (BLEU) measurement was used to score the progress. As it was expected earlier, sets of supplementary data enhance the general quality of translation for each and every language.

In order to verify the importance of our results we conducted the significance tests for 4 divers languages. The decision was made to use the Wilcoxon test. The Wilcoxon test (also known as the signed-rank test or the matched-pairs test) is one of the most popular alternatives for the Student's t-test for dependent samples. It belongs to the group of non-parametric tests. It is used to compare two (and only two) dependent groups that is two measurement variables. The significance tests were conducted to evaluate how the improvements differ from each other. Changes with low significance were marked with *, significant changes were marked with ** and very significant with *** in presented Tables III and IV.

Bi-lingual sentence extraction has particular importance in dealing with unsubstantiated learning processes for multiple tasks involved. With the help of this methodology we can easily resolve the dissimilarities between Polish and other languages. It is a method that is independent from language matters, it is adaptable to new environments for any language pair. Our experiments validated the performance of the method. The corpora received as consequence of the experiments, can maximize the quality of MT in an under-resourced text domain. However, in few scenarios, only small differences have been observed in BLEU scores. Keeping that aside, it can be said that even such small differences, can influence the real life situations positively especially for infrequent translation cases. Moreover, the results of our work are freely accessible for research community (corpora is hosted at OPUS[4] and tools at GitHub[5]). In order to see things from sensible outlook, we can say that such methodology does not require large scale training or special language specific

Table I.

Results of mining after progress

Language Pair	Number of bi-sentences	Number of unique PL tokens	Number of unique foreign tokens

rammer resources, and despite of that they produce gratifying results.

Because statistically classified data contains some amounts of noisy data, in future we plan to develop precise filtering strategies for bi-lingual corpora. The results of current solution are highly related to SVM classifier. In other words, we plan to train more classifiers for different text domains in order to discover more bi-lingual sentences.

***Abstract*—The paper analyzes existing approaches for approximate string matching based on linear search with Levenshtein distance, AllScan and CPMerge algorithms using cosine, Jaccard and Dice distance measures. The methods are presented and compared to our approach that improves indexing time using Locally Sensitive Hashing. Advantages and drawbacks of the methods are identified based on theoretical considerations as well as empirical evaluations on real-life dictionaries.**

***Index Terms*—approximate string matching, misspelling correction, LSH, CPMerge, AllScan, Levenshtein distance, neural net indexer**

I. Introduction

AN APPROXIMATE string matching is a task of finding a specific word in a given dictionary, that is similar to the word provided by the user to at least a certain degree.

This task is encountered in a wide spectrum of applications, especially for calculating similarity between texts [1]. One of the examples is misspelling detection in a written text and recommendation for a correct word. This solution is used in most interfaces where a user enters a text, e.g.: in web search engines, while she or he enters a query, or in mobile phones, while typing messages. Among other examples, there is plagiarism detection [2], [3] or spam filtering [4], that checks whether a text contains words intentionally modified in order to evade naive spam filters, e.g. vulgar words with added dots instead of some letters in internet posts.

The typical approaches for approximate string matching use some kind of edit distance, such as Levenshtein distance [5]. The two words are matched, if an edit distance between them is below a specified threshold. A useful algorithm should then return a number (possibly all) of words from a predefined dictionary that approximately match a given (input) word in a reasonable time.

In this paper we compare four different approaches to accomplish this, reporting their processing time as well as quality of matched words returned: linear search with Levenshtein distance, AllScan and CPMerge algorithms proposed in [6], and an approach based on Locality Sensitive Hashing. We identify their advantages and drawbacks.

The paper is constructed as follows. Section II describes Levenshtein, AllScan and CPMerge algorithms. Section III presents the approach based on Locally Sensitive Hashing. The experiments and the results of their evaluation in the approximate string matching task are provided in Section IV. Finally, Section V contains conclusions and an idea of further improvements.

II. Approximate string matching algorithms

At the very beginning we define basic symbols we use to describe the algorithms:

1) Σ - an alphabet, a finite set of symbols (letters)
2) Σ^* - a set of all possible words over Σ (e.g. a, b, ..., aa, ab, ...)
3) $V \subset \Sigma^*$ - a finite size dictionary
4) $sim(x, y)$ - a similarity function between words x and $y - f: \Sigma^* \times \Sigma^* \rightarrow [0, 1]$
5) $\alpha \in [0, 1]$ - similarity threshold
6) $|x|$ - length of word x
7) $|X|$ - the number of elements in set X

In general, a search for similar words, can be defined as constructing a set $Y_{x,\alpha}$ of certain words y from dictionary V, for which the similarity to a given word x is greater or equal to α:

$$Y_{x,\alpha} = \{y \in V | sim(x, y) \geq \alpha\}. \quad (1)$$

A. Linear search with Levenshtein distance

The most popular approaches for approximate string matching use edit distance. In general, an edit distance measures two strings dissimilarity by counting how many edit operations are required to change one word into the other. Levenshtein distance considers three single character modifications: insertion, deletion and substitution [7]. Each of them has an equal cost of 1.

Formally, Levenshtein distance $lev(x, y)$ between two words x and y of lengths $|x|$ and $|y|$, is equal to $lev_{x,y}(|x|, |y|)$, where $lev_{x,y}(i, j)$ is a discrete function of two non-negative arguments defined as:

$$lev_{x,y}(i, j) = \min \begin{cases} lev_{x,y}(i-1, j) + 1 \\ lev_{x,y}(i, j-1) + 1 \\ lev_{x,y}(i-1, j-1) + 1_{(x_i \neq y_j)} \end{cases}, \quad (2)$$

if $\min(i, j) \neq 0$,

$$lev_{x,y}(i, j) = \max(i, j), \quad \text{if} \min(i, j) = 0.$$

For example, the distance between words *written* and *writes* equals 2, because we need two modifications to transform first

string into the second one:
written $\rightarrow$ *writen* (deletion of *t*)
writen $\rightarrow$ *writes* (substitution of *s* for *n*)

In order to make use of (1) explicitly, a Levenshtein-derived similarity measure can be defined:

$$sim_{lev}(x,y) = \frac{\max(|x|,|y|) - lev(x,y)}{\max(|x|,|y|)}. \quad (3)$$

Because we need to browse the whole dictionary, the complexity of this algorithm is $O(n)$ where n denotes number of objects in the dictionary in term of dictionary size. This is the main main disadvantage of this straightforward approach. On the other hand, this method provides all matching words in the result, so that no one similar word is ever missed. Another useful property it has is that there is no need for preprocessing of the dictionary, that may require additional computations and storage space, which will be the case for methods described next. The approach finds many modifications e.g.: Damerau-Levenshtein distance [8] or others [9], [10], but the complexity usually remains linear. Thus, in experiments we use the basic Levenshtein implementation as a baseline.

B. Shingle word representation

The rest of compared algorithms for approximate string matching do not use edit distance to compare strings in their raw form. Instead, they all incorporate a preprocessing step, called *shingling* [11], which converts a string into a set of *n*-grams. The similarity of two strings are then determined indirectly by computing the similarity between the corresponding sets of *n*-grams.

In our experiments, we split words into letter trigrams and call them *features* that represent a particular word. For example, a word `rotation` is represented by a set `{$$r, $ro, rot, ota, tat, ati, tio, ion, on$, n$$}`, where `$` sign denotes 'no letter'.

It should be noticed that such a tri-gram representation is chosen arbitrarily and can be further improved [12]. However, to compare the approaches of approximate string matching we decided to stick to one fixed representation.

There is a number of similarity measures between feature sets than can be used for shingle-based strings representation. One of the most popular is cosine similarity, defined by (4).

$$sim_{cos}(x,y) = cos(X,Y) = \frac{|X \cap Y|}{\sqrt{|X||Y|}}, \quad (4)$$

where X and Y are *feature sets* (containing $|X|$ and $|Y|$ elements) of x and y respectively .

Other measures, like Jaccard or Dice distance, can also be successfully applied here [13]. They are defined by (5) and (6) respectively.

$$sim_{jacc}(x,y) = jaccard(X,Y) = \frac{|X \cap Y|}{|X \cup Y|} \quad (5)$$

$$sim_{dice}(x,y) = dice(X,Y) = \frac{2|X \cap Y|}{|X| + |Y|} \quad (6)$$

To provide an illustrative example let us assume two words: $x =$ `rotation` and $y =$ `aviation`. We then have $X =$ `{$$r, $ro, rot, ota, tat, ati, tio, ion, on$, n$$}` and $Y =$ `{$$a, $av, avi, via, iat, ati, tio, ion, on$, n$$}`. Hence $|X| = 10, |Y| = 10$. The cosine similarity of these words is equal to $cos(X,Y) = \frac{5}{\sqrt{10*10}} = 0.5$. Jaccard and Dice distances are as follows: $jaccard(X,Y) = \frac{5}{15} = 0.33$, $dice(X,Y) = \frac{2*5}{10+10} = 0.5$

C. AllScan algorithm

The AllScan algorithm first shingles word x obtaining a feature set X. All words in the vocabulary must also be shingled accordingly in a preprocessing phase. Then, AllScan computes lower and upper bounds for *length* of word y potentially similar to x to at least α. For cosine similarity, this bounds are determined by inequality:

$$\left\lceil \alpha^2 |X| \right\rceil \leq |Y| \leq \left\lfloor \frac{|X|}{\alpha^2} \right\rfloor. \quad (7)$$

Inequality (7) comes from (1) and (4), after observing that for minimal length of y we have $|X \cap Y| = |Y|$, while for maximal length of y, it is $|X \cap Y| = |X|$.

To give an example, if we assume $\alpha = 0.7$ and $x =$ `rotation`, $|X| = 10$. Therefore Y set size must be between 5 and 20, because $|Y| \geq \lceil 0.7^2 * 10 \rceil \geq 5$ and $|Y| \leq \lceil \frac{10}{0.7^2} \rceil \leq 20$

Additionally, there is a minimum *overlap* τ value defined for each possible word length from (7). The τ means minimal value of the same letter trigrams, which have to occur in both strings to exceed the similarity threshold value α. For cosine similarity, it is therefore:

$$\tau = \left\lceil \alpha \sqrt{|X||Y|} \right\rceil. \quad (8)$$

Let us assume $\alpha = 0.7$ and words `rotation` and `aviation` ($|X| = |Y| = 10$). Equation (8) gives 7. Hence the feature sets of the words have to contain at least seven shingles in common to be similar in 0.7. They have only four such shingles, so they do not satisfy the minimal overlap value.

Based on obtained $|Y|$ and τ values, the algorithm retrieves all words from the dictionary that satisfy a given matching criterion, i.e. it returns all the words, similarities of which exceed the threshold.

The main advantage of this approach is the retrieval of all matching words (that satisfy given similarity measure), but the problem is its performance. Although the search space is reduced due to y length bounds calculation, the overall complexity of AllScan algorithm is still $O(n)$ in term of dictionary size, both preprocessing the dictionary and searching.

D. CPMerge

CPMerge algorithm [6] extends AllScan by reduction of the dictionary that is searched during single retrieval. The improvement limits the size of the dictionary, removing words which certainly are not a result. It uses Property 1 to

determine which words are candidates to be in a result set. The result set is much smaller than the whole dictionary and it causes significant speedup.

Property 1 *Let there be a set X (of size $|X|$) of word x n-grams and a set (of any size) Y of word y n-grams. Consider any subset $Z \subseteq X$ of size $(|X| - \tau + 1)$. If $|X \cap Y| \geq \tau$, then $Z \cap Y \neq \varnothing$.*

Assume $x =$ `rotation` ($|X| = 10$) and word y with length 6 ($|Y| = 8$). If $\alpha = 0.5$ then $\tau = 5$ (from (8)). Hence, $|Z|$ must be 6 and if $|X \cap Y| \geq 5$ then $Z \cap Y$ must have at least one element.

As previous algorithms, CPMerge returns all matching words as a result. It is faster than AllScan algorithm, due to described improvements, but its complexity is still $O(n)$. Full explanation is available in [6].

III. LSH-BASED APPROACH

To improve the efficiency of dictionary indexing we propose an approach based on special type of constructing the hash indexes. The idea is to construct such an index that works in opposite way to MD5 signature [14]. If the source strings differ slightly, the output hash would be also modified slightly. One way to create such hash function can be based on Locality-Sensitive Hashing [15] used to reduce dimensionality of high-dimensional data. It can be used in many applications where nearest neighbors need to be effectively computed [16], such as in tasks of entity resolution, fingerprint comparison or finding similar documents.

The algorithm takes data and computes a hash, which is a lower-dimensional representation of a given input. The result must preserve similarity, i.e. if words are similar then their hashes must be similar as well. In contrast to conventional hashing functions, LSH tries to maximize probability of a collision for similar items.

The main goal of incorporating LSH idea to approximate string matching is to significantly improve time performance. The LSH-based approach to this task consists of three phases:

1) Shingling (described above)
2) Min-Hashing – converts large sets to short signatures, while preserving similarity
3) Locality-Sensitive Hashing – places similar words into the same bucket

Firstly, an empty set C of shingles is created. During shingling of each word from the dictionary, shingles are added to collection C, so that after this step C is a sorted set of all shingles that occur in the shingled dictionary. Every trigram has a corresponding unique number (index of the shingle in C).

Secondly, we take the indices of a word shingles and store them in a vector. This vector representation is an input for Min-Hash algorithm, which calculates the signature. It should be noticed that different strategies can be used here [17]. We used the most popular version of Min-Hash algorithm.

Min-Hash internally creates occurrence matrix (of size #shingles $\times$ #words) filled with ones at positions where a given string contains a specific shingle. An example of such a matrix is shown in Table I. Then, rows of the matrix are permuted n times and at every permutation, for each word (each column) an index of the first row containing 1 is saved. In result, each word has a signature, which is a vector of these indices.

TABLE I
SAMPLE OCCURRENCE MATRIX

	the	those	these
$$t	1	1	1
$th	1	1	1
the	1	0	1
he$	1	0	0
e$$	1	0	0
tho	0	1	0
hos	0	1	0
ose	0	1	0
se$	0	1	1
e$$	0	1	1
hes	0	0	1
ese	0	0	1

In the third step, we partition these signatures into b bands. Every band is hashed, using locality sensitive hashing, into one of k buckets. In this case, hash function is of the form: $f: \mathbb{Z}^{\lfloor \frac{n}{b} \rfloor} \rightarrow \mathbb{Z}$

We chose $n = 100, b = 20$ and we want each bucket contains about one hundred hashes, so k must be $\frac{dict\_size}{100}$.

Candidate words are in buckets, which contain at least one hash from word typed by user. Then, a similarity between given hash and all hashes in bucket is calculated. If the similarity exceeds the threshold, a string associated with the hash is added to the result list.

The complexity of LSH searching is sub-linear, better than that of previous approaches, although worse than O(1). In contrast to previously described algorithms, LSH has a big disadvantage – it does not guarantee that all matching words are in the result set. Bigger dictionary can cause worse results [18].

IV. EXPERIMENTS

In our experiments, we measured processing time depending on various settings of the compared algorithms. In the case of LSH algorithm, we also measured the quality of obtained results in terms of recall and precision.

In every test, we randomly choose words from polish dictionary for games containing over 2,700,000 words, taking into account words with length less or equal to 15. The dictionary is available online [19].

The processing times were measured ten times. Averages of them are reported below.

A. The time of constructing the search structure

At the very beginning, we tested the time of building searching structures needed for algorithms and how it depends on the number of words in a dictionary. The time for Levenshtein and CPMerge algorithms are the same as in the case of AllScan, because data preparation process is exactly the same.

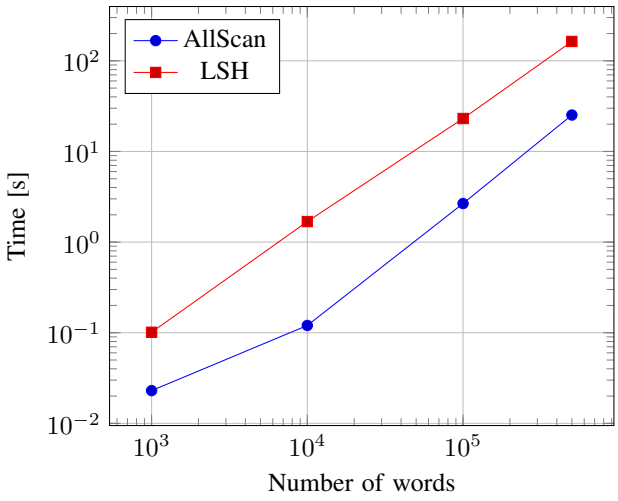

Fig. 1. Building time depending on the number of words

As we can see in Fig. 1, the time grows linearly in relation to the number of words with LSH having bigger coefficient.

B. Searching time

1) Dictionary size: The second test measured the search time of algorithms depending on the number of words in the dictionary. In this experiment we assumed the following values:

distance (allscan, cpmerge) = cosine
length of a given word ($|x|$) = 10
similarity threshold (α) = 0.7

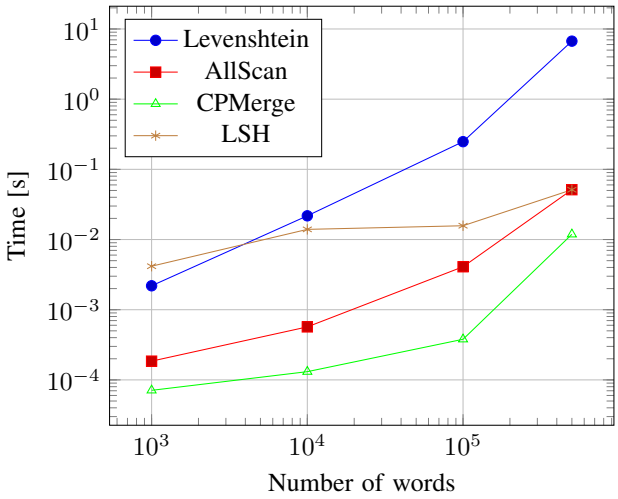

Fig. 2. Searching time depending on the number of words

Fig. 2 shows that the fastest algorithm is CPMerge. However, its search time grows squarely, what in comparison to LSH sub-linear growth allows us to state that LSH should be faster for big data.

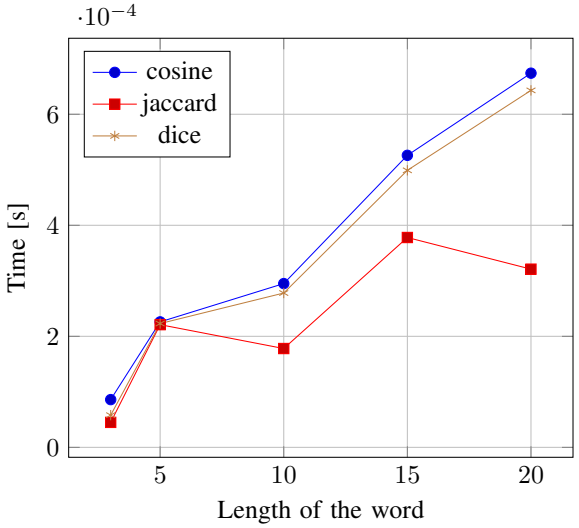

Fig. 3. Searching time depending on the length of a given word

2) Length of given words: To evaluate search time in the function of the length of given words we assumed the following values:

algorithm = cpmerge
number of words (V) = 100 000
similarity threshold (α) = 0.7

We measured the results for all three distance metrics.

Fig. 3 shows that processing time is the smallest for Jaccard distance, as the range of candidate words is the narrowest. All times grows linearly. Subtle deviations are caused by the number of candidate words changing stepwise in relation to word length.

3) Similarity threshold value: To evaluate search time depending on similarity threshold and distance metric we assumed:

searching algorithm = cpmerge
number of words (V) = 100 000
length of given words ($|x|$) = 15

As can be seen in Fig. 4, time falls in relation to similarity. This is because the number of candidate words is decreasing. The algorithm is the fastest for Jaccard distance due to the same reason as above, i.e. the smallest set of candidate words.

C. Number of words found

In this experiment we tested the impact of α similarity threshold on the number of returned similar strings. CPMerge algorithm had the following settings:

number of words ($|V|$) = 100 000
length of given words ($|x|$) = 10

Every given word had a typo in order to search for similar, but not identical, word.

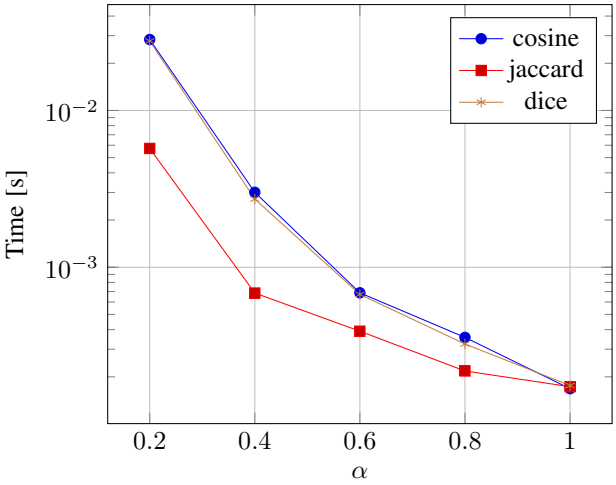

Fig. 4. Searching time depending on similarity threshold

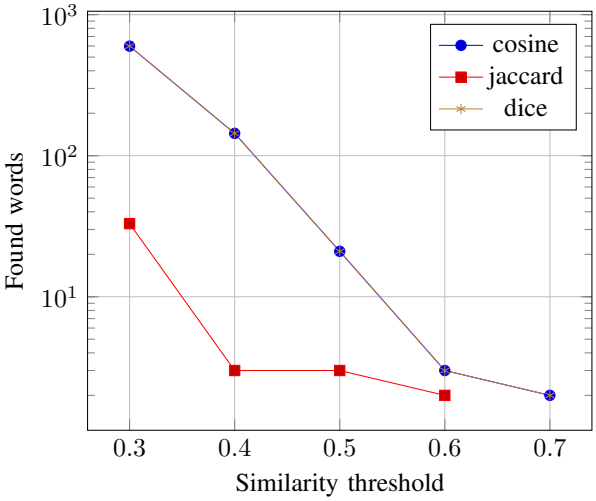

Fig. 5. Number of found word depending on similarity threshold

Fig. 5 shows that the number of found words falls exponentially in relation to assumed similarity threshold. As previously noticed, Jaccard distance returns the smallest set of candidates.

D. Recall and precision of LSH algorithm

We used the following measures for evaluating the quality of the approximate string matching of LSH algorithm: $recall = \frac{found\&relevant}{relevant}$ and $precision = \frac{found\&relevant}{found}$. Recall indicates what fraction of all matching words is returned in the result. Precision indicates what is the fraction of correct matches in the result set. In this task it is beneficial to maximize both recall and precision, therefore we also show their balanced harmonic mean, i.e. F-measure: $F_1 = \frac{2*P*R}{P+R}$.

1) Dictionary size impact: We assumed:
number of hash functions (n) = 100
number of bands (b) = 20
similarity threshold (α) = 0.7
number of buckets (k) = $\frac{number\_of\_words}{100}$

TABLE II
LSH RECALL AND PRECISION DEPENDING ON DICTIONARY SIZE

	100	1000	10000	100000
relevant	89	93	93	105
found	76	69	48	48
precision	1	1	1	1
recall	0.85	0.74	0.52	0.46

2) Similarity threshold impact: We assumed the following values:
number of words (V) = 100 000
number of hash functions (n) = 100
number of bands (b) = 20
number of buckets (k) = 1000

TABLE III
LSH RECALL AND PRECISION DEPENDING ON SIMILARITY THRESHOLD

	0.4	0.5	0.6	0.7
relevant	10911	1806	261	103
found	453	189	91	46
precision	1	1	1	1
recall	0.04	0.10	0.35	0.45

Table III shows that recall for low threshold is very low, which means LSH algorithm, in this configuration, is almost useless.

E. Wikipedia editors misspellings correction

In the following two tests we used a list of misspellings made by Wikipedia editors [20].

1) Comparison of algorithms: We set: number of words (V) = 1922
number of misspellings = 2455
similarity threshold (α) = 0.5
distance (cpmerge) = cosine
number of hash functions (lsh: n) = 100
number of bands (lsh: b) = 20
number of buckets (lsh: k) = 19

TABLE IV
COMPARED ALGORITHMS AT WIKI TYPOS CORRECTION TASK

	Levenshtein	AllScan & CPMerge	LSH
recall	0.89	0.89	0.74
precision	0.56	0.48	0.64
F-measure	0.69	0.63	0.69

Allscan results are the same like results of CPMerge algorithm, because they differ only in the processing time.

2) Similarity threshold impact on CPMerge: The setting were:

searching algorithm = CPMerge
distance (cpmerge) = cosine
number of words (V) = 1922
number of misspellings = 2455

TABLE V
CPMERGE AT WIKI TYPOS CORRECTION TASK DEPENDING ON SIMILARITY MEASURE

	0.2	0.3	0.4	0.5	0.6	0.7
recall	0.99	0.98	0.94	0.89	0.81	0.67
precision	0.03	0.12	0.29	0.48	0.64	0.63
F-measure	0.06	0.21	0.44	0.63	0.71	0.65

V. CONCLUSIONS

The most straightforward approach to approximate string matching is to incorporate some edit distance, like Levenshtein. Nevertheless, searching time of this method is the highest, because it has to browse the whole dictionary. $O(n)$ complexity disqualifies this approach for big dictionaries. AllScan and CPMerge reduces the size of the set of words to process, so they are faster than Levenshtein-based approach. However, their processing time still very much depends on dictionary size. All three methods have a significant advantage – they correctly (depending on similarity measure in use) return all words similar to a given string within assumed margins.

On the other hand, LSH provides results in acceptable time, but it degrades recall value. This is the main disadvantage of the algorithm, which causes that many similar words are not in the returned list.

We wish to have a solution, that is fast and that provides recall on very high level. To reach this goal we propose and test an initial solution that employs feed-forward neural network as indexer. The network takes a word as input and returns its index in the dictionary. With constant searching time, recall above 97% and high precision, this method can potentially beat all algorithms compared in this article in the task of approximate string matching. The idea extending the approach based on feedforward network is to use a denoising autoencoder. The approach based on on auto-associative network reconstructs its input given at the output layer through a bottleneck hidden layer, while the input additionally contains some noise, i.e. misspelled words in this case. In this approach, we would learn a network using one exact word and some words with typos and expect a correct word to be reconstructed.

***Abstract*—Pattern-based methods of IS-A relation extraction rely heavily on so called Hearst patterns. These are ways of expressing instance enumerations of a class in natural language. While these lexico-syntactic patterns prove quite useful, they may not capture all taxonomical relations expressed in text. Therefore in this paper we describe a novel method of IS-A relation extraction from patterns, which uses morpho-syntactical annotations along with grammatical case of noun phrases that constitute entities participating in IS-A relation. We also describe a method for increasing the number of extracted relations that we call *pseudo-subclass boosting* which has potential application in any pattern-based relation extraction method. Experiments were conducted on a corpus of about 0.5 billion web documents in Polish language.**

I. Introduction

RELATION extraction is a necessary step of any ontology induction or taxonomy induction task. Typically it takes as input morpho-syntactically annotated text and produces a set of triples (E_1, R, E_2), where E_1 and E_2 are entities and R is a relation in which E_1 and E_2 participate as a pair. In case of ontology induction or information extraction in open domain (as described, e.g., in [1], [2], [3], [4]) no restrictions are imposed on R. There are many types of relations that can be extracted this way, such as *quality*, *part* or *behavior* [5]. In case of taxonomy induction the main interest is in the IS-A (hyponym-hypernym) relation. Approaches to IS-A extraction described in literature rely on evidence from pattern extraction and statistical information (cf. [6], [7], [8]). In methods that are based solely on statistical information it is not uncommon to assume (cf. [7]), that relation extraction is performed only for a predefined list of concepts extracted earlier with a different method (e.g. [9]). Pattern-based methods rely heavily on so called Hearst patterns, first described in [10]. These are ways of expressing instance enumerations of a class in natural language. Typical forms are „c *such as* i1, i2 or i3" or „c, *for example* i1, i2 or i3". Terms extracted with such patterns may serve as input for elaborate taxonomy and ontology construction methods as, e.g., [11]. While these lexico-syntactic patterns prove quite useful, they may not capture all taxonomical relations expressed in text. Therefore in this paper we describe a novel method of IS-A relation extraction from patterns, which uses morpho-syntactical annotations along with grammatical case of noun phrases that constitute entities participating in IS-A relation. As it will be shown in the paper, the method allows for extraction of additional knowledge from text, that is often not expressed with Hearst patterns. The method is unsupervised, as it is based on hand-crafted patterns, dictionary filtering and manually adjusted support level. Precision of this method, understood as the ratio of correct extracted IS-A relations to all extracted relations is estimated using manual scoring of about 110 relations randomly selected from the method's output. Based on an internet corpus of documents, the method produces a big number of IS-A relations. Most of them (roughly 90%) occur only once in the corpus introducing a high level of noise. We show in conducted experiments that even for a slight increase of support (given as a number of occurrences), the estimated precision of this method increases strongly. We also describe a new method for increasing the number of extracted relations for any support level bigger than 1. The method is based on very simple heuristic for detection of hyponymy between class part of extracted relations, thus we call it *pseudo-subclass boosting* (*PSC* in short). It is worth mentioning that this boosting approach can be applied in any pattern-based relation extraction method. Experiments were conducted on a corpus of about 0.5 billion web documents in Polish language crawled in NEKST project (http://www.nekst.pl) and maintained up to date. These include primarily HTML documents, but also other formats found on websites like PDFs and DOCs. In order to process such high volume of data it was implemented using MapReduce framework [12] implemented in Apache Hadoop project (http://hadoop.apache.org) and Hive (http://hive.apache.org). All examples mentioned in the article are real data, taken from working instance of NEKST system.

II. Our approach

It is known that languages that have inflection and free word order are much harder for automatic analysis[1] than, e.g., English. As pointed out in [14, pp. 100], free word order implies non-projective grammar. It is shown in [15] and [16] that dependency parsing for non-projective grammars is NP-hard, apart from a very narrow subclass called edge-factored grammars. This challenge is addressed, among others, by transition-based dependency parsing [17] used in the pre-processing step for the algorithm described in this paper. We argue that inflection in a language is not only a drawback but

The study is cofounded by the European Union from resources of the European Social Fund. Project PO KL „Information technologies: Research and their interdisciplinary applications", Agreement UDA-POKL.04.01.01-00-051/10-00.

[1]See e.g. [13] for problems with relation mining in German, in which the word order is much less free than in Polish; note that they use an initial lexicon while we do start from scratch when extracting relations.

TABLE I. SUFFIXES IN INSTRUMENTAL CASE FOR POLISH

	masculine	neuter	feminine
singular	-em		-ą
plural	-ami (-mi)		

can also be a great advantage. Typical constructs that express the hypernymy relation explicitly in Polish language are:

$$NP_1^{Nom} \text{ to } NP_2^{Nom}, \tag{1}$$

$$NP_1^{Nom} \text{ jest } NP_2^{Abl}. \tag{2}$$

Both of them are a way of saying NP_1 *is* NP_2 and in both cases noun phrase NP_1 is expressed in nominative. They differ in grammatical case of NP_2, where in the first construct we have nominative and in the second: instrumental. The second pattern has its equivalent for past tense:

$$NP_1^{Nom} \text{ był/była/było } NP_2^{Abl}. \tag{3}$$

Obviously in case of past tense construction it is possible that IS-A relation no longer holds[2]. The problem exists to a lesser extent also in present tense, which for example can be a consequence of outdated web documents. Assessment of correctness with respect to a given point in time is, in our opinion, a research direction of its own, thus it is out of scope of this paper.

As will be shown later, combination of word and grammatical case pattern allows for relation extraction with quite high precision. It is possible partially thanks to the fact that instrumental case in Polish language is *regular* for nouns and has unique suffixes shown in Table I (after [18, pp. 145, 148]). This makes automatic analysis of sentence tokens easy for this case.

We propose a rule-based approach for IS-A relation extraction with the following procedure:

- run each sentence in corpus through POS-tagger and dependency parser,
- select dependency trees with promising structure,
- apply dictionary filtering for the head of NP_2,
- apply a set of construction rules to dependency tree in order to build instance name out of NP_1 and class name out of NP_2,
- apply a set of filtering rules.

This method is additionally extended with a technique that we call *pseudo-subclass boosting* which increases the number of extracted relations.

It is worth noting that *automatic* detection of IS-A patterns is possible. Experiments described in [19] show that handcrafted ontologies like WordNet can be used successfully as a training set for such pattern discovery task. However, our problem setting differs from that research significantly. Apart from the already mentioned inflection challenge and free word order language, our corpus consists of about 11 billion sentences, which is four orders of magnitude more than the Reuters corpus used in [19] and imposes efficiency limitations. On the other hand, the gain in size comes at the price of quality – Internet documents tend to have much more noisy content than printed journal articles. We have no knowledge of any research on IS-A patterns detection in similar setting (that is web-scale), which leads us to first tackle a more realistic problem of extracting IS-A relations with *known* patterns. Nevertheless, this is a task worth trying given experience gained from research reported here.

[2]The relation was valid in the past only

A. POS tagging and dependency parsing

For part-of-speech tagging we use the Apache OpenNLP (http://opennlp.apache.org) tagger trained with Maximum Entropy classifier on NKJP [20] corpus. Additionally, for known words, we optimized the tag disambiguation process by narrowing tags that can be chosen by information taken from the PoliMorf dictionary [21]. For Polish language, whose tagset contains around 1000 tags [22], this simple optimization gives an improvement of tagging in terms of accuracy and processing speed at the same time. To give an example, the word *artykułów* (inflected form of the word *article*) has only two possible tags `subst:pl:gen:m3` and `subst:pl:gen:p3`. Using this knowledge in OpenNLP tagger reduces search space for this word 500 times. Dependency parsing is based on MaltParser framework [23] trained on Polish Dependency Bank that consists of 8030 sentences [24]. To obtain high processing speed (essential for such large volume of text data) the liblinear classification model has been used.

B. Promising dependency tree structure selection

By *promising* structure of a dependency tree we mean one that matches any of the patterns depicted in Figures 1, 2 and 3, where **form**, **dep** and **pos** mean: token form, dependency relation type (as described in [24]) and part-of-speech tag (as described in [20]) respectively.

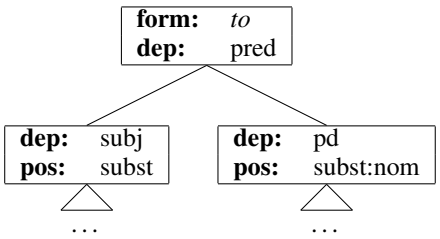

Figure 1. Dependency tree structure for construct (1)

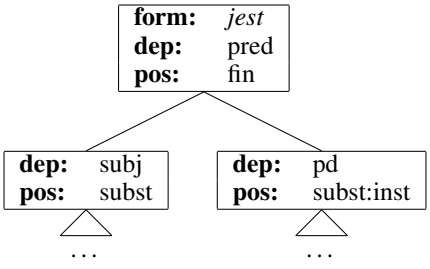

Figure 2. Dependency tree structure for construct (2)

In both nominative and instrumental case, the base structure has a predicate word with outgoing dependency arcs to

two other words with subjective and predicative complement relation type. The difference between structure 1, 2 and 3 is in the grammatical case of the predicative complement and part of speech of the predicate. Our intuition is that selected structures are natural sources of IS-A relation. This claim is supported by the estimated precision obtained in conducted experiments.

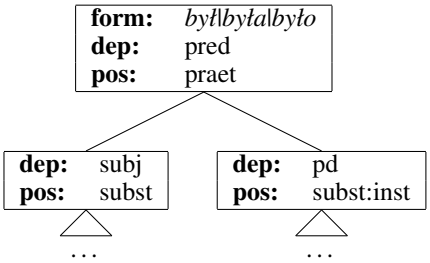

Figure 3. Dependency tree structure for construct (3)

Figure 4 illustrates an example of sentence that matches pattern 2, parsed with our dependency parser and printed in CoNLL [25] format. It is worth noting that in this case the part-of-speech tagger made an error in assigning a case to the adjective *myśliwski* (hunting), where instrumental instead of locative should appear. This may happen because singular masculine adjective suffixes for instrumental (as noted in [18, p. 160]) are not unique as with nouns. That's why in our analysis we focus only on the grammatical case of the head of noun phrase and assume the same case for its dependent adjective tokens. This assumption is justified by the fact, that for Polish language agreement exists between noun and adjective in a noun phrase [26, p. 174]. POS tag in the example is repeated twice because CoNLL format specifies CPOSTAG and POSTAG allowing for coarse-grained and fine-grained part-of-speech tagsets which are the same for Polish language. The following steps illustrate how pattern 2 applies to the example sentence from figure 4:

- find a root word of the sentence (*jest* in our case), and check its dependency relation (must be *pred*) and a POS tag (must be *fin*),
- if the root word has two descendants, then test if:
  - its left descendant (*golden*) has correct dependency relation (must be *subj*) and a POS tag (must be *subst*),
  - its right descendant (*pies*) has correct dependency relation (must be *pd*) and a POS tag (must be *subst:inst*),
- if all requirements are fulfilled, the sentence is moved to the phase of dictionary filtering (section II-C) and instance and class name construction (section II-D).

Given a sentence whose dependency tree matches one of above-mentioned patterns, we construct NP_1 from its left sub-tree and NP_2 from its right sub-tree. Head (or root) of left and right sub-tree will be denoted N_1^H and N_2^H respectively.

C. Dictionary filtering for the head of NP_2

Preliminary experiments showed that many of sentences matching constructs (1) and (2) contain very general, ambiguous nouns in NP_2 like *problem*, *aspect*, *element* or *outcome*. Those nouns cannot be considered proper classes in the sense of IS-A relation, rather they are catch-all phrases used to express various thoughts about what is contained in NP_1.

We eliminated those nouns by manually evaluating a random sample of about 1000 experiment results and creating a dictionary of such meaningless „classes". In this step of our extraction procedure we filter extractions with this dictionary. This process was repeated in three iterations. Size of the dictionary started with 95 catch-all phrases increased by 50, and 20 reaching the level of about 170.

D. Construction rules for NP_1 and NP_2

We construct both instance name (from NP_1) and class name (from NP_2) out of lemmatized tokens. The first step is to serialize tokens present in both dependency sub-trees with operators *leftOffspring* and *rightOffspring*, which operate as follows:

1) put all nodes of dependency sub-tree in a list L,
2) sort L by CoNLL token id descending (for *leftOffspring* operator)/ascending (for *rightOffspring* operator),
3) find index i_H of sub-tree head in L,
4) create sub-list L' from i_H to the first occurrence of interpunction or end of L,
5) in case of *leftOffspring*: sort L' by CoNLL token id ascending,
6) concatenate lemmas of tokens in L' and return.

Computational complexity of this algorithm is $O(n)$, where n is the sentence length. Actual sorting of tokens in case of steps 2. and 5. is not necessary and was introduced to simplify the description[3]. Boundaries detection of instance name is quite simple because it is typically directly defined by left sub-tree of all considered dependency structures (Figures 1, 2 and 3). Therefore it is constructed as concatenation:

$$leftOffspring(N_1^H) + N_1^H + rightOffspring(N_1^H)$$

Creation of class name is more complicated as it is often preceded by degrees of comparison and followed by the rest of the sentence which may be loosely coupled with the class itself. Consider the following sentences:

> Trójmorski Wierch jest jedyną polską górą, z której spływają wody aż do trzech mórz.

(*Trójmorski Wierch is the only Polish mountain, from which waters flow to as many as three seas.*)

> Korona norweska to waluta oznaczana międzynarodowym kodem – NOK.

(*Norwegian krone is a currency marked with the international code – NOK.*)

In the first example, the word *jedyną* (the only) cannot be considered as part of class name. Likewise, anything that comes after word *waluta* (currency) in the second example is merely a description of Norwegian krone, not part of a class name. To address such issues construction rules for class name simply omit the output of *leftOffspring* operator and truncate

[3]It unifies the procedure for left and right part of the sentence.

1	Golden	golden	subst	subst	sg:nom:m3	3	subj
2	retriever	retriever	subst	subst	sg:nom:m2	1	app
3	jest	być	fin	fin	sg:ter:imperf	0	pred
4	psem	pies	subst	subst	sg:inst:m2	3	pd
5	myśliwskim	myśliwski	adj	adj	sg:loc:m3:pos	4	adjunct
6	.	.	interp	interp	_	3	punct

Figure 4. Tree pattern match example in CoNLL format for the Polish sentence "Golden retriever jest psem myśliwskim" (*Golden retriever is a hunting dog*). Note that the parser did not produce fully correct dependency tree (e.g. "Golden" is tagged as noun and linked directly with "jest"). This does not affect our extraction process.

rightOffspring output: it is iterated from left to right only as long as the tokens have POS tag from set {adj, subst, ger} *and* dependency type from set {adjunct, app, conjunct, obj}. So the class name results from concatenating:

$$N_2^H + truncate(rightOffspring(N_2^H))$$

This forces extraction of shorter phrases, which increases the probability of observing a given instance-class pair more than once. As we show in section III, this highly influences the precision of the method. Extraction results for above examples are: *Trójmorski Wierch* `IS-A` *góra* [*Trójmorski Wierch IS-A mountain*] and *Korona norweska* `IS-A` *waluta* [*Norvegian crown IS-A currency*], while from such sentence:

> Narodowy Bank Belgijski jest bankiem centralnym od 1850 roku.[4]

we acquire *Narodowy Bank Belgijski* `IS-A` *bank centralny* [*Belgian National Bank IS-A central bank*].

E. Final filtering rules

It is common that NP_1 contains reference to earlier parts of text. Two types of such reference can be distinguished:

1) explicit:
   > Ten wikipedysta jest numizmatykiem.[5]
2) implicit:
   > Pisarka jest członkiem Związku Pisarzy Białorusi.[6]

In both cases NP_1 typically contains a class of referenced entity, not the entity itself which leads to erroneous extractions. As long as this reference is explicit, we filter such cases with a dictionary of referencing words (pronouns and textual references like *above-mentioned*). The case where reference is implicit is much harder, and at this point left for further research, as described later in section VI.

F. Pseudo-subclass (PSC) boosting

Our experiments showed that the number of extracted relations drops significantly with increase of support level t. To compensate this loss we designed a boosting method that is based on the following intuition: if *I* `IS-A` *C* and *I* `IS-A` *C'* are extracted relations and *C* is a substring of *C'*, then there is high chance that *C'* is a way of describing *I* more precisely than *C*, i.e., *C'* is a pseudo-subclass of *C*. If so, we can boost our confidence in the fact that *I* `IS-A` *C* is properly extracted. To give an example:

> Kraków to najchętniej odwiedzane miasto przez turystów w Polsce. Kraków – dawna stolica Polaków jest miastem magicznym.[7]

Above two sentences allow for boosting confidence in extraction *Kraków* IS-A *miasto* (*Cracow* IS-A *city*). From the first sentence we get the relation *Kraków* IS-A *miasto* and from the second *Kraków* IS-A *miasto magiczne* (*Cracow* IS-A *magic city*). As "miasto magiczne" is a superstring of "miasto", the second sentence supports the first extracted relation. In general, to detect class/pseudo-subclass matches for each extraction *R* = *I* `IS-A` *C* we generate a list *L* of

- prefix lists of tokens from *C*,
- suffix lists of tokens from *C* that don't include leading adjectives.

In Map phase of MapReduce job, we emit the pair *(I, C)* with *R*'s occurrence count and pairs *(I, c)* (with the same count) for each $c \in L$. Reduce phase aggregates our data by matched pairs and here we acquire knowledge about pseudo-subclasses' occurrence count and type of constructs they were discovered in. Figure 5 illustrates a more elaborate case of pseudo-subclass boosting. Each numbered row represents a relation *mukowiscydoza* IS-A ... extracted from text. Row 13 is an example of suffix list boosting with *wieloukładowa* being an adjective removed at the stage of creating list *L*. Rows 2-12 boost relation *mukowiscydoza* IS-A *choroba*, additionally rows 4-7 boost *mukowiscydoza* IS-A *choroba genetyczna*, etc.

III. Experiments

Experiments were conducted on a corpus of about 0.5 billion web documents in Polish language with roughly 11 billion sentences. Tables II, III and V present the results of passing the entire collection through the algorithm described in section II.

Method evaluation was conducted for four levels of the value of t, which, as earlier described, is the minimal IS-A relation occurrence count acceptance threshold. Precision evaluation was based on manual scoring of about 110 randomly selected relations from given experiment's results. Estimated precision was calculated by the formula 4.

$$\hat{Pr} = \frac{TP}{TP + FP} \tag{4}$$

Figure 5. Tree representation of pseudo-subclass boosting.

where TP is the number of relations scored as correct and FP is the number of relations scored as erroneous. Note that we cannot compute other traditional measures as accuracy, recall or F-measure. This is due to the fact, that in Open Relation Extraction setting the number of false negatives (relations incorrectly left out in the extraction process) is not known.

Tables II, III and IV show results of these experiments. Column *nom* contains number of unique IS-A relations extracted only from nominative construct, *inst* is the number of unique relations only from instrumental constructs, *nom∩inst* refers to count of relations extracted from nominatives and instrumentals. Table III refers to the number of relations that were additionally accepted only thanks to pseudo-subclass boosting which helped to observe a given relation more than t times or with both grammar cases.

Total number of extracted IS-A relations, for either nominative or instrumental construction, is slightly above 4 milion (table II). Increase of support level results in drop of accepted relations (up to 1 order of magnitude between consecutive levels). Final count of relations (for $t = 4$) does not exceed 90000, which is almost 2 orders of magnitude lower than the total.

Pseudo-subclass boosting method allows to extract around 86000 more relations at support level 2. Nominal number of additional relations decreases for higher support levels, but increases in terms of relative gain (as shown in the last column of table III).

Estimated precision of our method is 61% at the lowest support level, and achieves 87% for level 4 (table IV). Increasing the number of accepted relations with pseudo-subclass boosting comes at the cost of lower estimated precision. At support level 2 this loss is 1%, but for 3 and 4 jumps to several percent. Estimated precision of our method, equipped with pseudo-subclass boosting, increases with the increase of t, saturating at the level of about 80%. Table IV contains also estimated precision of our implementation of Hearst patterns which is substantially lower (from 14% to 29%).

Experiments were performed on a cluster of 70 machines with total of 980 CPU cores and 4.375TB of RAM. Total processing time of raw web documents: lemmatization, POS tagging, dependency parsing and IS-A relation extraction was under 24 hours.

IV. Relation to Hearst patterns

In order to compare our method with the most popular approach, we implemented Hearst patterns extraction algorithm as follows:

- Detect enumeration phrase R (one of „*taki jak*", „*taki jak na przykład*", „*taki jak np.*" which are special cases of phrase "*such as*" in English) in a sentence, based on lexical constructions proposed in [10].
- Check if words from R to the end of the sentence form a comma separated list of phrases (with the last element optionally separated by conjunction: „*i*" or „*oraz*"). The list is assumed to represent instances of a class.
- Detect the class name in words left to R with a Conditional Random Field model [27]. Words in this part of sentence are labeled with either „1" or „0". The sequence of „1" nearest to R is assumed to represent the class. The model was trained on manually annotated set of around 600 sentences. Its precision calculated on 10-fold cross validation is 93.89%.

Table V shows the number of extracted Hearst patterns and overlap between this method and our approach (percentage

TABLE II. NUMBER OF EXTRACTED RELATIONS FOR DIFFERENT VALUES OF MANUALLY ADJUSTED ACCEPTANCE SUPPORT LEVELS t. NUMBER OF RELATIONS EXTRACTED ARE GIVEN IN COLUMNS: "**NOM**" FOR NOMINATIVE CONSTRUCT AND "**INST**" FOR INSTRUMENTAL CONSTRUCTS. COLUMN "**NOM∩INST**" CONTAINS THE NUMBER OF RELATIONS EXTRACTED WITH BOTH NOMINATIVE AND INSTRUMENTAL CONSTRUCTS.

	nom	**inst**	**nom∩inst**	**total**
$t = 1$	1647500	2380021	39865	4027521
$t = 2$	138877	264764	9895	403641
$t = 3$	52430	100320	4938	152750
$t = 4$	29210	55232	3154	84442

TABLE III. NUMBER OF ADDITIONAL RELATIONS EXTRACTED THANKS TO PSEUDO-SUBCLASS BOOSTING (FOR DIFFERENT VALUES OF SUPPORT LEVEL t). COLUMN "**NOM**" CONTAINS RESULTS FOR NOMINATIVE CONSTRUCT AND "**INST**" FOR INSTRUMENTAL CONSTRUCTS. COLUMN "**NOM∩INST**" CONTAINS THE NUMBER OF ADDITIONAL RELATIONS EXTRACTED WITH BOTH NOMINATIVE AND INSTRUMENTAL CONSTRUCTS.

	nom	**inst**	**nom∩inst**	**total**	**PSC gain**
$t = 1$	0	0	0	0	0%
$t = 2$	24335	61244	2931	85579	21.20%
$t = 3$	13122	38004	2116	51126	33.47%
$t = 4$	8726	26702	1521	35428	41.95%

TABLE IV. ESTIMATED PRECISION ($\hat{Pr}$ – SEE EQUATION 4) OF EXTRACTION FOR DIFFERENT ACCEPTANCE SUPPORT LEVELS. "PSC" STANDS FOR PSEUDO-SUBCLASS BOOSTING. OUR APPROACH IS MARKED WITH "**NOM∩INST**", WHILE "**HRST**" STANDS FOR HEARST PATTERNS.

t	**nom+inst** (no PSC)	**nom+inst** (with PSC)	**hrst**
1	0.61	0.61	0.47
2	0.71	0.72	0.56
3	0.87	0.79	0.58
4	0.87	0.81	0.62

values in brackets are calculated relative to the number of Hearst patterns-based extractions). The overlap varies from 0.57% to 1.02% for nominative scheme and from 1.19% to 2.65% for instrumental. Relations detected in all three methods constitute from 0.25% to 0.58% of relations extracted with the basic method. This suggests that our method allows for extraction of new relations, not expressed in language constructs described by Hearst, with even higher precision.

V. DISCUSSION

Experiments lead to interesting conclusions. Firstly, there is little intersection between IS-A relations extracted by the three methods: Hearst traditional method and our methods, one based on nominative, the other based on instrumental case. The IS-A relation space seems too sparse for such methods to produce overlapping results. Nominative construction produces less relations than instrumental, which presumably is a consequence of the fact that this construct is only applicable for present tense. Decrease in total extractions count is much bigger going from support level 1 to 2 (9.98 times) than when in other cases ($2 \rightarrow 3$: ~2.64 times, $3 \rightarrow 4$: ~1.81 times). It can be connected to the natural model of language, where distribution of word frequencies has power law probability distribution [28]. There is a lot of particular, domain specific taxonomical information that is infrequent in textual resources accessible on the Internet. On the other hand more common knowledge that can be found multiple times in text is substantially less frequent.

Of course pseudo-subclasses don't give any boost when $t = 1$ and do not affect precision, because we simply accept everything that passes the final filtering rules. In other cases PSC increases the number of extractions significantly (the higher t the better), although not as much as to eliminate the effect of increased t. This boosting method is very beneficial for support level 2 as it increases extractions count by 23% with no observable loss in precision (see Table IV). For $t = 3$ and $t = 4$ the gain in extractions count comes at the price of significantly lower precision.

Analysis of false-positive extractions reveal several types of errors made by this method:

1) Implicit reference – which leads to errors like
   - *autor* `IS-A` *dyrektor jednostki* (*author* `IS-A` *director of the unit*),
   - *sobota* `IS-A` *dzień koncertu głównego* (*Saturday* `IS-A` *main concert day*).
2) Wrong decision about phrase begin/ending point[8]:
   - *trening funkcjonalny* `IS-A` *rodzaj (. . . czego?)* (*functional training* `IS-A` *kind (. . . of what?)*),
   - ~~*zdecydowana większość*~~ *kandydatów do Parlamentu* `IS-A` *członek określonej partii politycznej* (~~vast majority of~~ *candidates to Parliament* `IS-A` *member of a particular political party*).
3) Ever growing dictionary mentioned in section II-C. After each iteration of catch-all phrases eliminations new such phrases emerge in result samples. Above-mentioned experiments revealed such false-positive classes as: *result*, *an essential element* and *something amazing*. The number of such phrases decreased in each dictionary-construction iteration, which allows us to assume that this set is relatively small. Nonetheless, we are aware that manual construction of this set doesn't take evolution of the language's vocabulary into account.

VI. FUTURE WORK

Plans for future development include dealing with issues detected in above-mentioned experiments. The problem of detecting implicit references to earlier parts of text is known in natural language processing as coreference resolution and

[8]Missing parts are added in brackets, unwanted parts are striked out.

TABLE V. NUMBER OF RELATIONS EXTRACTED WITH HEARST PATTERNS FOR DIFFERENT VALUES OF MANUALLY ADJUSTED ACCEPTANCE SUPPORT LEVELS t.

	hrst	**nom∩hrst**	**inst∩hrst**	**nom∩inst∩hrst**
$t = 1$	4007927	23044 (0.57%)	47953 (1.19%)	10222 (0.25%)
$t = 2$	781419	6492 (0.83%)	15567 (1.99%)	3434 (0.44%)
$t = 3$	356873	3488 (0.98%)	8728 (2.45%)	1899 (0.53%)
$t = 4$	224200	2295 (1.02%)	5939 (2.65%)	1298 (0.58%)

constitutes an independent field of research as described in [29, p. 614] or specifically for Polish: [30]. It is planned to adapt selected coreference resolution methods to our BigData environment and verify their effectiveness in increasing precision of our extraction method.

We plan to achieve better detection of phrase begin/ending points by replacing construction rules described in section II-D with Conditional Random Field classifier trained on sentences scored in our experiment with manually annotated proper phrase boundaries. Creating of such golden standard set of sentences with IS-A relations is of course more time consuming than the approach proposed in this paper. In case of Hearst patterns it turned out to be a necessity. Sentences with Hearst-like enumerations contain more complicated dependency structures which are harder to parse correctly.

Better catch-all phrases elimination can be done as a post-processing step. Membership in these classes should be uniformly distributed over instances and subclasses in the taxonomy, so there should be no significant correlation between membership in these classes and proper classes. Filtering methods based on such correlation will be investigated.

Taking into account the number of filtered out IS-A relations (starting from support level 2) it is worthwhile to consider development of other ways of assessing their correctness. The support level criterion (frequency based) effectively increases quality of extracted information, but at the same time significantly reduces its quantity. It would be interesting to choose one of the most popular classification methods (ea. Support Vector Machine or Random Forest classifier) and check its ability to learn a more sophisticated filtering criterion of incorrect IS-A relations. The feature space for this classification problem could be much richer than simple information about occurrence frequency. One can use more sophisticated characteristics of IS-A relation like for example: size of class and instance phrase (count in number of words), type of sources (nominative, instrumental), popularity of instance and class phrase independently (expressed in number of occurrences among all extracted IS-A relations).

It would be also interesting to compare precision of Hearst patterns implemented with pseudo-subclass boosting.

VII. CONCLUSIONS

This paper presents a novel method of IS-A relation extraction from patterns for Polish that is different from so popular Hearst patterns and is applicable in inflected languages with free word order. Thanks to this method we were able to extract knowledge that may not be expressed in enumeration constructs defined by Hearst. Additionally, a method for boosting relation extractions count is introduced. As mentioned at the beginning, thanks to its simplicity it has potential application in any pattern-based IS-A relation extraction method. As experiments showed, the algorithm achieves satisfactory precision [9] (although there is still room for improvement) and is capable of generating high number of taxonomical relations. This makes it a valuable input source of data for any taxonomy induction task.

It is needless to say that experiments described in this paper do not provide a full statistical overview of millions of IS-A relations extracted from the corpus of Polish Internet documents. We focus on an assessment of precision of the proposed IS-A relation extraction method. In-depth statistical analysis of such a dataset is desirable and remains as a task to be accomplished in the next publication devoted to the research path outlined in the previous section.

9th International Workshop on Computational Optimization

MANY real world problems arising in engineering, economics, medicine and other domains can be formulated as optimization tasks. These problems are frequently characterized by non-convex, non-differentiable, discontinuous, noisy or dynamic objective functions and constraints which ask for adequate computational methods.

The aim of this workshop is to stimulate the communication between researchers working on different fields of optimization and practitioners who need reliable and efficient computational optimization methods.

TOPICS

The list of topics includes, but is not limited to:

- unconstrained and constrained optimization
- combinatorial optimization
- continues optimization
- global optimization
- multiobjective optimization
- optimization in dynamic and/or noisy environments
- large scale optimization
- parallel and distributed approaches in optimization
- random search algorithms, simulated annealing, tabu search and other derivative free optimization methods
- nature inspired optimization methods (evolutionary algorithms, ant colony optimization, particle swarm optimization, immune artificial systems etc)
- hybrid optimization algorithms involving natural computing techniques and other global and local optimization methods
- computational biology and optimization
- distance geometry and applications
- optimization methods for learning processes and data mining
- application of optimization methods on real life and industrial problems
- computational optimization methods in statistics, econometrics, finance, physics, chemistry, biology, medicine, engineering etc.

Computational Optimizations in wildland fires for Bulgarian test cases

Nina Dobrinkova
Institute of Information and Communication Technologies – Bulgarian Academy of Sciences, acad. Georgi Bonchev bl. 2, Bulgaria, Email: ninabox2002@gmail.com

***Abstract*—In this article we are going to present the optimizations that has been done through different types of modeling actions on wildland fires for Bulgarian test cases. We will present approaches where meteorological data along with terrain specific relief and vegetation coverage are modeled in a way to present credible scenarios for wildland propagation used for calibration purposes of the different approaches. This work aims to prove that the used modeling tools can be used also in real time decision support for the responsible authorities when it comes to wildland fire propagation and the measures corresponding to limitation of its devastating consequences for the nature and human lives.**

I. Introduction

THE work presented in this paper is a year's long efforts which has been started because of an accident, that happened in Pirin Mountain near by the city of Razlok. In the year 2003 a helicopter with water tank flew very low trying to depress the rapidly burning wildland fire in the mountain. Unfortunately the engine oxygen has been vacuumed because of the flames, which caused helicopter's crash with four people crew dead [1]. This accident was very problematic for the Bulgarian society. That is why in the Bulgarian scientific community has been launched in the beginning of 2007 a pilot PhD program dedicated to the wildland propagation and its modeling opportunities as first attempts for computer based simulations on wildland propagations in Bulgaria.

In 2007 small team from Bulgarian Academy of Sciences (BAS) started adaptation of a US model, which was running in parallel mode. The model was called WRF-Fire (in 2010 renamed SFIRE). The input data for the model was needed to be first collected for specific test area and second preprocessed for model calibration.

The area of interest for the BAS team was first nearby Sofia, where idealized case has been run and second for real case calibration – test area near by the village of Leshnikovo, region of Harmanli has been chosen.

In this paper we will show the basis of the mathematical calculations and optimizations outlined from the research efforts and the achieved results.

This work has been supported by the Bulgarian Academy of Sciences Program for support of young researchers No: ДФНП-95-А1 and by the National Science Fund of the Bulgarian Ministry of Education, Youth and Science under Grant FNI I02/20.

II. WRF-Fire (SFIRE) mathematical basis

The mathematical background of the WRF-Fire model (SFIRE) is as position in the (x, y) plane. The model is semi-empirical and it represents the spread of the fire in direction of the fire line. This is the so called Rothermel modified formula. The burning region is represented as Ω for time t, which is represented with the point coordinates (x, y). The formula itself is:

$$\widetilde{S} = \min\{B_0, R_0 + \phi_w + \phi_s\}, \quad (1)$$

where B_0 is the fire spread against the wind direction, R_0 is the fire spread in absence of wind, $\phi_w = a\,(\vec{v}\cdot\vec{n})^b$ is the wind correction and $\phi_s = d\nabla z\cdot\vec{n}$ is the terrain correction, $\vec{v}$ is wind, ∇z is terrain variable along the normal $\vec{n}$ of the fire line, *a*, *b* и *d* are constants. In this case WRF-Fire use:

$$S = \begin{cases} 0, \text{ако } \tilde{S} < 0 \\ S_{max}, \text{ако } \tilde{S} > S_{max} \\ \tilde{S}, \text{ако } 0 \le \tilde{S} \le S_{max} \end{cases}, \quad (2)$$

where S_{max} is max fire spread. After the burning materials are burnt the model decrease them in the points (x, y) exponentially and that is represented with the formula:

$$F(x, y, t) = F_0(x, y)e^{-(t-t_i(x,y))/W(x,y)}, \quad (3)$$

where *t* is the time, t_i is the time for the burning, F_0 is the initial quantity of the burning materials (before they started to burn) and *W(x,y)*does not depend on the time, but from the burning materials. The heat transfer released by the fire, is represented in the atmosphere model as layer above the surface, which is situated in height [3]. The burning material quantity is represented by:

$$\Phi = -A(x, y)\frac{\partial}{\partial t}F(x, y, t). \quad (4)$$

This representation is needed because the atmosphere model WRF, does not support border values for heat transfer. The coefficients B_0, R_0, S_{max}, a, b, d, W and A, which describe the burning materials are measured in laboratory with experiments. For every surface point in the plane the coefficients of the burning materials are represented using the 13 Anderson categories [4]. These categories are developed for US originally and they have been defined by usage of the different sea levels on the surface. WRF-Fire has internally representation of every category and all additional characteristics, which gives opportunity for modifications when the fire is outside US.

WRF-Fire use also level-set functions for the spread of the fire [5]. This approach set as function $\psi = \psi(x, y, t)$, which define for Ω subregions using the rule:

$$\Omega(t) = \{(x, y) \in \Omega : \psi(x, y, t) < 0\}. \quad (5)$$

These subregions are burned and the fire line is defined as curve:

$$\Gamma(t) = \{(x, y) \in \Omega : \psi(x, y, t) = 0\}. \quad (6)$$

The function $\psi(x, y, t)$ satisfy the equation:

$$\frac{\partial \psi}{\partial t} + S(x, y) |\nabla \psi| = 0, \quad (7)$$

which can be solved numerically.

Formulas (1) - (7) are general description how mathematically the fire spread is represented inside the WRF-Fire (SFIRE) model. In the beginning the atmosphere model is interpolating the wind in order to get into the bigger domain of the atmosphere the fire changes. Afterwards is applied numerical method for the level-set function. The next step is to apply quadratic formulas for evaluation of the burnt material. In parallel it is evaluated also the released heat transfer into the atmosphere layers. The last step gives atmospheric change and that trigger the repetition of the model starts again.

III. Experimental results with WRF-Fire (SFire)

The experimental results which were obtained after evaluation of the WRF-Fire (SFIRE) model will be presented in this section as a brief summary where we will try to make as much as possible the use of the achieved results.

The first runs with the model were on ideal cases in order to see how the model correspond with the meteorological data and terrain data for the selected zone in south Bulgaria. The run used as inputs coordinates and information for village Leshnikovo, were the domain was set of size 4 by 4 km, with horizontal resolution of 50 m, for the atmosphere mesh, we used 80 by 80 grid cells and with 41 vertical levels from ground surface up to 100hPa. We didn't use nesting to keep the ideal case as basic as possible in order to evaluate the model capacity.

The domain, which we set was located 4 km west from village Zheleznitsa in the south-east part of Sofia district. The domain was covering the lower part of the forest part of Vitosha mountain.

The ignition line which we used was set in the center of the domain and to ignite it we set 345 m long line. The model does not consider ignition from point, because the atmospheric model does not cover such measurements. The ignition in parallel has been set to start 2 seconds after the simulation has begun. The results from this first simulation gave us idea how the model can be initialized and what the input data will be if we start simulation with real case forest fire for calibration of the model.

That is why we selected from the national data base in the ministry of forests, food and agriculture fire which has been burning in the period 14-17 August 2009.

For the initialization of the model with real case we had to use algorithm for implementation of the real data in a way WRF-Fire (SFIRE) to recognize it. We set two domains the first was covering area of 48 km^2 with resolution 300m (160x160). This domain was producing boundary and initial meteorological conditions for the inner domain and in this domain there were no fire simulations.

The inner domain was located in the middle of the coarse domain. The resolution in Domain 2 we set as 60m and the area covered is 9.6 km^2 (161x161). Domain 2 was centred on the fire ignition line and it was covering the areas of villages Ivanovo, Leshnikovo and Cherna Mogila. This area was located in South-East Bulgaria close to the Bulgarian-Greece border.

Following the description in [6] we get the intermediate fails for topography and fuel. The only difference is in the geogrid program, where the output fail has 2 extra varaibles – NFUEL_CAT and ZSF. NFUEL_CAT is the variable containing the data for the 13th categories of fuel available to bur and ZSF is the variable containing data for the detailed topography. The result as burnt simulated area compared to the real burnt area can be seen on the figures 1 and 2.

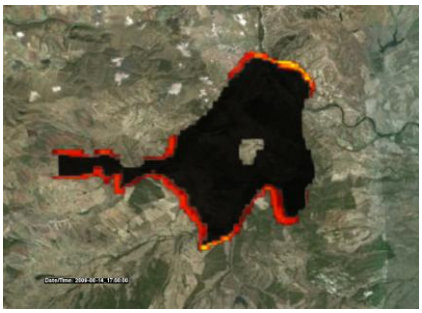

Fig. 1 The simulation fire burnt area

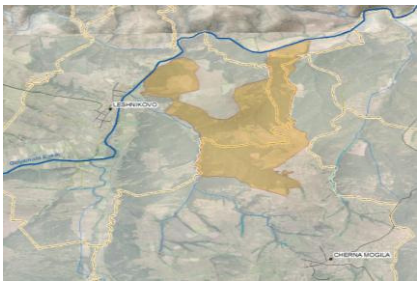

Fig. 2 The real fire burnt area

The simulation showed on figures 1 and 2 was done on the supercomputer at the University of Denver by distant connection. In Table 1 the simulation results are presented according to the number of the cores used.

TABLE 1: THE TIME REQUIRED FOR THE SIMULATION PRESENTED IN SECONDS DEPENDING ON THE NUMBER OF PROCESSORS RUNNING THE PARALLEL EXECUTION OF PROCESSES SHOWING THAT IN 120 CORES THE SIMULATIONS RUN AS REAL TIME. EVERYTHING ABOVE IS FASTER THAN REAL FIRE PROPAGATION.

With this simulations for the test site nearby Harmanli town has been elaborated a methodology for collection, procession and implementation of real data for test sites on Bulgarian territory. The selected model was having as input meteorological data, DEM and only 13 burning classes which led to the idea that we can experiment also with different models like BEHAVE Plus and FARSITE for our next tests.

IV. EXPERIMENTAL IMPLEMENTATION OF BEHAVE PLUS AND FARSITE SIMULATIONS IN THE TEST CASES OF ZLATOGRAD, MADAN AND NEDELINO MUNICIPAL AREAS IN BULGARIA

In the framework of bilateral cooperation program between Greece and Bulgaria 2007-2013 our team was having the opportunity to work in the Zlatograd forestry department located on the territories of Zlatograd, Madan and Nedelino municipal areas in Bulgaria.

The data we were working on was about fifteen wildfires that occurred in 2011 to 2012 within the Zlatograd municipal territory were provided by the Zlatograd forestry department. Based on initial BehavePlus results using standard fuel models, custom fuel models were developed for some vegetation types not well represented by the US fuel models.

Following evaluation of fuel models with BehavePlus, we performed analyses in FARSITE, a spatial fire growth system that integrates fire spread models with a suite of spatial data and tabular weather, wind and fuel moisture data to project fire growth and behavior across a landscape. We defined our test landscapes using a 500 m buffer zone around each of the fifteen Zlatograd fires.

Input for FARSITE consists of spatial topographic, vegetation, and fuels parameters compiled into a multi-layered “landscape file” format. Topographic data required to run FARSITE include elevation, slope, and aspect. Using the aforementioned 30 m DEM, we calculated an aspect layer, and then clipped elevation, aspect, and slope rasters to the extent of our fifteen test landscapes. Required vegetation data include fuel model and canopy cover. Fuel models within the 500 m buffered analysis area for each individual fire were assigned based on our BehavePlus analyses; fuel model assignments were tied to the dominant vegetation for each polygon based on the Zlatograd forestry department’s vegetation data. Canopy cover values were visually estimated from orthophoto images and verified with stand data from the Zlatograd forestry department. Additional canopy variables (canopy base height, canopy bulk density, and canopy height) that may be included in the landscape file were omitted, as these variables are most important for calculating crown fire spread or the potential for a surface fire to transition to a crown fire. None of the fifteen fires analyzed experienced crown fire.

Tabular weather and wind files for FARSITE were compiled using the weather and wind data from TV Met, Bulgarian meteorological company that included hourly records. Tabular fuel moisture files were created using the fine dead fuel moisture values calculated for the BehavePlus analyses for 1-hr timelag fuels. The 10-hr fuel moisture value was estimated by adding 1% to the 1-hr fuel moisture and the 100-hr fuel moisture was generally calculated by adding 3% to the 1-hr fuel moisture. The live fuel moisture values previously estimated for BehavePlus analyses were used to populate live herbaceous and live woody moisture values.

All simulations performed in FARSITE used metric data for inputs and outputs. An adjustment value was not used to alter rate of spread for standard fuel models, rather custom fuel models were created. Crown fire, embers from torching trees, and growth from spot fires were not enabled.

As an example of one of our successful FARSITE runs, we present the results from a single wildfire that burned in grassland vegetation, for which we developed custom fuel models. This fire occurred on

August 30, 2011, starting at 1400 and ending around 1800, and burned a total area of 0.3 ha. We used the following input parameters to model this small grassland fire in FARSITE:

Fuel moisture values: 6% (1-hr), 7% (10-hr), 9% (100-hr), 45% (live herbaceous), and 75% (live woody);

Daily maximum temperatures: 17-21°C;

Daily minimum relative humidity: 24-50%;

Winds: generally from the west-southwest at 1-2 k h-1

The fire size as calculated using FARSITE was 0.5 ha, which seems reasonable considering the modeled size would not have included the suppression actions that most likely occurred given the close proximity of a village to this fire figure 3.

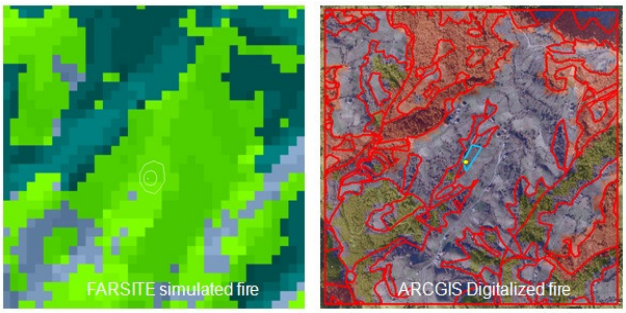

Figure 3: FARSITE run for a grassland fire, where size of the fire is very close to the real one, but the shape is different, because of wind information discrepancies

From this modeled fire we were able to estimate that grasslands and any grass and shrub covered areas will probably have the need to be further modeled before using as inputs for standard simulations with FARSITE or any similar tool in future. However FARSITE and BehavePlus provided reasonable outputs for future work in the field of fire behavior fuel modeling on the Bulgarian territory. The work done in more details is described in [7],[8],[9],[10].

III. Conclusion

The presented paper was having as main aim to provide a broader view on the tested modeling options for the Bulgarian wild land fires and the achieved results. There are still a lot of issues to be solved in the data preparation phase and the accuracy of the meteorological inputs. However the achieved results after all computations give promising options for future implementation of this modeling tools for more operational use in the responsible authorities first response facilities. With the presented test is given an idea what kind of simulations are more accurate when past wildland fires are modeled. Also the burning materials representations is very crucial which can be seen through the presented examples. This field still need to be more elaborated, but the first results gave good basis on how we can continue our future work.

***Abstract*—In combinatorial optimization, the goal is to find the optimal object from a finite set. Since such problems are hard to be solved, usually some metaheuristics is applied. One of the most successful techniques for a number of classes of problems is Ant Colony Optimization (ACO). Some start strategies can be applied, to the ACO algorithms, to improve their performance. Here, the InterCriteria Analysis (ICrA) is applied to the ACO algorithm. On the basis of the ICrA, we examine and analyse the ACO performance according to the different start strategies.**

I. Introduction

THE IDEA for the ACO arises fro the way that real ants look for food. The ACO algorithm was proposed, by Marco Dorigo, more than 20 years [6]. Later, several variants and supplements were added, to improve its performance [6]. In [7], various ACO start strategies, which lead to finding better solutions, were proposed.

The InterCriteria Analysis (ICrA) is aiming at going beyond the nature of the criteria involved in a process of evaluation of multiple objects against multiple criteria, and, thus to discover some dependencies between the ICrA criteria themselves [2]. Initially, the ICrA has been applied in temporal, threshold and trends analyses of an economic case-study of EU member states' competitiveness [4]. Further, the ICrA has been used to discover dependencies between parameters in mathematical models and performance criteria for metaheuristics such as GAs and ACO [1], [9]. Here, the ICrA is applied for analysis of an ACO algorithm, with various start strategies. The Multiple Knapsack Problem (MKP) is used as a test problem. The goal is to analyze the dependence between start strategies and algorithm performance, and correlations between strategies.

II. ACO Algorithm with Start Strategies

Let us consider the ACO algorithm applied to the solution of a problem represented by a graph. Here, the feasible solutions are represented by path in that graph. The solution process "compares the length" of available paths. In every iteration, an ant starts from a random node and creates a solution. If the last selected node is u, the ant selects the next node (v), to be included in the path, by applying probabilistic rule called transition probability.

$$p_{uv} = \tau_{uv}^{\alpha}\eta_{uv}^{\beta} / \left[\sum_{(u,w)\in E_S\,:\,w\not\subset X} \left(\tau_{uw}^{\alpha}\eta_{uw}^{\beta}\right)\right], \qquad (1)$$

Here, α and β are transition probability parameters, $\tau \in (0,1)$ is a numerical information called pheromone, and η is an heuristic information related to the problem. At the beginning, the value of the pheromone across elements is the same. In each iteration, we update the pheromone, on selected elements of the graph, according to the value of the objective function (elements belonging to the better solutions receive more pheromone than others). The random start is very important for good performance of the ACO algorithm, but for some classes of problems (e.g. subset problems), selection of the starting node can be significant. For better managing the search process we include semi-random start of the ants. Here, the nodes are divided into several subsets. An estimation of how good and how bad is to start from some subset is introduced according the number of good and bad solutions that started from this subset. Assume that D_j is the estimation of how good it is to start from subset j, and E_j is the estimation how bad it is to start from subset j [7].

$$D_j(i) = \phi.D_j(i-1) + (1-\phi).F_j(i), \qquad (2)$$

$$E_j(i) = \phi.E_j(i-1) + (1-\phi).G_j(i), \qquad (3)$$

where $i \geq 1$ is the current process iteration and, for each j $(1 \leq j \leq N)$:

$$F_j(i) = \begin{cases} f_{j,A}/n_j & \text{if } n_j \neq 0 \\ F_j(i-1) & \text{otherwise} \end{cases}, \qquad (4)$$

$$G_j(i) = \begin{cases} g_{j,B}/n_j & \text{if } n_j \neq 0 \\ G_j(i-1) & \text{otherwise} \end{cases}, \qquad (5)$$

$f_{j,A}$ is the number of the solutions among the best $A\%$, $g_{j,B}$ is the number of the solutions among the worst $B\%$, where $A+B \leq 100$, $i \geq 2$ and $\sum_{j=1}^{N} n_j = n$, where n_j $(1 \leq j \leq N)$

is the number of solutions obtained by ants starting from nodes subset j, n is the number of ants. Here, initial values of the weight coefficients are: $D_j(1) = 1$ and $E_j(1) = 0$. Parameter ϕ, $0 \leq \phi \leq 1$, shows the weight of the information from the previous iterations and from the last iteration. Several start strategies and combinations between them are proposed. If thresholds for good estimation D and for bad estimation E are fixed, the proposed start strategies are as follows [7]:

1) If $E_j(i)/D_j(i) > E$ then, for current iteration, the subset j is forbidden. The starting node is randomly chosen from $\{j \mid j \text{ is not forbidden}\}$;
2) If $E_j(i)/D_j(i) > E$ then, for current simulation, the subset j is forbidden. The starting node is randomly chosen from $\{j \mid j \text{ is not forbidden}\}$;
3) If $E_j(i)/D_j(i) > E$ then, for K_1 consecutive iterations, the subset j is forbidden. The starting node is randomly chosen from $\{j \mid j \text{ is not forbidden}\}$;
4) Let $r_1 \in [\frac{1}{2}, 1)$ and $r_2 \in [0, 1]$ to be random numbers. If $r_2 > r_1$, a node from subset $\{j \mid D_j(i) > D\}$ is randomly chosen, otherwise a node from the not forbidden subsets is randomly chosen. r_1 is chosen and fixed at the beginning.
5) Let $r_1 \in [\frac{1}{2}, 1)$ and $r_2 \in [0, 1]$ to be random numbers. If $r_2 > r_1$, a node from subset $\{j \mid D_j(i) > D\}$ is randomly chosen, otherwise a node from the not forbidden subsets is randomly chosen. r_1 is chosen at the beginning and increase with r_3 every iteration, $r_3 \in (0, 1)$ is a parameter.

Here $K_1, K_1 \in [0, \textit{number of iterations}]$ is a parameter.

We can apply one of start strategies, or combine some of them. Strategies 1, 2, and 3 can be combined with strategies 4 and 5. When an ant chooses a start node, first applied strategy is one of 1, 2, or 3, after that, strategy 5 or 6 is used. Thus, together with a completely random start, there are 12 strategies that can be applied (see, also [7]).

III. Multiple Knapsack Problem

The start node selection is very important for the subset problems, because only some nodes of the graph of the problem belong to the solution. The Multiple Knapsack Problem (MKP) is a representative of the class of subset problems. It also arises as a sub-problem in a group of more complex problems. Some of important applications that can be formulated as a MKP are cargo loading problems, cutting stock, bin-packing, budget control and financial management. The MKP is also used in a fault tolerance problem [11]. Authors of [5] designed a public cryptography scheme whose security is based on the difficulty of solving the MKP. In [8] two-processor scheduling problems are proposed to be solved as a MKP. Other applications include industrial management, naval, aerospace, computational complexity theory, etc. The MKP can be formulated as follows:

$$\begin{array}{c} \max \sum_{j=1}^{n} p_j x_j \\ \text{subject to} \sum_{j=1}^{n} r_{ij} x_j \leq c_i \quad i = 1, \ldots, m \\ x_j \in \{0, 1\} \quad j = 1, \ldots, n \end{array} \tag{6}$$

$$x_j = \begin{cases} 1 \text{ iff the object } j \text{ is chosen,} \\ 0 \text{ otherwise.} \end{cases}$$

where m are the resources (the knapsacks), n are the objects, p_j is a profit of every object j, c_j (knapsack capacity) is the resource budget, r_{ij} is the consumption of resource i by object j. The goal is maximizing the sum of profits for a limited budget.

There are m constraints in this problem, so the MKP is also called m-dimensional knapsack problem. Let

$$I = \{1, \ldots, m\}, J = \{1, \ldots, n\},$$

with $c_i \geq 0$ for all $i \in I$. A well-stated MKP assumes that $p_j > 0,\ r_{ij} \leq c_i \leq \sum_{j=1}^{n} r_{ij}$ for all $i \in I,\ j \in J$. Note that the $[r_{ij}]_{m \times n}$ matrix and the $[c_i]_m$ vector are both non-negative.

IV. InterCriteria Analysis

Let us be given an Index Matrix (IM, [3]) whose index sets for rows consist of the names of the criteria and for columns of objects. We will obtain an IM with index sets consisting of names of the criteria both for rows and for columns. Elements of this IM correspond to the degrees of "agreement" and degrees of "disagreement" of the considered criteria. The following two points are assumed [10]. (1) All criteria provide an evaluation for all objects and all these evaluations are available. (2) All the evaluations of a given criteria can be compared among themselves. Further, by O, we denote the set of all objects $O_1, O_2, \ldots, O_n$ being evaluated, and by $C(O)$ the set of values assigned by a given criteria C to the objects. Let $x_i = C(O_i)$. Then the following set can be defined:

$$C^*(O) \stackrel{\text{def}}{=} \{\langle x_i, x_j \rangle | i \neq j \,\&\, \langle x_i, x_j \rangle \in C(O) \times C(O)\}.$$

In order to find the degrees of "agreement" of two criteria, the vector of all internal comparisons of each criteria is constructed. This vector fulfills exactly one of the following three relations: R, $\overline{R}$ and $\tilde{R}$. For a fixed criterion C, and any ordered pair $\langle x, y \rangle \in C^*(O)$ it is required that: $\langle x, y \rangle \in R \Leftrightarrow \langle y, x \rangle \in \overline{R}$, $\langle x, y \rangle \in \tilde{R} \Leftrightarrow \langle x, y \rangle \notin (R \cup \overline{R})$, $R \cup \overline{R} \cup \tilde{R} = C^*(O)$

For a criterion C, let us define a preference matrix between objects $1, 2, \ldots, n$ so that C_{ij} is 1 if i is better than j, -1 if i is worse than j, and 0 if i and j are equivalent or incomparable over criterion C. We determine the degree of "agreement" ($\mu_{C,C'}$) between the two criteria as the proportion of matching components. This can be done in several ways, e.g. by counting the matches or by taking the complement of the Hamming distance. The degree of "disagreement" ($\nu_{C,C'}$) is the proportion of components of opposing signs in the two vectors. The difference $\pi_{C,C'} = 1 - \mu_{C,C'} - \nu_{C,C'}$ is considered as a degree of "uncertainty".

V. Numerical Results

We combined the ICrA with the ACO for different start strategies applied to the MKP [7]. Ten test problems from the "OR-Library" with 100 objects and 10 constraints (available from

http://people.brunel.ac.uk/~mastjjb/jeb/orlib) were used. The ACO algorithm is applied to various number of nodes in node subsets. The node subsets consist of the same number of nodes, namely 1, 2, 4, 5 and 10. The average results over the 10 test problems and 30 runs of every problem with every strategy was obtained. The ranking is from 10 to 100. The ICrA objects $(O_1, O_2, \ldots, O_{20})$ are the different conditions, namely nodes 1, 2, 4, 5 and 10, in four cases of ϕ, $\phi = [0\ 0.25\ 0.5\ 0.75]$. The ICrA criteria $(C_1, C_2, \ldots, C_{12})$ are 12 different start strategies for the ACO. The ICrA resulted in two IM ,with the relations between considered 12 criteria. The resulting IMs, for $\mu_{C,C'}$ and $\nu_{C,C'}$, are shown in Table I and Table II.

TABLE I: Index matrix for $\mu_{C,C'}$

C_9	0.695	0.695	1.000	0.984	0.753	0.753
C_{10}	0.679	0.679	0.984	1.000	0.747	0.747
C_{11}	0.800	0.800	0.753	0.747	1.000	1.000
C_{12}	0.800	0.800	0.753	0.747	1.000	1.000

For better understanding of the results, the values of the $\mu_{C,C'}$, $\nu_{C,C'}$, $\pi_{C,C'}$ of the criteria pairs, are sorted by the value of the $\mu_{C,C'}$. The list is presented in Tables III and IV. Table III shows the criteria pair with high degrees of "agreement" ($\mu_{C,C'}$) and low value for the degree of "disagreement" ($\nu_{C,C'}$). Table IV shows the criteria pair with high degree of "uncertainty". Regarding Tables III and IV we observe that relations between criterion C_1 and criteria C_5 and C_6 have the highest value of $\mu_{C,C'}$ ($\mu_{C,C'} = 1$), i.e. these criteria are in strong positive consonance. Henceforth, the ACO algorithm performs in a similar way with random start and start strategies 4 and 5. In strategies 4 and 5 there are no forbidden regions (as in the random start). In these cases, only the probability to choose the next element in the solution is different. Other pairs that have the highest value of $\mu_{C,C'}$ ($\mu_{C,C'} = 1$) are $C_7 - C_8$ and $C_{11} - C_{12}$. These strategies (Strategies 1-4, 1-5, 3-4 and 3-5) show also very similar performance.

C_3	0.295	0.295	0.079	0.079	0.263	0.263
C_4	0.137	0.137	0.189	0.195	0.084	0.084
C_5	0.000	0.000	0.000	0.000	0.000	0.000
C_6	0.000	0.000	0.000	0.000	0.000	0.000
C_7	0.000	0.000	0.242	0.258	0.137	0.137
C_8	0.000	0.000	0.242	0.258	0.137	0.137
C_9	0.242	0.242	0.000	0.016	0.205	0.205
C_{10}	0.258	0.258	0.016	0.000	0.211	0.211
C_{11}	0.137	0.137	0.205	0.211	0.000	0.000
C_{12}	0.137	0.137	0.205	0.211	0.000	0.000

The criteria pairs still in a consonance, are pairs of criteria C_2, C_3, C_4 and C_7, C_8, ..., C_{12}. They correspond to Strategies 1, 2 and 3, combined with 4 and 5. In all this strategies there are forbidden regions, therefore the ACO performs in a similar way when we apply "any of them". The criteria pairs with value of $\mu_{C,C'} = [0.75 - 0.25)$ are in dissonance, i.e. there are no dependencies between these criteria (they are independent). The ACO algorithm with random strategies and the ACO algorithm with strategies with forbidden regions perform in a very different way, thus we can not find relations between them.

VI. Conclusion

In this paper, an ICrA is used with the ACO algorithm, to establish the relations and dependencies between the ACO performance and the start strategies. Twelve start strategies are studied. Part of them disallow some regions of the search space for one or more iterations. We can conclude that criteria corresponding to the strategies without forbidden regions are in positive consonance, as well as the criteria corresponding to the strategies with forbidden regions. The criteria corresponding to the strategies with forbidden regions are in dissonance with criteria corresponding to the strategies without forbidden regions.

***Abstract*—Following the long-term goal of substituting conventional power generation with cleaner energy will lead to an integration of a large share of small energy generation units imposing large problem sizes for coordination. The expected huge number of entities leads to a need for new techniques reducing the computational effort for coordination. Predictive scheduling is a frequent task in energy grid control. For a number of energy resources, schedules have to be found that fulfill several objectives at the same time. Considering day-ahead scenarios with 96-dimensional schedules imposes additional challenges to this already hard combinatorial problem. We explore the effects of reducing complexity by partitioning the data domain of the optimization problem for a sequential approach that integrates energy models for constraint handling directly into the optimization process. We explore the effects of different partitioning schemes and evaluate the trade-off between accuracy and effort with several simulation studies.**

I. Introduction

DESPITE being environmentally friendly and sustainable, the increasing amount of renewable electricity generation has a major drawback. In contrast to conventional power plants, the generation from e. g. solar and wind power can neither be predicted with high accuracy nor scheduled precisely. Furthermore, as storage of electrical energy is a rather difficult and expensive task, balancing supply and demand in the grid in real-time is one of the most important functions of power system control centers. Thus, to incorporate renewables accordingly, methods have to be established that can compensate for the missing flexibility of those energy sources. For instance, controlling flexible loads to use electrical power in times of high availability (i. e. high wind or solar radiation) can help using renewable power more efficiently [1].

From an algorithmic perspective, the task of scheduling energy units can be seen as combinatorial optimization problem: For each unit (i. e. controllable loads and generators), an optimal schedule has to be found such that for every time interval of a predefined planning horizon, a specific amount of electrical power (positive or negative) is assigned. A combination of schedules is optimal if the aggregated power equals a target profile that is given by the use case. For example, given the inverse of a predicted feed-in time series for wind and photovoltaic power plants as target profile, an optimal schedule assignment for the controllable energy units would lead to a perfect balancing of supply and demand in the considered system at each interval of the prediction horizon. Another use case is the operation of a virtual power plant (VPP): Given a target power profile that is to be offered in an energy market, the members of the VPP must collaborate in such a way that the VPP as a whole will produce the target profile. From the outside perspective, no difference between a VPP and a classical power plant would be evident [1].

However, the schedule optimization task becomes hard to solve in the presence of device-specific restrictions. Many flexible generators and loads are controllable in principle, but at the same time have to obey specific individual constraints. For instance, a cogeneration plant (e. g. a combined heat and power plant, CHP) produces thermal and electrical power simultaneously. As the generation of those two forms of power are strictly coupled within the unit and the use of the heat is subject to further restrictions such as the size of an attached thermal buffer storage, the electrical generation is severly confined as well [2], [3]. Due to such constraints, many established optimization algorithms cannot be applied to this task. For instance, meta-heuristics like evolutionary algorithms or simulated annealing are not able to cope with constraints per se and would have to be tailored specifically for the actual use case and the involved energy units.

In [4], a method has been introduced that is able to transform a problem with restrictions into a restriction-free representation using a machine learning approach. This so-called *support vector decoder model* allows generic optimization algorithms to operate in a restriction-free representation of the constrained search space of the original optimization problem. The method has been successfully applied to the schedule optimization problem [3]. In this context, the influence of the length of the planning horizon on solution quality became apparent: Usually, the method is applied to representations of the planning horizon as a whole by interpreting feasible schedules of energy units as elements to the combinatorial problem. However, the longer the planning horizon (and the schedules, consequently), the lower the solution quality of the employed optimization algorithms. At first glance, this may seem like an inherent restriction of the problem to solve. But interestingly, preliminary experiments indicated a potentially increasing solution quality when the optimization algorithm is applied in a successive manner to sequential partitions of the planning horizon. Thus, the objective of this paper is to explore the potential benefit of partitioning the search space

978-83-60810-90-3/$25.00

of the given combinatorial problem in the data domain in combination with sequential optimization of the individual data partitions.

In Section II, the motivating optimization problem as well as the support vector decoder model are briefly recapped from previous works. Following, Section III first revisits relevant related work in the field of high-dimensionality optimization strategies before describing the introduced concept of data partitions for the considered combinatorial problem in more detail. Section IV then evaluates the approach by employing a simulation study in the aforementioned application domain. Finally, Section V concludes the paper.

II. Methodical Background

We start with some preliminary definitions. First, let $\mathcal{U}$ be the set of DER units in the VPP and Z_U be the set of operational states of unit U. We regard the schedule of an energy unit as a vector $\boldsymbol{p} = (p_1, \ldots, p_d) \in \mathbb{R}^d$ of mean power p_i generated (or consumed) during the ith time interval. The starting time and the width of a time interval (today usually 15 minutes) are defined separately and have no effect on this representation. For the used support vector decoder it is advantageous to use schedules with scaled power values [5]. Scaling is done according to respective minimum (p_{min}) and maximum (p_{max}) nominal active power output (or input):

$$\begin{aligned} \rho : \mathbb{R}^d &\to \mathcal{X} \subset [0,1]^d \\ \boldsymbol{p} &\mapsto \boldsymbol{x} = \rho(\boldsymbol{p}), \text{with } x_i = \frac{p_i - p_{min}}{p_{max} - p_{min}}; \end{aligned} \tag{1}$$

For this paper we go with the example of predictive scheduling for active power planning in day-ahead scenarios (not necessarily 24 hours but for some given future period).

One of the crucial challenges in operating a VPP arises from the complexity of the scheduling task due to the large amount of (small) energy units in the distribution grid [6]. In the following, we consider predictive scheduling, where the goal is to select exactly one schedule $\boldsymbol{x}_i$ for each energy unit U_i from a search space of feasible schedules with respect to a future planning horizon, such that a global objective function (e. g. a target power profile for the VPP) is optimized by the sum of individual contributions [7]. A basic formulation of the scheduling problem is given by

$$\delta \left(\sum_{i=1}^{m} \boldsymbol{x}, \boldsymbol{\zeta} \right) \to min \tag{2}$$

such that

$$\boldsymbol{x}_i \in \mathcal{F}^{(U_i)} \ \forall U_i \in \mathcal{U}. \tag{3}$$

In equation (2) δ denotes an (in general) arbitrary distance measure for evaluating the difference between the aggregated schedule of the group and the desired target schedule $\boldsymbol{\zeta}$. W.l.o.g., in this contribution we use the Euclidean distance $\| \cdot \|_2$. To each energy unit U_i exactly one schedule $\boldsymbol{x}_i$ has to be assigned. The desired target schedule is given by $\boldsymbol{\zeta}$. $\mathcal{F}^{(U_i)}$ denotes the individual set of feasible schedules that are operable for unit U_i without violating any (technical) constraint. Solving this problem without unit independent constraint handling leads to specific implementations that are not suitable for handling changes in VPP composition or unit setup without having changes in the implementation of the scheduling algorithm [8].

In [9] a so called support vector decoder has been introduced. Basically, a decoder is a constraint handling technique that gives an algorithm hints on where to look for feasible solutions. It imposes a relationship between a decoder solution and a feasible solution and gives instructions on how to construct a feasible solution [10]. For example, [11] proposed a homomorphous mapping between an n-dimensional hyper cube and the feasible region in order to transform the problem into an topological equivalent one that is easier to handle. In order to be able to derive such a decoder mapping automatically from any given energy unit model, [9] developed an approach based on a support vector model [5]. We will briefly describe this method.

The basic idea is to start with a set $\mathcal{X} = \{\boldsymbol{x}_i\}_n$ of feasible example schedules derived from the simulation model of an energy unit and use this sample as a stencil for the region (the sub-space in the space of all schedules) that contains only feasible schedules. The set $\mathcal{X}$ can be easily generated after a sampling method from [12]. The schedule sample is then used as a training set for a support vector based machine learning approach [13] that derives a geometrical description of the sub-space that contains the given data (in our case: the feasible schedules). Given a set of data samples, the inherent structure of the scope of action of a unit where the data resides in can be derived as follows: After mapping the data to a high dimensional feature space by means of an appropriate kernel, the smallest enclosing ball in this feature space is determined. When mapping back this ball to data space, it forms a set of contours (not necessarily connected) enclosing the given data sample. An in-depth discussion can be found e. g. in [13].

At this point, the set of alternatively feasible schedules of a unit is represented as pre-image of a high-dimensional ball $\mathcal{S}$. Figure 1 shows the situation. This representation has some advantageous properties. Although the pre-image might be some arbitrary shaped non-continuous blob in $\mathbb{R}^d$, the high-dimensional representation is still a ball and thus geometrically easier to handle (right hand side of figure 1). The relation is as follows: If a schedule is feasible, i.e. can be operated by the unit without violating any technical constraint, it lies inside the feasible region (grey area on the left hand side in figure 1). Thus, the schedule is inside the pre-image (that represents the feasible region) of the ball and thus its image in the high-dimensional representation lies inside the ball. An infeasible schedule (e. g. $\boldsymbol{x}$ in Fig. 1) lies outside the feasible region and thus its image $\hat{\Psi}_x$ lies outside the ball. But we know some relations: the center of the ball, the distance of the image from the center and the radius of the ball. Hence, we can move the image of an infeasible schedule along the difference vector towards the center until it touches the ball. Finally, we calculate the pre-image of the moved image $\tilde{\Psi}_x$ and get a schedule at the boundary of the feasible region: a

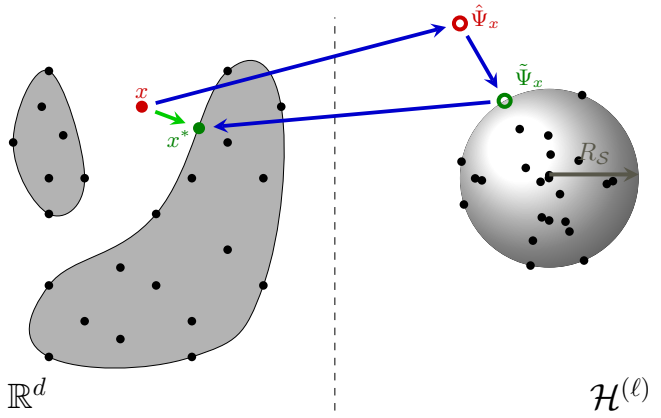

Fig. 1. General support vector model and decoder scheme for solution repair and constraint handling.

repaired schedule $\boldsymbol{x}^*$ that is now feasible. We do not need a mathematical description of the original feasible region or of the constraints to do this. The decoder that does the trick is derived directly from the training set $\mathcal{X}$ generated from the respective simulation model. More sophisticated variants of transformation are e. g. given in [4]. For a detailed description of the support vector decoder approach we refer to [4]. Formally, we have a mapping (the decoder γ)

$$\begin{aligned} \gamma : [0,1]^d &\rightarrow \mathcal{F}_{[0,1]} \subseteq [0,1]^d \\ \boldsymbol{x} &\mapsto \gamma(\boldsymbol{x}) \end{aligned} \tag{4}$$

that transforms any given (maybe in-feasible) schedule into a feasible one. Thus, we are able to transform the scheduling problem given Eq. (2) into an unconstrained formulation.

With these preliminaries in constraint handling we can now reformulate our optimization problem as

$$\delta\left(\sum_{i=1}^{m} \rho_i^{-1} \circ \gamma(\boldsymbol{x}_i), \boldsymbol{\zeta}\right) \rightarrow min, \tag{5}$$

where γ_i is the decoder function of unit i that produces feasible, scaled schedules from $\boldsymbol{x} \in [0,1]^d$ and σ_i^{-1} scales them unit specific entrywise to correct active power values (inverse to Eq. (1)) resulting in schedules that are operable by that unit. Please note, that this is a constraint free formulation. With this problem formulation, many standard algorithms for optimization can be easily adapted as there are no constraints (apart from a simple box constraint $\boldsymbol{x} \in [0,1]^d$) to be handled and no domain specific implementation (regarding the energy units and their operation schedules) has to be integrated. Equation (5) is used as a surrogate objective to find the solution to the constrained optimization problem equation (2).

Using a decoder fairly eases the implementation of a solver because no complex constraints have to be considered. On the other hand, such a decoder may introduce additional complexity into the optimization problem by the transformation. For this reason, we scrutinized the fitness landscapes of both problems (untransformed and transformed) to gain insight into the problem structure with means from standard fitness landscape analysis [14]. Indeed, our findings indicate a slightly growing in complexity by an increased ruggedness with a growing number of local minima [15]. But, this situation can be easily countered by using a heuristics that copes well with rugged non-linear problems like Simulated Annealing (SA).

Simulated Annealing [16] is an established Markov Chain Monte Carlo Method (MCMC) for non-linear optimization. It mimics a physical cooling process. In general, MCMC methods are an effective tool for statistical sampling applied to optimization problems [17]. The basic idea is a Markov Process that samples a target probability distribution $\pi(x) = \frac{1}{z} e^{-E(x)}$ with z as a problem specific normalization parameter and E measuring the error of the optimization objective. Originally, the method has been mainly applied to physical problems finding a minimum energy state and thus E is sometimes still written Hamiltonian $\mathcal{H}$, e.g. in [18]. We will use the term E. In this process a new state σ_{t+1} is generated from σ_t by drawing from a proposal transition distribution $Q(\sigma_{t+1}|\sigma_t)$ [19], [20]. The new state is accepted with probability

$$A(\sigma_t \rightarrow \sigma_{t+1}) = \min\left(1, \frac{\pi(\sigma_{t+1}) Q(\sigma_{t+1}|\sigma_t)}{\pi(\sigma_t) Q(\sigma_t|\sigma_{t+1})}\right). \tag{6}$$

The proposal distribution Q is a free parameter and must be adjusted to the individual problem at hand. Starting from a random initial state σ_0, the process needs a while to reach equilibrium and independence from σ_0. After this burn-in phase the samples represent the target distribution π.

In systems with deep local minima the process can be trapped without escape in reasonable time. This waiting time dilemma [21] is due to a stringent requirement for equilibrium. To escape, the process must generate subsequent states with higher energy and the probability for such a move declines roughly exponentially with the energy differences that has to be overcome. Thus, the expected waiting time for such escape grows also exponentially. For high-dimensional problems like the one that we scrutinize here, this problem is even more prevalent [21]. Several techniques have been proposed to overcome the problem of getting trapped, e.g. [22], [21], [23]; one is the concept of Simulated Annealing (SA).

SA introduces a variable temperature T into the target distribution: $\pi(x) = \frac{1}{z} e^{-E(\boldsymbol{x})/T}$. The effect is that the Markov Chain may escape local minima easier at a higher temperature. The general idea of Simulated Annealing is to interpret the fitness landscape of an optimization problem as a thermodynamic system with the objective function $E(\boldsymbol{x})$ denoting the error interpreted as the energy level of a proposed solution $\boldsymbol{x}$. Initially, the system is at a high temperature. During the Markov process, the system is gradually cooled down to the ground state with the global energy minimum.

Algorithm 1 shows the basic flow within our SA with integrated decoder. This integration has first been proposed in [15]. By mimicking a cooling process, temporarily worse solutions are allowed – depending on temperature and difference in solution quality – in order to escape local minima. In our approach, a solution is described by two matrices $\boldsymbol{X}_{ij}$ and $\boldsymbol{M}_{ij}$ denoting for each energy unit i and for each time interval

j of the schedule a scaled active power value in $[0, 1]$. In many objective scenarios, indicator values that describe the schedule with respect to different objectives might additionally be prevalent. For demonstration purposes, we stick with the single objective case here. In this sense, each row within the matrix is the schedule for one of the units. $\boldsymbol{X}$ contains schedules from the unconstrained search space (hypercube $[0, 1]^d$ not further constrained by technical issues from the units' operations). $\boldsymbol{X}$ is initialized with random values. $\boldsymbol{M}$ concurrently holds the respective feasible values generated by the support vector decoder: $\boldsymbol{M}_i = \gamma_i(\boldsymbol{X}_i)$. Thus, $\boldsymbol{M}$ always represents a feasible (scaled) solution to the problem.

$\boldsymbol{X}$ and $\boldsymbol{M}$ represent the genotype and phenotype of a solution respectively. In each iteration of the SA exactly one schedule $\boldsymbol{x}$ from $\boldsymbol{X}$ is randomly chosen and mutated. Modification is done at a randomly chosen element x_k by adding a random value $p \sim N(0, 1)$:

$$x_k \leftarrow \begin{cases} x_k + p - 1 & \text{if } x_k + p > 1 \\ x_k + p + 1 & \text{if } x_k + p < 0 \\ x_k + p & \text{else.} \end{cases} \tag{7}$$

Additionally, it can be useful especially for high-dimensional schedules to allow mutations at more than one element at a time. Only this mutated schedule has to be mapped by the respective decoder in order to keep $\boldsymbol{M}$ consistent with $\boldsymbol{X}$.

The system evolves as follows: at each temperature level T^t a Markov chain samples $E(\boldsymbol{x})$. $\boldsymbol{M}$ always represents a feasible, mutated solution that can be evaluated by Eq. (5). The new proposal solution part $\boldsymbol{x}^{t+1}$ is accepted (according to the Metropolis-Hastings criterion) with probability

$$A(\boldsymbol{x}^t \to \boldsymbol{x}^{t+1}) = \min\left(1, e^{\frac{-\Delta E}{T^t}}\right), \tag{8}$$

with $\Delta E = E(\boldsymbol{x}^{t+1}) - E(\boldsymbol{x}^t)$. In each iteration, temperature T^t is updated with with cooling rate $\lambda \in [0, 1[$: $T^{t+1} \leftarrow \lambda \cdot T^t$.

Algorithm 1 Basic scheme for the Simulated Annealing step (with integrated support vector decoder).

$\boldsymbol{X}_{ij} \leftarrow \boldsymbol{x}_i \sim U(0, 1)^d,\ 1 \le i \le n$
$\boldsymbol{M}_{ij} \leftarrow \gamma_i(\boldsymbol{X}_i),\ 1 \le i \le n$
$\vartheta \leftarrow \vartheta_{start}$
while $\vartheta < \vartheta_{min}$ **do**
  choose random $k;\ 1 \le k \le n$
  $\boldsymbol{x}^* \leftarrow \boldsymbol{X}_k$
  mutate($\boldsymbol{x}^*$)
  $\boldsymbol{M}^* \leftarrow \boldsymbol{M};\ \boldsymbol{M}^*_k \leftarrow \gamma_k(\boldsymbol{x}^*)$
  if $e^{-\frac{E(\boldsymbol{M}^*) - E(\boldsymbol{M})}{T}} > r \sim U(0, 1)$ **then**
    $\boldsymbol{M} \leftarrow \boldsymbol{M}^*;\ \boldsymbol{X}_k \leftarrow \boldsymbol{x}^*$
  end if
  $T \leftarrow \text{cooling}(T)$
end while

A major advantage of this approach is the anytime property: at any time, a feasible solution exists. The Markov chain may evolve in $[0, 1]^{d \cdot n}$ without taking care of technical constraints of the individual energy units. The decoder guarantees (apart from minor inaccuracies that might easily be corrected [4]) the feasibility of the solution.

III. Partitioning the Search Space

By employing the support vector decoder approach in combination with a heuristic solver for the optimization problem as described in the previous section, we are able to solve the scheduling problem for energy units efficiently without needing to adapt any part of the process to unit-specific properties such as technical constraints. The whole process is visualized in Algorithm 2. The resulting matrix $\boldsymbol{M}$ comprises m rows and d columns, where the i^{th} row vector represents the chosen schedule for energy unit U_i (for the remaining symbol definitions refer to Section II).

Algorithm 2 Predictive Scheduling

$m \leftarrow$ amount of energy units
$n \leftarrow$ sample size per energy unit
$d \leftarrow$ length of planning horizon
for all energy unit $U_i \in \mathcal{U}$ **do**
  $s_i \leftarrow$ predicted state of U_i at the beginning of the planning horizon
  repeat
    initialize simulation model for U_i with s_i
    simulate feasible schedule of length d
  until $\mathcal{F}^{(U_i)}$ contains n feasible schedules
  scale sample $\mathcal{F}^{(U_i)}$ using ρ_i
  calculate support vector model $\mathcal{S}_i$
  build support vector decoder γ_i
end for
return $\boldsymbol{M} \leftarrow \left(\text{solve } \delta\left(\sum_{i=1}^{m} \rho_i^{-1} \circ \gamma(\boldsymbol{x}_i), \boldsymbol{\zeta}\right) \to min\right)$

In the considered application domain, predictive planning is commonly done for *day-ahead* planning horizons, i. e. d corresponds to 24 hours with a schedule resolution of 15 minutes. In our problem formulation, this yields a 96-dimensional search space for each energy unit. Due to the curse of dimensionality [24], this may introduce significant negative effects. For instance, with larger problem dimensions, the required amount of training data for the support vector model increases exponentially [25]. This affects both the generation of feasible schedule samples via simulation, as well as learning the support vector models from these samples. Moreover, solving the optimization problem itself gets more time-consuming due to combinatorial explosion. Finally, as the support vector decoder model is based on approximation, mapping accuracy deteriorates with larger dimensions. This may lead to infeasible schedules being misleadingly recognized as feasible.

According to [26], strategies to circumvent the curse of dimensionality in such a case can be categorized as follows:

- *Decomposition:* Given that the problem is separable, decomposition subdivides the problem into smaller parts that are easier to solve.

- *Screening:* Less significant and redundant decision variables/dimensions are pruned from the problem description in order to reduce dimensionality.
- *Mapping:* The problem is mapped to a representation comprising less dimensions. For example, by exploiting correlations between variables in the original space, a mapping can be designed that yields a correlation-free space with less dimensions.
- *Space Reduction:* Using expert knowledge, parts of the search space are excluded from optimization.
- *Visualization:* An expert prunes insignificant parts of the search space using visualization techniques for high-dimensional data. In contrast to *Space Reduction*, this is done interactively during the optimization process.

For the considered support vector decoder approach, the strategies Screening, Visualization, and Space Reduction with expert's help are inappropriate, as they rely on specific knowledge about the individual problem instance to solve, which contradicts the main motivation for our approach. Because neigbouring values in the unit schedules are often quite similar (i. e. the gradient between two time intervals is usually rather small) and thus show some correlation, Mapping might be applicable. After optimization, however, the resulting low-dimensional power profile would have to be inversely mapped to a feasible high-dimensional schedule again, which would introduce further problems.

Finally, Decomposition offers a viable solution. We cannot split the problem along the m axis with respect to the result matrix $\boldsymbol{M}$ in Algorithm 2 (i. e. by optimizing over disjunct sets of energy units), because in each time step along the d axis, the schedule selections of *all* participating units have to be regarded in order to minimize δ. On the other hand, the problem formulation might allow us to optimize over each time step along the d axis independently: If the employed distance measure δ is a *metric*, it gets minimal if the individual distances along the d axis are minimal. This holds true for the Euclidean distance $\|\cdot\|_2$ we are using in this paper. Therefore, from the optimization point of view, the given problem seems to be separable along the d axis. Formally, we define such a *partitioning* of the search space as

$$\begin{aligned} \pi &: \mathbb{N}^2 \to \mathbb{N} \\ (d, j, k) &\mapsto l = \pi(d, j, k), \end{aligned} \tag{9}$$

where $l = \pi(d, j, k)$ denotes the length of the j^{th} partition along the d axis. The parameter k may hold arbitrary implementation-specific values (cf. the equidistant partitioning below). For a partitioning to be valid, the concatenation of all generated partitions must yield the whole planning horizon:

$$\sum_{j=1}^{\infty} \pi(d, j, k) = d \tag{10}$$

Moreover, for convenience we require

$$\forall i: \ \pi(d, j, k) = 0 \ \Rightarrow \ \pi(d, j+1, k) = 0, \tag{11}$$

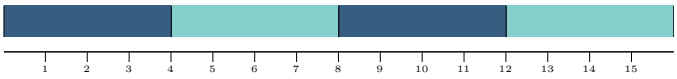

Fig. 2. Equidistant partitioning for $d = 16$ and $k = 4$.

i. e. as soon as the partitioning function yields the first zero partition, every following partition must be zero as well. Using this rather general definition of π, we may now define different partitioning strategies. For example, the *equidistant partitioning* subdivides the planning horizon into k partitions of equal size

$$\pi_{\text{eq}}(d, j, k) = \begin{cases} \lceil \frac{d}{k} \rceil & \text{if } j \leq k \ \wedge \ j \leq d \bmod k, \\ \lfloor \frac{d}{k} \rfloor & \text{if } j \leq k \ \wedge \ j > d \bmod k, \\ 0 & \text{else.} \end{cases} \tag{12}$$

Figure 2 shows an example for this partitioning with $d = 16$ and $k = 4$. There are many other possible partitioning strategies, ranging from simple arithmetic fragmentations to more sophisticated strategies involving expert knowledge about the use case at hand (i. e. the structure of the target profile or the δ function). A particular promising approach is the *entropy partitioning*, which exploits the entropy in the feasible schedule samples to determine intervals of high vs. low flexibility in the units' scopes of actions, and partitions the search space accordingly. But in order to remain maximally independent from such expert knowledge, we go with the example of equidistant partitioning in the remainder of this paper.

In order to implement a partitioning scheme like e. g. the equidistant partitioning in our approach, we have to extend Algorithm 2. Special care has to be taken regarding the simulation of feasible schedules: Originally, in Algorithm 2, each simulation model was initialized with the state of the energy unit right at the beginning of the planning horizon, and was executed for d time steps, such that each schedule sample exactly covers the planning horizon. Using partitions, however, schedule samples cannot be generated beforehand for the whole planning horizon. In order to identify a unit's flexibility for a certain partition, the exact state of the unit at the beginning of this partition has to be known. Thus, before being able to process a partition, we have to assign fixed schedules to the units for the preceding partition. As a consequence, the overall process ranging from schedule simulation to solving the optimization problem has to be executed for each partition separately. This ensures that, after the process finished for all partitions, the concatenated result schedules are feasible overall. On the other hand, with this approach we achieve a reduction of the design space (without expert knowledge as proposed in [26]) as every subsequent optimization process is already tackled to a fixed operational state of each unit at the beginning of a partition. The resulting process is visualized in Algorithm 3.

IV. Evaluation

The objective of this paper is to explore the potential benefit of partitioning the search space of the given combinatorial

Algorithm 3 Predictive Scheduling with Partioning

1: $m \leftarrow$ amount of energy units
2: $n \leftarrow$ sample size per energy unit

25: **end while**
26: **return** $\boldsymbol{M} \leftarrow \left[\boldsymbol{M}^j\right]$

problem in the data domain, followed by sequential optimization of the individual partitions. In the previous section, a partitioning framework has been introduced for this, along with a detailed description of the according optimization process chain. In order to evaluate the proposed approach with respect to the objective, a simulation study has been conducted.

A. Simulation Setup

Following the considered example use case, we set up a simulated virtual power plant for active power planning in day-ahead scenarios, comprising CHP units with an 800 l thermal buffer store each. We used the simulation model of an EcoPower CHP as described in [3]. For each of those devices, the thermal demand for a four-family house during winter was simulated. The devices were operated in heat driven operation and thus primarily had to compensate the simulated thermal demand. Additionally, after shutting down, a device would have to stay off for at least two hours. However, due to their thermal buffer store and the ability to modulate the electrical power output within the range of $[1.3,\ 4.7]$, the devices still have some flexibility available.

For the generation of feasible schedule samples, a *successive sampling strategy* was employed: Instead of guessing whole schedules and checking feasibility afterwards (using a device's simulation model), which leads to large rejection rates, a period-wise guessing in combination with partial feasibility checks is applied repeatedly to construct feasible schedules in a successive manner, cf. [12]. Preliminary experiments indicated 200 as an adequate size for $\mathcal{F}^{(U_i)}$, so we set $n = 200$ in the present study.

The planning horizon was set to $d = 96$ time intervals, i. e. 24 hours in 15 minute resolution, which is a common use case in the application domain. As motivated in the previous section, we employ the equidistant partitioning function π_{eq} in this study. Regarding the parameter k, which defines the length of the partitions and thus inversely determines the number of partitions to be generated according to (12), several experiments with $k \in [1, 96]$ have been conducted. For instance, $k = 1$ yields 96 partitions of length 1, while $k = 96$ corresponds to a single partition of length 96, i. e. no partitioning at all. This way, the influence of a partitioning on the optimization can be explored in a structured manner.

While k represents the primary influence factor in our study, other parameters may cause relevant interaction effects. Here, especially the magnitude of the problem size along the m axis (i. e. the number of energy units in the VPP, cf. Section III) is of particular interest, as it affects the problem complexity for each partition likewise. Similarly, different target profiles ζ have to be examined with respect to the units' available flexibilities. For example, a target profile might turn out to be easily realizable due to well matching schedule options in the units' search spaces, or vice-versa. The question arises whether this influences the potential benefit of a partitioning, and how a partitioning should be done in order to gain optimal results.

In all experiments, we used the Simulated Annealing solver as outlined in Section II. Each examined parameter configuration was simulated 100 times, so that the results can be interpreted with statistical soundness.

B. Results

The evaluation focuses on solution quality, which is calculated as remaining error after optimization:

$$\delta\left(\sum_{i=1}^{m} \rho_i^{-1}(\boldsymbol{x}_i), \boldsymbol{\zeta}\right), \quad \boldsymbol{x}_i \in \boldsymbol{M} \tag{13}$$

where $\boldsymbol{M}$ denotes the $m \times d$ schedule matrix after all partitions have been processed (line 26 in Algorithm 3). In the following, results are visualized as box-charts, where the box spans from the upper to the lower quartile of the data. The median is shown as horizontal line within a box, whereas the whiskers span over $1.5 \times$ the interquartile range. Outliers are illustrated by circle markers.

First of all, the general influence of different k values (i. e. different partition sizes) is examined. As already stated in the introduction, preliminary experiments indicated a potentially increasing solution quality when the optimization algorithm is applied in a successive manner to sequential partitions of the planning horizon. For a more thorough analysis, we conducted 100 simulations for each $k \in \{2, 8, 24, 48, 96\}$. The results are visualized in Figure 3. The optimization error clearly decreases with more and thus smaller partitions (from right to left in the figure). Comparing the extreme points, the partitioning even

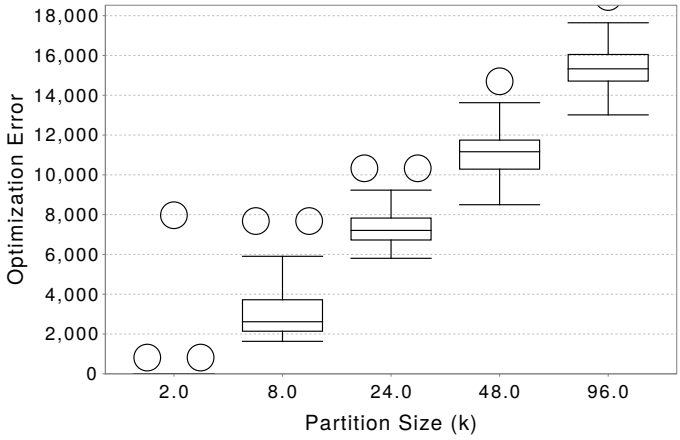

Fig. 3. Remaining optimization error for different partition sizes.

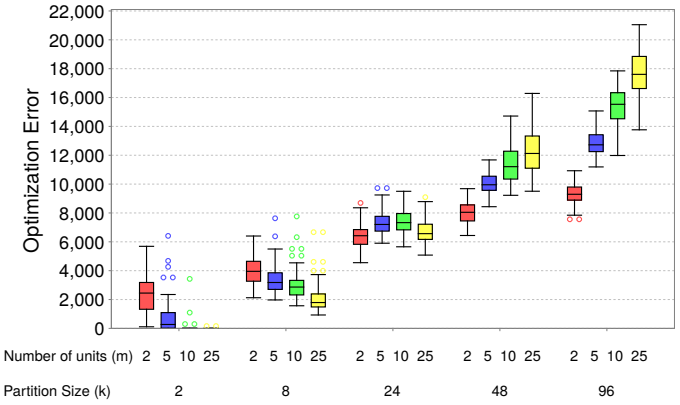

Fig. 4. Remaining optimization error for different partition sizes and varying amounts of energy units.

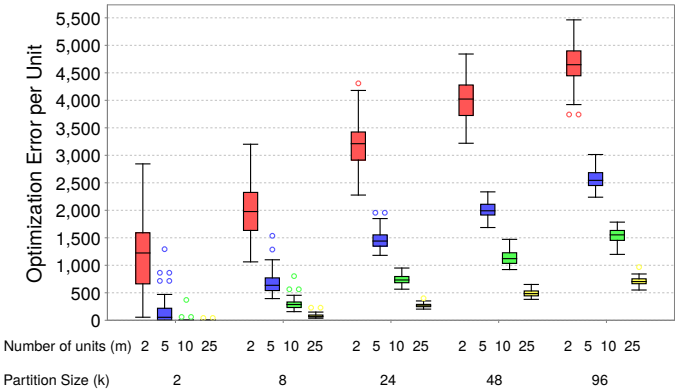

Fig. 5. Remaining optimization error per energy unit for different partition sizes and varying amounts of energy units.

allows approaching the theoretical optimum $\delta = 0$ when the partitions are generated as small as possible ($k = 2$: despite a few outliers, the box is squashed to a single line at $\delta = 0$), while the no-partitioning case yields the worst results most of the time ($k = 96$).

These results support our hypothesis strikingly, but they originate from a single experiment configuration only: On the one hand, a fixed number of energy units was involved, $m = 10$. On the other hand, the target profile ζ was generated by aggregating randomly chosen sample schedules (one for each energy unit) at the beginning of each experiment run. This way, ζ formed an "easy" target, because the energy units were able to approach it optimally in principle. In the following, we will vary this configuration in these two aspects, in order to gain more insights into the involved effects.

1) Interaction with the Number of Energy Units: In the considered application use-case of predictive scheduling for active power planning in day-ahead scenarios, virtual power plants may comprise different amounts of energy units, depending on e. g. regional conditions. From the optimization point of view, this corresponds to the problem size along the m axis. In a partitioned setting (i. e. $k < d$), each subproblem is of size $m \times k$. Hence, m affects the problem complexity for each partition likewise. To reveal possible interactions with the magnitude of k, the previous experiment with $k \in \{2, 8, 24, 48, 96\}$ was repeated for $m \in \{2, 5, 10, 25\}$. Figure 4 visualizes the results. Similar to Figure 3, the optimization error generally decreases with smaller partitions. Within each block, however, different effects with respect to the magnitude of m are visible: For the case of small partitions, the optimization error is lower with larger values of m, while this trend reverses for large partitions. As this is based on the absolute error, which is naturally different for varying magnitudes of m, Figure 5 complementarily shows the same results against the normed optimization error with respect to the number of units, i. e. the remaining error per energy unit. Here, the trend towards a lower error for small partitions is again clearly visible, whereas the magnitude of m results in a change of the slope for this trend. Concluding, m seems to affect the problem complexity as a whole only, and does not seem to interact with the partition size k.

2) Interaction with the Target Profile: In active power planning, usually an application-specific target profile is given. For instance, in day-ahead energy market scenarios, a target profile would be chosen such that the economic outcome of the VPP is maximized. In contrast, in supply-demand-matching scenarios, the target profile might be e. g. a constant zero value, such that the considered set of energy units (flexible producers and consumers) can be treated as autonomous energy-wise. While it is advisable to configure VPP and target profile in a matching way, so that the latter is actually a feasible target for the former, not all target profiles are equally easy to realize.

In our study, we abstract from application-specific scenarios as follows. As a first step, a feasible target can be formed by aggregating randomly chosen sample schedules (one for each energy unit). This way, the existence of the theoretical optimum ($\delta = 0$) is guaranteed. We denote this type of target with ζ_0. To generate more difficult target profiles in an easy but structured way, ζ_0 can simply be shifted in magnitude:

$$\zeta_i = \zeta_0 + i \tag{14}$$

Please note that ζ is a vector, and the summation is performed element-wise, of course. Matching the size of the considered

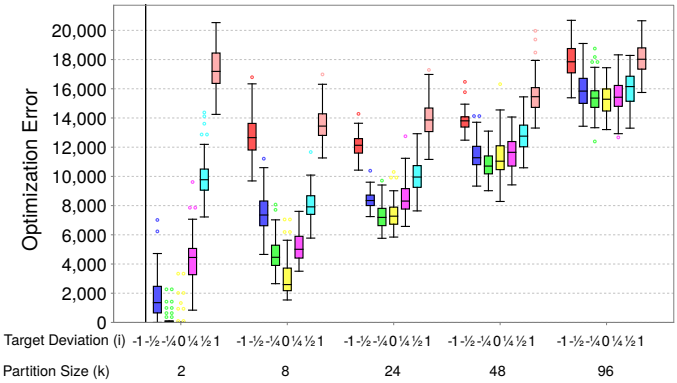

Fig. 6. Remaining optimization error for different partition sizes and varying target profile deviations.

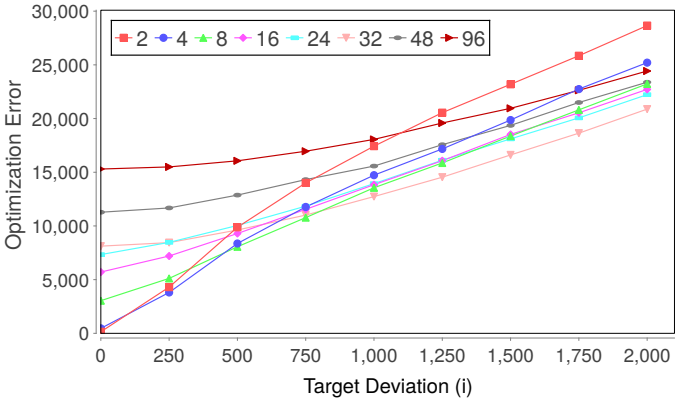

Fig. 7. Remaining optimization error for varying target profile deviations (horizontal axis) and different partition sizes (individual data series).

VPP in the present study, we choose values for i between $0\,\mathrm{kW}$ and $\pm 1\,\mathrm{kW}$ in the following experiment, in order to deviate the target profile from "easy to solve optimally" towards "hard to solve optimally". Thus, as in the previous section, the original experiment with $k \in \{2, 8, 24, 48, 96\}$ was repeated for all ζ_i with $i \in \{-1, -0.5, -0.25, 0, 0.25, 0.5, 1\}$ in kW. The results are presented in Figure 6. Similar to the results from Figure 4, the general trend of better optimization results with smaller partitions is visible. The case $k = 2,\ i = -1$ is an exception. Here, the optimization was not able to find a feasible schedule at all in the available time. This is due to the very low values in the target profile in combination with a large number of partitions: Due to the independent optimization of individual partitions, the simulated CHP units stay off at the beginning of the planning horizon until the thermal buffer stores are exhausted. At that point in time, however, thermal demand exceeds the available power from the CHPs, so that no feasible schedule cannot be found anymore. With larger partitions, the effect is not present, as the optimization can act anticipatory towards feasibility (i. e. by choosing schedules that lead to a poor optimization error, but in turn form a feasible solution). This effect indicates that a strong partitioning can yield better optimization results if enough flexibility is present, but might also lead to infeasible solutions in extreme cases.

In addition to the general trend regarding the value of k, a u-shaped course can be seen within each configuration of the same partition size. In other words, solution quality seems to deteriorate with larger deviations from ζ_0, which is not surprising at all. In order to focus on the interaction between these two effects, Figure 7 visualizes the results in a transposed way, i. e. the deviation i is visualized along the horizontal axis, while the partition sizes k are presented as line charts. For visualization purposes, the shown data comprises mean values only. Furthermore, in this experiment a larger amount of configurations was examined: $k \in \{2, 4, 8, 16, 24, 32, 48, 96\}$ and $|i| \in \{0, 0.25, \ldots, 2\}$. The results reveal an interesting relationship: For smaller target deviations, configurations with smaller partitions yield superior optimization results. In contrast, for larger target deviations, larger partition sizes yield better results.

In summary, the last experiment supports our previous hypothesis: With enough flexibility in a given problem configuration (in terms of feasible solution combinations with respect to the fitness function), the solver significantly benefits from a partitioning. On the other hand, in more difficult problem formulations (i. e. with less flexibility in terms of feasible solutions), the solver cannot cope with a large number of independent partitions.

V. Conclusion

The objective of this paper was to explore the potential benefit of partitioning the search space of the given combinatorial problem in the data domain using the example of predictive scheduling in the smart grid domain. We combined the partitioning approach with a sequential optimization solving each partition successively. Simulation models of different energy units have been integrated directly in the process for handling individual search spaces and operational constraints.

Several methods to cope with the challenge of high dimensionality in optimization problems have been proposed in the past. A good overview on methods for computationally expensive black-box functions (as might be the case when using simulation models for computing objectives) is e. g. given in [26]. Our approach is a mixture of design space reduction and decomposition into sub-problems. To achieve this we have to introduce simulation models as black-boxes into the optimization process for sequentialization. Introducing this sequence of independently solvable sub-problems reduces the overall computationally effort and at the same time reduces the design space so that modeling is more accurate and optimization effort is reduced [26]. At the same time this reduction leads to a limited choice especially for later sub-problems. Sub-space parts of the design space may be missed [26]. On the other hand, with our method, we may focus on the whole sub-space at once without a need for subsequent refinement like in other methods [26].

Our results support the hypothesis of an increasing solution quality when applying the optimization algorithm in a

successive manner to sequential partitions of the planning horizon. For our experiments we mainly used a simulated annealing approach as solver although our results can be generalized to other solvers. In general, any solver benefits for partitioned data domains in predictive scheduling if a problem configuration contains enough flexibility in terms of feasible solution combinations. With decreasing flexibility, additional complexity induced by a growing number of partitions prevails.

So far all simulations have been done with scenarios regarding predictive scheduling. Additional use cases like load balancing can be easily adapted by exchanging the objective functions, as the problem structure is similar to predictive scheduling. Future work will concentrate on methods to classify the situation at hand in order to automatically decide on appropriate partition of the combinatorial problem.

Heuristics for Job Scheduling Reoptimization

Elad Iwanir, Tami Tamir

***Abstract*—Many real-life applications involve systems that change dynamically over time. Thus, throughout the continuous operation of such a system, it is required to compute solutions for new problem instances, derived from previous instances. Since the transition from one solution to another incurs some cost, a natural goal is to have the solution for the new instance close to the original one (under a certain distance measure). We study reoptimization problems arising in scheduling systems. Formally, due to changes in the environment (out-of-order or new machines, modified jobs' processing requirements, etc.), the schedule needs to be modified. That is, jobs might be migrated from their current machine to a different one. Migrations are associated with a cost – due to relocation overhead and machine set-up times. In some systems, a migration is also associated with job extension. The goal is to find a good modified schedule, with a low transition cost from the initial one.**

We consider reoptimization with respect to the classical objectives of minimum makespan and minimum total flow-time. We first prove that the reoptimization variants of both problems are NP-hard, already for very restricted classes. We then develop and present several heuristics for each objective, implement these heuristics, compare their performance on various classes of instances and analyze the results.

I. Introduction

REOPTIMIZATION problems arise naturally in dynamic scheduling environments, such as manufacturing systems and virtual machine managers. Due to changes in the environment (out-of-order or new resources, modified jobs' processing requirements, etc.), the schedule needs to be modified. That is, jobs may be migrated from their current machine to a different one. Migrations are associated with a cost due to relocation overhead and machine set-up times. In some systems, a migration is also associated with job extension. The goal is to find a good modified schedule, with a low transition cost from the initial one.

This work studies the reoptimization variant of two classical scheduling problems in a system with identical parallel machines: (i) minimizing the total flow-time (denoted in standard scheduling notation by $P||\Sigma C_j$ [13]), and (ii) minimum makespan (denoted by $P||C_{max}$).

The minimum total flow-time problem for identical machines can be solved efficiently by the simple greedy Shortest Processing Time algorithm (SPT) that assigns the jobs in non decreasing order by their length. The minimum makespan problem is NP-hard, and has several efficient approximation algorithms, as well as a polynomial-time approximation scheme [15]. These algorithms, as many other algorithms for combinatorial optimization problems, solve the problem from scratch, for a single arbitrary instance without having any constraints or preferences regarding the required solution - as long as they achieve the optimal objective value. However, many of the real-life scenarios motivating these problems involve systems that change dynamically over time. Thus, throughout the continuous operation of such a system, it is required to compute solutions for new problem instances, derived from previous instances. Moreover, since the transition from one solution to another consumes energy (used for the physical migration of the job, for warm-up or set-up of the machines, or for activation of the new machines), a natural goal is to have the solution for the new instance close to the original one (under certain distance measure). Solving a reoptimization problem involves two challenges:

1) Computing an optimal (or close to the optimal) solution for the new instance.
2) Efficiently converting the current solution to the new one.

Each of these challenges, even when considered alone, gives rise to many theoretical and practical questions. Obviously, combining the two challenges is an important goal, which shows up in many applications.

A. Problem description

An instance of our problem consists of a set J of n jobs and a set M_0 of m_0 identical machines. Denote by p_j the processing time of job j. An initial schedule S_0 of the jobs is given. That is, for every machine, it is specified what are the jobs it processes. At any time, a machine can process at most one job and a job can be processed by at most one machine. We consider the scenario in which a change in the system occurs. Possible changes include addition or removal of machines and/or jobs, as well as modification of processing times of jobs in J. We denote by M the set of machines in the modified instance and let $m = |M|$.

Our goal is to suggest a new schedule, S, for the modified instance, with good objective value and small transition cost form S_0. Assignment of a job to a different machine in S_0 and S is denoted *migration* and is associated with a cost. Formally, we are given a *price list* $\theta_{i,i',j}$, such that it costs $\theta_{i,i',j}$ to migrate job j from machine i to machine i'. Moreover, in some systems job migrations are also associated with an extension of the job's processing

978-83-60810-90-3/$25.00

time. Formally, in addition to the transition costs, we are given a job-extension penalty list $\delta_{i,i',j} \geq 0$, such that the processing time of job j is extended to $p_j + \delta_{i,i',j}$ when it is migrated from machine i to machine i'.

For a given schedule, let C_j denote the *flow-time* (also known as 'completion time') of job j, that is, the time when the process of j completes. The *makespan* of a schedule is defined as the maximal completion time of a job, that is, $C_{max} = \max_j C_j$.

While the schedule does not specify the internal order of jobs assigned to a machine, we assume throughout this work that jobs assigned to a specific machine are always processed in SPT-order (Shortest Processing Time), that is, $p_1 \leq p_2 \leq \ldots$. For a given set of jobs, SPT-order is known to achieve the minimal possible total flow-time, $\min \sum_j C_j$ [22], [8]. Clearly, the internal order has no effect on the makespan.

Given S_0, J and M, the goal is to find a good schedule for J that is close to the initial schedule S_0. We consider two problems:

1) Rescheduling to an optimal schedule using the minimal possible transition cost.
2) Given a budget B, find the best possible modified schedule that can be achieved without exceeding the budget B.

If the modification includes machines' removal, and the budget is limited, then we assume that a feasible solution exists. That is, the budget is at least the cost of migrating the jobs on the removed machines to some machine. Formally, $B \geq \sum_{j \ on \ i \in M_0 \setminus M} \min_{i' \in M} \theta_{i,i',j}$.

Applications: Our reoptimization problems arise naturally in manufacturing systems, where jobs may be migrated among production lines. Due to unexpected changes in the environment (out-of-order or new machines, timetables of task processing, etc.), the production schedule needs to be modified. Rescheduling tasks involves energy-loss due to relocation overhead and machine set-up times. In fact, our work is relevant to any dynamic scheduling environment, in which migrations of jobs are allowed though associated with an overhead caused due to the need to handle the modification and to absorb the migrating jobs in their new assignment.

With the proliferation of cloud computing, more and more applications are deployed in the data centers. Live migration is a common process in which a running virtual machine (VM) or application moves between different physical machines without disconnecting the client or application [7]. Memory, storage, and network connectivity of the virtual machine are transferred from the original host machine to the destination. Such migrations involve a warm-up phase, and a memory-copy phase. In pre-copy memory migration, the Hypervisor typically copies all the memory pages from source to destination while the VM is still running on the source. Alternatively, in post-copy memory migration the VM is suspended, a minimal subset of the execution state of the VM (CPU state, registers and, optionally, non-pageable memory) is transferred to the target, and the VM is then resumed at the target. Live migration is performed in several VM managers such as Parallels Virtuozzo [18] and Xen [24]. Sequential processing of jobs that might be migrated among several processors is performed also in several implementations of MapReduce (e.g., [3]), and in RPC (Remote Procedure Call) services, in which virtual servers can be temporarily rented [4].

B. Related Work

The work on reoptimization problems started with the analysis of dynamic graph problems (see e.g. [10], [23]). These works focus on developing data structures supporting update and query operations on graphs. A different line of research, deals with the computation of a good solution for an NP-hard problem, given an optimal solution for a close instance. Among the problems studied in this setting are TSP [1], [5] and Steiner Tree on weighted graphs [11].

The paper [21] suggests the framework we adopt for this work, in which the solution for the modified instance is evaluated also with respect to its difference from the initial solution. This framework is in use also in [20], to analyze algorithms for data placement in storage area network. Job scheduling reoptimization problems with respect to the total flow-time objective was studied in [2], were algorithms for finding an optimal scheduled using the minimal possible transition cost and algorithms for optimal utilization of a limited number of migration were described.

Lot of attention, in both the industry and the academia is given recently to the problem of minimizing the overhead associated with migrations (see e.g., [7], [14]). Using our notations, this refers to minimizing the transition costs and the job-extension penalties associated with rescheduling a job. Our work focuses in determining the best possible schedule given these costs.

C. Our Contribution

Our study includes both theoretical and comprehensive experimental results. We consider reoptimization with respect to the two classical objectives of minimum makespan and minimum total flow-time, and distinguish between instances with unlimited and limited budget. Our results are presented in Table I. For completeness, we include in the table previous results regarding the minimum total flow-time with unlimited budget [2].

We first analyze the computational complexity status of these problems. While the hardness result for the minimum makespan problem is straightforward, the hardness for the minimum total flow-time problem with limited budget is complex and a bit surprising - given that the minimum flow-time problem is solvable even on unrelated machines

[6], [16], and that the dual variant of achieving an optimal reschedule using minimum budget is also solvable [2]. Our hardness results are valid already for very restricted classes, with a single added machine and no job-extension penalties.

In order to be able to evaluate our heuristics against an optimal solution, we develop and implement an optimal solver based on *branch and bound* technique. Naturally, the solver could not handle very large instances, but we were able to run it against small but diverse instances to compare the different heuristics to the optimum. For example, problems instances with 4 machines and 20 jobs were easily solved.

We then present several heuristics for each objective function. Some of the heuristics distinguish between modifications that involve addition or removal of machines. For both objectives we also developed and applied a genetic algorithm [9], [19]. All the heuristics were implemented, their performance on various classes of instances have been compared, and the results were analyzed. Our experimental study concludes the paper.

II. Computational Complexity

In this section we analyze the computational complexity of reoptimization scheduling problems. We distinguish between the minimum makespan and the minimum total flow problems, as well as between the problem of finding an optimal solution using minimum budget and finding the best solution that can be obtained using limited budget. Due to space constraints, some of the proofs in this section are omitted.

We use the following notations: For a multiset $A = \{a_1, a_2, \ldots, a_{|A|}\}$ of integers, let $MAX(A) = \max_{j=1}^{|A|} a_j$ and $SUM(A) = \sum_{j=1}^{|A|} a_j$. Also, let $\vec{A}$ denote the vector consisting of the elements of A in non-decreasing order and define $SPT(A) = \vec{A} \cdot (|A|, \ldots, 2, 1)$. For example, for $A = \{5, 3, 1, 5, 8\}$ it holds that $SUM(A) = 22$, $\vec{A} = (1, 3, 5, 5, 8)$ and $SPT(A) = (1, 3, 5, 5, 8) \cdot (5, 4, 3, 2, 1) = 5 + 12 + 15 + 10 + 8 = 50$. Note that $SPT(A)$ is the value of an optimal solution for the minimum total-flow problem on a single machine for an instance consisting of $|A|$ jobs with lengths in A.

For the minimum makespan reoptimization problem, our result is not surprising - the classical load-balancing problem $P||C_{max}$ is known to be NP-complete even with no transition costs or extensions. For completeness we show that this hardness carry over to the simplest class of the reoptimization variant.

Theorem 2.1: The minimum makespan reoptimization problem is NP-complete even with a single added machine, unlimited budget, and no job-extension penalty.

The analysis of the minimum total flow problem is more involved. The corresponding classical optimization problem $P||\sum C_j$ is known to be solvable in polynomial time by the simple SPT algorithm. For the reoptimization problem, an efficient optimal algorithm for finding an optimal solution using minimum budget is presented in [2]. The algorithm is based on a reduction to a minimum weighted perfect matching in a bipartite graph. This reduction cannot be generalized to consider instances with limited budget, and the complexity status of the problem of finding the best solution that can be obtained using limited budget remains open in [2]. We show that this problem is NP-complete, even with no job-extension penalties and a single added machine.

Our proof refers to the compact representation of the problem. In a compact representation, the jobs assigned on each machine are given by a set of pairs $\langle p_j, n_j \rangle$, where n_j is the number of jobs of length p_j assigned on the machine. We first prove two simple observations:

Observation 2.2: Let A' be a subset of A then $SPT(A') + SPT(A \setminus A') < SPT(A)$.

Given a multiset A, and an integer Z, let $x > MAX(A)$. Extend A to a multiset A^* by adding to it Z elements of value x.

Observation 2.3: $SPT(A^*) = \frac{Z(Z+1)}{2}x + Z \cdot SUM(A) + SPT(A)$.

Using the above observations, we are now ready to prove the hardness result.

Theorem 2.4: The minimum total flow-time reoptimization problem with limited budget is NP-complete even with a single added machine, and no job-extension penalty.

Proof: The reduction is from the *Partition* problem: given a set $A = \{a_1, a_2, \ldots, a_n\}$ of integers, whose total sum is $2B$, the goal is to decide whether A has a subset $A' \subset A$ such that $SUM(A') = SUM(A \setminus A') = B$. The Partition problem is known to be NP-complete [12].

Given an instance of Partition $A = \{a_1, a_2, \ldots, a_n\}$, whose total sum is $2B$, let $Z = SPT(A)$. We construct the following instance for the reoptimzation problem: The initial schedule, S_0, consists of a single machine and $n+Z$ jobs. The first n jobs correspond to the Partition elements, that is, for $1 \leq j \leq n$ let $p_j = a_j$. Each of the additional Z *dummy jobs* have length x for some $x > B$. Assume that one machine is added, and that the transition cost of migrating job j from the initial machine to the new machine is p_j. Assume also that the budget is B.

Since the budget is B and each dummy jobs have length more than B, none of these jobs can be migrated to the new machine. Thus, a modified schedule S is characterized by a subset $A' \subset A$ of jobs corresponding to the partition elements, whose total length is at most B. These jobs are migrated to the new machine and assigned in SPT order on it. The remaining jobs are be assigned in SPT order on the initial machine. since x is larger than any a_i, the Z jobs of length x will be assigned after the jobs corresponding to $A \setminus A'$.

Finally, we note that the reduction is polynomial. Calculating $SPT(A)$ requires sorting and is performed in

TABLE I
SUMMARY OF OUR RESULTS.

Objective Function	Optimal Reschedule Using Minimum Budget			Best Reschedule Using Given Limited Budget		
	NP-hard	Optimal Solution	Heuristics	NP-Hard	Optimal Solution	Heuristics
$\min C_{max}$	Yes	Branch and Bound	• LPT-based greedy • Loads-based greedy • Genetic algorithm	Yes	Branch and Bound	• LPT-based greedy • Loads-based greedy • Genetic algorithm
$\min \sum_j C_j$	No [2]	Reduction to min-weight perfect matching [2]	–	Yes	Branch and Bound	• Greedy reversion • Cyclic reversion • SPT-like

time $O(n \log n)$. The instance constructed in the reduction consists of $n + Z$ jobs where $Z = SPT(A)$. The compact representation of this instance includes at most $n + 1$ different pairs, where all $\langle p_j, n_j \rangle$ values are polynomial in n.

Claim 2.5: The minimum total flow-time in an optimal modified schedule is less than $\frac{Z(Z+1)}{2}x + (B+1)Z$ if and only if a partition of A exists.

The above claim completes the hardness proof. ∎

Remark: It is possible that two multisets A, B will have the same cardinality, and that $SUM(A) > SUM(B)$ while $SPT(A) < SPT(B)$. For example, for $A = \{1, 2, 10\}$ and $B = \{3, 4, 5\}$, we have $|A| = |B| = 3$, $SUM(A) = 13 > 12 = SUM(B)$ while $SPT(A) = 15 < 24 = SPT(B)$. This emphasis an additional challenge of the reoptimization problem: an optimal solution may not use the whole budget. Such anomalies also explains why our hardness proof cannot be a simple reduction from the subset-sum problem, and the dummy jobs are required.

III. Optimal Algorithms

A. A Brute-force Solver based on Branch and Bound

Our brute-force solver was designed to utilize high performance multi-core machines in order to find optimal solutions for the problems that were shown to be NP-complete. The solution space for a scheduling problem can be described by a tree of depth n, where depth k corresponds to the assignment of job k, for $1 \leq k \leq n$. Specifically, the root (depth 0) corresponds to an empty schedule - none of the jobs were assigned; at level 1 there are m nodes, representing job 1 being assigned to each of the m machines. At level k there are m^k nodes, corresponding to all possible assignment of the first k jobs. This implies that the brute-force solver may need to consider m^n assignments find the optimal one.

We note that, as detailed in Section I-A, once the partition of jobs among the machines is determined, the internal job order on each machine either has no effect on the solution (in the $\min C_{max}$ problem), or is the unique SPT-order (in the $\min \sum_j C_j$ problem). Thus, the solution space need not distinguish between assignments with different internal order of the same set of jobs on every machine.

Obviously, even without considering different internal orders, iterating over all of the m^n configurations is not feasible when dealing with large instances. Our solver uses a *branch and bound* technique combined with other optimizations to effectively trim tree-branches that are guaranteed not to yield an optimal solution.

In particular, the solver keeps in memory the best solution it found so far (its objective value and its transition cost). When processing a tree node if the already accumulated transition cost is larger than the budget or if the objective-function value is larger than the current best, then the solver can safely discard this tree branch as it is guaranteed not to yield a feasible optimal solution. For partial assignments, the objective-value is calculated by combining the value (makespan or total flow-time) of the already assigned jobs, and a lower bound on the yet-to-be-assigned jobs. For the minimum makespan problem, the lower bound is calculated by assuming perfect load-balancing ($\sum_j p_j/m$), and for total flow-time the lower bound is calculated by assuming SPT-order with no job-extension penalties.

In addition, we find out that considering the jobs from longest to shortest, that is, depth 1 corresponds to the longest job in the initial assignment, etc.) drastically helps in trimming branches earlier in the process.

The solver was designed to use multi-core machines in order to shorten the run time, by doing the work in parallel on the different cores. In the heart of the design stands a concurrent queue to which tasks are enqueued. Different threads concurrently dequeue these tasks, in a consumer-producer like mechanism. A 'task' for that matter is a request to process a tree node. That is, when the solver starts the queue is empty and a task to process the root node is added, which ignites the process. The solver is done when the queue is empty.

The solver's ability to solve problems instances of different sizes is determined by the given machine, to be more

specific, by the CPU's clock speed, the number of available cores and sufficient memory (as the entire process is in memory). For example, the solver was able to handle a problem with 9 machines and 20 jobs in about 100 minutes, when ran on a machine with 8 cores and 32GB of RAM memory.

B. An Optimal Algorithm for $\Sigma_j C_j$

An algorithm for finding an optimal reschedule with respect to the minimum total flow-time objective is presented in [2]. The algorithm returns an optimal modified schedule using the minimal possible budget. The algorithm is based on reducing the problem to a minimum-weight complete-matching problem in a bipartite graph. The algorithm fits the most general case - arbitrary modifications, arbitrary transition costs and arbitrary job-extension penalties.

We have implemented this algorithm, and use its results as a benchmark so we can evaluate how well our heuristics perform. The algorithm is based on matching the jobs with possible slots on the machines. For completeness, we give here the technical details that are relevant to its implementation. Recall that n and m represent, respectively, the number of jobs and machines in the modified instance. Let $G = (V, E)$, where $V = J \cup U$. The vertices J correspond to the set of n jobs (a single node per job). The set U consists of mn nodes, q_{ik}, for $i = 1, \ldots, m$ and $k = 1, \ldots, n$, where node q_{ik} represents the k^{th} from last position on machine i. The edge set E includes an edge (v_j, q_{ik}) for every node in J and every node in U (a complete bipartite graph). The edge weights consist of two components: a dominant component corresponding to the contribution of a job assigned in a specific position to the total flow-time, and a minor component corresponding to the associated transition cost. Both components are combined to form a single weight. Formally, for a large constant Z,

- For every job that is assigned to i in S_0, let $w(v_j, q_{ik}) = Zkp_j$.
- For every $i' \neq i$, let $w(v_j, q_{i'k}) = Zk(p_j + \delta_{i,i',j}) + \theta_{i,i',j}$.

These weights are based on the observation that a job assigned to the k-th from last position, contributes k times its processing-time to the total flow-time (see details in [2]). We implemented the algorithm by using the Hungarian method [17], a combinatorial optimization algorithm that solves the assignment problem in polynomial time. The solver's run time is $O(|V|^3)$, where $|V| = n(m + 1)$. In practice, this optimal solver can easily handle instances with 30 machines and 300 jobs.

IV. Our Heuristics

In this section we describe the heuristics we have designed and implemented. Some heuristics were designed for specific modification (e.g. machines removal, limited budget), or for specific objective function, while some are general and fit all our reoptimization variants.

A. Heuristics for Minimum Makespan

We suggest two greedy heuristics, both intended to solve the *minimal makespan* problem ($\min C_{max}$). In the first, we select the next migration to be performed according to the job's processing times, while in the second, we select the next migration according to the loads on the machines. Both algorithms begin with S_0 as the initial configuration. If the modification involves machines' removal, we first perform migrations of jobs assigned to the removed machines and migrate each such job j assigned to a removed machine i, to a machine $i' \in M$ for which $\theta_{i,i',j}$ is minimal. Ties are broken in favor of short extension penalty. As mentioned in the introduction, we assume that the budget is sufficient for this reschedule, as otherwise no feasible solution exists. Following the above preprocessing, we perform the following:

1. LPT-Based: In every iteration we consider the jobs in non-increasing processing-time order. When considering job j, we check whether migrating it to one of the two least loaded machines increases the load-balancing, formally, assume j is assigned to machine i, and we consider moving it to machine i', we check whether $p_j + \theta_{i,i',j} + L_{i'} < L_i$. If the answer is positive and the remaining budget allows, the migration is performed. We repeat the iterations until a complete pass over the jobs yields no migration.

2. Loads-Based: In every iteration we try to migrate some job out of the most loaded machine. We first consider the pair of most-loaded and least-loaded machines. Denote these machines by i and i'. We consider jobs on machine i according to order $\theta_{i,i',1} \leq \theta_{i,i',2} \leq \ldots$. When considering job j we check whether migrating it to machine i' increases the load-balancing, that is, $p_j + \theta_{i,i',j} + L_{i'} < L_i$. If the answer is positive and the remaining budget allows, the migration is performed, and a new iteration begins (maybe with a different pair of most- and least-loaded machines). If the answer is negative for all the jobs on i, we move to the next candidate for target machine i' - the second least-loaded machine, etc. The iteration ends when some beneficial migration from the most-loaded machine is detected. If none such migration exists, the algorithm terminates.

B. Heuristics for Minimum Total Flow-time

The minimum total flow-time reoptimization problem can be solved optimally assuming unlimited budged. While the optimal algorithm presented in Section III-B solves optimally the $\Sigma_j C_j$ problem using the minimal possible budget, it cannot be modified to solve the problem when the budget is limited. In fact, as shown in Section II, this variant is NP-hard. We propose two heuristics that use the optimal algorithm as a first step and then each, in its own

way, change the assignment to reach a feasible solution which obeys the budget constraints. A third algorithm that we propose, tries to reach an SPT-like schedule.

1. Greedy Reversion: The optimal algorithm returns an assignment S minimizing the total flow-time, which might not conform to the budget limitation. The following steps are performed to reach a feasible solution. First, we sort all the jobs which migrated in the transition from S_0 to S in non-increasing order according to the transition cost their migration caused.

We then distinguish between two cases:

1) The modification consists of only machines' *addition*. We revert the transitions one by one until we reach an allowed budget.
2) The modification includes machines' *removal*. We revert the transitions of jobs which do not originate from a removed machine, one by one until we reach an allowed budget. If after all possible reverts were done, the budget is still not met, we continue to the next step: 'Handling jobs of removed machines'.

Handling jobs of removed machines: This step is performed only when removed machines are involved, and all the jobs assigned to remaining machines are back in their initial machines. We sort the jobs originated from removed machines in non-increasing order according to the transition cost their migration (determined by the optimal algorithm) caused. Job after job, we migrate a job j assigned in S_0 to a removed machine $i \in M_0 \setminus M$ to the machine $i' \in M$ for which $\theta_{i,i',j}$ is minimal, breaking ties in favor of better objective value. As explained in the introduction, we assume that the budget is sufficient to complete all these migrations.

2. Cyclic Reversion: The optimal algorithm returns an assignment S minimizing the total flow-time, which might not conform to the budget limitation. Similar to the previous heuristic, we choose the most expensive transition involved, denote by j the corresponding job. We migrate job j back to its origin machine, $M_{0,j}$. Since we wish to keep jobs distributed as evenly as possible, we now choose a job that migrated to $M_{0,j}$ and migrate it back to its initial machine. We choose the job whose migration to $M_{0,j}$ was most expensive. We keep these cyclic reverts until one of following conditions holds: a) We made a complete loop and reached back the machine from which we started. b) We have reached a machine to which no job was migrated. If the budget conforms to the limitation, we stop, Otherwise we choose a job with the most expensive transition cost and start a new revert cycle.

If the modification includes machines' *removal*, jobs originated from the removed machines cannot be selected to migrate back to their original machine. If the budget is not met after all the allowed reverts were performed, we continue to the step 'Handling jobs of removed machines', as described in the greedy heuristic.

3. SPT-like: It is known that SPT ordering is optimal for $P||\Sigma_j C_j$. We therefore try to reach a schedule that fulfils the following basic properties of an SPT schedule:

1) In any optimal schedule the number of jobs on any machine is either $\lfloor \frac{n}{m} \rfloor$ or $\lceil \frac{n}{m} \rceil$.
2) The jobs can be partitioned into $\lfloor \frac{n}{m} \rfloor$ rounds, such that the k-th round consists of all the jobs that are k from last on some machine. In an SPT schedule, each of the jobs in the k-th round is not shorter than each of the jobs in the $k+1$st round.

This heuristic consists of three stages. The first stage, applied when machines were removed, is to move to some feasible schedule - each of the jobs assigned to a removed machine, is migrated into a machine for which the transition cost is the lowest.

In the second stage, we try to make the machines as balanced as possible in terms of number of jobs. While the budget allows and while there exists a pair of machines, one with more than $\lceil \frac{n}{m'} \rceil$ jobs and the other with less than $\lfloor \frac{n}{m'} \rfloor$ jobs, we migrate the cheapest-to-move job on the first machine, to the second one.

In the third phase, we try to make our solution as close to the SPT ordering as possible, we compare the solution round after round to the desired SPT ordering, and switch jobs whenever required, as long as the budget allows.

C. Genetic algorithm

In the Genetic algorithm the idea is for the solution to be obtained in a way that resembles a biological evolution process [9], [19]. That is, we let the method's evolutionary process find the solution by itself. The idea is to define the *Genome* of a single solution and a *Ranking* method $Rank : Genome \rightarrow \mathbb{R}$. The genome of a single solution represents and gives all the needed information regarding the solution. In our case the Genome is simple, for a problem instance with m machines and n jobs, a solution genome id, g, defined as $g = (g_1, g_2, ..., g_n)$, where $g_i \in [1, m]$ and $g_i \notin \{x|\text{x is a removed machine id}\}$, in other words each cell with index i represents the $i-th$ jobs and the cell's value is the machine this job is assigned to in the modified schedule. The ranking method is used to define how good is a given solution. In our case the ranking method sorts the different genomes first by the objective method value (C_{max} or $\Sigma_j C_j$) and then by the transition cost. We create a $population$ (generation 1), which is a collection of $genomes$, we rank each member of the population and sort them from best to worst.

When solving a reoptimization problem with limited budget, to guarantee the algorithm end up with a feasible solution, we create at least one feasible genome in generation1. In the case of 'machines addition', this solution will be S_0 as it is both valid and requires no transition cost. In the case of 'machines removal', a job j assigned in S_0 to a removed machine $i \in M_0 \setminus M$ is assigned in the feasible

genome to the machine $i' \in M$ for which $\theta_{i,i',j}$ is minimal. We assume that the budget is sufficient for this reschedule, as otherwise no feasible solution exists.

The next step is the evolutionary-like step, in which we create the next generation according to the following methods:

1) Elitism mechanism: We take the best 5% genomes and move them 'as-is' to the next generation. This guarantee that the next generation will be at least as good as the current one. To deal with the case of limited budget, we also pass 'as-is' the best solution which meets the given budget. This must be done since the genetic process is pushing the genomes population for a better objective values as a primary goal and to minimize the transition cost as a secondary goal.
2) Cross over: From the entire genomes population, we choose randomly 2 elements, denoted g_x and g_y, we choose a pivot point from the range of $ind \in [1, n-1]$, and create two new items:

$$newItem1_i = \begin{cases} g_{x_i} & \text{if } i \leq ind \\ g_{y_i} & \text{if } i > ind \end{cases}$$

and

$$newItem2_i = \begin{cases} g_{y_i} & \text{if } i \leq ind \\ g_{x_i} & \text{if } i > ind \end{cases}$$

43% of the next generation is a result of this operator.
3) Mutate: We choose a random genome, we choose from its genome a random cell and change its value. 43% of the next generation is a result of this operator.
4) Fresh Items: We generate new genomes. These new elements have the potential of shifting the results in a new direction and to help avoid local optimum. 9% of the next generation is be a result of this operator.

Each genome in the newly created population is then re-evaluated, meaning, its score is computed. The process repeats itself until it fails to improve any further and the genome with the best ranking is selected as output from the most recent generation. Obviously if we examine the best solution from generation $i+1$ compared to that of generation i we will notice that the 'quality' of the best solution is non decreasing over the generations as we have the 'Elitism mechanism' which ensures us that the best individuals will survive to the next generation.

V. Experimental results

The datasets for our experiments were created using our own data generator which supports any parameters combination of number of machines and jobs, number of added or removed machines, number of added or removed jobs, as well as the distributions of job lengths, job-extension penalty, and transition costs.

Instances on which we run our heuristics could be very large (hundreds of jobs, and several dozens of machines). Instances on which we run our brute-force solver (introduced in Section III-A) had to be smaller. In particular, we ran the brute-force solver on instances with 20 jobs and 4 machines. We find out that even such small instances can provide a good comparison between different heuristics; therefore, the brute-force solver is helpful for concluding how far from the optimum our heuristics perform. The optimal algorithm for $\min \Sigma_j C_j$, based on a reduction to perfect matching (introduced in Section III-B), was able to handle relatively large instances of 15 machines and 300 jobs. In our basic template for job creation, the jobs' lengths were uniformly distributed in $[1, 20]$. The job-extension penalty of job j was uniformly distributed in $[1, \frac{p_j}{2}]$, and the transition costs were uniformly distributed in $[1, 5]$.

To generate problems instances for a specific experiment we took a template instance, decided on one parameter that will vary in the different runs, and set the rest of the parameters to basic values. For example, to understand how the number of added machines affects the heuristics performance, we fixed all the other parameters (jobs' lengths, transition costs, etc.), and run the heuristics on multiple instances which vary only in the number of added machines. To avoid anomalies, we have generated for each experiment 5 instances with the same parameters, based on 5 templates instances (same configuration, different instance) and considered the average performance as the result.

Another parameter that could affect the performance of our heuristics is the initial assignment - which may be random, SPT or LPT. We found out that in practice the initial assignment does not affect the results significantly and the results we present in the sequel were all generated with a randomize initial assignment - which is a bit more 'challenging' and therefore emphasizes the differences among the heuristics.

The results of our experiments are presented and analyzed below. In all the figures, the bars show the objective value ($\Sigma_j C_j$ or C_{max}), and the lines show the corresponding transition cost.

A. Results for the Minimal Total Flow-Time problem

1) Machines' Addition: The template for heuristics that analyze the $\min \Sigma_j C_j$ problem consists of 15 machines and 300 jobs. We start by showing how the different heuristics performs on instances with both transition costs and job-extension penalties, where the number of added machines was set to $m/2$. As shown in Fig. 1, with unlimited budget the genetic algorithm is the closest to the known optimum, calculated by the perfect matching algorithm result. As budget is limited, the performance of the genetic algorithm drops. As expected, the lower the budget, the higher the objective value. Also, the differences

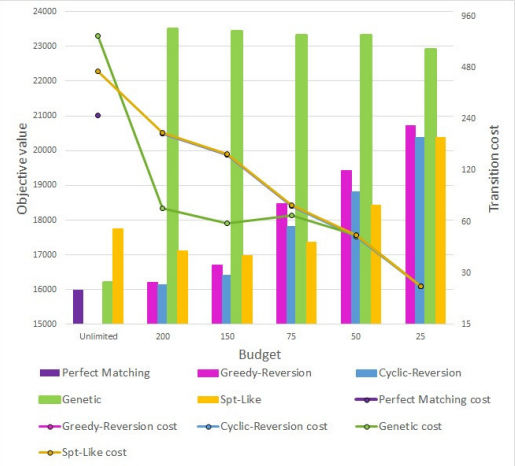

Fig. 1. Results for $\min \Sigma_j C_j$ with $m/2$ added machines and variable budget.

between the heuristics are less significant as the budget decreases, as less transitions are allowed. Interesting fact is that the genetic algorithm has a slight improvement as the limitation is getting stricter. We explain this by the fact that before starting the algorithm we include in the population items that obey the allowed budget. Later, these items are influencing the genetic process and are helping the algorithm to converge to a good solution, better than with a more relaxed budget limitation.

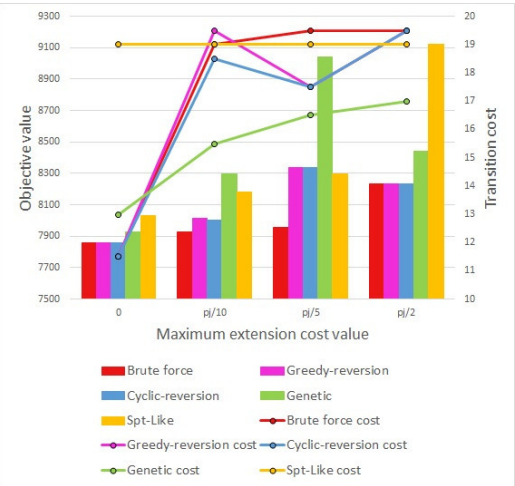

Fig. 2. Results for $\min \Sigma_j C_j$ with variable extension penalty.

The goal of our next experiment was to see how close the heuristics get to the actual optimum. For this test we have used our brute-force solver on relatively small problem instances (4 machines and 20 jobs), two machines were added and the budget was set to 20. The results for various extension penalties are shown in Fig. 2. We observe that both 'Greedy-reversion' and 'Cyclic-reversion' heuristics were very close to the optimum.

2) Machines' Removal: Fig. 3 presents the performance of the different heuristics when the modification is machines' removal and the budget is limited to 150. According to our parameters, this budget is expected to be sufficient for the migration of about 20% of the jobs. The initial assignment was of 300 jobs on 15 machines. Not surprisingly, we see an increase of the objective value as the number of removed machines increases. All of the heuristics performed more or less the same, both in terms of the achieved objective value and in term of the budget utilization, with an exception of the Genetic algorithm which manage to use a significantly lower budget.

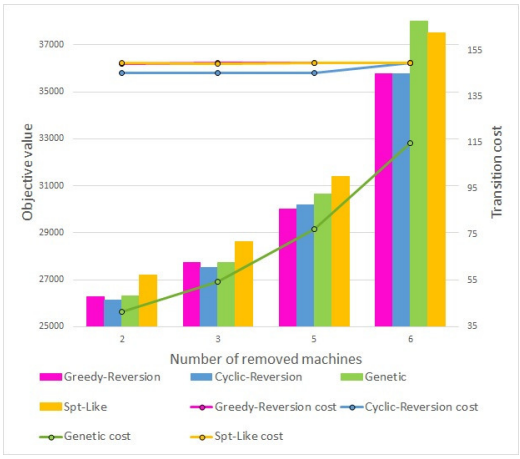

Fig. 3. Results for $\Sigma_j C_j$ for machines' removal and limited budget.

Fig. 4 presents the results for the same instance and the same modification only with unlimited budget. This problem is the one for which we have an efficient optimal algorithm (see Section III-B). The genetic algorithm perform very close to the optimum for every number of removed machines. In fact, for two removed machines its transition cost is lower than the optimum and only slightly higher in the total flow-time (recall that the optimal algorithm 'insists' on finding a reschedule that minimizes the total flow-time). On the other hand the SPT-Like heuristic is both very costly and gives poor results. This can be explained by the fact that insisting on a complete SPT order requires many transition, and involves many job-extension penalties.

B. Results for the Minimum Makespan problem

1) Machines' Addition: Our template for experiments analyzing the $\min C_{max}$ problem consists of 30 machines and 500 jobs. Fig. 5 presents results for adding 15 machines and variable budget. The 'Loads-based' heuristic is the best heuristic. The genetic algorithm perform poorly compared to the other heuristics, but on the other hand, it does not utilize the whole budget.

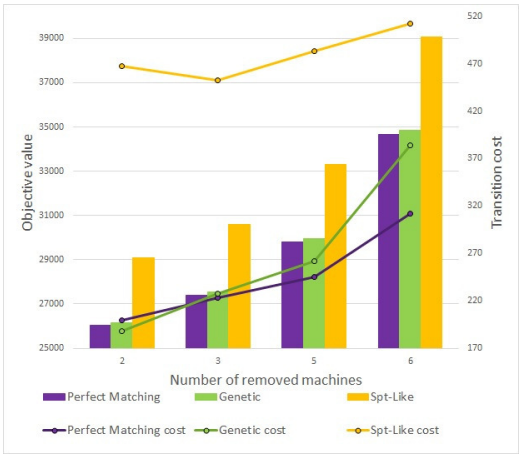

Fig. 4. Results for $\Sigma_j C_j$ for machines' removal and unlimited budget.

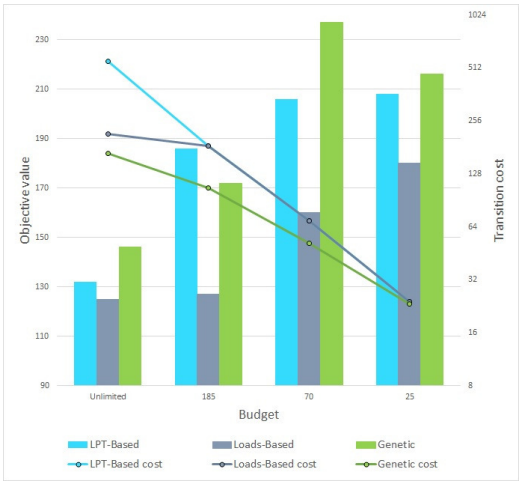

Fig. 5. Results for $\min C_{max}$ with $m/2$ added machines and variable budget.

In the our next experiment we measure how close the heuristics get to the optimum. We have used our brute-force solver on relatively small problem instances, consisting of 4 machines, 20 jobs, and a limiting budget of 20. The results for various extension penalties are shown in Fig. 6. Once again, the 'Loads-based' heuristic outperform the others, and is relatively close to the optimum. The 'LPT-based' heuristic seems to perform (relatively) better as the job-extension penalty increases.

2) Removing machines: Our next experiments compare the performance of the different heuristics when the modification is machines' removal. We performed two experiments - with budget limited to 250 and with unlimited budget. Due to space constraints, the figures are omitted. Our results show that with unlimited budget, all three heuristics (LPT-based, Loads-based and genetic) perform more or less the same. While a similar makespan is achieved, the

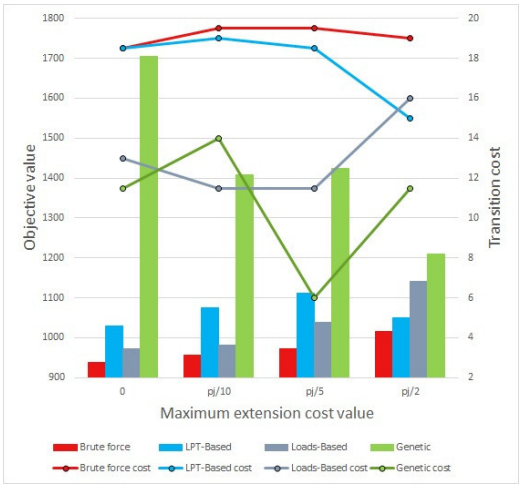

Fig. 6. Results for $\min C_{max}$ with variable extension penalty.

Loads-based heuristic requires the lower transition cost, then the LPT-based (that needs 10% higher cost) and the genetic ($15-20\%$ higher than Loads-based). With limited budget, the Loads-based and LPT-based heuristics perform significantly better than the genetic algorithm, but they also require a much higher budget.

VI. Conclusions and Future Work

We presented theoretical and experimental results for the reoptimization variant of job scheduling problems. We have shown that the problems of finding the minimum total flow-time with limited budget, finding the minimum makespan with limited budget and finding the minimum makespan with unlimited budget are NP-Complete. We have designed and implemented several heuristics for each of these problems, and performed a comprehensive empirical study to analyze their performance. To see how well these heuristics perform compared to the actual optimum, an efficient branch-and-bound brute-force solver was designed and implemented. An optimal algorithm for the minimum total-flow problem with unlimited budget was also implemented.

In general, our experiments reveal that while the problems are NP-hard, heuristics whose time complexity is polynomial in the number of jobs and machines, perform very well in practice. Simple algorithms, that are based on adjustment of known heuristics for the one-shot problem (with no modifications) are both simple to implement and provide results that are, on average, within $10\%-15\%$ from the optimum. More complex algorithms, that are based on a preprocessing in which a perfect matching algorithm is implemented, perform on average even better.

We have observed that while the Genetic algorithm does not perform well when given a limited budget, it performs relatively well with unlimited budget for the

minimum C_{max} problem, and close to optimum for $\Sigma_j C_j$. It also takes a considerable amount of time to run. In some scenarios, its objective value may not be competitive compared to other heuristics, however, its budget utilization is impressively good (see for example Fig. 3). A known issue of genetic algorithm is that the parameters must be carefully tuned in order for the algorithm to converge into a good solution. Future work on this algorithm might refactor the population size or operators we have used (Elitism, Crossover, Mutation) by adding new operators, modify the existing or change the possibilities of each to create a more optimized genetic algorithm. Another direction to explore is to create a dedicated score method for each variant of the problems. For real life applications where budget utilization is a big concern, we are sometimes allowed to use lot of budget but strive to use as less as possible. The genetic algorithm is a good choice for such scenarios.

Our greedy heuristics performed well, both on the $\Sigma_j C_j$ and the C_{max} problems. We have observed that the 'Loads-based' heuristic outperformed the 'LPT-based' both in terms of objective value and budget utilization. With unlimited budget, the budget utilization difference was more significant. For $\min \Sigma_j C_j$, the 'Cyclic-reversion' showed better performance compared to the 'Greedy-reversion', This result does not surprise us as a more balanced solution is expected to yield better results for the minimum total flow-time problem. In terms of budget utilization, it was expected that this greedy, budget oriented method will utilize as mush budget as possible.

An additional direction for future work is to develop algorithms for the minimum makespan problem with a guaranteed approximation ratio. While tuning existing approximation-algorithm for the classical one-shot problem seems to be a promising direction, the presence of transition-costs and job-extension penalties give rise to new challenges and considerations. Finally, it would be interesting to consider different objective functions, or different scheduling environments, for example, jobs with deadlines or precedence constraints, as well as unrelated or restricted machines.

***Abstract*—This paper is devoted to an evaluation of selected fuzzy particle swarm optimization algorithms. Two non-fuzzy and four fuzzy algorithms are considered. The Takagi-Sugeno fuzzy system is utilized to change the parameters of these algorithms. A modified fuzzy particle swarm optimization method is proposed, in which each of the particles has its own inertia weight and coefficients of the cognitive and social components. The evaluation is based on the common nonlinear benchmark functions used for testing optimization methods. The ratings of the algorithms are assigned on the basis of the mean of the objective function and the relative success.**

I. Introduction

PARTICLE swarm optimization (PSO) is a stochastic optimization technique that was developed by Kennedy and Eberhart [1]. The PSO is mainly inspired by the social behavior of organisms that live and interact within large groups, for example, schools of fish, flocks of birds or swarms of bees. The usefulness of PSO in solving a wide range of optimization problems has been repeatedly confirmed. It has been applied to: the intelligent identification and control of a dynamic system [2]; solving an economic dispatch problem in power systems [3]; human motion tracking [4]; feature selection [5]; automatic incident detection [6]; fuzzy anomaly detection in networks [7]; the estimation of hurdles clearance parameters [8] and many more problems. Many variants of the PSO have been developed since it was introduced in 1995 [1]. The most common are algorithms with a constriction factor [9] and with a linear inertia weight [10]. Among the PSO modifications we can distinguish algorithms that utilize fuzzy systems [2], [3], [11]–[15]. For example, in papers [2], [11] a fuzzy system was used to dynamically modify the inertia weight. Another approach was presented in [3], where a fuzzy system is used to change the inertia weight and the coefficients of the cognitive and social components.

The goal of this study is to evaluate selected fuzzy PSO algorithms and to propose a modified fuzzy PSO algorithm. In our research, we use the Takagi-Sugeno system [16] instead of the Mamdani system [17] because it has shorter processing time. In this paper, we consider six different versions of PSO, including two non-fuzzy, and four fuzzy algorithms. The evaluation is based on nonlinear benchmarks in the form of Ackley, Griewank, Rastrigin and Rosenbrock functions. The calculations were conducted using Matlab software and the "PSO Research Toolbox" by Evers [18].

II. Particle swarm optimization

The particle swarm model consists of a group of particles that are randomly initialized in the d-dimensional search space. During an iterative process, particles explore this space effectively by exchanging information to find the optimal solution. Each i-th particle is described by its position $\mathbf{x}_i$, velocity $\mathbf{v}_i$, and best position $\mathbf{pbest}_i$. Moreover, the particles have access to the best global position $\mathbf{gbest}$ that has been found by any particle in the swarm.

In the basic PSO algorithm [1], the velocity and the position of each particle in k-th iteration are updated using the following equations:

$$\mathbf{v}_i^{k+1} = \mathbf{v}_i^k + c_1\mathbf{r}_1(\mathbf{pbest}_i^k - \mathbf{x}_i^k) + c_2\mathbf{r}_2(\mathbf{gbest}^k - \mathbf{x}_i^k) \quad (1)$$

$$\mathbf{x}_i^{k+1} = \mathbf{x}_i^k + \mathbf{v}_i^{k+1} \quad (2)$$

where $\mathbf{r}_1$, $\mathbf{r}_2$ are vectors with uniformly distributed random numbers in the interval $[0, 1]$, and c_1, c_2 are positive constants equal to 2.

The velocities of particles are determined by three components. The first component is the inertia that models the particle's tendency to continue moving in the same direction. The second component is cognitive and attracts particles towards the best position previously found by the particle. The last component is a social component that moves particles towards the best position found earlier by any particle. Selection of the best global position and the best position for i-th particle is based on the objective function (denoted later by $f(\cdot)$).

A. PSO1: Clerc, Kennedy algorithm [9]

Many approaches have been developed to improve the performance of the basic PSO algorithm. One way is to use the constriction factor χ that was proposed by Clerc and Kennedy [9]. The application of this factor controls the velocity magnitude.

The velocity equation has the form:

$$\mathbf{v}_i^{k+1} = \chi[\mathbf{v}_i^k + c_1\mathbf{r}_1(\mathbf{pbest}_i^k - \mathbf{x}_i^k) + c_2\mathbf{r}_2(\mathbf{gbest}^k - \mathbf{x}_i^k)] \quad (3)$$

where χ is calculated as $\chi = \frac{2}{|2-\varphi-\sqrt{\varphi^2-4\varphi}|}$ and $\varphi = c_1 + c_2$, $\varphi > 4$. In this paper, the following typical values are used: $c_1 = c_2 = 2.05$, $\varphi = 4.1$ and $\chi = 0.7298$.

978-83-60810-90-3/$25.00

B. PSO2: Eberhart, Shi algorithm [10]

Another way to improve the performance of PSO is to use the inertia weight ω. The inertia weight is significant for the performance of PSO, because it balances the global exploration and local exploitation abilities of the swarm. Exploration is facilitated when the inertia weight is high, but convergence is slower. On the other hand, when the inertia weight is low then convergence is faster, but it sometimes leads to local solutions. Hence, linearly decreasing inertia weight is proposed in [10].

The velocity equation has the form of

$$\mathbf{v}_i^{k+1} = \omega^k \mathbf{v}_i^k + c_1 \mathbf{r}_1 (\mathbf{pbest}_i^k - \mathbf{x}_i^k) + c_2 \mathbf{r}_2 (\mathbf{gbest}^k - \mathbf{x}_i^k) \quad (4)$$

The inertia weight ω is calculated by the formula

$$\omega^k = \omega_{max} - \frac{\omega_{max} - \omega_{min}}{iter_{max}} \cdot k \quad (5)$$

where ω_{max} is the initial weight, ω_{min} is the final weight and $iter_{max}$ is the maximum number of iterations. The limits for ω are set to $\omega_{max} = 0.9$ and $\omega_{min} = 0.4$.

III. Takagi-Sugeno system

Consider the Takagi-Sugeno (T-S) fuzzy system with two inputs y_1, y_2 and one output u. For the input y_1 we define m fuzzy sets A_i (Fig. 1), for which the vertices are placed in points p_i, where $i = 1, \ldots, m$. Similarly, for the input y_2, we define n fuzzy sets B_j with vertices in points q_j, where $j = 1, \ldots, n$. The coordinates p_i and q_j are written in the form of the vectors $\mathbf{p} = [p_i] = [p_1, \ldots, p_m]$ and $\mathbf{q} = [q_j] = [q_1, \ldots, q_n]$, respectively.

The output of the system is described by $m{\cdot}n$ fuzzy inference rules in the form of

$$R_{ij}: \text{ IF } y_1 \in A_i \text{ AND } y_2 \in B_j, \text{THEN } u = z_{ij} \quad (6)$$

where $z_{ij} \in \mathbb{R}$ is the consequent of the rule R_{ij}. The rules (6) are written in the following table:

$y_1 \backslash y_2$	B_1	$\ldots$	B_n
A_1	z_{11}	$\ldots$	z_{1n}
$\vdots$	$\vdots$	$\ddots$	$\vdots$
A_m	z_{m1}	$\ldots$	z_{mn}

(7)

The output u of the Takagi-Sugeno system is calculated as the weighted average of z_{ij} and determined by

$$u = TS(y_1, y_2) = \frac{\sum_{i=1}^{m} \sum_{j=1}^{n} w_{ij}(y_1, y_2) z_{ij}}{\sum_{i=1}^{m} \sum_{j=1}^{n} w_{ij}(y_1, y_2)} \quad (8)$$

where $w_{ij}(y_1, y_2) = A_i(y_1) \cdot B_j(y_2)$ denotes the degree of fulfillment of the rule R_{ij}.

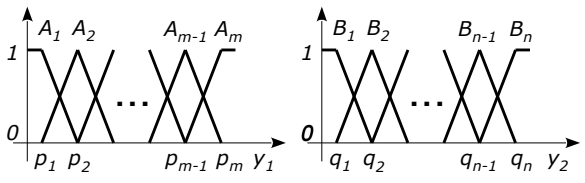

Fig. 1. Fuzzy sets for the inputs y_1 and y_2

IV. Fuzzy PSO

A. FPSO1: algorithm based on the work by Shi, Eberhart [11]

Better PSO performance can be obtained using the nonlinearly changing inertia weight that balances global and local search abilities. It is difficult to design a mathematical model to adapt the inertia weight dynamically. The solution to this problem may be obtained using a linguistic description of the search process. For example, we can use a fuzzy inference system for tuning the inertia weight [11].

In the FPSO1 algorithm, the inertia weight is described by the formula

$$\omega^{k+1} = \omega^k + \Delta\omega, \quad \Delta\omega = TS(nf^k, \omega^k) \quad (9)$$

where the T-S fuzzy system (8) is used to calculate the change of inertia weight $\Delta\omega$. The input nf^k is the normalized objective function value described by

$$nf^k = \frac{fg^k - f_{min}}{f_{max} - f_{min}} \quad (10)$$

where $fg^k = f(\mathbf{gbest}^k)$, f_{min} is the optimal solution (for the test functions considered in this paper, it is equal to 0), f_{max} is the worst solution (in our paper $f_{max} = f(\mathbf{gbest}^0)$). The fuzzy sets for the inputs nf^k and ω^k have vertices in points $\mathbf{p} = [0, 0.5, 1]$, $\mathbf{q} = [0.4, 0.7, 1]$, respectively, and the fuzzy rules have the form of

$nf^k \backslash \omega^k$	B_1	B_2	B_3
A_1	Z	N	N
A_2	P	Z	N
A_3	P	Z	N

(11)

where $N = -0.1$, $Z = 0$ and $P = 0.1$.

B. FPSO2: algorithm based on the work by Alfi, Fateh [2]

The improvement of the FPSO1 algorithm was proposed by Alfi and Fateh [2]. In their method, the inertia weight is calculated for each particle according to its current state. This is justified because each particle in the swarm is in a different place in a complex environment and may have a different balance between global and local search abilities.

In the FPSO2 algorithm, the change of inertia weight is determined by the T-S system (8) as

$$\Delta\omega_i = TS(nf_i^k, \omega_i^k) \quad (12)$$

where

$$nf_i^k = \frac{fp_i^k - f_{min}}{fp_i^0 - f_{min}} \quad (13)$$

and $fp_i^k = f(\mathbf{pbest}_i^k)$. The vertices of fuzzy sets for nf_i^k and ω_i^k are chosen as $\mathbf{p} = [0, 0.5, 1]$, $\mathbf{q} = [0.4, 0.6, 0.8]$ respectively, and the fuzzy rules are

$nf_i^k \backslash \omega_i^k$	B_1	B_2	B_3
A_1	P	N	N
A_2	P	Z	N
A_3	P	Z	N

(14)

where $N = -0.1$, $Z = 0$ and $P = 0.1$.

C. FPSO3: algorithm based on the work by Niknam [3]

In the FPSO3 algorithm, the fuzzy system proposed by Niknam [3] is used to change not only ω, but also the coefficients c_1 and c_2. These coefficients determine the influence of the personal best position $\mathbf{pbest}_i$ and the global best position $\mathbf{gbest}$ on the particle velocity. For example, if c_1 is larger than c_2, then the particle has the tendency to move to the personal best position, rather than to the global best position found by the swarm.

In the FPSO3 algorithm, three T-S systems are used to determine ω, c_1 and c_2:

$$\omega = TS(nf^k, nu^k) \tag{15}$$
$$c_1 = TS(nf^k, nu^k) \tag{16}$$
$$c_2 = TS(nf^k, nu^k) \tag{17}$$

The input nf^k is defined in (10) and nu^k is the normalized number of iterations without change of the best global position:

$$nu^k = \frac{u^k - u_{min}}{u_{max} - u_{min}} \tag{18}$$

where u^k is the number of iterations without change of the best global position, $u_{min} = 0$ and $u_{max} = iter_{max}$. The fuzzy sets are defined by the vectors $\mathbf{p} = [0.2, 0.4, 0.6, 0.8]$, $\mathbf{q} = [0.2, 0.4, 0.6, 0.8]$. The fuzzy rules for ω are defined as

$nf \setminus nu$	B_1	B_2	B_3	B_4
A_1	PS	PM	PB	PB
A_2	PM	PM	PB	PR
A_3	PB	PB	PB	PR
A_4	PB	PB	PR	PR

(19)

In table (19) we have $PS = 0.4$, $PM = 0.6$, $PB = 0.8$ and $PR = 1$. The fuzzy rules for c_1/c_2 are defined as

$nf \setminus nu$	B_1	B_2	B_3	B_4
A_1	PR/PR	PB/PB	PB/PM	PB/PM
A_2	PB/PB	PM/PM	PM/PS	PS/PS
A_3	PB/PM	PM/PM	PS/PS	PS/PS
A_4	PM/PM	PM/PS	PS/PS	PS/PS

(20)

In table (20) we have $PS = 1.2$, $PM = 1.4$, $PB = 1.6$ and $PR = 1.8$.

D. MFPSO: authors' proposition

The modified fuzzy PSO (MFPSO) algorithm proposed by the authors combines the previously described concepts developed by Alfi, Fateh [2] and Niknam [3]. In this algorithm, each of particles has its own coefficients ω, c_1 and c_2 changing according to the linguistic description represented by the fuzzy rules. In this way, each of the particles may be treated individually. For example, if a particle has found the new local best position $\mathbf{pbest}_i$, then the inertia weight ω should be decreased and the coefficients c_1 and c_2 should be increased. On the other hand, if $\mathbf{pbest}_i$ has not changed for a long time, then a better strategy would probably be to increase ω and decrease c_1 and c_2 to improve the ability of exploration.

In the MFPSO algorithm, the authors propose ω, and c_1, c_2 for each particle to be determined using three T-S systems:

$$\omega_i = TS(nf_i^k, nu_i^k) \tag{21}$$
$$(c_1)_i = TS(nf_i^k, nu_i^k) \tag{22}$$
$$(c_2)_i = TS(nf_i^k, nu_i^k) \tag{23}$$

where nf_i^k is defined in (13), nu_i^k has the form of

$$nu_i^k = \frac{u_i^k - u_{min}}{u_{max} - u_{min}} \tag{24}$$

and u_i^k is the number of iterations without change to the best personal position for the i-th particle. It should be noted that in equation (18), nu^k is calculated based on the global best position $\mathbf{gbest}$, whereas in equation (24) nu_i^k is calculated based on the personal best position $\mathbf{pbest}_i$. The vertices of fuzzy sets for nf_i^k and nu_i^k are defined as $\mathbf{p} = [0.2, 0.45, 0.65, 0.9]$, $\mathbf{q} = [0.2, 0.45, 0.65, 0.9]$.

The fuzzy rules for ω are the same as in (19). The fuzzy rules for c_1 and c_2 are given in tables (20). In (20) we have $PS = 1.4$, $PM = 1.7$, $PB = 1.9$ and $PR = 2.2$. For example, the rule R_{11} has the form

$$\begin{aligned} R_{11}: &\text{ IF } nf_i^k \in A_1 \text{ AND } nu_i^k \in B_1, \\ &\text{THEN } \omega = PS \text{ AND } c_1 = PR \text{ AND } c_2 = PR \end{aligned} \tag{25}$$

and the rule R_{44} has the form

$$\begin{aligned} R_{44}: &\text{ IF } nf_i^k \in A_4 \text{ AND } nu_i^k \in B_4, \\ &\text{THEN } \omega = PR \text{ AND } c_1 = PS \text{ AND } c_2 = PS \end{aligned} \tag{26}$$

Other rules can be interpreted similarly.

V. Results and discussion

In order to evaluate the algorithms, four common nonlinear benchmarks [11], [19] in the form of Ackley, Griewank, Rastrigin and Rosenbrock functions were used. For these functions, the asymmetric initialization method, similar to [11], was used. The velocities of particles were clamped to v_{max}, however, the positions of the particles were not limited. In Table I, the initialization ranges and v_{max} for the test functions are listed. In our experiments, two dimension sizes were chosen: $d = 10$ and $d = 30$. The number of iterations was set to 1000 and 2000 corresponding to the dimensions 10 and 30. The number of particles was equal to 30 and the number of trials was equal to 30 in all experiments. The parameters of algorithms were chosen on the basis of the papers [11] and [14]. The calculations were conducted using Matlab software and the "PSO Research Toolbox" by Evers [18]. The maximum average time of execution for one trial on a mobile workstation equipped with Intel(R) Core(TM) i7-2820QM did not exceeded 10 s.

The results for benchmark functions are presented in Table II. This table contains the basic statistics for the final value of the objective function and the iteration ($iter\_success$) in which the algorithm achieved the given value (th) of the

objective function. The ratings of the algorithms for all benchmark functions are summarized in Tab. III. The following performance measures were used to evaluate the algorithms:

- mean of the objective function (mfg),
- relative success defined as $rs = \frac{mean\ \ of\ \ iter\_success}{success\_rate}$.

For these measures, the sums of the ratings are shown in Tab. III. These ratings were assigned in such a way that the best algorithm has six points and the worst has one point. For $success\_rate = 0$ (the algorithm has not succeeded) the number of points is equal to zero.

For the dimension $d = 10$ and the measure mfg the highest rating has the algorithm MFPSO proposed by the authors, while for the measure rs the highest rating have the PSO1, FPSO1 and FPSO3. For the dimension $d = 30$ and the measure mfg the highest rating has the algorithm PSO2, while for the measure rs the highest rating has the FPSO1. Analyzing the sum of ratings for mfg it can be seen that the best algorithm is the MFPSO. For rs the MFPSO is the one before last. However, it should be emphasized that in the evaluation of optimization algorithms the most important criterion is the obtained objective function value.

VI. CONCLUSION

In this paper, the evaluation of selected fuzzy particle swarm optimization algorithms was presented. Two non-fuzzy and four fuzzy algorithms were considered. The main contributions of this paper are as follows:

- the application of the Takagi-Sugeno system that is more computationally efficient than the Mamdani system,
- a proposal for the use of the MFPSO algorithm, in which each of the particles has its own inertia weight and the coefficients of the cognitive and social components,
- the evaluation of selected fuzzy PSO algorithms using common benchmark functions.

Further work will focus on improving the proposed algorithm, building models to support the training process in sport [20], and the analysis of athletes' technique [8].

***Abstract*—We consider the problem of scheduling multi-task jobs on identical machines in parallel. Each multi-task job consists of one or more tasks. Each job has a release date and a due date. A task of a job can be processed by any one of the machines. Multiple machines can process the tasks of a job concurrently. The completion time of a job is the time at which all its individual tasks have been completed. A job is late if it is completed after its due date. We study the problem of minimizing the total number of late jobs. We show that while some special cases are solvable, the general problem is NP-hard and there exists no polynomial time ρ-approximation algorithm, for any $\rho > 1$. We present a general algorithm for the problem and derive from it six heuristics whose performance is evaluated by experimental results.**

I. Introduction

THE PROBLEM under consideration is scheduling multi-task jobs on identical machines in parallel. It can be stated as follows: Assume there are m identical machines and n jobs. Each job j $(j = 1, 2, \ldots, n)$, which is available at time r_j and has a due date d_j, consists of k_j $(1 \leq k_j \leq k)$ individual tasks (or operations), where k is the maximum number of tasks that a job may have. Each task $l = 1, 2, \ldots, k_j$ of job j, denoted by o_{lj}, can be processed by any one of the machines, and its processing time is denoted by p_{lj}. The individual tasks of a job can be assigned to multiple machines so that they can be processed concurrently. When a machine switches over from one task to another, no setup is required. The completion time of job j, denoted by C_j, is the time at which all individual tasks of job j have been completed. If we let C_{lj} denote the completion time of task o_{lj}, it is clear that $C_j = \max_{1 \leq l \leq k_j} \{C_{lj}\}$. For the ease of description, we also let $P_{i,j}$ and $C_{i,j}$ denote the total processing time and the completion time of job j on machine i, respectively. By definition, $C_j = \max_{1 \leq i \leq m} \{C_{i,j}\}$. A job is late if $C_j > d_j$, and by standard notation, $U_j = 1$ if $C_j > d_j$ and $U_j = 0$ otherwise. We are interested in minimizing the total number of late jobs $\sum U_j$. Let $jbs\ n$ denote n jobs and $tsk\ k$ denote the maximum number of tasks that a job may have. The problem is denoted by $Pm \mid jbs\ n, tsk\ k, r_j \mid \sum U_j$, where m, n, and k can be either fixed or arbitrary. If any of these is not fixed, it is removed from the notation. For example, $P \mid jbs\ 10, tsk \mid \sum U_j$ denotes that m and k are arbitrary but the number of jobs n is 10. If $r_j = 0$ for all jobs, r_j is removed from the notation as well.

The above problem is a more general description of the fully flexible case of customer order scheduling models described in [1], so it is not limited to any specific application contexts, e.g. manufacturing environments. In addition to the application examples surveyed in [1], we yet give another real-life application example in software project management, with the objective to minimize $\sum U_j$. It is not unusual that in a software development team, new projects with various due dates are requested from business lines. A development manager usually creates a parent task for each new project, and creates multiple child tasks (for example, independent modules or loosely coupled modules as a result of well-designed software architecture) associated with the parent task so that multiple software developers in the development team can work on the project simultaneously. A parent task (project) is completed if and only if all child tasks are completed. All software developers (assuming that they have the same skills at the same proficiency levels after certain cross-training) in the team can work on all child tasks. The challenge for the development manager is to find a good schedule for the team, to minimize the number of parent tasks (projects) that cannot be completed before their due dates, so that the relationship and partnership between the development team and the business teams can be positively built up.

Some past work has been done for this problem with the objective to minimize the total weighted completion time $\sum w_j C_j$ and its un-weighted version. Even when $w_j = 1$ for all j, the problem with an arbitrary k is ordinary NP-hard for any fixed $m \geq 2$ and strongly NP-hard when m is arbitrary (see Blocher and Chhajed [2]). On the other hand, when $k = 1$, the problem becomes the classical problem $P \mid\mid \sum w_j C_j$ which is strongly NP-hard, and for any fixed $m \geq 2$, the problem is equivalent to $Pm \mid\mid \sum w_j C_j$ which is ordinary NP-hard (see [3]). In the aspect of algorithms, when $w_j = 1$, Blocher and Chhajed [2] presented six heuristics with empirical analysis of the performance of the heuristics. One of the heuristics was also studied by Yang [4], [5] where it was shown a worst-case performance bound of $7/6$ for $m = 2$. For arbitrary m, two classes of nine heuristics with proven worst-case performance bounds of either $(2 - 1/m)$ or m were studied by Leung, Li and Pinedo [6].

To the best of our knowledge, no past work has ever been done for this problem with the objective to minimize $\sum U_j$.

In this paper, we are interested in both the complexity and the algorithm aspects of the problem. The remainder of the paper is organized as follows. In Section II, we present some preliminary results regarding some properties of optimal schedules. In Section III, we show that some cases are NP-hard, while some other cases are polynomially solvable. Then, after showing the non-approximability for the general case without release dates, we present in Section IV a general algorithm scheme for the problem and derive from it six heuristics, whose performance is evaluated by experimental results in Section V. Finally, we present conclusions in Section VI.

II. Preliminary Results

We first look into some properties of an optimal schedule for problem $P \mid jbs, tsk \mid \sum U_j$:

Lemma 2.1 (Optimal Property): For problem $P \mid jbs, tsk \mid \sum U_j$, there exists an optimal schedule in which:

a) the tasks (if more than two) of a job are assigned consecutively on each machine;
b) the early jobs are scheduled in nondecreasing order of their due dates on each machine.

Proof: **a)** Suppose that there exists an optimal schedule in which some tasks of job j assigned on machine i are not consecutive, we keep the last task of job j where it is, but make necessary interchange to shift all its other tasks backward so that they become consecutive, thus the completion time of job j remains unchanged. However, other jobs, whose tasks are shift forward due to the interchanges, would be completed earlier. Thus, no new late jobs are introduced, and the resulting schedule remains optimal.

b) Suppose that in an optimal schedule there exist two early jobs, j_1 and j_2, and a machine i, such that $C_{i,j_2} < C_{i,j_1}$ but $d_{j_1} < d_{j_2}$. We assume the tasks of both jobs are scheduled consecutively according to **a)**. We remove job j_2, and push forward all jobs before j_1 (and j_1 itself), to fill the hole produced by removing j_2, then place j_2 right after j_1. Clearly, all jobs except j_2 are completed earlier. As for job j_2, its new completion time $C'_{i,j_2} = C_{i,j_1} \leq d_{j_1} < d_{j_2}$. Thus, job j_2 is still completed on time, and the resulting schedule remains optimal. ■

Note that in an optimal schedule, the tasks of a job are not necessarily to be assigned across all machines. Some machines may be assigned with multiple tasks of the job, while some other machines may not be assigned with any tasks of the same job. To illustrate this, consider an example as follows: $m = 2, n = 2$, $p_{11} = p_{21} = 2, d_1 = 4$, $p_{12} = 4, d_2 = 5$. Clearly, in an optimal schedule for this instance, the only task of job 2 must be assigned to one machine, while the two tasks of job 1 must be assigned to another machine. This yields a schedule with no late jobs.

For any instance I of $P \mid jbs, tsk \mid \sum U_j$, to derive a lower bound for it, we can construct an instance I' of problem $1 \mid\mid \sum U_j$ which can be solved in $O(n \log n)$ by Moore-Hodgson's algorithm [7]: For each job j, construct a job j for I' with processing time $p'_j = \sum_l p_{lj}/m$ and due date $d'_j = d_j$. Let S_{OPT} and S'_{OPT} denote an optimal schedule for instance I and I', respectively. Then, we have the following lower bound which might be useful for the design of a branch-and-bound algorithm, or for evaluating the performance of heuristic algorithms by experimental analysis as what we will show later.

Lemma 2.2 (Lower Bound): For any instance I of problem $P \mid jbs, tsk \mid \sum U_j$, and its corresponding instance I' of problem $1 \mid\mid \sum U_j$ constructed in the way described above, the optimal objective value for I has the following lower bound:

$$\sum_j U_j(S_{OPT}) \geq \sum_j U_j(S'_{OPT}).$$

Proof: Consider an optimal schedule S_{OPT} for instance I, let S_e denote the sub-schedule of all early jobs in S_{OPT}. We construct a schedule S' for instance I' as follows: **a)** For the jobs in S_e, schedule the corresponding jobs of I' in nondecreasing order of d'_j which equals to d_j, let the sub-schedule be S'_e; **b)** Append the rest jobs to the end of S'_e in arbitrary order.

We shall show that all jobs in S'_e are on time as well. Without loss of generality, we assume that the early jobs in S_e are indexed by $1, 2, \ldots, |S_e|$. Consider any partial schedule for jobs $1, 2, \ldots, j^*$ in S_e where $1 \leq j^* \leq |S_e|$. Since job j^* is early, we have $C_{j^*} = \max_{1 \leq i \leq m} \left\{ \sum_{j=1}^{j^*} P_{i,j} \right\} \leq d_{j^*}$. Due to the fact that this partial schedule may not be aligned up at the end of each machine, we have $\max_{1 \leq i \leq m} \left\{ \sum_{j=1}^{j^*} P_{i,j} \right\} \geq \sum_{j=1}^{j^*} \sum_{l=1}^{k_j} p_{lj}/m = \sum_{j=1}^{j^*} p'_j = C'_{j^*}$, it follows that $C'_{j^*} \leq d_{j^*} = d'_{j^*}$, implying that job j^* is early in S'_e. Thus, $\sum_j U_j(S') \leq \sum_j U_j(S_{OPT})$. The lower bound follows due to the fact that $\sum_j U_j(S') \geq \sum_j U_j(S'_{OPT})$. ■

III. Complexity Results

In this section, we investigate the cases that are either NP-hard or polynomially solvable. The goal is to establish a borderline between the hard cases and the polynomially solvable ones.

A. NP-hard Cases

Before we proceed further, we first introduce the following NP-complete problems (see Garey and Johnson [8]) that will be used for reduction later:

Definition 1 (Partition Problem): Given a list $A = (a_1, a_2, \ldots, a_n)$ of n positive integers, can A be partitioned into two subsets A_1 and A_2 such that $A_1 \cup A_2 = A$ and $\sum_{a_j \in A_1} a_j = \sum_{a_j \in A_2} a_j = B = \frac{1}{2} \sum_{a_j \in A} a_j$?

Definition 2 (3-Partition Problem): Given a list $A = (a_1, a_2, \ldots, a_{3m})$ of $3m$ positive integers such that $\sum_j a_j = mB, B/4 < a_j < B/2$ for each $1 \leq j \leq 3m$, is there a partition A into m subsets $A_1, A_2, \ldots, A_m$ such that $\cup_i^m A_i = A$ and $\sum_{a_j \in A_i} a_j = B$ for each $1 \leq i \leq m$?

Note that even though these two problems are closely related, the **Partition** problem is NP-complete in the ordinary sense, while the **3-Partition** problem is strongly NP-complete.

To show the NP-hardness of several cases, we first start with two restricted cases.

Theorem 3.1: Problem $P \mid jbs, tsk\ 1, d_j = d \mid \sum U_j$ is NP-hard in the strong sense.

Proof: We shall show that the 3-Partition problem is reducible to problem $P \mid jbs, tsk\ 1, d_j = d \mid \sum U_j$. Given an instance of $A = (a_1, a_2, \ldots, a_{3m})$ of 3-Partition, we construct an instance of $P \mid jbs, tsk\ 1, d_j = d \mid \sum U_j$ as follows: There are m machines and $3m$ jobs such that $p_{1j} = a_j$ and $d_j = B$ for each $1 \leq j \leq 3m$. The transformation clearly takes polynomial time. The decision version of the scheduling problem asks if there exists a schedule such that $\sum U_j = 0$?

If the 3-Partition instance has a "Yes" solution, we let the partition be $A_1, A_2, \ldots, A_m$. For each A_i $(1 \leq i \leq m)$, we schedule on machine i the three jobs constructed from the three elements which are in A_i. Thus, we have a schedule such that the finish time on each machine is exactly B, implying that no job is late, i.e., $\sum U_j = 0$.

Conversely, if the scheduling problem instance has a schedule such that $\sum U_j = 0$, it implies that the finish time on each machine has to be exactly B. Due to $p_{1j} = a_j$ and $B/4 < a_j < B/2$, each machine must have 3 jobs exactly, otherwise, the finish time with less/more jobs on a machine would be strictly less/larger than B. Let A_i be the triplet corresponding to the 3 jobs scheduled on each machine $1 \leq i \leq m$, then $A_1, A_2, \ldots, A_m$ is a "Yes" solution to the 3-Partition instance. ■

Theorem 3.2: Problem $Pm \mid jbs, tsk\ 1, d_j = d \mid \sum U_j$ is NP-hard in the ordinary sense for every fixed $m \geq 2$.

Proof: It is sufficient to consider the special case for $m = 2$. We shall show that the Partition problem is reducible to $P2 \mid jbs, tsk\ 1, d_j = d \mid \sum U_j$. Given an instance of the Partition problem, we construct an instance of $P2 \mid jbs, tsk\ 1, d_j = d \mid \sum U_j$ as follows: Let there be n jobs, $p_{1j} = a_j, d_j = B$ for each job $1 \leq j \leq n$. The decision version of the scheduling problem asks if there exists a schedule such that $\sum U_j = 0$?

It is easy to see that the Partition problem instance has a "Yes" solution if and only if the $P2 \mid jbs, tsk\ 1, d_j = d \mid \sum U_j$ instance has a schedule such that $\sum U_j = 0$. ■

Theorem 3.1 and Theorem 3.2 immediately imply the NP-hardness of their general cases, respectively:

Theorem 3.3: As generalization of the cases with common due dates,

a) both problem $P \mid jbs, tsk\ 1 \mid \sum U_j$ and problem $P \mid jbs, tsk \mid \sum U_j$ are strongly NP-hard;
c) both problem $Pm \mid jbs, tsk\ 1 \mid \sum U_j$ and problem $Pm \mid jbs, tsk \mid \sum U_j$ are NP-hard in the ordinary sense for every fixed $m \geq 2$.

On the other hand, when it is restricted to only one job, which has arbitrary number of tasks, the special cases are still NP-hard, as shown below:

Theorem 3.4: Problem $P \mid jbs\ 1, tsk \mid \sum U_j$ is NP-hard in the strong sense.

Proof: We shall show that the 3-Partition problem is also reducible to $P \mid jbs\ 1, tsk \mid \sum U_j$. Given any 3-Partition instance, we construct an instance of the scheduling problem as follows: Let there be 1 job with $3m$ tasks such that $p_{l1} = a_l$ for each $l = 1, 2, \ldots, 3m$; and let $d_1 = B$. The decision version of the scheduling problem asks if there exists a schedule such that $U_1 = 0$?

Similar argument as described in Theorem 3.1 shows that the 3-Partition instance has a "Yes" solution if and only if the scheduling instance has a schedule such that $U_1 = 0$. ■

Theorem 3.5: Problem $Pm \mid jbs\ 1, tsk \mid \sum U_j$ is NP-hard in the ordinary sense for every fixed $m \geq 2$.

Proof: It is sufficient that we consider the special case $m = 2$. Again, a simple reduction from the Partition problem shows that the problem is NP-hard in the ordinary sense for $m = 2$. ■

With the presence of release dates, all the NP-hard cases presented above would be harder. Further, we show that the problem $1 \mid jbs, tsk, r_j \mid \sum U_j$ is NP-hard in the strong sense.

Theorem 3.6: Problem $1 \mid jbs, tsk, r_j \mid \sum U_j$ is NP-hard in the strong sense.

Proof: Since problem $1 \mid jbs, tsk\ 1, r_j \mid \sum U_j$ is equivalent to $1 \mid r_j \mid \sum U_j$ which is strongly NP-hard (due to that $1 \mid r_j \mid \sum L_{max}$ is strongly NP-hard [9] and L_{max} is reducible to U_j [10], [11], [12]), thus its general version $1 \mid jbs, tsk, r_j \mid \sum U_j$ is also NP-hard in the strong sense. ■

B. Polynomially Solvable Cases

We start with the single-machine cases:

Theorem 3.7: The following problems:

a) $1 \mid jbs, tsk\ k \mid \sum U_j$; and
b) $1 \mid jbs, tsk \mid \sum U_j$.

can be solved in polynomial time.

Proof: As a direct result of **a)** in Lemma 2.1, by aggregating the tasks of each job j into a single task with processing time $\sum_l p_{lj}$, both $1 \mid jbs, tsk\ k \mid \sum U_j$ and $1 \mid jbs, tsk \mid \sum U_j$ can be solved in polynomial time by Moore-Hodgson's algorithm [7]. ■

Now we consider a special case in which the tasks of all jobs have identical processing times:

Theorem 3.8: Problem $P \mid jbs, tsk, p_{lj} = p \mid \sum U_j$ can be solved in $O(n \log n + \sum k_j)$ time.

Proof: We can find the optimal schedule in two steps: (1) identify the early job set E; and (2) schedule the early jobs in E. To find the early jobs, we can do the following:

a) Sort and reindex the jobs such that $d_1 \leq d_2 \leq \ldots \leq d_n$.
b) $E = \emptyset$, $sumK = 0$
c) For each $1 \leq j \leq n$
   $E = E \cup \{j\}$, $sumK = sumK + k_j$
   If $\lceil \frac{sumK}{m} \rceil * p > d_j$
      Let $i = \text{argmax}_{x \in E}\, k_x$
      $E = E \setminus \{i\}$, $sumK = sumK - k_i$

To schedule the early jobs, we simply take the tasks of the early jobs from E in non-decreasing order of the due dates, and assign them one by one to the machines 1, 2, $\cdots$, m, then 1 2, $\cdots$ m again, and so on.

First we show that our schedule is optimal. Without loss of generality, we assume that for any job j, we have $\lceil \frac{k_j}{m} \rceil * p \leq d_j$. Otherwise, it must be late in any schedule.

Notice that in step (1) the jobs are processed in non-decreasing order of their due dates and in (c), if $\lceil \frac{sumK}{m} \rceil * p >$

d_j, we remove the job with the largest number of tasks (thus maximum processing time) from E. This guarantees that if job $j \in E$ after step (1) , then $\lceil \frac{\sum_{i \in E, i \leq j} k_i}{m} \rceil * p \leq d_j$. By the way we schedule the tasks in step (2), we have $C_j = \lceil \frac{\sum_{i \in E, i \leq j} k_i}{m} \rceil * p$, thus $C_j \leq d_j$. So all jobs in E are scheduled on time. Also notice that $|E|$ must be maximum due to the fact that the largest job is chosen to be tardy in (c).

For the time complexity, step (1) can be implemented in $O(n \lg n)$ time if we use priority queue to maintain the jobs in E, and step (2) can be implemented in $\sum k_j$. ■

With the presence of release dates, some special cases are still polynomially solvable. Before we proceed further, we first show that (as we are not aware of any proof in the literature), the classical problem $1 \mid r_j, d_j = d \mid \sum U_j$ can be solved in polynomial time, even though the general case $1 \mid r_j \mid \sum U_j$ is strongly NP-hard.

Theorem 3.9: Problem $1 \mid r_j, d_j = d \mid \sum U_j$ can be solved in $O(n \log n)$ time.

Proof: Consider the following algorithm:

a) For each job with $r_j + p_j > d$, simply mark it as late and exclude it from the next steps.
b) For the remaining jobs, define a new deadline $d'_j = d - r_j$.
c) Treat time d as time 0, and schedule the jobs with new deadlines and release times 0 backwards by applying Hodgson-Moore algorithm.

The correctness of the algorithm lies in the fact that the modified problem is equivalent to the original one and Hodgson-Moore algorithm is optimal for the modified problem. ■

Theorem 3.10: Problem $1 \mid jbs, tsk, r_j, d_j = d \mid \sum U_j$ can be solved in $O(n \log n + \sum k_j)$ time.

Proof: The key observation is that, due to the common due date, there exists an optimal schedule for any problem instance in which the tasks of each early job are scheduled consecutively. Otherwise, shifting the separated tasks (except the first one) of the job forward so that they are consecutive, and shifting the in-between tasks of other jobs backward would not violate their release dates and the common due date, and the schedule remains feasible and optimal. Thus, by aggregating all tasks of each job as a single task with processing time of $\sum_l p_{lj}$, problem $1 \mid jbs, tsk, r_j, d_j = d \mid \sum U_j$ can be polynomially solved by an equivalent $1 \mid r_j, d_j = d \mid \sum U_j$ problem according to Theorem 3.9. Since aggregating the tasks takes $O(\sum k_j)$ time, the algorithm runs in $O(n \log n + \sum k_j)$ time. ■

Theorem 3.11: Problem $1 \mid jbs, tsk, r_j, p_{lj} = 1 \mid \sum U_j$ can be solved in $O(n^5)$ time.

Proof: Consider the following algorithm:

a) For any instance I of problem $1 \mid jbs, tsk, r_j, p_{lj} = 1 \mid \sum U_j$, construct an instance I' of the classical preemptive scheduling problem $1 \mid r_j, pmtn \mid \sum U_j$ with $p'_j = \sum_l p_{lp}, r'_j = r_j, d'_j = d_j$.
b) Solve I' by Lawler's Dynamic Programming algorithm in $O(n^5)$ time [11], [13].
c) Construct the schedule for I exactly from the optimal schedule for I', by mapping the jobs one by one.

Apparently, the obtained schedule is optimal and the running time is dominated by Lawler's algorithm which runs in $O(n^5)$ time. ■

Since the cases with release dates are harder than the ones with no release dates, we focus on the design and analysis of algorithms for the latter cases in the next two sections.

IV. Heuristic Algorithms for Problem $P \mid jbs, tsk \mid \sum U_j$

Due to the strong NP-hardness of problem $P \mid jbs, tsk \mid \sum U_j$, it would be of interest to see if there exists any good approximation algorithm for it. Unfortunately, the following negative result shows that there exists no such approximation algorithm unless $P = NP$.

Theorem 4.1: Unless $P = NP$, there exists no polynomial time ρ-approximation algorithm ($1 < \forall \rho < \infty$) for both problem $P \mid jbs, tsk \mid \sum U_j$ and problem $Pm \mid jbs, tsk \mid \sum U_j$ (for any fixed $m \geq 2$).

Proof: It is sufficient to consider a special case of the problem, i.e., $P \mid jbs\ 1, tsk \mid \sum U_j$, for which we have only 1 job with arbitrary number of tasks to be scheduled on m machines where m is not fixed. Given any problem instance I, since it has only 1 job, being either late or on time, the objective value returned by $\mathcal{A}$ must be $\sum U_j \in \{0, 1\}$. We consider the following four cases:

Case1. The optimal objective value is 0 and $\mathcal{A}$ returns 0, which is optimal.
Case2. The optimal objective value is 1 and $\mathcal{A}$ returns 1, which is optimal.
Case3. The optimal objective value is 0 and $\mathcal{A}$ returns 1. The performance ratio is ∞.
Case4. The optimal objective value is 1 and $\mathcal{A}$ returns 0, which is impossible.

First of all, Case 4 can be excluded for $\mathcal{A}$, since it contradicts to the optimality of the optimal objective value. As for other cases, we claim that there exists at least one problem instance so that Case 3 is true for $\mathcal{A}$. Otherwise, assume that "only" Case 1 and Case 2 are true for $\mathcal{A}$, it simply implies that $\mathcal{A}$ is optimal. Since $\mathcal{A}$ is also polynomial by assumption, it would imply $P = NP$. Therefore, our claim must be true unless $P = NP$, implying that the algorithm $\mathcal{A}$ must be unbounded due to Case 3.

Similar arguments apply to $Pm \mid jbs, tsk \mid \sum U_j$ for its special case when $m = 2$. ■

An observation on the non-approximability of $P \mid jbs\ 1, tsk \mid \sum U_j$ and $Pm \mid jbs\ 1, tsk \mid \sum U_j$ is that, each of them intrinsically consists of a NP-hard subproblem to solve (i.e., the C_{max} problem on parallel machines) and yet its objective value is limited to only two numbers, i.e., either 0 or 1. Thus, there is no much freedom for any algorithm to approximate within.

We first present a general algorithm scheme to identify and schedule a set of early jobs, and then derive some specific

algorithms from it by customizing the task sorting criterion and the machine selection criterion.

General-Scheme GS **for** $P \mid jbs, tsk \mid \sum U_j$

Input. A set of n multi-task jobs; the number of machines m.
Output. A set of early jobs E and their schedule S_e.

Sort the n jobs such that $d_1 \leq d_2 \leq \ldots \leq d_n$.
for each job $j = 1, 2, \ldots, n$
  ≪***sort its tasks by certain criterion***≫
  assuming the sorted order is o_{1j}, o_{2j}, …, $o_{k_j j}$

Let $E = \emptyset$, and S_e be an empty schedule
$j = 1$, $firstTry = true$.
While $j \leq n$
  $late = false$
  $l = 1$.
  while ($l \leq k_j$ and $late = false$)
    ≪***select machine*** i^* ***by certain criterion***≫
    assign task o_{lj} to machine i^* in S_e.
    if o_{lj} is late
      late = true.
      remove all tasks o_{1j}, o_{2j}, …, o_{lj} from S_e.
      if $firstTry = true$
        let $j^* = \text{argmax}_{k \in E \cup \{j\}} \{\sum_l p_{lk}\}$
        if $j^* = j$, then $j = j + 1$.
        else
          remove all tasks of j^* from S_e.
          $firstTry = false$.
      else $j = j + 1$, $firstTry = true$.
    else
      if $l = k_j$
        if $firstTry = true$, then $E = E \cup \{j\}$.
        else $E = E \setminus \{j^*\} \cup \{j\}$.
        $j = j + 1$, $firstTry = true$.
      $l = l + 1$.
return S_e

It should be noted that, when $k = 1$ and $m = 1$, the above general algorithm schema would work in the same way as Moore-Hodgson's algorithm for $1 \mid\mid \sum U_j$. Thus, we can regard it as generalization of Moore-Hodgson's algorithm. To derive a specific algorithm from the above general scheme, we need to specify two criteria as marked within $\ll \ldots \gg$. The first criterion to be specified in Step 1 is for sorting the individual tasks of each job $j = 1, 2, \ldots, n$, while the second one in Step 2 is for choosing a machine to process the task under consideration.

Intuitively, we consider two **Task Sorting Criteria**:

- **Arbitrary Order.** No sorting, just keep the original ordering of the tasks as given in input. Thus, it takes no extra running time.
- **Non-increasing Order.** Sort the tasks of job j in non-increasing order of their processing times such that $p_{1j} \geq p_{2j} \geq \ldots p_{k_j j}$ for each $j = 1, 2, \ldots, n$. It takes $O(k \log k)$ time for each job.

To assign a task to a machine, we consider three **Machine Choosing Criteria**:

Smallest Load. Choose the machine with the smallest load. This is used in the well-known Longest Processing Time first rule (LPT) and List Scheduling algorithm (LS) for problem $P \mid\mid C_{max}$ [16].

First Fit. Choose the first machine which can process the task before the job's due date. The First-Fit algorithms were originally designed for the Bin Packing problem [17].

Best Fit. Choose the machine with the largest load but can still process the task before the job's due date.The Best-Fit algorithms were also originally designed for the Bin Packing problem.

TABLE I
SIX ALGORITHMS DERIVED FROM THE TWO TYPES OF CRITERIA

Algorithm	Machine Choosing	Sorting	Task Assignment
GS_{LS}	Smallest Load	Arbitrary	LS
GS_{LPT}	Smallest Load	Non-increasing	LPT
GS_{FF}	First Fit	Arbitrary	First Fit
GS_{FFD}	First Fit	Non-increasing	First Fit Decreasing
GS_{BF}	Best Fit	Arbitrary	Best Fit
GS_{BFD}	Best Fit	Non-increasing	Best Fit Decreasing

Naturally, combination of these two types of criteria produces six different concrete algorithms, which are enumerated in Table I.

In essence, each algorithm derived from the above general algorithm scheme combines the Earliest Due Date first (EDD) rule [18] (at job level), and either an algorithm for problem $P \mid\mid C_{max}$ [16] or an algorithm for the Bin Packing problem [17] (at task level).

Clearly, all algorithms derived from the general scheme run in polynomial time. It is not surprising that, due to Theorem 4.1, the performance ratio of these algorithms is not bounded. To illustrate this by a simple example, we consider the following instance: $n = 1, m = 4, k = 9, p_{11} = 7, p_{21} = 4, p_{31} = p_{41} = 5, p_{51} = p_{61} = 6, p_{71} = 7, p_{81} = p_{91} = 4, d_1 = 12$. The "trial" assignment of tasks by all these six algorithms, as illustrated by Table II, would result in schedules in which the job is late. Thus, all these heuristic algorithms return $\sum_j U_j = 1$. However, in an optimal schedule, as illustrated by the last column in the same table, the job is on time, and the objective value is 0. Thus, the performance ratio of all these heuristic algorithms is ∞ .

Even though the above worst-case example shows that the heuristic algorithms could perform arbitrarily bad, in practice, we expect that their average performance could be much better. To this end, we evaluate these algorithms by experimental results in the next section.

V. EXPERIMENTAL EVALUATION

To evaluate the above heuristic algorithms, we choose the number of jobs $n = 500$, and the number of machines $m = 20$. Problem instances of varying hardness are generated according

TABLE II
TRIAL ASSIGNMENT OF TASKS FOR THE WORST-CASE EXAMPLE

Machine	GS_{LS}	GS_{LPT}	GS_{FF}	GS_{FFD}	GS_{BF}	GS_{BFD}	OPT
1	7, 4, 4	7, 4, 4	7, 4	7, 5	7, 4	7, 5	7, 5
2	4, 6, 4	7, 4	5, 5,	7, 5	5, 5, 4	7, 5	7, 5
3	5, 6	6, 5	6, 6	6, 4	6, 6	6, 4, 4	6, 6
4	5, 7	6, 5	7, 4, 4	6, 4, 4	7, 4	6, 4	4, 4, 4

to different characteristics of the due dates, in a similar way described in Leung, Li and Pinedo [19].

First of all, for each job $j = 1, 2, \ldots, n$, the number of tasks k_j is randomly generated from the uniform distribution $[1, 10m]$. Then, for each task $l = 1, 2, \ldots, k_j$, p_{lj} is generated from the uniform distribution $[1, 100]$. Finally, after all jobs are generated, for each job $j = 1, 2, \ldots, n$, its due date d_j is generated from the following uniform distribution:

$$[P(1 - \delta_1/2 - \delta_2), P(1 + \delta_1/2 - \delta_2)],$$

where

$$P = \sum_{j=1}^{n} \sum_{l=1}^{k_j} p_{lj}/m,$$

and δ_1 and δ_2 determines the range in which the due dates lie and adjusts the tightness of the due dates, respectively. Also, in generating d_j, we ensure that

$$d_j \geq \max \left\{ \sum_{l} p_{lj}/m, \max_{l} \{p_{lj}\} \right\}.$$

Otherwise, job j would always be late.

We set $\delta_1 = 0.2, 0.4, 0.6, 0.8, 1.0$ and $\delta_2 = 0.2, 0.4, 0.6, 0.8, 1.0$. For each combination of δ_1 and δ_2, 100 instances are generated. Thus, there are 2500 instances in total. The algorithms are implemented in Java. The running environment is Windows 7 64-bit Operating System running on a dual core (2.50GHz + 2.50GHz) PC with 4GB RAM memory.

To compare the algorithms, for each generated instance I_i $(i = 1, 2, \ldots, 100)$, we also construct the corresponding single-machine instance I_i' as described in Lemma 2.2. The instance I_i' is solved optimally by Moore-Hodgson's algorithm, and then the result, denoted by $LB(I_i')$, is used as a reference objective value (lower bound) to evaluate the objective value produced by a heuristic algorithm A for I_i, denoted by $\sum_j U_j(A, I_i)$. Table III shows the collective results for all six algorithms. Each algorithm A has two columns, namely $\bar{\varepsilon}$ and $\bar{t}$, which are defined as follows. For each setting of δ_1 and δ_2, $\bar{\varepsilon}$ is defined for A as:

$$\bar{\varepsilon} = \frac{1}{100} \sum_{i=1}^{100} \left(\sum_{j} U_j(A, I_i) - LB(I_i') \right);$$

and let $t(A, I_i)$ denote the running time (in milliseconds) of algorithm A on solving instance I_i, $\bar{t}$ is defined for A as:

$$\bar{t} = \frac{1}{100} \sum_{i=1}^{100} t(A, I_i).$$

From the table, we have the following findings:

- The objective values produced by all six algorithms are actually very close to the lower bound values, the gaps are mostly less than 3, which means that the algorithms perform close to an optimal algorithm for these randomly generated instances.
- The frequencies that the six algorithms achieve the lowest $\bar{\varepsilon}$ are $(5, 9 \mid 11, 14 \mid 13, 22)$ corresponding to their order listed in the table. Thus, in terms of Machine Choosing Criterion, the algorithms based on Best-Fit criterion performs better than those based on First-Fit criterion, which in turn are better than those based on Smallest-Load criterion. In terms of Task Sorting Criterion, the algorithms based on non-increasing task sorting criterion perform better than those without task sorting.
- In terms of running time, the First-Fit based algorithms run faster than those based on Best-Fit criterion, which in turn run faster than algorithms based on Smallest-Load criterion.
- Interestingly, task sorting in initialization actually does not increase the running time, but helps reduce the running time. This could be due to that task sorting helps produce better results and hence results in less iterations for Step 2 and Step 3.
- Regarding the sensitivity of algorithms' performance to the hardness of problem instances, overall, $\bar{\varepsilon}$ increases when δ_2 increases. The explanation is that higher δ_2 results in tighter due dates generated for the instances. Hence, the number of late jobs is expected to be higher, and the gap between the heuristic result and lower bound result is expected to increase accordingly. On the other hand, $\bar{t}$ also increases when δ_2 increases. Indeed, when the number of late jobs increases with higher δ_2, more iterations are required by Step 2 and Step 3 of the algorithms.

The above findings are sufficient to give us an overview of the performance of the algorithms and provide guidelines for us to choose the best ones among them for practical use. Considering both solution quality and running time, we recommend that algorithm GS_{BFD} is the best choice.

VI. CONCLUSIONS

In this paper, we studied the problem of minimizing the total number of late multi-task jobs on identical and flexible machines in parallel. We first investigated the complexity aspect of the problem. As summarized in Table IV, complexity

results were established for some cases that are either NP-hard or polynomially solvable. Due to the NP-hardness of the general case, we then investigated its approximability. Unfortunately, the result was negative, as we showed that, unless $P = NP$, there exists no ρ-approximation algorithm ($1 < \forall\rho < \infty$) even for the case with no release dates. Thus, we designed a general algorithm scheme and derived from it six heuristic algorithms whose performance was evaluated by experimental results. The findings from the experimental results provided guidelines for choosing the best algorithm among them for practical use, and we recommended algorithm GS_{BFD} as the best choice.

We did not consider setup times, preemption and weights for the problem. It will be interesting to study the problem with these additional constraints. Even for release dates, we only considered the single machine cases. Hopefully, the heuristics presented in this paper can be extended to the parallel machine cases with release dates. We did not consider an exact algorithm in this paper either. It seemed that the design of an exact algorithm with intelligent search of an optimal solution is not trivial at all, even though we looked into some properties and derived a lower bound for optimal schedule. Indeed, although it has been shown that there exists an optimal schedule which complies with the EDD rule. However, the subproblem to assign the individual tasks to the parallel machines is NP-hard. This not only makes it hard for the design of an exact algorithm with intelligent search, but also makes it non-trivial for the design of effective local search heuristics or meta-heuristics. All of these are worthy of further research for the problem.

***Abstract*—Cluster Deletion (CD) problem asks to transform a given graph into a cluster graph by at most k edge deletions. CD is a combinatorial problem arising in the field of classification. In this paper, we introduce a graph transformation which enabled the identification of new polynomially solvable classes of CD problem. We show that if a graph is K_3-free or (*diamond*, *kite*, *house*, *xbanner*)-free then cluster deletion problem can be solved in polynomial time on that graph.**

***Index Terms*—graph clustering; cluster deletion; Line Graph; P_3 adjacency graph; forbidden patterns; diamond graph; claw graph; fork graph**

I. Introduction

CLASSIFICATION is the problem of identifying to which of a set of categories a new observation belongs [1]. In the terminology of machine learning, classification may be supervised or unsupervised. The corresponding unsupervised procedure is known as clustering which is considered the most important unsupervised learning problem [2]. On the other hand, many combinatorial problems are modelled using graphs, in particular, the partitioning of graph vertices into clusters is a classification task that may be used to better manage many real-world problems. From the theoretical point of view, the clustering task is closely related to partitioning problems. As every other problem of this kind, clustering aims to finding structures or patterns in a collection of unlabeled data. The goal is to partition these elements into subsets called clusters such that two meta-criteria are satisfied: homogeneity (elements in a same cluster should be highly similar to each other) and separation (elements from different clusters may have low similarity to each other). In the graph theoretic approach to clustering, data are often represented in the form of a graph G. Ideally, the resulting graph would be a cluster graph, that is, a graph in which every connected component is a clique, i.e., a complete subgraph. From the practical point of view, clustering algorithms can be applied in many fields, for instance in social networks, in Wireless sensor network (WSN) [3], in particular in optimizing energy distribution between access points [4], [5], or in designing electronic integrated circuits [6]...

In this paper, we deal with a specific version of the graph clustering problem, namely, cluster deletion (CD), which allows a graph partitioning, into a set of complete subgraphs, just by removing edges. This problem is known to be NP-hard [7] for general graphs. However, it may become easier and polynomial-time solvable in specific graphs, for instance split graphs, block graph, proper interval graph, cographs [8], [9]. Graph classes on which CD is polynomial-time solvable can also be specified by forbidding the occurrence of certain (small) subgraphs in the input graph. For instance, CD is polynomial-time solvable on a sub-class of P_4-sparse graphs that strictly includes P_4-reducible graphs (which are, in turn, a superclass of cographs) [10]. Those results were obtained for unweighted graphs. For weighted graphs, the cluster deletion problem can be solved in polynomial time on the class of K_3-free graphs for which the CD equivalent to maximum weighted matching [8], [11].

On the other hand, there are several works showing that CD problem is NP-hard on some subclasses of weighted graphs such, (C_5, P_5)-free graphs,($2K_2$, $3K_1$)-free graphs and (C_5, P_5, bull, 4-pan, fork, co-gem, co-4-pan)-free graphs [9].

Our aim is to derive polynomial subproblems of *CD* by resorting to graph transformation. In the literature, there are several graph transformation, among them the widely used line graph [12]. A graph H is a line graph of a graph G if the vertices of H are in a one-to-one correspondence with the edges of G, with two vertices being adjacent in H if and only if the corresponding edges of G have a vertex in common. Clearly, any graph matching in G corresponds to an independent set in its line graph, and therefore, the maximum independent set problem in the class of line graphs is equivalent to the maximum matching problem in general graphs. What is worth noting here is that finding a maximum matching in a graph is a polynomial problem [13], which implies that the maximum independent set problem in polynomially solvable in line graphs [14]. For this reason this graph transformation has been widely used both for reducing and solving the maximum independent set problem. Another transform, known as conic reduction [15], transforms a graph G into a graph G' with $\alpha(G') = \alpha(G) - 1$, where $\alpha(G)$ denotes the maximum cardinality of a maximum independent set in a graph G, that is, the stability number of G. Yet another interesting transformation is the one based on the removal of simplicial vertices [16]. Let v be a vertex and let $N(v)$ be the neighbours set of v. v is simplicial if $N(v)$ is a clique. For each simplicial vertex v, we have $\alpha(G) = \alpha(G \setminus N[v]) + 1$ holds such that $N[v] = N(v) \cup \{v\}$. Thus, given a simplicial vertex, it is easy to reduce the problem of determining $\alpha(G)$ to the same problem on a smaller graph. There are other graph transformation, such as clique reduction [17], C-reduction [18], graph reduction for QoS Prediction [19],

978-83-60810-90-3/$25.00

SWR reduction [20]. All these transformations may simplify combinatorial problems on graphs.

In the present paper, we introduce a new transformation called the P_3-*adjacency graph* and we use it to identify new polynomially-solvable classes of *CD*.

In the next section, we present a new proof of the tractability of the CD problem for unweighted K_3-free graphs which is much easier that the one proposed in [11]. Indeed, we prove that when the initial unweighted graph *G* is K_3-free, its $P_3(G)$ will correspond to its line graph and then finding a minimum deletion edge-set is equivalent to finding a maximum independent set in $P_3(G)$. In other words, solving the *CD* problem on a K_3-free graph amounts to finding a maximum matching in the line graph of *G*. Next, we show that if *G* is diamond-free then any maximum independent set of $P_3(G)$ provides a solution of *CD*. Secondly, we introduce a new collection of forbidden patterns, namely *kite*, *house*, *open-envelope* and *xbanner*, and prove that $P_3(G)$ is claw-free when *G* is (*kite*, *house*, *open-envelope*, *xbanner*)-free. This enables a polynomial computation of a maximum independent set of $P_3(G)$, and then, provides an optimal solution for *CD* on *G* in polynomial-time.

II. Definitions and notations

A graph is a mathematical structure consisting of a set of vertices and a set of edges connecting the vertices. There are several types of graphs, among which, one can distinguish simple graphs, which are defined by an ordered pair (V, E), where V is a finite set of vertices and $E \subseteq \mathcal{P}_2(V)$ is the set of edges, with $\mathcal{P}_2(V)$ being the set of all pairs of V. From a simple graph $G = (V, E)$, one can extract a partial graph $G_p = (V, E_p)$ obtained by removing some of the edges of *G*, we have therefore $E_p \subseteq E$.

Definition 1. *Let $G = (V, E)$ be a simple graph and let $U \subseteq V$. The simple graph $(U, E(U))$ is the sub-graph of G induced by U, where $E(U) = E \cap \mathcal{P}_2(U)$*

A sub-graph of a given simple graph is therefore defined as follows:

Definition 2. *A graph $G_s = (V_s, E_s)$ is the sub-graph of a graph $G = (V, E)$ if there exists $U \subseteq V$ such that G_s is the sub-graph of G induced by U i.e V_s = U and $E_s = E(U)$.*

A complete graph is a simple graph in which every pair of distinct vertices is connected by a unique edge. The complete graph with n vertices is denoted by K_n. A clique of a simple graph $G = (V, E)$ is a complete subgraph of *G*. The K_3 graph is the complete graph with three vertices and a P_3 graph is the path on three vertices as it is illustrated in Fig. 1.
Observe that a complete graph cannot contain any P_3 as an induced subgraph.

Let C be a collection of small graphs, that will be designated by patterns. *G* is said to be C-*free* if *G* contains no member of C as an induced subgraph.

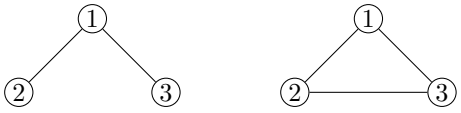

Fig. 1. A P_3 graph (left) and K_3 graph (right)

Besides, in the literature there exists a known class of graph called line graph which represents the adjacencies between the edges of a given graph.

Definition 3. *The line graph of a simple graph G= (V,E) is the graph $L(G)$= (V',E'), where:*

- *Each vertex of $L(G)$ represents an edge of G; and*
- *two vertices of $L(G)$ are adjacent if and only if their corresponding edges share a common endpoint in G.*

Example 1. *Fig 2. shows a simple graph and its line-graph.*

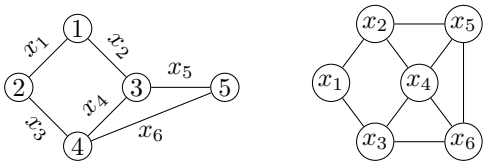

Fig. 2. Graph *G* (left) and its line graph L(G) (right)

The relevance of the line graph class is that many combinatorial problems, that are NP-hard on general graphs, are polynomially solvable on line graphs. The clustering problem is one of these combinatorial tasks. It consists in making the fewest changes to the set of edges of an input graph in order to obtain a set of cliques. There are three variations of graph clustering: cluster completion, cluster deletion and cluster editing. In the graph completion variations, edges can only be added. In cluster deletion, edges can only be deleted. In cluster editing, both edge additions and edge deletions are allowed. More formally, the cluster deletion (*CD*) problem consists in finding, for a given graph *G*, a P_3-free partial graph. An optimal solution for a *CD* instance given by a simple graph $G = (V, E)$ is a P_3-free partial graph $G_p = (V, E_p)$ of *G* that minimizes $|E - E_p|$.

III. A polynomial CD class

In this paper, we precisely consider the cluster deletion problem which allows a graph partitioning just by removing edges. This version partitions the graph into a set of complete subgraphs, i.e., cliques, and the goal is to remove the fewest edges from the input graph. We propose an algorithm that solves CD by resorting to a new graph transformation, which is defined as follows:

Definition 4. *The P_3 adjacency graph of a simple graph G= (V,E) is a simple graph, which we denote by $P_3(G)$, such that:*

- *Each vertex of $P_3(G)$ represents an edge of G; and*

- *two vertices of $P_3(G)$ are adjacent if and only if their corresponding edges form a P_3 sub-graph of G.*

Example 2.

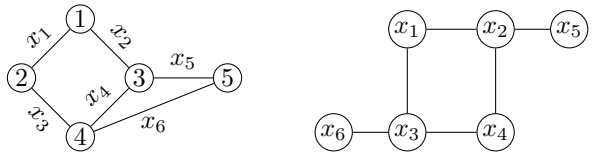

Fig. 3. Graph *G* (left) and its P_3(G) graph (right)

Lemma 1. *$P_3(G) = L(G)$ if and only if G is K_3-free*

Proof. Let $G = (V, E)$ be a simple graph with the associated P_3 adjacency graph $P_3(G) = (E, E_{P_3})$ and line graph $L(G) = (E, E_L)$.
($\Rightarrow$) Assume that $P_3(G) = L(G)$ while *G* contains a K_3 as an induced subgraph, and proceed to get a contradiction.

By Definition 3, a K_3 graph formed by edges x, y, z of *G* will be transformed into a K_3 in $L(G)$ whose edges are $\{x, y\}$,$\{x, z\}$,$\{y, z\}$. On the other hand, since any K_3 of *G* cannot contain a P_3, by Definition 4, x, y and z will not be connected in $P_3(G)$. We deduce that $E_L \neq E_{P_3}$, which contradicts our assumption. So, $P_3(G) = L(G)$ cannot hold true unless *G* is K_3-free.

($\Leftarrow$) Suppose that *G* is K_3-free and show that $P_3(G) = L(G)$, which amounts to establishing that $E_{P_3} = E_L$ since $P_3(G)$ and $L(G)$ have the same vertex-set by definition. So, let $\{x, y\}$ be any edge of E_{P_3}. According to Definition 4, the edges of *G* that correspond to vertices x and y in $P_3(G)$ must form an induced P_3 subgraph in *G*, and then, they must share a common endpoint. This implies that, $\{x, y\} \in E_L$. Thus, we have $E_{P_3} \subseteq E_L$. Conversely, let $\{x, y\}$ be in E_L, which implies that the edges x and y must share a common endpoint in *G*. Moreover, since *G* is K_3-free, it cannot contain a third edge which form a K_3 subgraph with x and y. This implies that x and y form a P_3 in *G*, which implies that $\{x, y\} \in E_{P_3}$. Thus, $E_L \subseteq E_{P_3}$. It follows, that $P_3(G) = L(G)$. □

Example 3. *Consider the graph G_1 depicted in Fig. 4. Its $L(G_1)$ and $P_3(G_1)$ are as shown in Fig. 5.*

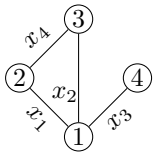

Fig. 4. A graph that contains both P_3 and K_3.

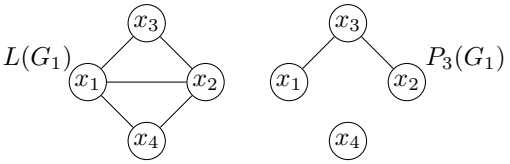

Fig. 5. The line graph and the P_3 adjacency graph of G_1.

We notice that $L(G_1)$ and $P_3(G_1)$ are different. This is due to the K_3 subgraph induced by vertices $1, 2$ and 3.

Example 4. *The figure below represents a graph G_2 composed of four vertices and containing two P_3 but no K_3:*

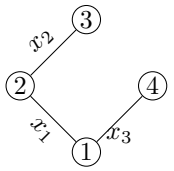

Fig. 6. A simple graph containing two P_3 but no K_3.

Fig. 7 represents the $L(G_2)$ associated with $P_3(G_2)$.

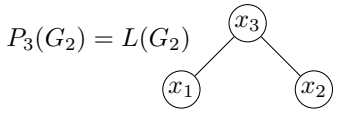

Fig. 7. The line graph and P_3 adjacency graph of G_2

Transforming G_2 into $L(G_2)$ and $P_3(G_2)$ gives the same simple graph because G_2 is K_3-free. This observation is in accordance with Proposition 1.

Lemma 2. *Let $G = (V, E)$ be a K_3-free graph. If $E' \subseteq E$ is a maximum independent set of $P_3(G)$ then (V, E') is a CD solution for G.*

Proof. ($\Leftarrow$) Assume that (V, E') is a *CD* solution for *G*. Since (V, E') is composed of a set of cliques and a clique cannot contain any P_3 as an induced subgraph, the vertices of $P_3(G)$ that correspond to the edges of E' will be pairwise not connected. This means that they form an independent set of $P_3(G)$.

It remains to prove that E' is a maximum independent set of $P_3(G)$. To this end, assume the converse is true, that is, there exists $E'' \subseteq E$ such E'' is an independent set of $P_3(G)$ and $|E''| > |E'|$. Since E'' is an independent set of $P_3(G)$, then, by Lemma 1, the partial graph of *G* defined by (V, E'') is P_3-free. Moreover, we have $|E - E''| < |E - E'|$ since $|E''| > |E'|$. This implies that (V, E') is not a CD solution for G which contradicts the hypothesis.

($\Rightarrow$) Let E' be a maximum independent set of $P_3(G)$. Assume that (V, E') is not a solution of *CD* for *G* and proceed to get a contradiction.

If (V, E') is not a solution of the *CD* instance defined by G then either (V, E') contains a P_3 or there exists a P_3-free partial graph (V, E'') such that $|E - E''| < |E - E'|$. By Lemma 1, the first case cannot hold true. In turn, the second case cannot hold because, otherwise, E' will not be a maximum independent set of $P_3(G)$ since $|E''| > |E'|$. □

Combining Lemma 1 and 2, we deduce that

Theorem 1. *The CD problem limited to the class of K_3-free graphs can be solved in polynomial time for simple graphs.*

Proof. According to Lemma 2, solving a *CD* instance defined by G amounts to finding a maximum independent set in $P_3(G)$. On the other hand, according to Lemma 1, if G is K_3-free, then $P_3(G)$ is identical to its line graph. In addition, it is well established that the maximum independent problem is polynomial on the class of line graphs. It follows that the *CD* problem for K_3-graphs can be solved by first constructing a P_3 adjacency graph , and then, by computing, in polynomial time, a maximum independent set in the latter graph. Finally, since the P_3 adjacency graph can be built in $O(|V|^4)$ step, the overall process is polynomial. □

In what follows, we identify a wider tractable class of *CD*, which is also defined via forbidding certain graph patterns.

Lemma 3. *Let $G = (V, E)$ be a diamond-free graph and let $E' \subseteq E$. (V, E') is a CD solution for G if and only if E' is a maximum independent set of $P_3(G)$.*

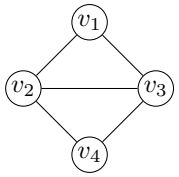

Fig. 8. Diamond graph

Proof. ($\Leftarrow$) Let E' be a maximum independent set of $P_3(G)$. Assume that (V,E') is not a *CD* solution for G. This implies that either (V, E') contains P_3 as an induced subgraph or there is a P_3-free partial graph (V, E'') such that $|E''| > |E'|$. Assure the former case, i.e., (V, E') contains a P_3, say u-v-w, and proceed to get a contradiction. Denote by e, the edge $\{u, v\}$ and by e', the edge $\{v, w\}$. Since e and e' are in E' and $E' \subseteq E$, which is a maximum independent set of $P_3(G)$, the latter two edges must not form a P_3 in (V, E). On the other hand, e and e' form a P_3 in (V, E'). This implies that $\{u, w\}$ is in E but not in E'. This cannot occur unless there is another edge $\{x, u\} \in E'$ that forms a P_3 with $\{u, w\}$ but neither with e nor with e'. Moreover, since $\{x, u\}$ and $\{u, w\}$ form a P_3, $\{x, w\}$ must not be in G. It follows that $(\{u, v, w, x\}, E(\{u, v, w, x\}))$ is an induced diamond subgraph of G, which contradicts the hypothesis. In the latter case, there is a P_3-free partial graph (V, E'') such that $|E''| > |E'|$. This implies that E' is not a maximum independent set of $P_3(G)$, which also contradicts the hypothesis.

($\Rightarrow$) Let (V,E') be a CD solution for G and assume that E' is not a maximum independent set of $P_3(G)$, then proceed to get a contradiction.

Since E' is not a maximum independent set of $P_3(G)$ then either E' is not an independent set of $P_3(G)$ or it is not maximum. From the definition of $P_3(G)$, the former case implies that there exist $e, e' \in E'$ that form a P_3 in G, which contradicts the fact (V, E') is a *CD* solution for G. The latter case implies that there exists a maximum independent set $E'' \subseteq E$ such that $|E''| > |E'|$. Using ($\Leftarrow$), we deduce that (V, E') is not a *CD* solution for G and this contradicts the hypothesis. □

The complete bipartite graph $K_{1,3}$ is known as the *claw* graph. It is illustrated by Fig. 9. In what follows, the goal

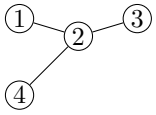

Fig. 9. A complete bipartite graph $K_{1,3}$ (Claw graph or Y graph)

is to obtain a $P_3(G)$ free from claw. Recall that this allows to polynomially solve the maximum independent set problem in $P_3(G)$. Thus, interested by determining the patterns which entail a claw in $P_3(G)$.

Lemma 4. *Let $G = (V, E)$ be a simple graph. $P_3(G)$ has a claw as an induced subgraph if and only if G contains one of the graphs in Fig. 10 as an induced subgraph.*

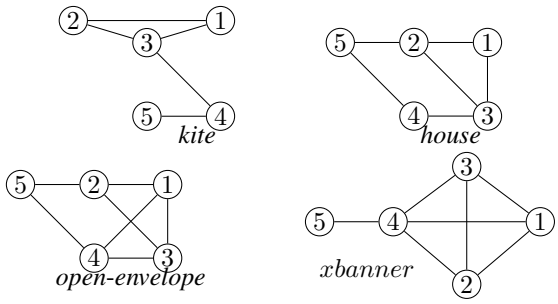

Fig. 10. The set of minimal graphs, which when they are present in G as subgraphs entail a claw in P_3(G) [21]

Proof. ($\Rightarrow$) Let G be a simple graph and let $P_3(G)$ be the P_3 adjacency graph of G. Assume that $K_{1,3}$ is a subgraph of $P_3(G)$ and, by the same time, G does not contain any *kite*, *house*, *open-envelope* and *xbanner* as an induced subgraph and proceed to get a contradiction. By referring to Definition 4 and since $K_{1,3}$ is composed by a vertex which has three not connected neighbors, if $P_3(G)$ contains a $K_{1,3}$ then G must contain three P_3 subgraphs sharing a common edge, say a. So, we should have in G one of the following two subgraphs:

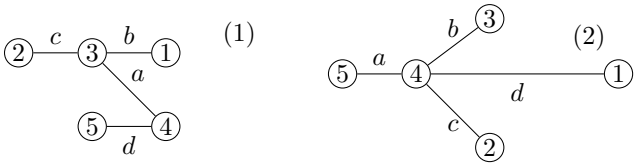

Fig. 11. Minimal patterns that entail a claw in $P_3(G)$

To ensure that a claw graph (Fig. 9) occurs in the P_3 adjacency graph of G, we add, in all possible manners, the edges that keep the claw graph as an induced subgraph of $P_3(G)$. This results in the following four patterns, which correspond exactly to the forbidden patterns of Fig 12 and contradicts the hypothesis.

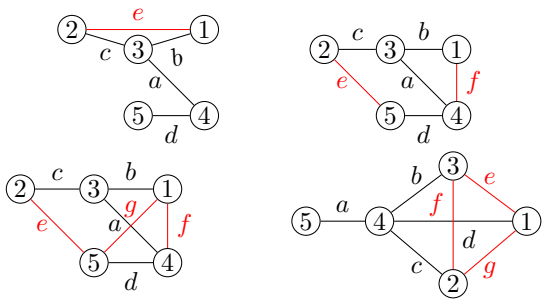

Fig. 12. After change: the set of minimal graphs, which when they are present in G as subgraphs, entail a claw in $P_3(G)$

($\Leftarrow$) If G contains a *kite*, *house*, *open-envelope* or *xbanner* as an induced subgraph, then $P_3(G)$ will respectively contain one of the following graphs as an induced subgraph (see Fig. 13, Fig. 14, Fig. 15).

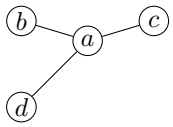

Fig. 13. P_3(kite) and P_3(xbanner)

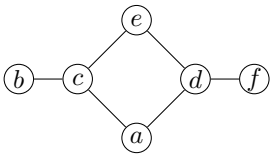

Fig. 14. P_3(house)

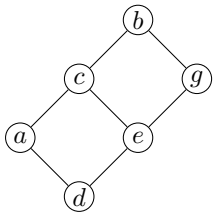

Fig. 15. P_3(open-envelope)

Observe that all these subgrahs contain a $P_{1,3}$ as an induced subgraph. □

Theorem 2. *The CD problem is polynomial in the class of (kite, house, xbanner, diamond)-free graphs.*

Proof. Let G be a (*kite*, *house*, *xbanner*, *diamond*)-free graph. Since *diamond* is an induced subgraph of *open-envelope* and by Lemma 4, $P_3(G)$ is claw-free. On the other hand, by Lemma 3, a maximum independent set of $P_3(G)$ corresponds to a *CD* solution for G. Since maximum independent set problem can be solved in polynomial time in claw-free graphs [12], *CD* can be solved in polynomial time in (*kite*, *house*, *xbanner*,*diamond*)-free graphs. □

IV. Conclusion

In this paper, we identified polynomial classes of the *CD* problem. We introduced a new graph transformation, namely, the P_3 adjacency graph. We used this transformation in order to show that whenever a simple graph G is diamond-free, any maximum independent set of $P_3(G)$ provides a solution of CD. Next, we showed that *CD* problem can be solve in polynomial time in K_3-free and (*kite*, *house*, *xbanner*,*diamond*)-free unweighted graphs.

***Abstract*—Given a set of points in a Euclidean space having dimension $K > 0$, we are interested in the problem of finding a realization of the same set in a Euclidean space having a lower dimension. In most situations, it is not possible to preserve all available interpoint distances in the new space, so that the best possible realization, which gives the minimal error on the distances, needs to be searched. This problem is known in the scientific literature as the Multidimensional Scaling (MDS). We propose a new methodology to discretize the search space of MDS instances, with the aim of performing an efficient enumeration of their solution sets. Some preliminary computational experiments on a set of artificially generated instances are presented. We conclude our paper with some future research directions.**

I. Introduction

GIVEN a set of points X in a Euclidean space $\mathbb{R}^K$, with $K > 0$, Multidimensional Scaling (MDS) consists in finding a realization of X in $\mathbb{R}^k$, with $0 < k < K$, such that the interpoint distances in $\mathbb{R}^K$ are preserved as much as possible [3]. The *initial* dimension K is generally very large, while the new dimension k is generally a priori unknown. However, for a fixed *destination* dimension k, the MDS can be seen as a particular class of the Distance Geometry Problem (DGP) [16]. In fact, in the DGP, suitable embeddings of a given simple weighted undirected graph $G = (V, E, d)$ are searched, in a way that the distances between embedded vertices u and $v \in V$ are as close as possible to the weights on the edges $(u, v) \in E$, when available. In the MDS, the graph G can be simply deduced from the original set of points in $\mathbb{R}^K$. A *valid embedding* is an embedding of G satisfying all distance constraints, with a given tolerance.

In recent works, it was shown that the DGP can be discretized when some particular assumptions are satisfied [17]. The discretization makes it possible to work with a finite search space, which is otherwise continuous. This search space has the structure of a tree, which is binary when all available distances can be considered as exact. The DGP is NP-hard [27], and even if its discretization does not reduce its complexity [14], it allows for employing a Branch & Prune (BP) framework for an ad-hoc exploration of the discretized search space [14], [24]. The present work is a preliminary step for the *discretization* of the MDS. In this work, in order to mainly focus on the problem discretization, we will suppose that the topology of the embeddings in both dimensions K and k can be represented well by considering all real inter-point distances.

We warn the reader that a previous work, devoted to the discretization of the MDS, was already published in [1]. However, differently from that work, we will consider, in our first analysis, the basic MDS without any additional constraints. This decision was taken with the aim of developing, first of all, an efficient procedure for the discretization of the MDS, to be extended thereafter for tackling more complex problems. In fact, differently from [1], the algorithms for discretized MDS that we propose in this paper are particularly tailored to this special class of problems.

The rest of the paper is organized as follows. In Section II, we will focus on previous works for the discretization of the DGP. Then, in Section III, we will make a parallel between the DGP and the MDS, while trying to extend and adapt the methodologies, already developed for the DGP, for the discretization of the MDS. Our computational experiments will be presented in Section IV. Finally, Section V will conclude the paper.

II. Distance Geometry Problem

The Distance Geometry Problem (DGP) consists in embedding a simple weighted undirected graph $G = (V, E, d)$ in a k-dimensional space so that all weights d_{uv} on the edges of G are realized as distances between the positions assigned to its vertices [16]. More formally, the DGP asks whether

978-83-60810-90-3/$25.00

it is possible to find an embedding $x : V \to \mathbb{R}^k$ satisfying constraints based on the available edge weights:

$$\forall (u,v) \in E, \quad ||x_u - x_v|| = d_{uv}.$$

Notice that, in these distance constraints, we can obtain the equation of a hyper-sphere in $\mathbb{R}^k$ by fixing one of the two vertices in a certain position. The discretization of the DGP is based on the idea to intersect as many hyper-spheres as necessary to obtain a discrete set of possible positions for a given vertex $v \in V$ (see Section II-A).

A classical approach to the DGP is to reformulate it as an unconstrained global optimization problem [23]. The satisfaction of the constraints based on the distances can be measured by computing the difference between the actual value $||x_u - x_v||$ of the distance, and its expected value d_{uv}. In order to verify the overall satisfaction of the available constraints, a penalty function can be introduced, whose general term is related to the generic constraint. Various penalty functions can be defined for the DGP, and one of the most used penalty functions is the so-called Medium Distance Error (MDE):

$$MDE(x) = \frac{1}{|E|} \sum_{(u,v)\in E} \frac{|\,||x_u - x_v|| - d_{uv}\,|}{d_{uv}}. \qquad (1)$$

Finding the global minimum of this penalty function allows to obtain solutions to the DGP. If all distances are compatible to each other and they are not affected by numerical errors, the MDE value for a valid embedding x needs to be equal to zero.

There are two main applications of the DGP that can be commonly found in recent publications. One application arises in biology, and it is concerned with the identification of protein conformations by exploiting some known interatomic distances that can be obtained by experimental techniques [19]. Another common application is given by the so-called Sensor Network Localization Problem (SNLP) [2], [5], where the positions of the sensors forming a network need to be identified.

As already mentioned above, when some particular assumptions are satisfied, the DGP can be discretized, so that its search space can be reduced from a continuous (and infinite) domain to a discrete (and finite) domain. We will give some details about the discretization of the DGP in Section II-A, and we will focus on discretization orders (vertex orders for G which make the discretization assumptions satisfied) in Section II-B.

A. The Discretization

Let $G = (V, E, d)$ be a simple weighted undirected graph representing a DGP instance. Let $G[\cdot]$ be the subgraph of G induced by a subset of vertices in V; let $\mathcal{V}_S(\cdot)$ be the volume of the simplex defined by the vertices given as arguments. The discretization in dimension $k > 0$ of a DGP instance can be performed when there exists an order defining sequence $r : i \in \mathbb{N} \longrightarrow v \in V \cup \{\diamondsuit\}$ of length $|r|$ (for which $r_i = \diamondsuit$ if $i > |r|$) such that the following two assumptions are satisfied:

Algorithm 1 The BP algorithm.

```
1: BP(i, k, G, r, ε)
2: let v = r_i;
3: compute x'_v in dimension k;
4: if (x'_v is feasible with tolerance ε) then
5:    if (i = |r|) then
6:       print new solution;
7:    else
8:       BP(i + 1, k, G, r, ε);
9:    end if
10: end if
11: compute x''_v in dimension k;
12: if (x''_v is feasible with tolerance ε) then
13:    if (i = |r|) then
14:       print new solution;
15:    else
16:       BP(i + 1, k, G, r, ε);
17:    end if
18: end if
```

(a) $G[\{r_1, r_2, \ldots, r_k\}]$ is a clique;
(b) $\forall i \in \{k+1, \ldots, |r|\}$, there exist k "reference" vertices, i.e. there exist $j_1, j_2, \ldots, j_k$ such that
   1) $j_1 < i$, $j_2 < i$, …, $j_k < i$;
   2) $\{(r_{j_1}, r_i), (r_{j_2}, r_i), \ldots, (r_{j_k}, r_i)\} \subset E$;
   for which
$$\mathcal{V}_S(r_{j_1}, r_{j_2}, \ldots, r_{j_k}) > 0.$$

Vertex orders satisfying assumptions (a) and (b) are named *discretization orders*: more details about these special orders are given in Section II-B. The class of DGP instances for which at least one discretization order exists for the corresponding graph is named Discretizable DGP (DDGP) [24].

The search space of DDGP instances is finite. It has the structure of a tree, where nodes contain candidate vertex positions, organized layer by layer. In fact, assumption (a) allows us to place the first k vertices given by the vertex order r in k fixed positions. In this way, we can avoid to consider congruent solutions that can be obtained by rotating and/or translating other solutions. Assumption (b) ensures the existence of at least k *reference vertices* for every vertex having a rank $i > k$: a vertex u can play the role of "reference" for a given vertex v if u precedes v in the vertex ordering r, and $(u, v) \in E$. We say that the corresponding distances d_{uv} are the *reference distances* for the vertex v. We exploit the k reference vertices for defining k spheres centered in the reference vertices and having as radius the corresponding reference distances: in dimension k, the intersection of these k spheres provides us with a subset of vertex positions having cardinality 2 [8], [14]. The condition on the volume of the simplex in assumption (b) ensures that this sphere intersection does not provide a full circle (which is obviously not discrete).

We employ a Branch & Prune (BP) algorithm [25] for the solution of DDGP instances (see Alg. 1 for a sketch). The algorithm recursively calls itself for the exploration of the

search tree. In the algorithm call, i is the current rank in the given vertex order r: it is supposed that the coordinates of all vertex positions on the current branch are stored in the global memory. The value of k corresponds to the dimension in which we wish to embed the graph G. ε is our tolerance for the errors that can affect the generated vertex coordinates: as soon as new vertex positions are computed by performing the sphere intersection, in fact, their feasibility is verified by exploiting additional distances that were not used in the discretization process. In order to do so, we consider the corresponding terms of equation (1), and we declare as "infeasible" a new generated position if at least one of such terms is greater than the predefined tolerance ε. Once a new solution is found by the BP algorithm, the quality of such a solution can be verified by applying equation (1): since all its terms are smaller than our tolerance ε, we expect to obtain good-quality solutions.

The complexity of one single BP call corresponds to the complexity of computing twice a new vertex position, and of verifying whether the exploration of the tree should continue in those two directions or not. If, for example, x'_v is feasible (see Alg. 1), then this position could be part of a solution, and therefore the branch of the binary tree rooted at x'_v needs to be explored. In this case, the algorithm invokes itself for computing the possible positions for the next rank. Instead, if for example x''_v is not feasible with the given tolerance, then the current branch does not contain any solution. It is therefore pruned: the algorithm does not invoke itself in this case. This algorithm phase is fundamental and named *pruning phase*.

There are two main approaches to deal with the uncertainty on the values of the available distances. In [15], for example, intervals are used for representing such an uncertainty, and the terms of equation (1) are adapted for providing a positive measure only when the actual distance is not contained in the given interval (for both feasibility verification during the execution of BP, and computation of the MDE function once a new solution is found). However, in some applications (such as the MDS), the uncertainty on the distance values is not known a priori, and therefore our approach will consist in considering instances with only exact distances, which we will need to tackle by admitting larger values for the tolerance ε. In other words, since the range of the intervals to be assigned to uncertain distances cannot be predefined, we will try to define them during the execution of the BP algorithm: the tolerance ε represents in this case the maximal allowed interval range.

B. Vertex Orders

A *discretization order* is a vertex order associated to the graph G such that the discretization assumptions (a) and (b) are satisfied [9], [13]. Given a graph G representing a DGP instance, one question that can immediately arise is whether this instance belongs to the DDGP class or not. When instances are stored in text files, an order may be implicitly associated to the vertices of G, but such an order may not satisfy the discretization assumptions. In order to find suitable discretization orders, a greedy algorithm was proposed in [13] and extended subsequently for dealing with interval distances [20]. A heuristic, that has as worst-case complexity the one of the greedy algorithm, was also proposed in [10], for dealing more efficiently with very large instances.

In some particular applications (the reader can refer for example to [15]), additional assumptions on the discretization orders are required, and the problem of finding a discretization order may become NP-hard [4]. Naturally, the above-mentioned greedy algorithm cannot guarantee the generation of a vertex order that, apart from the discretization assumptions, could as well satisfy the additional ones.

For example, we say that a discretization order satisfies the *consecutivity assumption* if the reference vertices for a given vertex v, and v itself, are consecutive in the order. Orders satisfying the consecutivity assumption can be seen as sequences of overlapping cliques, which can be searched on the pseudo de Bruijn graphs introduced in [21]. Even if it implies the execution of an exponential search, the use of such pseudo de Bruijn graphs aided the identification of discretization orders satisfying the consecutivity assumption for the backbones of protein instances.

The complexity of this ordering problem can also increase when *optimal* discretization orders are required. We say that an order is optimal when the rank assigned to every vertex maximizes some predefined objective functions [22]. For example, when low-rank vertices have the maximal number of reference vertices, a direct impact on the width of the corresponding search tree can be observed: it becomes smaller. Several objectives, together with their priority orders, can be defined and used for finding optimal discretization orders. If the objectives are given by a set of simple functions, then the problem of finding an optimal discretization order (without any other additional assumption) still has a polynomial complexity, and the greedy algorithm can be extended for dealing with this class of vertex orders [9].

III. Multidimensional Scaling

Since one of the first pioneer papers on this topic [29] in 1952, the MDS received an increasing interest. Surveys on the MDS can be found in the scientific literature: a recent example is [11], published in 2013. In the cited survey, the MDS is defined as the set of statistical techniques that are employed for reducing the dimensionality of a given set of data, with the aim of improving the visual appreciation of the underlying relational structures contained therein. The main idea is to attempt mapping the data into a (generally Euclidean) space, where *similar* items are represented by near points in the mapping, and *dissimilar* items are represented by points that are located proportionally further apart. By doing so, the complexity in the data is reduced, and the primary dimensions, along with the items differ, are identified. The MDS has a wide range of applications, and the interested reader can refer to the citations in [11] for additional information about these applications.

One of the best-known methods for dimensionality reduction, especially in the field of mathematical statistics, is Principal Component Analysis (PCA) [7], [12]. PCA was

proposed by Karl Pearson in 1901 [26], and it consists of an orthogonal transformation that can project an ensemble of the high-dimensional data into a new set of coordinate systems (principal axes) in the order of the variances. One of the most notable advantages of PCA is the preservation of the distance metric during the linear transformation. However, this essential feature of PCA, i.e., the use of linear transformation, also prevents PCA from discovering intrinsic non-linear degrees of freedom underlying complex natural phenomena.

One of the most prominent approaches in non-linear dimensionality reduction is the *Isomap* method proposed by Tenenbaum et al [28]. Unlike PCA, Isomap method has a better ability for successfully capturing the intrinsic global geometric features of the given set of points. It was noted recently, however, that the application of the Isomap method is able to provide good results only when transferring the data between two similar geometries [6].

Let X be a set consisting of points of the Euclidean space $\mathbb{R}^K$. Since the coordinates for each point in X are known, it is possible to compute their relative distances. With this information, we can define a simple weighted undirected graph $G = (V, E, d)$. In the graph, every vertex $v \in V$ represents one single point in X, and an edge $(u, v) \in E$, together with the weight that is associated to it, represents the relative distance between the two corresponding points in X. All graphs G constructed in this way have the following two properties: they are complete, and all the weights associated to the edges (the distances) are exact. These graphs represent instances of the DGP.

A very simple but nice example of MDS is given in [11] and is concerned with the problem of drawing a small geographic map. All relative distances between the cities of Los Angeles, New York, Chicago and Dallas are given, and the aim is to find their correct locations on a two-dimensional map. When the information on the distances is precise, a very accurate map can be generated, i.e. a map for which the distances between points are proportional to the true distances between city pairs (modulo translations and rotations). In general, however, solutions where the overall distance information is precisely verified may not exist, so that approximated mappings need to be searched.

Let G be the simple weighted undirected graph defined as described above from a known set in dimension K. In the example of the 4 US cities, the distances are measured by approximating a surface on Earth with a plane containing the 4 cities: a small error is introduced in the distances because of the plane approximation of the Earth region. In general, every graph is embeddable in dimensions $k \geq |V|$ without introducing any error in the distances. However, when the number of vertices in V is large, the dimensionality is huge. The main interest therefore is to reduce the data dimensionality, and to converge to small dimensions, such as 3, 2, or even 1, where the visualization of the data is possible. In the example of the 4 US cities, the embedding of the corresponding graph G needs to be searched in dimension $k = 2$. Recall that K is the initial dimension of our MDS instances, while k is the destination dimension.

In this work, we will extend the concept of discretizability to MDS instances (see Section III-A), and we will provide two variants of the BP algorithm that are particularly tailored to the MDS (in both Sections III-A and III-B).

A. The Discretization

The methodology that we propose for discretizing the MDS is strictly related to the previous works on the discretization of the DGP (see Section II-A). The entire theory of the discretization can be in fact inherited almost unchanged: the novelties in this paper are mostly *operational*: we propose some ad-hoc strategies to be integrated in our new algorithms.

Since all relative distances are generally available in MDS instances, the main task that is required for performing the discretization is the selection, for every vertex $v \in V$ that does not belong to the initial clique, of a k-plet of reference vertices. We point out that this task has a fundamental importance. In fact, once a k-plet of reference vertices has been selected for the vertex v, the corresponding reference distances remain fixed in the search tree, i.e. we cannot allow the introduction of any error in the corresponding distances.

The main idea for our first variant on the BP algorithm for the MDS is to try to consider all possible k-plets of reference vertices, and to choose, at each recursive call, the k-plet for which the minimal error is observed during the pruning phase. If this minimal error is larger than a predetermined tolerance $\varepsilon > 0$, then the current branch of the tree is pruned and the search is backtracked.

In order to measure the quality of partial embeddings (up to the current rank of the discretization order), we need to consider the following function, that we name *partial* MDE (pMDE, see equation (1)):

$$pMDE(x, r, i) = \frac{1}{|E(r, i)|} \sum_{(u,v) \in E(r,i)} \frac{|\,||x_u - x_v|| - d_{uv}\,|}{d_{uv}}, \tag{2}$$

where

$$E(r, i) = \{(u, v) \in E \,|\, \exists j < i \,:\, u = r_j,\, v = r_i\}.$$

Notice that, while the vertex ordering associated to G is irrelevant for the computation of the MDE, it becomes important for the pMDE. The value of $pMDE(x, r, i)$ is in fact the average error introduced in the partial embedding x of G up to the rank i, in the vertex ordering r.

The sketch of our BP variant for the MDS is given in Alg. 2. The algorithm keeps the general structure of Alg. 1, but, every time it invokes itself recursively, it verifies all the possible k-plets of reference vertices for the current vertex v, and chooses the best k-plet p_{best} in terms of introduced error pMDE. We are aware that the choice of the k-plet is greedy, and that it might have, in theory, a negative impact on the computations. However, our computational experiments (see Section IV) show that our methodology works quite well in conjunction with the algorithm pruning phase, which does not allow the overall introduced error to grow more than desired.

Algorithm 2 A variant of the BP algorithm for the MDS.

BP$(i, k, G, r, \varepsilon)$
let $v = r_i$;
for (every k-plet p of reference vertices for v) **do**
  compute x'_v and pMDE(x'_v) in dimension k;
  compute x''_v and pMDE(x''_v) in dimension k;
end for
let p_{best} be the k-plet leading to the lowest pMDE;
let $\hat{x}'_v$ and $\hat{x}''_v$ be the two positions for v given by p_{best};
if $(pMDE(\hat{x}'_v, r, i) < \varepsilon)$ **then**
  if $(i = |r|)$ **then**
    print new solution;
  else
    BP$(i + 1, k, G, r, \varepsilon)$;
  end if
end if
if $(pMDE(\hat{x}''_v, r, i) < \varepsilon)$ **then**
  if $(i = |r|)$ **then**
    print new solution;
  else
    BP$(i + 1, k, G, r, \varepsilon)$;
  end if
end if

In comparison with Alg. 1, Alg. 2 has a higher complexity. The worst-case complexity is achieved (as in Alg. 1) when the pruning phase is never able to prune away infeasible tree branches. In this case, the algorithm needs to invoke itself

$$\sum_{i=k+1}^{|r|} 2^{i-k}$$

times. At each call, moreover, it is necessary to select the best k-plet of reference vertices in a set of $i - 1$ vertices, where i is the rank in r of the current vertex. The number of combinations of k objects among $i - 1$ objects, without repetitions and without assigning a specific order to them, are

$$\frac{(i-1)!}{k!(i-k-1)!}.$$

Therefore, the complexity of finding all these possible combinations depends upon the current layer of the tree i. As a consequence, the worst-case complexity of Alg. 2 is

$$\sum_{i=k+1}^{|r|} \frac{2^{i-k}(i-1)!}{k!(i-k-1)!}.$$

B. Vertex Orders

The reader might have remarked that, while vertex orders have been presented as a fundamental concept for the discretization of DGPs, there is only a quick mention to vertex orders in the previous section, devoted instead to the discretization of the MDS. In fact, the completeness of graphs G representing MDS instances ensures that all vertex orders allow for the discretization (the discretization assumptions in Section II-A are always satisfied). However, as already done for the DGP (see Section II-B), we may want to select optimal vertex orders for a given instance of the MDS, which may help us in improving the performances of the BP algorithm.

Algorithm 3 Another variant of BP for the MDS.

BP$(i, k, G, r, \varepsilon, \bar{V})$
for (every new candidate vertex $v \in \bar{V}$) **do**
  for (every k-plet p of reference vertices for v) **do**
    compute x'_v and pMDE(x'_v) in dimension k;
    compute x''_v and pMDE(x''_v) in dimension k;
  end for
end for
let $\bar{v} \in \bar{V}$ be the vertex leading to the lowest pMDE;
let $r_i = \bar{v}$;
let p_{best} be the k-plet leading to the lowest pMDE;
let $\hat{x}'_{\bar{v}}$ and $\hat{x}''_{\bar{v}}$ be the two positions for $\bar{v}$ given by p_{best};
if $(pMDE(\hat{x}'_{\bar{v}}, r, i) < \varepsilon)$ **then**
  let $\bar{V} = \bar{V} \setminus \{\bar{v}\}$;
  if $(\bar{V} = \emptyset)$ **then**
    print new solution;
  else
    BP$(i + 1, k, G, r, \varepsilon, \bar{V})$;
  end if
end if
if $(pMDE(\hat{x}''_{\bar{v}}, r, i) < \varepsilon)$ **then**
  let $\bar{V} = \bar{V} \setminus \{\bar{v}\}$;
  if $(\bar{V} = \emptyset)$ **then**
    print new solution;
  else
    BP$(i + 1, k, G, r, \varepsilon, \bar{V})$;
  end if
end if

In terms of partial orders, a vertex order that allows for the discretization of the MDS can be any order with an initial k-clique at the first rank, and all other vertices at rank two. In other words, once the initial clique has been embedded, as well as some other vertices until the vertex v, any of the remaining vertices can be embedded as next. This observation leaded us to develop another variant of the BP algorithm for the MDS.

Consider we have already embedded m vertices of our graph G, with $m > k$ and $m < |V|$. Instead of considering a predefined vertex ordering, we can assume here that every non-embedded vertex can be the candidate to be embedded as next. Moreover, for each of such candidate vertices, different k-plets can be selected to play the role of reference vertices in the discretization (see Section II-A). For every candidate vertex, and for every k-plet, an error on the pruning distances can be computed, and the best vertex and k-plet can be selected together. If the minimal obtained error is greater than our tolerance ε, then the current tree branch needs to be pruned.

The sketch of this second variant of the BP algorithm for the MDS is given in Alg. 3. In the algorithm call, the discretization order r is initially empty, and it is constructed

step by step during the several recursive calls. In this situation, backtracking also means changing vertex ordering, because every tree branch may admit a different optimal order. In practice, at each recursive call, the best vertex $\bar{v}$ and the best k-plet, which lead to the minimal pMDE value, are selected at the same time. This double choice is performed, as in Alg. 2, in a greedy manner. In the algorithm call, we also added the set $\bar{V}$, which is supposed to contain the vertices of the graph that have not been yet embedded.

The complexity of this algorithm is evidently higher, in comparison with Algs. 1 and 2. With respect to Alg. 2, an additional task needs to be performed at every recursive call of the algorithm: it is necessary to select the next vertex to be considered. This task requires a search over the remaining vertices to be embedded (with complexity $n - i$, where $n = |V|$) of the optimal one, i.e of the one for which it is possible to identify the best k-plet of reference vertices. Therefore, the overall worst-case complexity of Alg. 3 is

$$\sum_{i=k+1}^{|r|} \frac{2^{i-k}(|V|-1)(i-1)!}{k!(i-k-1)!},$$

which is much higher of the original complexity of Alg. 1.

IV. Computational experiments

A. Generation of MDS instances

We consider artificially generated instances, with $K > 3$ and $k = 3$. Let n be the number of points in the original set $X \subset \mathbb{R}^K$; let $e \in [0, 1]$. The procedure we employ for the instance generation consists in the following steps:

- we generate n random points in the cube of $\mathbb{R}^3$ with sides equal to 1;
- we add $K - 3$ coordinates to each point, having random values extracted from the interval $[0, e]$;
- we compute all relative distances between point pairs in $\mathbb{R}^K$;
- we define a simple weighted undirected graph G containing this distance information.

We point out that the error e introduced in these instances is distributed over the set of distances, as well as over the added coordinates, in a quite uniform manner. This property is unlikely to be satisfied by real instances in general. We also remark that the overall introduced error per instance naturally depends upon the value of e, but also on the distance size n.

B. Preliminary experiments

All the experiments presented in this section have been performed on a laptop computer equipped with an Intel Core i5 with 2.4 GHz and 8GB/1600 MHz RAM, running Mac OS X 10.11.3.

Table I shows some experiments where a set of instances that are embeddable in dimension 3 are considered (our introduced error e, in fact, is here set to 0). We fix the destination dimension to $k = 3$, while various initial dimensions K are taken into consideration. The ε value is set to 0.001 in all the experiments, even if $e = 0$, in order to deal with some errors introduced by imprecise computer arithmetics. In all generated instances, the total number of solutions is always 2 (when G is embeddable in dimension k, then the total number of solutions is 2, because all distances are available [18]). We point out however that, in general when an approximated embedding is searched, the introduced errors in the distances may lead to the identification of multiple solutions. The experiments lasting more than 2 hours were aborted. When executing Algs. 1 and 2, a vertex order was predefined. In Alg. 1, moreover, the selected reference vertices are always the k immediate preceding ones in the predefined ordering r. The computational time is measured in seconds.

The table shows that Alg. 2 is able to find better quality solutions w.r.t. the ones obtained by the standard Alg. 1, in terms of MDE. Such an improvement does not appear so evident instead when comparing Alg. 2 and Alg. 3: the MDE values remain mostly unchanged. It seems therefore that it is not important in which place of the ordering a vertex is located, but mostly which its reference vertices are. The computational times that we report reflect the theoretical worse-case complexities provided in Sections III-A and III-B. For instances with $n = 200$, Alg. 3 would have taken more than 2 hours to run to termination.

Table II shows some computational experiments where valid embeddings cannot be identified in the destination dimension k without introducing some errors in the distances. All considered instances have size $n = 20$, and part of the experiments already reported in Table I are here provided again for completeness. As the error e increases, the MDE values in the found solutions show that the quality of the solutions decreases as well. In some cases, Alg. 1 is not able to find any solution, because of the propagation of such errors on our search tree. Alg. 2 is instead always able to get the solutions, and the MDE reflects the initial introduced error e. Alg. 3 is always able to find solutions as well (the increase in the complexity is here not so important because all instances are small), and it finds better quality results in some cases.

Table III shows some experiments with our artificially generated instances having larger size ($n = 50$, 100 and 200), for larger errors (we consider $e \in \{0.01, 0.02\}$) and where we compare Alg. 2 to Alg. 3 only. The table shows that the quality of the solutions found by the two algorithms is comparable (in this set of experiments, only one time Alg. 3 was able to do better than Alg. 2), but the computational time grows too much when executing Alg. 3. In fact, the instances with $n = 200$ would have taken more than 2 hours, and these experiments were therefore aborted.

Finally, only Alg. 2 is considered in our last table of experiments. These experiments are aimed at stressing our algorithm with high initial dimensions; the destination dimension is still fixed to 3. As already pointed out, the errors introduced in our instances are quite uniformly distributed over the set of distances, and over the coordinates. This is the reason why we consider small errors e, but repeated uniformly over the n vertices forming the instance, and its $K - 3$ additional dimensions. In fact, as Table IV shows, the MDE values

in the found solutions strongly depend upon the difference between destination and initial dimensions. However, with a rather constant computational time, all the experiments were able to provide a good approximation of a valid embedding of G.

V. CONCLUSIONS

When the destination dimension k is fixed, the Multidimensional Scaling (MDS) can be seen as a DGP where an embedding of the graph G is available in dimension K, and it is necessary to find a valid embedding of the same graph in the given destination dimension. Actually, the graph G, which is the input of the DGP with the dimension k, can be generally obtained from the known embedding in dimension K. However, not all distances between vertices in dimension K can be realized in dimension k, and therefore approximated valid embeddings need to be searched.

This work represents the first step for the discretization of the MDS. The main ideas and the main methodology are inherited from previous works on the discretization of the DGP. We proposed two algorithms, that are variants on the BP algorithm, which was previously proposed for solving discretizable DGP instances. Our Alg. 2 seems to achieve the best trade-off between solution quality and increase in complexity w.r.t. the original BP algorithm.

The computational experiments that we have reported in this paper take into consideration a set of artificially generated instances, where the errors on the distances are introduced in a quite uniform manner. In order to deal with more realistic instances, there are several points to be improved in our approach. For example, the simplex inequalities (i.e. the triangular inequalities in dimension 3) need to be verified before executing our algorithms, and, when necessary, some distances may need to be corrected. Because of the nature of the problem, every corrected distance may imply to modify other distances accordingly, in order to avoid invalidating the geometry of the obtained embeddings.

From an algorithmic point of view, moreover, the branching phase of the algorithm can be improved by verifying, every time a given branch is pruned, whether other k-plets of reference vertices can be chosen for the vertices over the same branch. On the one hand, in fact, pruning allows us to focus the searches on the feasible parts of the tree, but with the risk, in presence of errors, to prune too much and obtain no solutions. On the other hand, however, branching over all the possible k-plets of reference vertices can be very expensive. It is necessary therefore to identify the best trade-off.

Finally, as a future work, we may also consider the possibility to let one of the k reference vertices to be related to an interval distance, as it was already done in works related to the discretization of the DGP. The decision not to consider yet interval distances during the discretization process is motivated by the fact that work is still in progress for an efficient management of interval distances during the generation of DGP discrete search spaces.

ACKNOWLEDGMENTS

The present work was entirely performed during WG's 1-year stay at IRISA, Rennes (France), which was funded by the Brazilian program "Ciencias sem Fronteiras". CL also wishes to thank FAPESP and CNPq for financial support.

***Abstract*—The modeling of machines and their operation modes is a key approach for optimization of their performance as well as for avoiding unwanted operational states which may lead to the occurrence of faults, and finally, to the breakdown. The developed model of a machine should be always parametrized, i.e. the certain number of parameters should be selected in the certain ranges. The most of the parameters can be selected based on engineering documentation and experts' knowledge, however, for some of them this knowledge cannot be directly acquired which leads to the parameter uncertainty. One of the approaches allowing selection of these uncertain parameters is a tuning procedure of a model. The paper deals with a concept of heuristic optimization method for automatic tuning of key parameters of longwall scraper conveyor model. In the first part of the paper, the evolutionary algorithm for tuning this model is proposed. In the case study, the merits and limitations of the evolutionary approach are analysed. The obtained results prove that the proposed approach of tuning of the considered model has high practical potential and it may be applied in real mining conditions.**

I. Introduction

THE longwall scraper conveyors are the machines used in the mechanized underground coal mines for transporting a coal. Since these machines usually work in extremely difficult operational conditions it is essential to monitor their performance in order to prevent unwanted operational modes and machinery downtime as well as to implement the knowledge obtained from the monitoring process into the re-designing processes which allows increasing their reliability, effectiveness and safety. However, considering the operational conditions in the underground coal mines as well as difficulties in physical access to sources of various signals and difficulties with their measurement, the monitoring of physical working parameters is often limited to few main quantities, which causes that the measurement data is incomplete, and makes the diagnosis and prognosis of these machines difficult. In order to predict an inappropriate behavior of a conveyor and prevent its unwanted operational modes, it is essential to develop a simulator (or mathematical/numerical model) which allows testing various operational scenarios, including the occurrence of various types of faults.

The model-based approach in diagnostics and condition monitoring of underground mines machinery is widely applicable in numerous industrial solutions. To date, many of such models were developed for scraper and belt conveyors. For the mentioned purposes, Cenacewicz, Przystałka and Katunin [1], [2] developed the models of belt and scraper conveyors for evaluation of their dynamical behavior under certain operational scenarios.

In the most cases, modeling of dynamic behavior of such machinery is difficult, since many operational parameters are not available or even not measurable or impossible to acquire. This leads to the incompleteness and uncertainty of a developed model. Thus, in order to achieve such parameters one can perform simplifications of the model, assume them basing on literature data and experts' knowledge, or use knowledge discovery and optimization techniques. Currently, the most common approach in this task is the manual adjustment of values of behavioural parameters of the model taking into account the data included in technical documentation or in domain literature as well as domain expert's knowledge. Obviously, such an approach is ineffective and leads to the increasing error with an increase of number of uncertain parameters and overall level of model uncertainty. On the other hand, in the recent years, heuristic methods based on the natural phenomena of evolution, such as simulated annealing algorithm, genetic algorithms, differential evolution, harmony or tabu search ideas, swarm-inspired methods, etc. have been developed and applied to model and solve real-life global optimization problems [3]. Furthermore, this kind of optimization algorithms has long been applied for tuning values of unknown parameters of different types of models [4], [5].

The problem of unknown parameter estimation is not enough discussed in many studies related to analytical modeling of mining conveyors, see e.g. [6] and [2]. To the best knowledge of the authors of this paper, this is one of the first attempts on applying a heuristic optimization technique for automatic tuning of parameters of longwall scraper conveyor model. The main goal of this study is the introduction of the new approach based evolutionary tuning of the mathematical

The research presented in the paper was financed by the National Centre of Research and Development (Poland) within the framework of the project titled "An integrated shell decision support system for systems of monitoring processes, equipment and hazards" carried out in the path B of Applied Research Programme - grant No. PBS2/B9/20/2013. This publication is financed from the statutory funds of the Faculty of Mechanical Engineering of the Silesian University of Technology in 2016.

model of the longwall scraper conveyor. This approach allows for adjusting the values of uncertain parameters of the model, and thus make it fully defined. This, in turn, allows for using this model for modeling of various scenarios of operation as well as for diagnosing the considered machine using the model-based diagnostics approach.

II. Concept of the evolutionary algorithm for tuning of conveyor model

The mathematical model of the considered scraper conveyor consists of the following submodels: model of a doubled main drive, model of auxiliary drive, model of mine breaker and contactor control, power supply model, model of equations of motion, model of masses, and model of motion resistance. A detailed mathematical and phenomenological description can be found in [2].

The dynamic behavior of the described model strongly depends on values of key parameters corresponding to physical properties of the real conveyor system. The total number of these parameters can be declared as D. As it is mentioned above, the most of them can be easily established in the direct way because there is the possibility for gauging and quantifying physical properties of the plant. On the other hand, the rest values declared as $\mathbf{x} = [x_1\ x_2\ \ldots\ x_d]$ can be indirectly found using signals of process variables which are collected during monitoring of the object and simulation of the model. We assume that the number of observed signals (real and simulated) is equal to J, whereas the number of experiments (scenarios) is I. Henceforth, real (r) and modeled (m) time series that are needed for tuning purposes may be denoted as

$$\mathbf{y}_r^{ij} = \left[y_r^{ij}(1)\ y_r^{ij}(2)\ \ldots\ y_r^{ij}(K)\right],$$

and

$$\mathbf{y}_m^{ij}(\mathbf{x}) = \left[y_m^{ij}(1,\mathbf{x})\ y_m^{ij}(2,\mathbf{x})\ \ldots\ y_m^{ij}(K,\mathbf{x})\right],$$

where j is the j-th signal (real or artificial) collected in the i-th experiment scenario, K is the number of samples.

The main objective of the tuning procedure is to adjust the values of the parameters x_1, x_2, …, x_d in order to obtain the smallest difference between the response of the system and the response predicted by the proposed model for each scenario. Therefore, the optimization problem can be written as follows:

$$\begin{array}{ll}\text{Minimize} & C(\mathbf{x}) = f\left[\mathbf{y}_r^{ij}, \mathbf{y}_m^{ij}(\mathbf{x}), I, J, K\right] \\ \text{subject to} & \Omega(\mathbf{x}),\end{array} \tag{1}$$

where f represents a function (with constant arguments I, J, K) for comparison of two time series, whilst Ω denotes boundaries and constraints in the optimization process. The optimal solution $\mathbf{x}^*$ is found if the criterion function C has a relative minimum value at $\mathbf{x} = \mathbf{x}^*$, that means if

$$\mathbf{x}^* = \arg\min_{\mathbf{x}\in\Omega} C(\mathbf{x}). \tag{2}$$

As to be expected, the criterion function C can be formulated in several ways. In this study, the authors propose two variants of this function. The first one is prepared applying the Minkowski distance of order p

$$C(\mathbf{x}, p) = \sum_{i=1}^{I}\sum_{j=1}^{J}\sqrt[p]{\sum_{k=1}^{K}\left|y_r^{ij}(k) - y_m^{ij}(k,\mathbf{x})\right|^p}. \tag{3}$$

This measure is a metric in a normed vector space which is considered as a generalization of both the Euclidean distance and the Manhattan distance. The second function is composed of three sub-criteria

$$C(\mathbf{x}, \mathbf{w}) = w_1 C_1(\mathbf{x}) + w_2 C_2(\mathbf{x}) + w_3 C_3(\mathbf{x}), \tag{4}$$

where w_1, w_2 and w_3 are used in order to control the significance of each component. The first criterion function in equation (4) is grounded on the mean absolute percent error and therefore it can be written as

$$C_1(\mathbf{x}) = \frac{100}{IJK}\sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}\left|\frac{y_r^{ij}(k) - y_m^{ij}(k,\mathbf{x})}{z^j}\right|, \tag{5}$$

where z^j corresponds to the range of the j-th sensor.

The second function is declared making use of cross-correlation as the base of a measure of the total lag τ between real and simulated signals

$$C_2(\mathbf{x}) = \tau = \sum_{i=1}^{I}\sum_{j=1}^{J}\tau^{ij}\left[R_{xy}\left(\mathbf{y}_r^{ij}, \mathbf{y}_m^{ij}(\mathbf{x})\right)\right]. \tag{6}$$

The last component is used in order to find the aggregate value of the maximum absolute errors which are present in signals collected under all scenarios

$$C_3(\mathbf{x}) = \sum_{i=1}^{I}\sum_{j=1}^{J}\max\left|\frac{\mathbf{y}_r^{ij} - \mathbf{y}_m^{ij}(\mathbf{x})}{z^j}\right|. \tag{7}$$

The solution of the optimization problem can be found using a limited number of strategies. Derivative-based approaches cannot be employed in this paper, mainly due to the form of the objective function C. Moreover, one can easily observe, that the return value of this function depends on the measurement noise in the real-world data as well as the virtual measurements (with simulated disturbances, noise and computing errors as well) obtained during numerical computations. In contrast, pure stochastic optimization methods, for example, Monte Carlo techniques will not be able to find an accurate solution with guaranteeing polynomial-time convergence because of the time of numerical computations of the conveyor model. Therefore, the authors decided to use the evolutionary algorithm which is known as one of the most common heuristic optimization methods.

III. CASE STUDY

A. Description of JOY BLS conveyor and its operating scenarios

The developed mathematical model was based on construction and parameters of the scraper conveyor of type JOY® BLS with the doubled and auxiliary drives. The parametrization of the described simulator was performed based on technical documentation of the modeled conveyor, and data available in the literature [7], [8]. The developed model is characterised by nearly fifty adjustable parameters. The operational parameters were determined theoretically or selected basing on the experts' knowledge.

The simulator of a scraper conveyor provides a possibility of simulation of eight operating scenarios, which represent the characteristic considering the operations performed during work such as idle run-up, idle run-up and run-down, etc. For the performed study four of them were selected due to the significant differences between these scenarios.

One should mention that some of operational parameters cannot be measured and were assumed according to literature data and technical data sheets. Therefore, it is essential to tune up the model in order to simulate its behavior during realization of considered scenarios properly. The five parameters ($d = 5$) that are subject to the tuning process in this study are as follows: the efficiency of the drive system: $x_1 = \eta$ [-]; the damping factor: $x_2 = \mu$ [-]; the torque losses of flexible and hydrodynamic couplings: $x_3 = \Delta M_p$ [Nm]; the approximation friction coefficient: $x_4 = a$ [-]; the unitary mass of excavated material: $x_5 = m_u$ [kg/m]. These parameters are selected since it is not possible to obtain their values in the direct way.

B. Tuning experiments and results

The verification tests were carried out with the assumption corresponding to the process variables collected during operational states of the machine. It was decided that only nine process variables ($J = 9$) could be used for tuning: the load of the engines $y_1 = M_{gn}$ [Nm]; the torque of the engines $y_2 = M_n$ [Nm]; the linear velocity of the chain $y_3 = v_n$ [m/s]; the phase currents of the first and second engine $y_4 = INZ1A$, $y_5 = INZ1B$, ..., $y_9 = INZ2C$ [A] (see [2] for details).

It was also assumed that the sampling rate of the sensors was equal to 500Hz, whereas the analog-to-digital converter resolution was set to 32bits. The noise powers of selected signals were as follows: $\sigma_{v_n} = 10\text{E}{-}08$, $\sigma_{Mgn} = \sigma_{Mpg} = 100$, $\sigma_I = 10\text{E}{-}02$. The reference signals $\mathbf{y}_r^{ij}$ were gathered while simulation of the model for selected scenarios ($I = 4$). The optimal values of parameters were chosen as follows: $x_1^r = 0.957$, $x_2^r = 0.1$, $x_3^r = 5$, $x_4^r = 3$ and $x_5^r = 461.54$. The time of the simulation was set to 40s. The error measure in the form of

$$\delta x = \frac{100\%}{d}\sum_{i=1}^{d}\delta x_i = \frac{100\%}{d}\sum_{i=1}^{d}\left|\frac{x_i^r - x_i^*}{x_i^r}\right|, \qquad (8)$$

was defined in order to evaluate the performance results.

The evolutionary algorithm implemented in Global Optimization Toolbox of Matlab® software was applied in this paper. For each optimization experiment, the boundary values of parameters were chosen taking into account literature data: $0.8 \le x_1 \le 0.99$, $0 \le x_2 \le 10$, $2 \le x_3 \le 8$, $2 \le x_4 \le 4$, $300 \le x_5 \le 570$. In the first step, the performance of the evolutionary algorithm was examined through analysing the influence of the variant of the criterion function C and the values of its parameters. The feasible population method was adapted to create a random well-dispersed initial population satisfying all constraints and bounds. Fitness scaling was done using the rank method, whereas the selection of the parents to the next generation was obtained by means of the stochastic uniform method. The elite count $\delta_s = 2$ and crossover fraction $p_c = 0.8$ were chosen. The heuristic crossover function was employed with the user-defined parameter $\lambda_h = 1.2$. The remaining individuals were mutated with the use of the adaptive feasible method. The population size was equal to 50, whilst the total number of generations was set to 20. Nine trials were performed in this part of the study: trials from 1 to 5 - fitness function was declared using Eq. (3) for $p = \{1, 2, \ldots, 5\}$; trials from 6 to 9 - fitness function was declared using Eq. (4) for $\mathbf{w} = [1\ 0\ 0]$, $\mathbf{w} = [0\ 1\ 0]$, $\mathbf{w} = [0\ 0\ 1]$, $\mathbf{w} = [0.9\ 0.01\ 0.09]$.

The results of experiments from this stage of the study are included in the first part of Table I. It can be stated that in the average sense, the minor errors can be achieved using the criterion function C in the form of Eq. 3. For this function, in each case beyond the 5th trial the mean error δx was close to 10%. Nevertheless, the smallest error was reached for the second criterion function that has been declared using Eq. 4 with $\mathbf{w} = [0.9\ 0.01\ 0.09]$. Hence, this variant of the fitness function was used in the next two steps.

In the second step, the authors analysed the influence of the population size and the crossover probability on the performance of the evolutionary algorithm. In order to examine this issue six experiments were conducted: trials 10 and 11 - fitness function was declared using Eq. (4) for $\mathbf{w} = [0.9\ 0.01\ 0.09]$ and the population size was equal to $\{30, 40\}$, the rest properties were the same as in the first step; trials from 12 to 14 - fitness function was declared using Eq. (4) for $\mathbf{w} = [0.9\ 0.01\ 0.09]$ and the crossover fraction was equal to $\{0.6, 0.7, 0.9\}$, the rest properties were the same as in the first step; trial 15 - fitness function was declared using Eq. (4) for $\mathbf{w} = [0.9\ 0.01\ 0.09]$, the population size was equal to 50 and the crossover fraction was equal to 0.7, the rest properties were the same as in the first step. This part of the research led us to state that, the smallest error could be achieved with the use of 20 individuals in the population, whereas the crossover fraction should be set to 0.7. It is easy to observe that, these settings can provide the mean error result smaller than 5%.

In the last part of the study, the analysis of the accuracy of the evolutionary optimization was carried out in the context of the sampling rate and resolution as well as the number

of the available sensors. The last three trials were done as follows: trial 16 - fitness function was declared using Eq. (4) for $\mathbf{w} = [0.9\ 0.01\ 0.09]$, only three sensors were used v_n, $INZ1A$ and $INZ2A$, the rest properties were the same as in the second step; trial 17 - fitness function declared using Eq. (4) for $\mathbf{w} = [0.9\ 0.01\ 0.09]$, all sensors were used, the sampling rate was equal to 1Hz, the resolution was set to 16bits, the rest properties were the same as in the second step; trial 18 - fitness function declared using Eq. (4) for $\mathbf{w} = [0.9\ 0.01\ 0.09]$, only three sensors were used v_n, $INZ1A$ and $INZ2A$, the sampling rate was equal to 1Hz, the resolution was set to 16bits, the rest properties were the same as in the second step.

The last analysis is very important from a technical point of view. It can be pointed out, that in mining engineering practice it is possible to use measuring devices with lower sampling rate and resolution for accurate tuning of a longwall scraper conveyor model. The sampling rate equals to 1Hz with the resolution equals to 16bits can be enough for this kind of problems to have the mean error significantly less than 10% provided that it involves the required number of measuring sensors.

Taking into account overall results of the study presented in Table I it can be concluded that the most important parameter is the damping factor. Even a small change in the value of this parameter can have a strong influence on the results of the simulation. On the other hand, the value of the loss of the torques of flexible and hydrodynamic couplings has almost no effect on the simulation.

IV. Conclusions

In this paper, the authors proposed and verified a concept of the heuristic optimization method for tuning values of parameters of longwall scraper conveyor model. In the considered model five of parameters were defined as uncertain, and the tuning problem was defined over these parameters. In turn, nine output parameters of the longwall scraper conveyor model were selected for tuning procedures. The tuning procedure was performed using four selected operational scenarios which were the most representative for the performed task.

The authors have formulated the optimization problem and applied the evolutionary computation in order to find the final solution. Two kinds of the criterion function was proposed. The first one was based on Minkowski's distance, whilst the second was prepared by means of weighted sub-criteria such as the mean absolute percent error, the cross-correlation function and the aggregate value of the maximum absolute errors. It was shown that the second type of the criterion function should be used in order to obtain the smallest mean errors during searching optimal values of parameters. The validation tasks confirm that the proposed tuning method is characterized by the high precision of tuning of uncertain parameters of the model, and may be successfully applied in real mining conditions.

***Abstract*—Designing a vehicle sharing system means locating stations which allow users to pick up and give back vehicles. One takes this strategic level decision while anticipating related rebalancing costs. We study here a strategic related bi-level *Vehicle Sharing Station Location* (VSSL) model, which involves as slave problem a static *Vehicle Sharing Rebalancing* (VSR) model.**

I. Introduction

Vehicle Sharing systems (see [4]), involving bikes or electric cars, are among the systems which currently strive in order to find their place in the urban mobility landscape as a compromise between full individual transportation and rigid public transportation. They most often work as one-way systems: customers should be allowed to pick up a *vehicle* at any station and give it back at any other station. But the system may fast become unbalanced, with either empty or overfilled stations, making arise two decision problems:

- a *strategic* level problem (see [4]) about the way stations are located and capacitated.
- an *operational* (or tactical) level problem (see [2, 3, 5, 6]), about the way the *Rebalancing Process* is performed.

This contribution deals with the *strategic level* problem, which has been scarcely studied, and which we refer to as the *Vehicle Sharing Station Location* (VSSL). We link it with the *operational level* known as the Vehicle Sharing Rebalancing Problem (VSRP).

Efficiently locating the *stations* of the system means:

- locating the stations close to the origins and destinations of the users, in such a way that a global *Access Demand* be maximized, or at least some target value be reached;
- minimizing investment and infrastructure costs;
- making in such a way that the expected running costs due to the periodic *Rebalancing Process* be the smallest possible.

While the two first criteria yield standard *Facility Location* models, (see [9]), dealing with the last one leads us to explicit those expected running costs due to the periodic *Rebalancing Process:* This process consists in periodically picking up some *vehicles* at *excess* stations, that means stations which may be considered as containing more than enough *vehicles*, and move them to *deficit* stations, while using *carriers* (trucks, self-platoon convoys…). Optimizing this process gives rise to *Vehicle Sharing Rebalancing* (VSR) models. While *on line* VSR models received very little attention, being only handled through application of empirical decision rules (see [5, 7]), several *static* VSR models (see [2, 3, 7, 8]) have already been proposed and studied through heuristics and ILP models.

Our purpose is here to cast operational VSR as a *slave* sub-problem of a strategic *Vehicle Sharing Station Location* (VSSL) model. We first consider that the input data for VSSl problem mainly consists in an origin/destination matrix OD, and in additional information about demands and costs, and derive (Section II) a bi-level *Vehicle Sharing Station Location* (VSSL) whose master problem IS a *Facility Location* model and slave sub-model is some static VSR model. Next we propose (Section III) a related bi-level algorithmic resolution scheme which decomposes in turn the VSR model into a simple *Min-Cost Assignment master* model and a *slave* PDP: *Pick up and Delivery* model (see [1, 5]) model. We end by providing a VSR lower bound and performing numerical experiments (Section IV).

II. The VSSL Model

A. Vehicle Sharing Station Location Instances

VSSL (*Vehicle Sharing Station Location*) input is a set *VS* of *virtual stations*, given together with:

- a *demand* matrix *OD*: for any *x, y* in *VS*, *OD(x, y)* means the *access demand* to the system in *x, y*, that means the number of *vehicles* which should be

picked up at station x and given back at station y by the users during a *reference* period P.
- a distance matrix $DIST$: $DIST(x,y)$ means the distance (time required) from x to y.

Demands and Costs: Solving VSSL means computing a real station subset X of VS and its related capacity function C Given a subset X of VS and a station u in VS, we denote by $Prox(u, X)$ the element x in X which is the closest to u Then the *Access Demand* $Acc(x, y, X)$ which is induced by X between two stations x and y of X is given by:
- $Acc(x, y, X) = \Sigma_{u, v \text{ in } VS \text{ such that } x = Prox(u, X), y = Prox(v, X)} OD(u,v).\Phi(Dist(u, Prox(u, X)).\Phi(Dist(v, Prox(v, X))$, Φ being a decreasing [0, 1]-valued function.

We set: $Global\text{-}Demand(X) = \Sigma_{x,y \text{ in } X} Acc(x, y, X)$.
This *Access Demand* induces, for any station x in X, a residual quantity $Res(x, X)$:
- $Res(x, X) = \Sigma_y Acc(y, x, X) - \Sigma_y Acc(x, y, X)$.

This *residual* quantity means the number of vehicles which is likely to be in excess ($Res(x, X) > 0$) or in deficit at station x at the end of standard period P.
The *Top Demand* in station $x \in X$, i.e. the variation between the least and the largest numbers of *vehicles* in station x during period P, is given by:

$Top(x, X) = Q(x, X).H(x, X)$ with :

$Q(x, X) = Sup(\Sigma_y Acc(y, x, X)), \Sigma_y Acc(x, y, X))$

$H(x, X) = \Pi(|Res(x, X)|/Q(x, X))$,

Π being a decreasing $[\alpha, 1]$-valued function, $\alpha > 0$.

Setting a station at node x in VS with capacity $C = C(x)$, has a fixed cost $Fix(x)$, augmented with a flexible cost $C.Prop(x)$, which linearly depends on C.
Besides, since running the system defined by X and function C periodically requires relocating *vehicles* from *excess* stations to *deficit* stations, we denote by $Run\text{-}Cost(X, C)$ the cost of this *rebalancing process*.

Constraints: $X \subseteq VS$ and C are subject to:
- *Capacity Constraints*: for any $x \in X$, $Top(x, X) \leq C(x)$;
- *Demand Constraints*: *Global Demand* should be at least equal to some target level *Goal*: $Global\text{-}Demand(X) \geq Goal$.

Then the VSSL model comes as follows:

VSSL Model : {Compute the subset X, the *Depot* station D, and the capacity function C in such a way that the *Capacity and Demand Constraints* be satisfied and that:
- $Cost = \Sigma_{x \in X} (Fix(x) + C(x).Prop(x)) + Depot\text{-}Cost(D) + Run\text{-}Cost(X, C, D)$ is minimal.

We denote by *Relax*-VSSL the restriction of VSSL which is obtained by removing the *Run-Cost* quantity.

B. The Vehicle Sharing Rebalancing Problem: VSR

Let us suppose that X and C are given, together with the *Depot* station D. For any station x, $v(x) = Res(x, X)$ *vehicles* are in *excess* at station x: if $v(x) < 0$, we talk about *deficit*. We suppose $\Sigma_{x \in X} v(x) = 0$, which means that D may bring additional *vehicles* to the system. *K-Max* is the number of available *carriers*, all with capacity *CAP* and initially located at D. This defines the *VSR* instance (X, v, C, D, *K-Max*).

VSR Feasible Solutions: A VSR tour γ is a finite sequence $\gamma_{Route} = \{x_0 = D, x_1, .., x_{n(\gamma)} = D\}$, *of stations,* given together with a *loading strategy,* that means with 2 sequences $\gamma_{Load} = \{L_0, L_1, .., L_{n(\gamma)}\}$ and $\gamma_{Time} = \{T_0 = 0, T_1, .., T_{n(\gamma)}\}$ of coefficients whose meaning is: a *carrier* which follows the route γ_{Route} loads, at time T_i , L_i *vehicles* at *station* x_i (unloads in case $L_i < 0$). This VSR tour γ is *feasible* if:
- For any $i = 0, .., n(\gamma)\text{-}1$,
$$T_{i+1} \geq T_i + DIST(x_i, x_{i+1}); \quad \text{(E1)}$$
- For any $i = 0, .., n(\gamma)\text{-}1$,
$$L^*_i = \Sigma_{j = 0..i} L_j \leq CAP; \quad \text{(E2)}$$
- $\Sigma_{j = 0..n(\gamma)} L_j = 0$; (E3)
- For any j such that $v(x_j) \geq 0$, $v(x_j) \geq L_j \geq 0$; (E4)
- For any j such that $v(x_j) \leq 0$, $v(x_j) \leq L_j \leq 0$. (E5)

Then *a feasible solution* for the *VSR* instance (X, v, C, D, *K-Max*, *DIST*) is a collection $\Gamma = (\Gamma(k), k = 1..K \leq K\text{-}Max)$ of *feasible tours*, such that, for any station x: $\Sigma_k \Sigma_{i \text{ such that } x(k)i = x} L(k)_i = v(x)$. (E6)
The cost of Γ is given by: $R\text{-}Cost(\Gamma) = \alpha.K +$
$\beta.\ Sup_k\ T(k)_{n(\Gamma(k))} + \chi.\ \Sigma_k\ T(k)_{n(\Gamma(k))}$
$+ \delta.(\ \Sigma_k \Sigma_j\ DIST(x(k)_j, x(k)_{j+1}).L^*_j)$,
where α, β, χ, δ are some scaling coefficients.

We derive the following **VSR Model**: {Compute a *feasible* VSR solution $\Gamma = (\Gamma(k), k = 1..K)$ which minimizes the above quantity $R\text{-}Cost(\Gamma)$}.

Remark 1: The $Run\text{-}Cost(X, C, D)$ quantity of the VSSL model is the optimal value of this *VSR* model.

III. ALGORITHMS

We deal with the VSSL model according to a GRASP hierarchical decomposition scheme:

VSSL-GRASP Scheme
Initialize X and C while solving *Relax*-VSSL;
Not *Stop*; While Not *Stop* do
Solve the slave VSR model induced by X; (*)
Derive an additional constraint $C\text{-}Aux(X)$, and update X, C through local search;

We implement the first instruction by adapting *Facility Location* algorithms (see [8]) into a *Relax*-VSSL procedure, while observing that the capacity function C derives from X and the *Top Demand* function x, $X \rightarrow Top(x, X)$ in a straighforward way. The resulting procedure is a GRASP Algorithm, which involves local search operators *Insert*(x) *Remove*(x), *Replace*(x, y) and *Merge*(x, y).

X being given, let us now explain how we deal with the resulting VSR sub-problem ((*) instruction).

A. Decomposing VSR into Min Cost Assignment and PDP: The Distance Strategy.

In case we could decide, for any pair (x, y), x *excess*, y *deficit* station, which quantity $Q_{x,y}$ has to move from x to y in order to achieve the *rebalancing process*, then we derive a VSR solution by solving the *Load Splitable* PDP instance (see [1]) defined by:

- *Requests* correspond to the 3-uple ($o(j) = x$, $d(j) = y$, $Load(j) = Q_{x,y} \neq 0$)
- Minimize $\alpha.K + \beta.$ Sup $_k$ $Length(\Gamma(k)) + \gamma.\ \Sigma_k$ $Length(\Gamma(k)) + \delta.\ \Sigma_j$ $Ride(j)$: k denotes the vehicles, ($\Gamma(k)$) the related PDP tours and $Ride(j)$ is the time spent by $Load(j)$ inside a *truc*k.

We check that:

Theorem 1: *We may restrict ourselves to vectors $Q = (Q_{x,y}$, x excess station, y deficit station) which are vertices of the Assignment polyhedron P-Assign:*

P-Assign: {$Z = (Z_{x,y}$, x excess, y deficit) such that:

- *For any excess station x, $\Sigma_{y\ deficit} Z_{x,y} = v(x)$;*
- *For any excess station x, $\Sigma_{x\ excess} Z_{x,y} = - v(x)$}*

This leads us to handle VSR through the following decomposition scheme:

***VSR Assignment/PDP Decomposition Scheme*:**

Initialize cost vector Q; Not *Stop*;

While Not *Stop* do

Derive Z and the *Request* set $J = J(Z)$)

Solve the *Load Splitable* PDP related instance;

Update Q;

The Distance Strategy: Initializing Q comes in a natural way by setting: for any x, y, x *excess*, y *deficit* stations, $Q_{x,y} = DIST(x, y)$. We call this strategy, the *Distance Strategy*. We may state:

Theorem 2: *If K is fixed and β, δ equal to 0 (we minimize the carrier riding time), then the Distance strategy induces a VSR approximation ratio of (1+CAP). This is the best possible ratio*.

Theorem 3: *If K is fixed and χ, δ equal to 0 (we minimize the makespan), then the Distance Strategy induces a VSR approximation ratio of (1+K.CAP). This is the best possible ratio*.

B. VSR-Assignment/PDP Algorithm

We follow the guideline of the previously described hierarchical decomposition scheme. As a matter of fact, we revisit it as follows

***VSR-Assignment/PDP Algorithm*:**

Initialize cost vector Q; Derive Z and the *Request* set $J = J(Z)$; Solve the *Load Splitable* PDP related instance through some generic *Insertion* algorithm and get a current VSR solution Γ; Not *Stop*;

While Not *Stop* do

Update cost vector Q and the *Request* set $J = J(Z)$; Let J_0 the set of formerly existing requests which have been removed from J and J_1 the set of newly created requests; Remove J_0 and next Reinsert J_1, in the sense of the *PDP Insertion* algorithm, into current solution Γ;

Cost vector Q and related *Request* set J are updated by:

- 1 th Step: Identify a subset $J_0 \subseteq J$ of *poorly inserted requests* (those with a large gap between cost $Q_{x,y}$ and mean *riding time* $R_{x,y}$);
- 2 th step: Set, for any x, y involved into J_0, x *excess*, y *deficit*, $Q_{x,y} = (Q_{x,y} + R_{x,y})/2$.

C. Retrieving Sensitivity Constraint C-Aux(X)

A key instruction inside the main loop of the *VSSL-GRASP* algorithm is the following:

"*Derive an additional constraint C-Aux(X)…*"

We implement it while using the dual solution λ_x, $x \in VS$ of the *Min-Cost Assignment* problem related to current vector Q, as a sub-gradient vector and derive the following Bender's like constraint *C-Aux*(X):

$\Sigma_{x \in VS}$ Res(x, X). $\lambda_x \leq \Sigma_{x \in VS}$ Res(x, X_0). λ_x .

D. A Lower Bound for the VSR model

We get a VSR lower bound *LB* by introducing (see [8]) a network with time indexed nodes and turning *Preemptive* VSR (*carriers* may exchange *vehicles* while performing the *Rebalancing* process) into a network flow model, which involves an integral *carrier* flow vector dominating some rational *vehicle* flow vector. Practically, we compute *LB* while using an ILP solver and applying some rounding process when the size of G is too large.

IV. Numerical Experiments

Since we can't provide exact reference values for the VSSL model, we separately evaluate the distinct components of the VSSL-GRASP Algorithm.

A. Testing VSR-Assignment/PDP and Relax-VSSL

A VSR instance is identified by the numbers *n*, *nd*, *K-Max*, by the matrix *DIST*, and by function *v*. *T-Max* is set to 480. We compute, for any instance:

- the value *LB* of the lower bound of Section III;
- the value *V-NP-Dist* (*V-NP*) of the solution related to the *Distance* strategy (*VSR-Assignment/PDP*) and its related CPU time;

Assignment/PDP) and its related CPU time; We get (on PC AMD Opteron 2.1GHz, while using gcc 4.1 compiler and the CPLEX12 library):

Table I:
Testing *VSR-Assignment/PDP*

n , n_A, K-Max	*V-NP-Dist/LB(%)*	*V-NP-Dist-CPU(s)*	*VNP/LB (%)*	*NP-CPU*
48, 20, 3	19.6	4.6	14.6	17.6
48, 30, 3	24.0	6.7	16.2	20.5
48, 40, 3	12.4	8.9	10.4	29.0
96, 20, 5	13.8	7.1	10.8	30.5
96, 60, 5	22.6	10.3	14.8	48.8
148, 40, 7	11.8	10.1	8.5	20.2
148, 80, 7	15.7	18.3	14.7	48.4

Comment: The LB value provides us with a rather good approximation. Though the *Distance* strategy is rather efficient, we improve V-NP values in a significant way by fully performing local search.

In order to test *Relax-VSSL*, we generate a set *VS* of *n* points of the Euclidian space R^2, (so *DIST* means the Euclidian distance), and an origin/destination matrix *OD*, with all values *OD(x, y)* between 0 and a given parameter *S*, and uniformly distributed. Functions Φ and Π are piecewise linear. We compute, for every instance, the gap *G* between the CPLEX optimal solution and the of *Relax-VSSL* together with related CPU times *T-ILP* and *T-Rel*. Then we get, while always setting *S* to 10:

Table II:
Testing *Relax-VSSL*

n , M	*G (%)*	*T-ILP (s)*	*T-Rel*
10, 5	1.1	29.6	4.1
15, 5	0	126	6.9
15, 10	0	*	14.0
20, 5	2.8	1588	10.7
20, 10	0	*	21.2

B. Testing VSSL-GRASP

A VSSL test is identified here by:

- the coefficients *n* (cardinality of *VS*, *S* (top *OD(x, y)* value), *q* (relative weight of *Run-Cost* inside the global cost of a solution);
- the number *M* of replications of the *VSSL-GRASP* scheme;
- the length L of the main loop of *VSSL-GRASP.*

We compute, for any instance, the gap *G* between the initial cost obtained through *Relax-VSSL* and the final cost obtained through *VSSL-GRASP*, together with related CPU times *T0* and *T1*. Then we get:

Table III:
Testing *VSSL-GRASP*

n , S, q (%) M, L	*G (%)*	*T0(s)*	*T1*
20, 10, 25%, 20, 50	8.5	42.5	288.4
20, 20, 50%, 20, 50	17.6	43.1	360.8
20, 30, 75%, 5, 10	30.6	11.2	152.6
20, 30, 75%, 20, 50	35.9	43.6	506.2
50, 10, 25%, 5, 20	5.0	29.6	304.0
50, 10, 50%, 5, 20	12.6	29.6	334.8
50, 10, 75%, 5, 20	28.4	29.6	350.6
50, 10, 75%, 10, 50	31.3	58.8	1482.0

Comment: Computing costs increase with the *S* value.

***Abstract*—The design of embedded vision systems carries a difficult challenge regarding the access times of memories holding image data for some particular cases of image treatments. This paper studies the optimization challenge reflecting the efficient operation of adhoc memory systems proposed by electronic designers to alleviate this problem. New algorithms are proposed for producing solutions to this 3-objective problem, and numerical experiments are conducted on real-world data for validating their efficiency.**

I. Introduction

The design of embedded vision systems carries many challenges, one of which is the efficient access to the image memory. An architectural solution was proposed by Mancini and al. [1] in the form of a software tool that creates an ad-hoc memory hierarchy for non-linear image accesses. But operating this kind of systems is itself an optimization challenge, involving 3 objectives reflecting 3 main electronic design parameters. To the best of our knowledge, this problem has not been studied before in the optimization literature.

The remaining of this paper is organized as follows. After describing the Memory Management Optimization design software, we explain the related optimization problematic set by the efficient operation of the circuits produced by this tool, and give a formal multi-objective mathematical model for this problem, as well as several sub-problems of interest. We then review the state of the art. After giving lower bounds for the 3-objective problem, we analyze the complexity of some of the mono-objective sub-problems. The description of new approaches, including a simple heuristic and two algorithms, is then given. Numerical experiments follow, which are conducted on real-world data in order to validate their efficiency, and a conclusion and perspectives section closes the paper.

II. Embedded Vision Systems Context: Architectural Solution and Optimization Problematic

A. Memory Management Optimization Tool

Among modern-day electronic devices, embedded vision systems such as picture and video cameras represent a specific design challenge with respect to memory management. Image sizes are measured in 100's of kbs or even Mbs, while the access times must be short enough to allow the quick handling of the data. For example, a live video feed may have 30 frames per second, meaning that the handling of one image (frame) must take less than 1/30 s. But it is a well-known fact in electronic memory design that access times grow with the size of the memory to be accessed. Due to this fact, it is not possible to reach the performance needed with the simple use of memories. Something has to be added to improve the access times.

For digital image treatments (also called *kernels*) that have linear access patterns to the memory addresses, usual caches as used for CPUs will solve this problem. But for non-linear access patterns, the problem remains a big hurdle for the easy and efficient design of kernel circuit designs. An illustration of a non-linear kernel is given in Fig. 1.

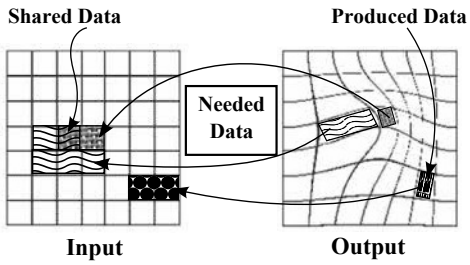

Fig. 1. Example of a non-linear kernel

To address this problematic, Mancini and al. [1] have designed a software generator of memory hierarchies tailored to one particular non-linear kernel. Their solution, called *Memory Management Optimization* (MMOpt), takes as input a non-linear kernel for which the memory hierarchy is to be produced, such as the one shown in Fig. 1; it analyzes its access patterns; it then designs a run-time behavior for the whole resulting block *Tile Processing Unit* (TPU); and it finally outputs the design of the TPU, together with the

information needed to orchestrate its operational behavior.

We give some details about the architecture of the TPU, as shown in Fig. 2. It is made of (a) a *Prefetching Unit* (PU) that loads data from external memory to local buffers, and (b) a *Processing Engine* (PE), that computes output data using prefetched input ones.

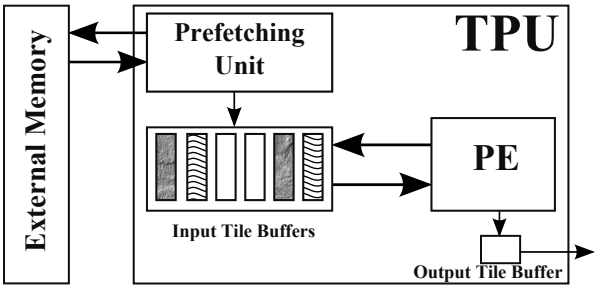

Fig. 2. Architecture template of the TPU

MMOpt computes and encodes into the TPU a schedule of prefetches and a schedule of computations. Hence memory accesses in the final system are deterministic (i.e. independent of pixel values), and this is a requirement of the input kernel for the whole MMOpt scheme to work out.

B. Optimization for MMOpt

When designing electronic circuits, some of the important design criteria are the area of the circuit produced, since it is directly related to production costs; the energy consumption, which may be limited, and which conditions the battery life for battery-powered devices; and the performance, which is usually a design parameter reflecting reactivity, and fluidity in the case of moving images.

TPUs produced by MMOpt embed schedules for the prefetches of input tiles and computations of output tiles (see Fig. 3).

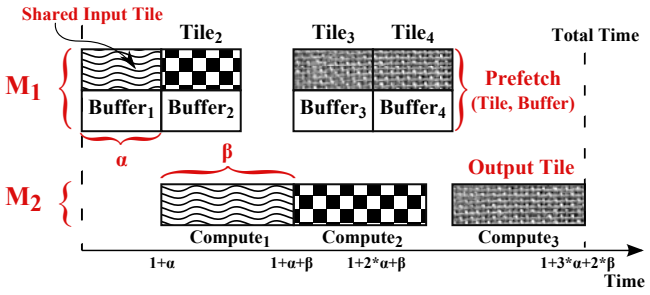

Fig. 3. Prefetches and computations schedules

The architecture of the TPU and those schedules will impact those three design parameters in the following way: the number of buffers of the TPU will account for most of its area; the number of prefetches reflects the main part of the energy consumption; and the performance is related to the completion time of the whole prefetches-computation schedule for the computation of one image.

Since MMOpt is a fully automatic electronic design software, computing good schedules is both a necessity and an opportunity for the circuit designers to deliver, with the help of MMOpt, low-cost, low-energy and efficient TPUs.

III. The 3-objective Process Scheduling and Data Prefetching Problem

As you may know, the Integer Linear Programming formulation is used in the operations research as a modeling approach for the optimization problems. In this study, we have chosen to formulate our optimization issue by an off-line, 3-objective model with clearly delineated inputs and outputs, which we now present. This multi-objective mathematical formulation is a very flexible modeling approach that allows a preciseness for dealing with many specific sub-problems.

A. Problem Statement and Assumptions

The main multi-objective optimization problem considered in this paper is called *3-objective Process Scheduling and Data Prefetching Problem* (3-PSDPP). It involves the definition of the number of buffers of the TPU, the scheduling of output tiles computations, and the scheduling of input tiles prefetches, while respecting a requirement constraint between prefetches and computations.

The main assumptions that apply to the 3-PSDPP are the following:

1) Input tile sizes are identical and each input tile fits exactly into one buffer.
2) There is no distinction between buffers, i.e. any input tile may be prefetched into any buffer.
3) All input (respectively output) tiles and the subset of input tiles required to compute each output tile are known in advance.
4) Only one input (output) tile can be prefetched (computed) at a time.
5) The prefetch operations and the computation steps may be carried out simultaneously.
6) Input (output) tile prefetch (respectively computation) times are constant and identical.

B. Formulation for 3-PSDPP

The 3-PSDPP problem consists of finding an appropriate computation sequence in which output tile will be computed, and an associated prefetch sequence in which input tile will be prefetched from the external memory to the buffers, that simultaneously minimizes the number of prefetches, the number of buffers, and the completion time. We now describe the input data of our problem 3-PSDPP, the expected output, the constraints, and the 3 formal objectives reflecting the 3 electronic design parameters (Mathematical Formulation given in Table I).

1) Inputs: a 3-PSDPP instance is represented by a 5-tuple $(\mathcal{X}, \mathcal{Y}, (\mathcal{R}_y)_{y\in\mathcal{Y}}, \alpha, \beta)$ where $\mathcal{X}$ is the set of input tiles to be prefeteched, and $\mathcal{Y}$ is the set of output tiles to be computed. Each output tile y requires its own set of input tiles, denoted

TABLE I
MATHEMATICAL FORMULATION FOR 3-PSDPP

Inputs	$\mathcal{X}= \{1,\ldots,X\}, \mathcal{Y}= \{1,\ldots,Y\}$, where $X, Y \in \mathbb{N}^*$ $\mathcal{R}_y \subseteq \mathcal{X}, \forall\ y \in \mathcal{Y}$ $\alpha, \beta\ \in \mathbb{N}^*$
Outputs	(N, Z, Δ), where $N, Z, \Delta \in \mathbb{N}^*$ $(p_i)_{i\in\mathcal{N}}$, where $p_i = (d_i, b_i, t_i)$ $(c_j)_{j\in\mathcal{M}}$, where $c_j = (s_j, u_j)$
Constraints	**(1)** $\forall\ y\ \in\mathcal{Y}, \exists\ j \in\mathcal{M}\ /\ s_j = y$ **(2)** $\forall\ j \in\mathcal{M}, \forall\ x \in\mathcal{X}, x \in \mathcal{R}_{s_j} \Rightarrow$ $(\exists\ a \in \{1,\ldots,u_j - \alpha\}, \exists\ i \in \mathcal{N}/t_i = a, d_i = x\ \&$ $(\forall a' \in \{a+\alpha,\ldots,u_j+\beta-1\}, \forall i' \in \{i+1,\ldots,N\},$ $t_{i'} = a' \Rightarrow b_{i'} \neq b_i))$ **(3)** $\forall\ i \in\mathcal{N}\backslash\{1\}, t_i\ \geq\ t_{i-1} + \alpha$ **(4)** $\forall\ j \in\mathcal{M}\backslash\{1\}, u_j\ \geq\ u_{j-1} + \beta$
Objectives	$\min\ Z, \min\ N, \min\ \Delta$

by $\mathcal{R}_y$. Also, the duration of a prefetch step α, and that of a computation step β, have to be given as input.

Remark 1. *The set of input tiles $(\mathcal{R}_y)_{y\in\mathcal{Y}}$ must be present in the buffers during the whole computation step of the tile y.*

Remark 2. *Each input tile x already prefetched earlier may be reused if it is still present in the buffer.*

2) Outputs: a feasible solution to such an instance is defined by $((p_i)_{i\in\mathcal{N}}, (c_j)_{j\in\mathcal{M}}, Z, N, \Delta)$.

- Configuration of the prefetched input tiles:
  we denote by $(p_i)_{i\in\mathcal{N}}$ the prefetch sequence, where $p_i = (d_i, b_i, t_i)$ encodes that input tile d_i is prefetched in the buffer b_i at the time t_i.
- Configuration of the computed output tiles:
  we denote by $(c_j)_{j\in\mathcal{M}}$ the computation sequence, where $c_j = (s_j, u_j)$ encodes that output tile s_j is to be computed at the time u_j.
- The values for the three criteria (Z, N, Δ):
  we denote by Z the number of buffers; N is the total number of prefetched input tiles; and Δ is the completion time, meaning the total time it takes for the whole operation of the TPU from the beginning of the first prefetch to the end of the last computation of one full image.

3) Constraints: the first constraint (1) on solutions is that for each output tile y, there exists a computation step j in which this output tile is computed. The second and main constraint (2) ensures that all the input tiles $\mathcal{R}_y$ required by y have to be prefetched from the external memory to the internal storage area (buffers) before the start date u_j of its associated computation step, and will not be overwritten until its end date. Input tiles already prefetched earlier can be reused, provided they have not been overwritten. Constraints (3) and (4) guarantee that different input (output) tiles cannot be pre-fetched (computed) simultaneously.

4) Objectives: in the formulation above, three objectives have to be minimized: the number of prefetches N reflects the main part of the energy consumption; the number of buffers Z of the TPU will account for most of its area, and is related to cost; and the completion time Δ accounts for the performance of the TPU.

C. Sub-Problems of 3-PSDPP

From this multi-objective problem 3-PSDPP, we derive several mono and bi-objective sub-problems. The mono-objective sub-problems we consider are *Minimum Buffers of 3-PSDPP* (MB-PSDPP), in which the number of buffers is to be minimized; *Minimum Prefetches of 3-PSDPP* (MP-PSDPP) in which the number of prefetches is to be minimized; and *Minimum Completion Time of 3-PSDPP* (MCT-PSDPP), in which the completion time is to be minimized.

For the remaining sub-problems to be presented, the number of buffers Z will be fixed as input data. Hence, we consider the *Prefetching and Scheduling Problem* (PSP), where the number of buffers is fixed as input, and the number of prefetches N is to be minimized. In addition, the variant of PSP, where the computation sequence is given as part of the input, is called the *Data Prefetching Problem* (DPP).

We will also consider the bi-objective sub-problem of 3-PSDPP, 2-PSDPP, where the number of buffers Z is fixed, and both N and Δ are to be minimized.

D. Related Work

In the study by Mancini and al. [2], two algorithms for optimizing the running of the TPU produced by the MMOpt tool are proposed.

The first algorithm is M_1, for which both the number of prefetches N and the completion time Δ are minimized. The second one, called M_2, aims at minimizing both the number of prefetches N and the number of buffers Z.

The algorithm M_1 proceeds in two steps which are, respectively, *Computations* and *Prefetches*. Furthermore, M_2 comprises three steps, the first two of which are those of M_1. The third step is *Delay Computations*.

For both algorithms M_1 and M_2, the authors [2] add a *Destinations* step for determining the sequence of destination buffers.

These different steps are outlined in Fig. 4.

1) Computations: this step encodes the order in which a batch of output tiles has to be successively computed, one at a time. The traffic to the external memory is then minimized by optimizing the obtained scheduling.

To construct the computation sequence, the authors [2] solve an instance of the *Asymmetric Traveling Salesman Problem* (ATSP) to find a Hamiltonian path in the complete directed graph $\overrightarrow{G}$ whose vertices are the set of output tiles, and whose arcs are weighted by $\varphi(k, l)$, where (k, l) is a pair of output tiles, in which the output tile k will be computed before the output tile l. The function $\varphi(k, l)$ defines the number of additional input tiles to be prefetched for computing the output tile l, when all input tiles shared between k and l are already prefetched.

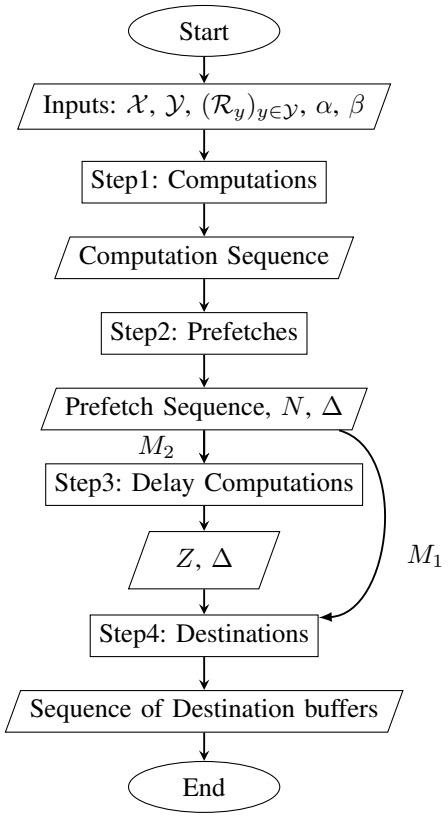

Fig. 4. Flowchart for algorithms M_1 and M_2

2) Prefetches: in this step, the authors [2] determine the schedule of prefetches associated to the computation sequence given by step 1. This schedule encodes which input tile should be prefetched from the external memory to the buffers at each moment. In fact, in parallel to each computation step, they prefetch the additional input tiles needed for the next computation.

3) Delay Computations: in this step, in order to reduce buffer usage, the authors [2] simply delay some computations by inserting fake computations when necessary. New trade-offs between the embedded memory area and the computing time can be then reached.

4) Destinations: this step simply consists in deciding in which buffer to place each prefetched input tile.

To the best of our knowledge, the 3-PSDPP problem has not been studied before in the operations research literature. We now relate some sub-problems of the 3-PSDPP problem to similar problems in the literature. Thus, we focus here on the uniform *Tool Switching Problem* (ToSP) arising in the flexible manufacturing context. The ToSP consists of finding an appropriate job sequence in which jobs will be executed, and an associated sequence of tool switches that minimizes the number of tool loading/unloading operations in the tool magazine of a single tool-switching machine. The general ToSP was first considered by Tang and Denardo [3]. They showed that the ToSP can be solved in polynomial time for a fixed job sequence, *Tooling Problem* (TP), using the *Keep Tools Needed Soonest* (KTNS) algorithm. On the other hand, when the job sequence is to be determined, Crama and al. showed that the ToSP is already NP-Hard for any fixed tool magazine capacity larger than or equal to 2 [4]. Different optimization techniques, including exact and heuristics methods, have been applied to its resolution (see Bard [5]; Privault and Finke [6]; Laporte and al. [7]; Konak and al. [8]; Amaya and al. [9]; Catanzaro and al. [10]).

IV. Models Analysis

For validating the efficiency of the proposed approaches, we develop three lower bounds lb_N, lb_Z, and lb_Δ for the different optimization criteria (N, Z, Δ). We then give complexity results for some of the mono-objective sub-problems of 3-PSDPP problem described in Section III-C.

A. Lower Bounds

Proposition 1. *$X - |\Omega|$ is a lower bound on the number of prefetches for the 3-PSDPP, where Ω denotes the set of input tiles which are not required by any output tile.*

Proof: For any solution to some given instance of 3-PSDPP, all input tiles that are required at least once for the computation of an output tile have to be prefetched at least once to some buffer. Hence the total number of prefetches cannot be less than $X - |\Omega|$. ■

Proposition 2. *$\max_{y\in\mathcal{Y}} |\mathcal{R}_y|$ is a lower bound on the number of buffers for the 3-PSDPP.*

Proof: Fix an instance of 3-PSDPP, and a feasible solution for that instance. When an output tile is computed, all the required input tiles have to be present in the buffers. Hence $\max_{y\in\mathcal{Y}} |\mathcal{R}_y|$ is a lower bound for the number of buffers in the solution. ■

Proposition 3. *$lb_1 = \alpha * X' + \beta$ and $lb_2 = \alpha + \beta * Y$ are lower bounds on the completion time Δ for the 3-PSDPP.*

Proof: Fix an instance of 3-PSDPP, and a feasible solution for that instance. Since all input tiles have to be loaded before the last computation starts, the completion time is at least $\alpha * X'$ (for the prefetches) plus β (for the computation of the last output tile).

Likewise, all output tiles have to be computed, and no computation can start before a first input tile has been prefetched. Hence the completion time is lower bounded by $\beta * Y$ (computation time for all output tiles) plus α (prefetch time for the first prefetch). ■

Thus, the completion time Δ is lower bounded by the maximum lb_1 and lb_2 ($lb_\Delta = \max\{lb_1, lb_2\}$).

B. Complexity Analysis

To prove that MB-PSDPP can be solved in polynomial time, we give an algorithm for which the number of buffers Z equals its lower bound ($Z_{\min} = lb_Z$). In this algorithm, we first fix the number of buffers Z to $\max_{y\in\mathcal{Y}} |\mathcal{R}_y|$. Then, for each output tile, we prefetch all its required input tiles into the Z buffers before

the corresponding computation step starts. The idea here is that a prefetch step and a computation step are not carried out in parallel.

To prove also that MP-PSDPP is solvable in polynomial time, we give another algorithm for which the number of prefetches N equals its lower bound ($N_{\min} = lb_N$). In this method, we first prefetch successively all the input tiles in $\mathcal{X}'$, where $\mathcal{X}' = \mathcal{X} \backslash \Omega$ and Ω denotes the set of the input tiles which are not required by any output tile. Then, when the prefetch steps are finished, all output tiles are successively computed.

For the MCT-PSDPP sub-problem, we have not yet been able to determine its complexity.

We now examine the two sub-problems of 3-PSDPP where N is to be minimized, and Z is fixed as input, namely PSP and DPP. We then prove the equivalence between PSP and the tool switching problem ToSP. In the description of the PSP problem, both input and output tiles ($\mathcal{X}$, $\mathcal{Y}$) are regarded as ToSP data (tools, jobs). The incidence matrix Tools×Jobs can then be regarded as the requirements of input tiles needed to compute all the output tiles $(\mathcal{R}_y)_{y\in\mathcal{Y}}$. The fixed number of buffers Z is the analogue of the capacity of the tool magazine. In addition, finding a computation sequence for minimizing the total number of prefetches corresponds to finding a job sequence for minimizing the total number of tools loadings. Thus, PSP is NP-Complete. When the computation sequence is given as input data, the same polynomial reduction works to prove the equivalence of DPP and Tooling Problem (TP). Hence, DPP is polynomially solvable.

This equivalence allows us to adapt the KTNS algorithm, as described by Tang and Denardo for solving the TP [3], to give an optimal solution for DPP. We call this adaptation *KTNS Adapted to DPP* (KAD). On the other hand, in the case of PSP, we developed an algorithm, named *KTNS Adapted to PSP* (KAP), to solve it.

We will also consider the bi-objective problem 2-PSDPP where the number of buffers Z is fixed, and both N and Δ are to be minimized. For solving the 2-PSDPP sub-problem, we developed a new solution approach called *Shifted Prefetches for bi-PSDPP* (SPbP).

To introduce both KAP and SPbP algorithms, respectively, for PSP and 2-PSDPP sub-problems of 3-PSDPP, we now present the specific adaptation KAD that it is an intermediate step in both KAP and SPbP algorithms.

V. Solution Methods

A. Constructive Heuristic

We propose now a constructive heuristic called H_1 for solving the 3-PSDPP, in which the number of buffers Z equals its number of required input tiles $X - |\Omega|$ and both N and Δ are to be minimized. In this method, the number of prefetches is optimum and we try to get the best possible completion time.

This algorithm proceeds in three phases. For each input tile x, we calculate its number of occurrences $O_c(x)$ in $(\mathcal{R}_y)_{y\in\mathcal{Y}}$. Then, the input tiles are sequenced in their decreasing order of $O_c(x), \forall x \in \mathcal{X}$. Finally, for each computation is determined when it can be scheduled at the earliest. The corresponding date is the end of the loading of the latest prefeteched tile among its required input tiles. Computations are scheduled greedily in this order, while making sure to respect these "at earliest" dates.

B. KTNS Adapted to DPP: KAD

We present an adaptation of the KTNS algorithm for solving the mono-objective sub-problem DPP (described in Section III-C). The KAD adaptation will be the second step of both KAP and SPbP algorithms presented in the following subsections.

We first restate the KTNS policy established by Tang and Denardo [3]. In our case, we can state the KTNS policy in this way:

1) At any instant, no input tile is prefetched unless it is required by the next output tile.
2) If an input tile must be prefetched, the input tiles that are kept (not removed) are those needed the soonest.

The pseudo-code of the KAD algorithm can be summarized as follows:

Algorithm 1 KAD

Input: $\mathcal{X}$, $\mathcal{Y}$, $(\mathcal{R}_y)_{y\in\mathcal{Y}}$, $(s_j)_{j\in\mathcal{M}}$, Z, α, β
Output: $(p_i)_{i\in\mathcal{N}}$, N, Δ

1: $M \leftarrow$ Incidence_Matrix ($\mathcal{X}$, $\mathcal{Y}$, $(\mathcal{R}_y)_{y\in\mathcal{Y}}$)
2: $P \leftarrow$ Permute (M, $(s_j)_{j\in\mathcal{M}}$)
3: $P' \leftarrow$ Flip_Blocks (P, Z)
4: $N, (d_i)_{i\in\mathcal{N}} \leftarrow$ Prefetches (P')
5: $(b_i)_{i\in\mathcal{N}} \leftarrow$ Destinations ($(d_i)_{i\in\mathcal{N}}$, P, Z)
6: $(t_i)_{i\in\mathcal{N}} \leftarrow$ Prefetches_StartDate ($(d_i)_{i\in\mathcal{N}}$, α, β)
7: $(u_j)_{j\in\mathcal{M}} \leftarrow$ Computations_StartDate ($(s_j)_{j\in\mathcal{M}}$, $(t_i)_{i\in\mathcal{N}}$, α, β)
8: $\Delta \leftarrow$ Completion_Time ($(u_j)_{j\in\mathcal{M}}$, β)

We now give some explanations about the pseudo-code. Given the computation sequence s_j, a number of buffers Z, and an $X \times Y$ *input tile-output tile* matrix M, where M_{xy} is 1 if output tile y requires x ($x \in (\mathcal{R}_y)_{y\in\mathcal{Y}}$) and 0 otherwise, we first determine the new incidence matrix P by permuting the columns of M according to the $(s_j)_{j\in\mathcal{M}}$.

In the second step, we determine the set of 0-blocks of P, as shown in Fig. 5. A 0-block is defined as a maximal subset of consecutive zeroes in a row of P. Intuitively, a 0-block is a maximal time interval which input tile i is not needed, but it is needed before and after this interval. Assume now that the 0-blocks of P have been ordered in increasing order of the index of their last column in P, the routine Flip_Blocks (P, Z) flips to 1 as many 0-blocks of P as possible, as long as each column $j (j = 1, \ldots, Y)$ of P contains no more than Z ones ($Z = 2$ in this example), as shown in Fig. 6.

The resulting matrix is denoted by P'. Then, the routine Prefetches(P') determines the total number of prefetches N, by counting all the blocks of 1 in P'. A 1-block can be defined

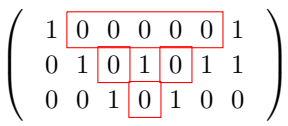

Fig. 5. KTNS-Initial Matrix

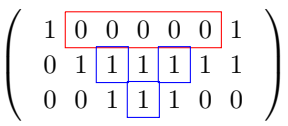

Fig. 6. KTNS-Final Matrix

as a maximal subset of consecutive ones in a row of P', for which an input tile i is not needed before and after this interval.

To construct the prefetch sequence $(d_i)_{i\in\mathcal{N}}$, we affect, for each output tile (column j in matrix P'), the set of associated input tiles (index of 1-blocks starting in column j) to be prefetched before the corresponding computation step. We determine then the associated sequence of destination buffers $(d_i)_{i\in\mathcal{N}}$, by affecting for each prefetched input tile a free buffer from the Z buffers. After that, we construct the associated schedules of prefetches-computations, in which the input tiles are prefetched one after the other. The same applies for computing the output tiles sequence. In the resulting prefetches-computations schedules, a prefetch step and a computation step are not carried out in parallel. Indeed, each computation step begins on the date where all its required input tiles have been prefetched. The routine Prefetches_StartDate() determines the start dates of the prefetches schedules. Similarly, the routine Computations_StartDate() determines the start dates of the computations schedules. The routine Completion_Time() computes then the completion time Δ.

C. Algorithm KAP for PSP

We have developed the KAP algorithm for solving the PSP sub-problem of 3-PSDPP, in which the number of buffers Z is fixed ($Z \geq \max_{y\in\mathcal{Y}}|\mathcal{R}_y|$) and the number of prefetches N is to be minimized. In contrast to DPP, the order in which the computations have to be carried out is not given as input, and has to be determined.

The KAP algorithm proceeds in two steps as follows:

1) Step1-Find a Computation Sequence (lines 1–3 of pseudo-code): in this step, we determine the computation sequence by solving the same instance of an ATSP as step 1 of both algorithms M_1 and M_2 (see Section III-D) [2].

2) Step2-KAD Algorithm (line 4 of pseudo-code): in second step, we resolve the DPP (described in Section V-B), by the KAD algorithm in order to determine the schedules of both the prefetches and computations with an optimal number of prefetches N.

The pseudo-code of the KAP algorithm can be summarized as follows:

D. Algorithm SPbP for 2-PSDPP

We have developed also the SPbP algorithm for solving the 2-PSDPP sub-problem of 3-PSDPP, in which the number of buffers Z is fixed ($Z \geq \max_{y\in\mathcal{Y}}|\mathcal{R}_y|$) and both the number of prefetches N and the completion time Δ are to be simultaneously minimized.

The SPbP algorithm proceeds in three steps as follows:

Algorithm 2 KAP

Input: $\mathcal{X}$, $\mathcal{Y}$, $(\mathcal{R}_y)_{y\in\mathcal{Y}}$, Z, α, β
Output: $(p_i)_{i\in\mathcal{N}}$, $(c_j)_{j\in\mathcal{M}}$, N, Δ

1: Let $\overrightarrow{G}=(Y,A)$ be a complete directed graph on Y
2: Let φ: $A \rightarrow \mathbb{N}$, $\overrightarrow{kl} \mapsto |\mathcal{R}_l \backslash \mathcal{R}_k|$
3: $(s_j)_{j\in\mathcal{M}} \leftarrow$ Short_Hamiltonian_Cycle ($\overrightarrow{G}$, φ)
4: N, $(d_i)_{i\in\mathcal{N}}$, $(b_i)_{i\in\mathcal{N}}$, $(t_i)_{i\in\mathcal{N}}$, $(u_j)_{j\in\mathcal{M}}$, $\Delta \leftarrow$ KAD ($\mathcal{X}$, $\mathcal{Y}$, $(\mathcal{R}_y)_{y\in\mathcal{Y}}$, $(s_j)_{j\in\mathcal{M}}$, Z, α, β)

1) Step1-Find a Computation Sequence (line 1 of pseudo-code): this step is the first one of KAP algorithm described in Section V-C.

2) Step2-KAD Algorithm (lines 2 of pseudo-code): this step is the second one of the KAP algorithm described in Section V-C

We give now a detailed description of the third step "Shifting Prefetches".

3) Step3-"Shifting Prefetches" (lines 3–9 of pseudo-code): In the resulting schedules of prefetches-computations, we apply the idea of "Shifting Prefetches", in which the completion time Δ is to be minimized. The originality of this step is to allow an overlap between the prefetch and computation steps. In this step, we shift in the prefetches schedule those that can be carried out in parallel with the previous computation step, by checking that no required input tiles of the output tile in this step were overwritten until its end date.

The pseudo-code of the SPbP algorithm can be summarized as follows:

Algorithm 3 SPbP

Input: $\mathcal{X}$, $\mathcal{Y}$, $(\mathcal{R}_y)_{y\in\mathcal{Y}}$, α, β, Z
Output: $(p_i)_{i\in\mathcal{N}}$, $(c_j)_{j\in\mathcal{M}}$, N, Δ

1: $(s_j)_{j\in\mathcal{M}} \leftarrow$ Computation_Sequence($\mathcal{X}$, $\mathcal{Y}$, $(\mathcal{R}_y)_{y\in\mathcal{Y}}$)
2: N, $(d_i)_{i\in\mathcal{N}}$, $(b_i)_{i\in\mathcal{N}}$, $(t_i)_{i\in\mathcal{N}}$, $(u_j)_{j\in\mathcal{M}}$, $\Delta \leftarrow$ KAD ($\mathcal{X}$, $\mathcal{Y}$, $(\mathcal{R}_y)_{y\in\mathcal{Y}}$, $(s_j)_{j\in\mathcal{M}}$, α, β, Z)
3: **for** $j = 2$ To $\mathcal{M}$ **do**
4: Prefetch[j] $\leftarrow \{i \in \mathcal{N}/P'[j][d_i] - P'[j-1][d_i] = 1\}$
5: Buffer[j] $\leftarrow \{b_i/i \in$ Prefetch[j]$\}$
6: Advanced_Prefetch[j] $\leftarrow$ $\{l/l \in$ Prefetch[j]&Buffer[j][l] $\notin b_i(\mathcal{R}_{s_{j-1}})\}$
7: Not_Advanced_Prefetch[j] $\leftarrow$ Prefetch[j]$\backslash$Advanced_Prefetch[j]
8: **end for**
9: $(t_i)_{i\in\mathcal{N}}$, $(u_j)_{j\in\mathcal{M}}$, $\Delta \leftarrow$ Schedule_Prefetches_Computations ($(s_j)_{j\in\mathcal{M}}$,Advanced_Prefetch[],Not_Advanced_Prefetch[], α, β)

E. Solutions for 3-PSDPP

Though our 3-PSDPP is a multi-objective optimization problem, we have developed two approaches. The first one

is the KAP algorithm for solving the mono-objective sub-problem PSP, where the number of buffers Z is fixed as input, and the number of prefetches N is to be minimized. The second one is the SPbP algorithm for solving the 2-PSDPP problem, in which the number of buffers Z is fixed, and both N and Δ are to be minimized.

The different steps of both both KAP and SPbP algorithms are outlined in Fig. 7. As shown in this figure, the KAP algorithm represents the two first steps of the SPbP algorithm.

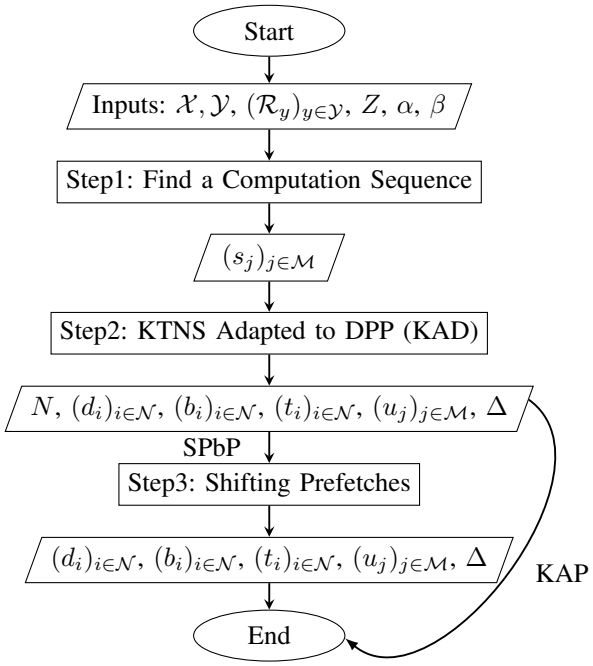

Fig. 7. Flowchart of KAP and SPbP algorithms

Therefore, we can use both KAP and SPbP as two methods for producing solutions to the main multi-objective optimization problem 3-PSDPP. By varying the number of buffers Z, both KAP and SPbP algorithms give a set of different solutions, in order to let the circuit designer pick his favorite compromise solution. It is an asset of these two methods that the circuit designer may choose his solution.

F. Example

In order to illustrate the process of both KAP and SPbP algorithms for solving two sub-problems of 3-PSDPP, where $z = 4$ buffers, let us consider the input data given in Fig. 8 for the case where $x = 5$ input tiles, $y = 3$ output tiles, $\alpha = 2$, and $\beta = 3$ time units.

We first determine the computation sequence $s_j = Y_2, Y_1, Y_3$, by finding a short Hamiltonian cycle in the graph $\overrightarrow{G}$ (see Fig. 9).

By running the *KAP* algorithm on our example, Fig. 10 gives the corresponding prefetches and computations schedules together with values of the outputs.

$$M = \begin{array}{c} \\ X_1 \\ X_2 \\ X_3 \\ X_4 \\ X_5 \end{array} \begin{array}{c} \begin{array}{ccc} Y_1 & Y_2 & Y_3 \end{array} \\ \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \\ 1 & 1 & 1 \\ 1 & 0 & 0 \end{pmatrix} \end{array}$$

Fig. 8. $X \times Y$ Matrix

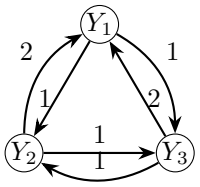

Fig. 9. Graph $\overrightarrow{G}$

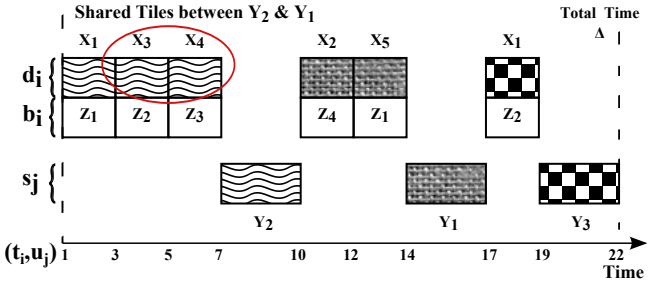

Fig. 10. KAP Schedules

Finally, we apply the **"Shifting Prefetches"** for minimizing the completion time Δ. The Fig. 11 shows that the completion time Δ is reduced by 2 units of time.

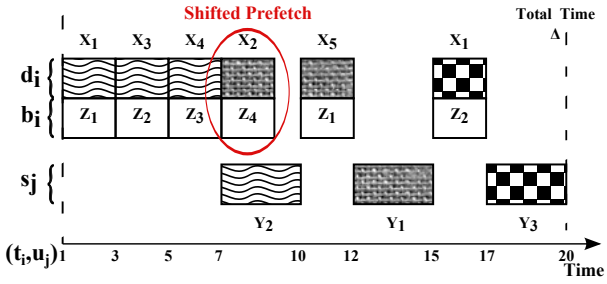

Fig. 11. SPbP Schedules

VI. Experiments and Results

In order to illustrate the practicability and efficiency of both KAP and SPbP algorithms, and the heuristic H_1, we use a set of 5 benchmarks from real-life non-linear image processing kernels already used by Mancini and al. [1].

A. Data Sets

Table II shows the characteristics of the test instances, together with the values for X (number of input tiles) and Y (number of output tiles to be computed).

As summarized in Table II, the benchmarks are variations of four kernels (fisheye, polar, fd resize, and fd haar) for which the input data structure (multi-resolution (an)isotropic mipmap input data) is modified. In fact, the first three kernels represent geometric non-linear transformations [11], [12]. The fourth kernel creates a pyramidal multi-resolution image [13]. The last one represents a kernel of a face detection application based on haar features [13]. The number of the input image

tiles varies between 350 and 7000 input tiles, and the number of the output tiles varies between 150 and 1200 tiles.

TABLE II
PARAMETERS VALUES OF DATA SETS

N°	**Kernel**	**Input data type**	X	Y
1	Fisheye	mipmap isotropic	352	158
2	Fisheye	mipmap anisotropic	704	158
3	Polar	mipmap anisotropic	4225	112
4	Fd Resize	mipmap isotropic	1280	1186
5	Fd Haar	pyramidal integral image	7040	428

Table III shows for each kernel the values of different lower bounds ($lb_Z, lb_N, lb_1, lb_2, lb_\Delta$), which are developed in Section IV-A. These lower bounds allow us to evaluate the performances of both proposed approaches KAP and SPbP.

TABLE III
LOWER BOUNDS FOR N, Z, AND Δ

Kernel N°	lb_Z	lb_N	lb_1	lb_2	lb_Δ
1	13	224	452	477	477
2	21	360	724	477	724
3	20	244	492	339	492
4	13	429	862	3561	3561
5	96	2272	4548	1287	4548

B. Numerical Results

This section presents an experimental analysis of the performance of both KAP and SPbP algorithms, respectively the heuristic H_1. The algorithms just described were coded in Python, except the ATSP part which was re-encoded as a TSP, and run through Concorde's Chained Lin-Kernighan implementation [14]. Tests were run on a computer powered by an Intel Core i5 processor with 4 GB of RAM. All our tests were carried out for the case where $\alpha = 2$ and $\beta = 3$ time units.

Table IV summarizes the numerical results for both KAP and SPbP algorithms, where the number of buffers is fixed to Z_1, respectively to Z_2, and those of the algorithms M_1, and M_2 on different data sets described in Table II. For the 5 kernels (given in line 1), the running time of both KAP and SPbP algorithms is in the order of a few minutes. The third line gives the number of prefetches N, the number of buffers Z, and the completion time Δ for the algorithms M_1, and M_2 (line 2). For both cases Z_1, and Z_2 (line 3), the N and Δ achieved by the KAP algorithm are then given in line 5. The sixth line (Gain 1) shows the gains as measured relatively to the lower bounds (lb_N and lb_Δ) of KAP algorithm, for both N and Δ relatively to those achieved by algorithms M_1, and M_2. Similarly, both N and Δ achieved by the SPbP algorithm are then given in line 7. The eighth line (Gain 2) shows the gains relative to the lower bounds (lb_N and lb_Δ) of SPbP algorithm, for both N and Δ relatively to those achieved by algorithms M_1, and M_2. The three last lines give for each of the algorithms M_1, M_2, KAP, and SPbP, the ratio of the achieved completion time Δ to the lower bound lb_Δ (given in Table III). The column Average provides the average gains (%) for all the kernels in the case of Z_1, respectively, of Z_2.

As illustrated in Table IV, the fixed Z_1 is larger than its lb_Z, for which the algorithm M_1 reaches the maximum number of buffers and the completion time is minimized. Whereas, Z_2 gives the minimum number of buffers (Z_2 equals its lower bound lb_Z).

By running the KAP algorithm, the traffic to the external memory is reduced with an average reduction of 57.5% (Z_1), respectively, of 36.8% (Z_2). In contrast, the completion time is increased, with an average increase of 14.9% (Z_1), respectively, of 22%(Z_2). This is due to the absence of overlap between the prefetches and computations in the schedules produced by the KAP algorithm.

In addition, due to the reuse of the KAP algorithm as a subroutine of the SPbP algorithm, the traffic to the external memory is reduced with the same average reduction of 57.5% (Z_1), respectively, of 36.8% (Z_2). In contrast to KAP, minimizing Δ by SPbP leads to a 37.1% (Z_1), respectively, to a 25% (Z_2) decrease in average of the completion time.

In the same way, a comparison between the completion time Δ achieved by each of the algorithms M_1, M_2, KAP, and SPbP and the lower bound lb_Δ, is considered. A comparison against the lower bound provides a measure of deviation from optimality. It is used as a performance indicator, and calculated by taking the ratio of Δ to lb_Δ. As shown in Table IV, for both cases Z_1, and Z_2, the completion time Δ of SPbP algorithm is in average more closer to the value of lb_Δ than the different values given by each of the algorithms M_1, M_2, and KAP. It is at most twice the value of lb_Δ. This is explained by inserting "Fake Computation" sometimes to stop processing or prefetching in order to optimize the use of resources. This means also that the SPbP algorithm gives a better completion time Δ than the other methods.

In summary, these numerical experiments show that the schedules produced by both KAP and SPbP algorithms, for a given number of buffers Z, have the optimal number of prefetches N. In contrast to KAP, SPbP gives the best completion time Δ. Hence, these results are numerical evidence validating the efficiency of our proposed approaches as compared to the one currently in use in the MMOpt tool.

In the same way, Table V shows the completion time Δ of the heuristic method H_1 for all the non-linear kernels given in Table II. Thus, a comparison between the completion time Δ obtained by method H_1 and the lower bound lb_Δ, is considered. It is calculated by taking the ratio of Δ to lb_Δ.

TABLE V
COMPARISON BETWEEN Δ OF H_1 AND lb_Δ

Kernel N°	**1**	**2**	**3**	**4**	**5**
Δ (H_1)	547	736	551	3658	4551
Δ (H_1) / lb_Δ	1.14	1.01	1.11	1.02	1.00

As shown in Table V, the completion time Δ of H_1 is

TABLE IV
NUMERICAL RESULTS OF M_1, M_2, KAP, AND SPBP

Kernel N°		**1**		**2**		**3**		**4**		**5**		**Average (Z1) %**	**Average (Z2) %**
		M_1	M_2	M_1	M_2	M_1	M_2	M_1	M_2	M_1	M_2		
MMOpt	Z	20	13	29	21	28	20	18	13	139	96

	Δ	26.0	21.0	36.9	31.5	32.1	22.7	29.4	13.5	61.1	36.3	37.1	25.0
Δ (MMOpt) / lb_Δ		1.90	2.04	1.85	2.01	2.07	2.19	1.42	1.44	1.73	1.77	1.79	1.89
Δ (KAP) / lb_Δ		2.24	2.34	1.91	2.08	2.11	2.33	1.72	1.81	1.40	1.60	1.87	2.03
Δ (SPbP) / lb_Δ		1.66	1.82	1.53	1.69	1.72	1.92	1.29	1.38	1.28	1.49	1.49	1.66

very closer to the value of lb_Δ. This means that the lb_Δ is a good lower bound on the completion time Δ for the 3-PSDPP problem.

VII. CONCLUSION AND FUTURE WORK

In this paper, we addressed the multi-objective optimization problem 3-PSDPP, that arises in the context of optimizing the memory hierarchy of non-linear kernels in order to enhance some electronic stakes (energy consumption, real time, and cost) in the MMOpt tool. We described some of its mono- and bi-objective variants, proved some lower bounds, and analyzed the complexity of some of them. We then presented a constructive heuristic to solve the 3-PSDPP problem, the KAP algorithm to solve the PSP sub-problem, and the SPbP algorithm to solve the 2-PSDPP sub-problem. The results on the same real-world data set as used by Mancini and al. [1] show a very significant improvement and reduce the amount of transferred data up to 30% and a reduction of the computing time up to 15%.

An interesting area for further research may be the improvement of the proposed methods, and the development of other approaches based on constructive heuristics and exact methods that would provide good solutions for other 3-PSDPP sub-problems. It would also seem interesting to use exact methods such as ILP for solving the NP-Hard variant of the PSP sub-problem. Additional research is also required to determine the complexity of the mono-objective sub-problem MCT-PSDPP, in which the completion time Δ is to be minimized.

***Abstract*— Context: Heuristic optimization has been of strong focus in the recent modeling of the Resource Constrained Project Scheduling Problem (RCPSP), but lack of evidence exists in systematic assessments. New solution methods arise from random evaluation of existing studies. Objective: The current work conducts a secondary study, aiming to systemize existing primary studies in heuristic optimization techniques applied to solving classes of RCPSPs. Method: The systemizing framework consists of performing a systematic mapping study (SM), following a 3-steped protocol. Results: 371 primary studies have been depicted from the multi-stage search and filtering process, to which inclusion and exclusion criteria have been applied. Results have been visually mapped in several distributions. Conclusions: Specific RCPSP classes have been grounded and therefore a rigorous classification is required before performing a systematic mapping. Focusing on recent developments of the RCPSP (2010-2015, a strong interest has been acknowledged on solution methods incorporating AI techniques in meta- and hyper-heuristic algorithms.**

I. Introduction

DEALING with resource allocation in a constrained project scheduling space has risen to a solid multidisciplinary topic under the (project) scheduling theory, addressed since late 60s, as the Resource(-)Constrained Project Scheduling Problem (RCPSP). Empirically, the goal of the RCPSP is to determine a time and resource-feasible schedule, with given precedence or resource constraints, following an objective function. A comprehensive characterization of the RCPSP positioning in the research literature has been given by Mohring et. al (2003), where RCPSP ‘‘one of the most intractable problems in Operations Research’’, has become ‘‘a popular playground for the latest optimization techniques, including virtually all local search paradigms’’.

A. Problem context and motivation

According to the (computational) complexity theory, the RCPSP has been widely characterized as belonging to the class of NP-hard (in the strong sense) problems, with NP-complete (in the strong sense) decision version, therefore combinatorial optimization techniques do apply. Several dimensions, namely research themes, fundament a typology construction for the Project Scheduling Problem (PSP)/ RCPSP space, mainly consisting of: project type, problem approaches, solution methods. Two main implications, can be therefore considered:

1) Proposing new solution methods require a solid mapping of recent and past advancements in solution techniques with an extensive literature search on multiple RCPSP dimensions. In such a context, a literature review process carried out to propose a new solution, involves a cross-domain scanning of a large amount of existing evidence in connected fields (Operations Research, Artificial Intelligence, Applied Mathematics), where computational comparison and benchmarking is of use in performance assessment.

2) Proposing new RCPSP solution methods follows trends of converging research areas, lacking in a systematic assessment in the RCPSP problem space to identify trends and gaps. Current solution methods move forward with connected fields, and include Intelligent Systems and AI techniques, without a stand-alone specific process to identify gaps, based on existing trends. Even though RCPSP research themes have been identified and fully characterized, current secondary studies in RCPSP have the form of reviews, surveys, classifications, and are to be included in the primary studies’ class, as they do not follow a rigorous systemic approach in synthesizing literature review, but provide more of narrative descriptions.

B. Proposed approach and outline

The current work applies the principles of systematic mapping studies (SM) to the RCPSP, with the aim of tracking existing solution methods and identifying trends and gaps based on several studies’ distributions with a focus stands in classic heuristic algorithms and its extended classes (meta-heuristics, hyper heuristics). Section 2 provides an overview of existing guidelines for the systematic mapping and implications in Operations Research and Scheduling. Section 3 describes the research protocol applied and the studies’ frequency resulted in each stage. Section 4 provides an analysis of several studies’ mappings according to time-based and problem space-based distributions. Suggestions for further improvement are described in Section 5.

II. BACKGROUND AND EVIDENCE

A. Systematic mapping and implications in scheduling

Although large-scale reviews are conducted under the Systematic Literature Review (SLR) umbrella, most of the large-scale SLRs in Software Engineering (SE) and IT are conducted using the Systematic Mapping guidelines [1]. Derived from Kitchenham's guidelines [2], Petersen and Budgen [1], have proposed an extension of guidelines for constructing systematic maps in software engineering. Additionaly, a more detailed presentation of the included studies in Kitchenham's [3] tertiary review, has been offered with respect to the SLRs characteristics. Of relevance, is the comparison between the number of potentially relevant studies and the effective number of relevant studies included in each aformentioned SLRs. According to Petersen [4], Dyba et al. performed a SLR based on 5453 potentially relevant studies, from which 78 have been extracted. The same number of primary studies was used by Hannay et al., Kampenes et al. and Sjøberg et al. with a result of 24, 78 and 103 finally selected studies. MacDonell & Shepperd used the least number of potentially studies (185), to a achieve a relevant set of 10 studies. Most of the aforementioned SLRs have included between 1-5% of the primary studies (Dyba et al. – 1.43%, Grimstad et al. – 2.49%, Hannay et al. – 0.44%, Kampenes et al. – 1.43%, Kitchenham et al. – 0.74%, Sjøberg et al. – 1.88%, MacDonell & Shepperd – 5.45%, Davis et al.- 4.6%), with an exception of Mendes (49%). Correlated to Kitchenham's [3] contribution in aggregating SLRs under a tertiary study, Bugen [5] has applied Kitchenham's guidelines [2] to SMs, and conducted informal tertiary studies.

Latest SM literature, focuses on refining guidelines and protocols, as well as providing improvement strategies. While emphasizing the benefits of using SM in educational environments, as means of building students' transferable research skills, 3 challenges are positively assessed by Kitchenham [6]: 1) no matter the level of studies (post-, undergraduate), students have the required skills of conducting SMs 2) SMs are valuable means of organizing evidence of current state of literature 3) SMs can be treated as solid projects as preparation for research careers. Several further directions, referred as improvements [7], still need to be covered in the future: search and selection process improvement; quality assessment grounding, studies aggregation process improvement. Based on these improvement statements, Petersen [8] offers a valuable update to the existing SM framework applied to software engineering, by mapping evidence regarding 4 research questions: frequency of publications in the SE field, covered topics, revenues of publications, and review process. A need of conducting SMs on existing or extracted topic-specific classifications has been pointed out, observing that the majority of SM studies deliver new classification schemes themselves, rather than building on existing ones.

In terms of extending its field applicability [8], the SM process can be alternatively used as means of evidence gathering in operational fields, for growing disciplines with multiple facets. Applicability of systematic studies to operational fields has been recently acknowledged in the manufacturing [9] and industrial software processes [10]. With respect to the scheduling field, a SLR has been conducted for staffing and scheduling problems in software projects, where 52 papers have been extracted and analyzed with the purpose of identifying main issues in adopting resource scheduling features in industry. Specific to software scheduling, a SLR has been performed [11] addressing uncertainty assessment in software projects, where 165 studies have been analyzed in 5 distributions.

B. Comparative studies in heuristic optimization for solving the RCPSP problem

The Project Scheduling field, specifically the RCPSP, can therefore be introduced as a successful candidate for extending MSs to new fields. In the fields of complexity, discrete and combinatorial mathematics [19], [20], the RCPSP's main characterization is the generalization of the job-shop scheduling problem [21], although the job shop scheduling problem is sometimes treated as a "special case" of the RCPSP [22]. Basically, the optimization problem is to define a start time for each project activity, based on precedence and resource constraints, while following a uni or multi-obective (project makespan minimization, time/cost/resource trade-offs etc).

Large amount of effort has been put during the past decade in building RCPSP classification schemes. Two main dimensions have been extensively tackled: general problem description [12][13] and solution methods[14]–[16], while [17] extends the attributes of the classification scheme to: type of constraints, type of precedence relations, type of resources, source, type of activity splitting, number of execution modes, number of objectives, type of objective function, level of information, distribution of information.

Heuristic methods have been considered as state-of-art solution techniques and a comprehensive description with computational analysis has been presented since late '90 [14]. Based on the Artificial Intelligent and Mathematic Optimization advancements, in the field of Computer Science (CS), classic heuristics applied to RCPSP (exact methods) have evolved into modern heuristics: meta-heuristics (MH) (including evolutionary MH, memetic algorithms, nature-inspired MH), hyper-heuristics, simheuristics and hybrid-heuristics. An attempt of mapping the solution space of the RCPSP, in terms of solution methods, has been presented by [18], where 174 studies (1971-2012) have been classified based on a defined taxonomy. No systematic assessment has been carried, though. Increased interest in the use of meta-heurisitics (both derived and applied or just applied) has been shown during the past 5 years: a computational comparison based on the PSPLIB J30, J60 and J120 problem sets has been presented by [19], [20]. MHs applied to the multi-mode, multi-skill and multi-objective RCPSP have been compared by [21]–[24]. Analysis and comparison of combined meta-heuristics (hybrid-MH) applied to the RCPSP and dynamic RCPSP has been summarized in [21]–[26].

III. Research Methodology

To assess the heuristic techniques applied to solving scheduling problems, with focus on the RCPSP formulations and recent developments, a systematic mapping has been conducted following guidelines of Kitchenham [27] as well as updates provided in [28], [4], [8].

A. Review question

On the basis of systemizing evidence regarding heuristic optimization applied to the RCPSP, the following research question has been considered:

RQ: Which is the evolution of the heuristic algorithms used as solution methods for the RCPSP and to which RCPSPs have they been applied?

B. Search strategy

The search strategy represents a combination between a set of search strings and databases on which to be applied. 4 databases have been selected: IEEE Xplore (http://ieeexplore.ieee.org/Xplore), Elsevier Science Direct (http://www.sciencedirect.com), SpringerLink (http://link.springer.com/), SCOPUS (http://www.scopus.com/) (Table 1). As the RQ of the current study addresses solution methods in forms of techniques and algorithms, IEEE Xplore has been considered relevant. On the other hand, the RCPSP is an OR specific problem, therefore, 2 multidisciplinary databases have been chosen: Springer Link, Science Direct.

TABLE I.
RATIONALE FOR DATABASE CHOICE

Database	Rationale and limitations
IEEE Xplore	multi-format export (includes .csv, .bibtex key), all metadata export (includes abstract); number of entries/export limited at 100
Science Direct	multi-format export (no .csv export, includes .bibtex key), metadata does not include abstract); number of entries/export limited at 100
Springer Link	multi-format export (includes .csv, .bibtex key), metadata does not include abstract); number of entries/export limited at 100
SCOPUS	aggregates literature from multiple databases; multi-format export (includes .csv, .bibtex key), metadata does includes abstract); number of entries/export limited at 100

Six search strings have been constructed based on the PICO strategy [8] (Population, Intervention, Comparison and Outcomes) and submitted for inquiry to each database: S1: project scheduling *heuristic*; S2:"project scheduling" *heuristic*; S3: resource constrained project scheduling *heuristic*; S4: resource-constrained project scheduling *heuristic*; S5: "resource constrained project scheduling" *heuristic*; S6: RCPSP* *heuristic*. The string generation strategy follows the principle of the selection process, where, firstly, a list of the literature-proposed heuristic algorithms was extracted, followed by a list of possible applicable algorithms and a mapping of solution methods on RCPS problem types. No manual search or snowballing has been performed. Special characters have been used to compress search strings, where applicable.

C. Study selection and frequency distribution

The process of study selection as been divided in 5 major steps.

The first phase focuses on preliminary study selection and assessment (Fig.1). Constructed search strings have been applied on the 4 databases individually, as an evidence of the studies frequency, in each case, was of interest. For each search string a list of studies has been exported automatically from each database, using built-in exporting options. Lists have been aggregated for each database (IN1) and duplicates have been removed automatically (IN2). Filtering based on title keywords has been applied ("project" AND "schedul"; RCPS), following a word-form derivation (i.e. "schedul": "scheduling", "schedule (s)", to extract studies relevant for the project scheduling area (IN3A), specific, RCPSP (IN3B). Results have been merged and duplicates removed (IN4). Studies referring to other scheduling scenarios (i.e. machine scheduling, network scheduling, etc.) have been excluded, being of no interest for the current work. A second filtering based on title keywords extracted studies that only address solution techniques. General keywords have been considered (i.e. "heuristic" or "algorithm") (IN5A). Solution-specific algorithms (i.e. metaheuristics optimization algorithm: Tabu Search, Simulated Annealing, Ant Colony Optimization etc.) do not contain any intuitive common keywords, therefore a specific filtering has been applied based on metaheuristic optimization taxonomies [29]–[32](IN5B).

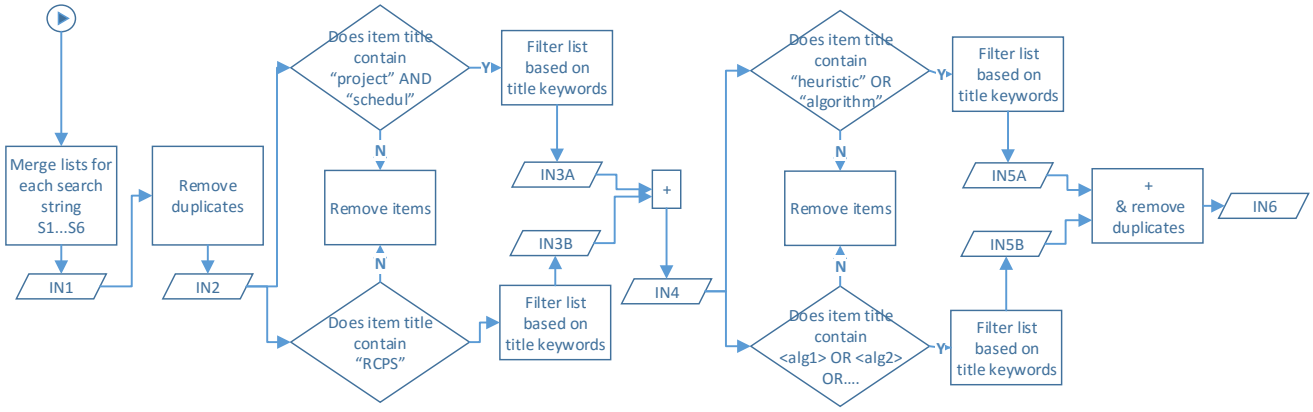

Fig. 1 MS preliminary study selection and assessment workflow

Based on the given references, Table II includes the criteria based on which filtering has been performed to identify specific modern heuristics.

TABLE II.
STUDIED FREQUENCY IN PRELIMINARY SELECTION AND ASSESSMENT

General solution method	Algorithm-specific keywords
General solution method	"heuristic" OR "algorithm"
PS/RCPS Modern Heuristic	"local search" OR "grasp" OR "variable neighbourhood" OR "guided local" OR "iterated local" OR "basic local" OR "simulated annealing" OR "hill climbing" OR "tabu search" OR "random optimization" OR "evolution" OR "genetic" OR "memetic" OR "swarm" OR "stochastic scatter" OR "ant colony" OR "particle" OR "bee colony" OR immune" OR "neural" OR "hybrid"
Modern heuristics	"electromagnetism" OR "frog" OR "multi-pass" OR "filter and fan"

Resulted lists from each database for all search strings (S1, S2…S6) have been merged in a single list and duplicates have been automatically removed (IN6). Studies distribution for each step are presented in Table III.

TABLE III.
STUDIED FREQUENCY IN PRELIMINARY SELECTION AND ASSESSMENT

Database	IN1	IN2	IN3	IN4	IN5	IN6
IEEE Xplore	817	289	127	133	63	51
Science Direct	7633	4768	330	342	102	70
Springer Link	11129	6679	343	373	94	77
SCOPUS	3864	1239	624	659	324	185

Relevancy-based study selection and assessment has been conducted in the second phase (Fig.2). Resulted lists from each database have been merged and duplicates have been removed automatically based on title. A casual manual check has been undertaken to remove duplicates. Filtering based on title keywords has been applied, to extract studies that addressed resource-oriented project scheduling (i.e. "resource"; RCPSP). Both keywords have been separately applied as the studies frequency in each case was of interest. Another relevancy-based criterion tested the relevancy of the solution method. Studies referencing the "algorithm" keyword in their titles have been manually checked for relevancy to the current work. All the 188 entries, have been though found relevant, therefore included in the further process. A total number of 359 entries have been obtained and submitted as input for the next phase

Language and content type exclusion (EC) and inclusion criteria (IC) have been applied in the 3rd step. The language criterion has been considered eliminatory. From entries that had language specified in metadata, studies in other languages than English, such as Spanish, Chinese have been excluded, (EC). From the resulted entries, only English studies were extracted (IC). In case of filled in language attribute, that did not respect the EC, the language EC was updated and entries re-checked to pass the IC. Entries with blank language field, have been checked manually based on the publication language. The language field has been updated for all the remained items. All studies with updated language field have been English-written, therefore successfully passed EC/IC check and included in the final list. A list of 339 studies have been obtained by applying the language EC/IC.

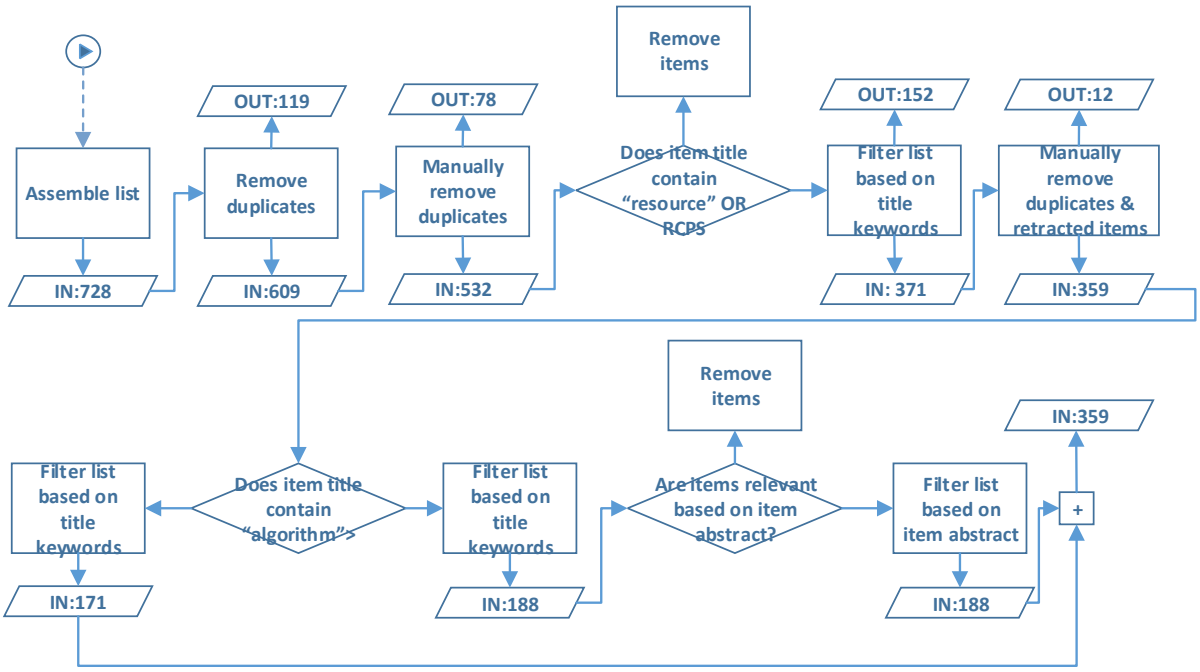

Fig. 2 MS relevancy study selection and assessment workflow

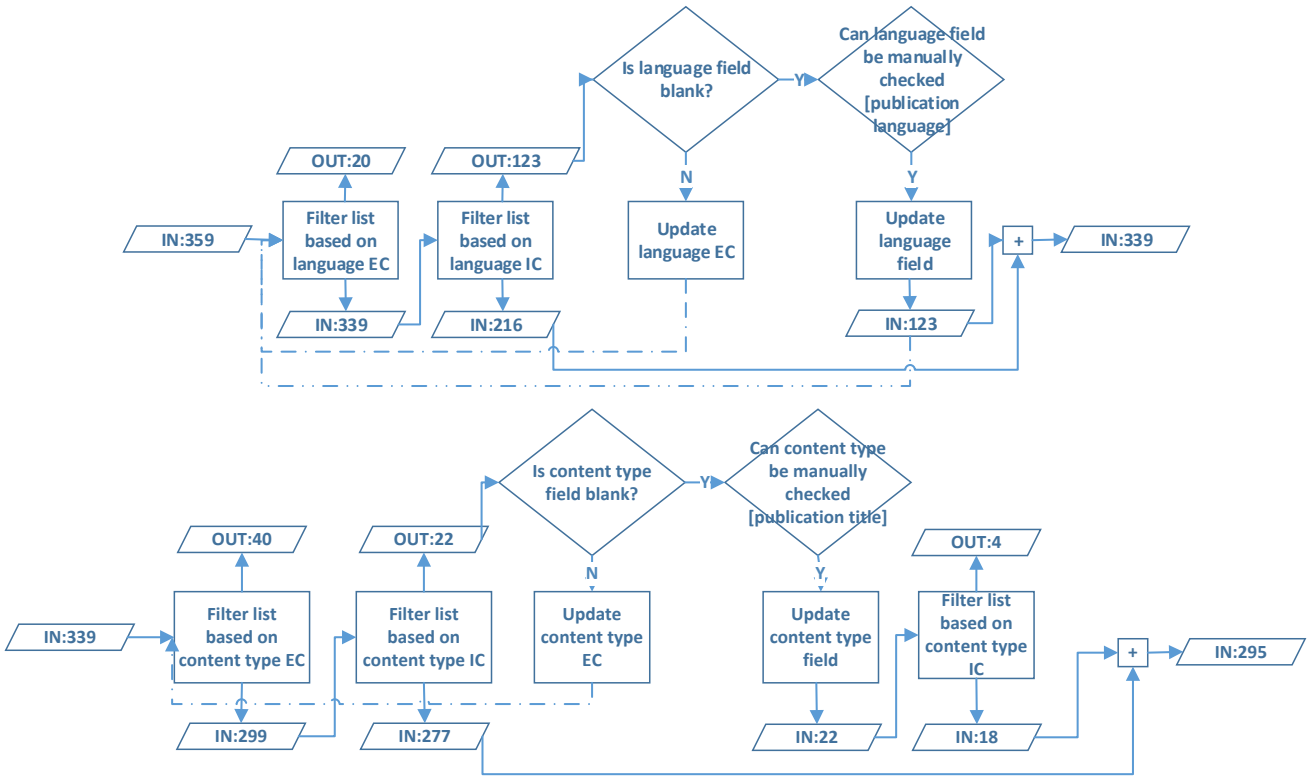

Fig. 3 MS relevancy study selection and assessment based on a) language IC/EC b) content type IC/EC

The next phase, consisted of applying a content type-based language EC/IC, in a similar way to the language-based EC/IC. Studies that have been categorized as technical papers or reports, reviews, workshop papers or book chapters have been excluded (EC). Papers published in peer-reviews publications (journals) or conference proceedings have been included (IC). Papers not categorized have been submitted for manual checking based on the "Publication title" attribute. 22 studies had the content type updated. Based on the IC criteria, 18 studies have been selected and 4 removed. A total number of 295 have been therefore obtained. Both phases of EC/IC (language and content type) are illustrated in Fig.3.

A manual refinement has been undertaken as a last step of the selection process, based on abstracts' screening. 4 studies had the full content published in Chinese and have been excluded based on language (4 studies). Studies that were proposing new solution approaches were of interest, therefore, (computational or experimental) evaluation or comparison papers, as well as classification papers, have been excluded (15 studies). Where in doubt, full text has been screened. Generalized studies that have not addressed a particular RCPS problem or solution method (i.e. generalized algorithms not addressing any heuristic/meta-heuristic solution method), as well as studies that could not be positioned in a classification scheme (either irrelevant or not accessible) have also been excluded (10 studies). A final list of 252 studies has been furtherly considered for mapping and analysis.

IV. Studies Analysis and Mapping

To answer the proposed research question (RQ), several types of mappings have been extracted: studies identification on RCPS problem types and solution algorithms classes, frequency of publications for classes of RCPSP solution methods and algorithms, as well as algorithm mapping on the specific RCPS problem types. Statistics have been extracted based on title, abstract or brief content screening (when required), without a full evaluation, as in case of SLRs [4].

In terms of visual representations, several assumptions have been made in the SM/SLR literature. With respect to SLRs, Kitchenham [27] emphasizes on the use of forest plots as being the most common mechanism for presenting quantitative results, while vulnerability to publication bias is likely to be assessed by using funnel plots. On the other hand, Petersen [8], in the study of SM guidelines updating, identifies 6 approaches to visualize SM mappings. Based on the analysis, bar plots and bubble plots proved to be the most common representations, while heatmaps, although rare, were considered interesting ways to directly visualize the relative amount of publications in different categories [8]. Based on the above observations, the current study proposes bar charts and bubble plots as visual representations. Three categories of mapping have been considered relevant to identify the evolution of heuristic optimization applied to the RCPSP: a) distribution of heuristic classes on years b) distribution of heuristic algorithms on years c) heuristic algorithms solving classes of RCPSP problems

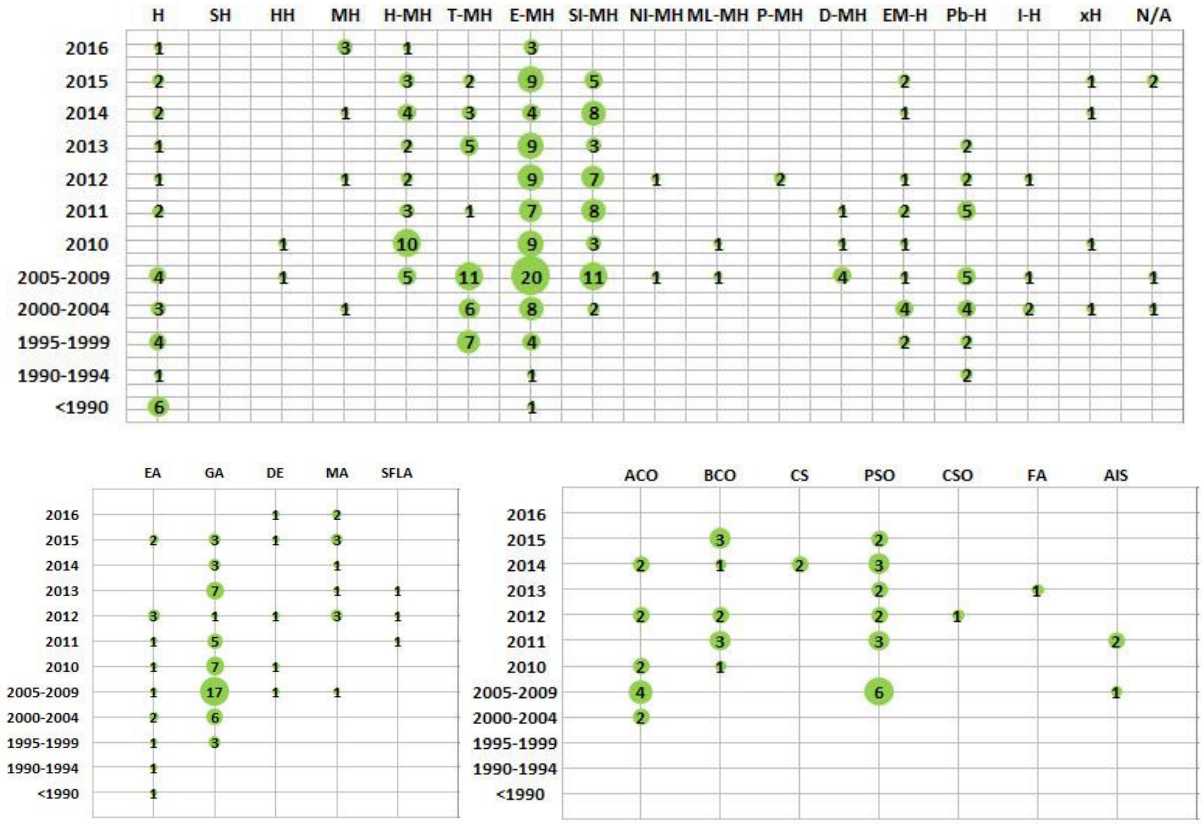

Fig. 4 Distribution of a) classes of heuristic algorithms on years b) Evolutionary methods on years c) Swarm Intelligence algorithms on years

Several year-based scales have been considered to be relevant for the studies mapping: unique discrete year values have been considered for the 2010 – 2016 (first decade) interval; 4 intervals have been considered between 1990 – 2009; one category for studies published before 1990. Acronyms have been used for RCPS problems definition or heuristic optimization classes and algorithms, following existing taxonomies. A bubble chart representation has been preferred, according to updated guidelines [8], where bubble plots are recommended ways of representing frequency distributions [4]. Bubbles have been positioned in the intersection of two x-y scatter plots. The size of the bubble indicates the number of studies for the given intersection point.

The first mapping, answers the given RQ by presenting a time-distribution of classes of heuristic optimization algorithms (Fig.4). The mapping process was conducted based on title, and when in doubt, the abstract was scanned. Studies addressing more than one solution method have been mapped to multiple categories. Several classes of algorithms have been identified: 2 classes referencing more generalized studies (H: general heuristics, MH: general metaheuristics); 2 classes of algorithms addressing extended heurisitics (SH: simheuristics, HH: hyper-heuristics); xH: other heuristics; N/A: not assigned heuristics. All the other classes (H-MH: hybrid MH; T-MH:trajectory-based MH; E-MH:evolutionary MH; SI-MH:swarm intelligence-based MH; NI-MH:nature-inspired MH excluding SI-MH; ML-MH: machine learning-inspired MH; P-MH: probability-based MH; D-MH: deterministic MH; EM-H: exact methods H; Pb-H: priority-based H; I-H: improvement H). Studies have been included in a separate category, when more than one algorithm was addressed as “improvement” of one class, and properties of H-MH; HH, MA (memetic algorithms) were applied (screening of abstracts). 252 studies have been extended to 288, some entries presenting more than one algorithm.

2 metaheuristic categories proved to be dominant: E-MH (29.1%) and SI-MH (16.3%), followed by the class of T-MH (11.4%) and H-MH (10.4%). In both cases, an increased interested is shown during 2013-2016: E-MH (25 studies), SI-MH (16 studies) compared to the period of 2005-2009, referenced in the literature: E-MH (20 studies), SI-MH (16 studies). From the state-of-the art heuristics, as advertised, Pb-H are the most popular algorithms, including: scheduling schemes and priority rules (7.6%).

Both E-MH and SI-MH classes have been decomposed on specific optimization algorithms (Fig.4.b and Fig.4.c). Studies belonging to the E-MH classes included solution methods such as: EA (evolutionary algorithms and strategies), GA (genetic algorithms), DE (differential evolution); MA (memetic algorithms), SFLA (shuffled frog leaping algorithm). Studies categorized as belonging to the class of SI-MH, addressed algorithms such as: ACO (ant colony optimization), BCO (bee colony optimization); CS (cuckoo search), CSO (cat swarm optimization), FA (firefly algorithm), AIS (artificial immune system).

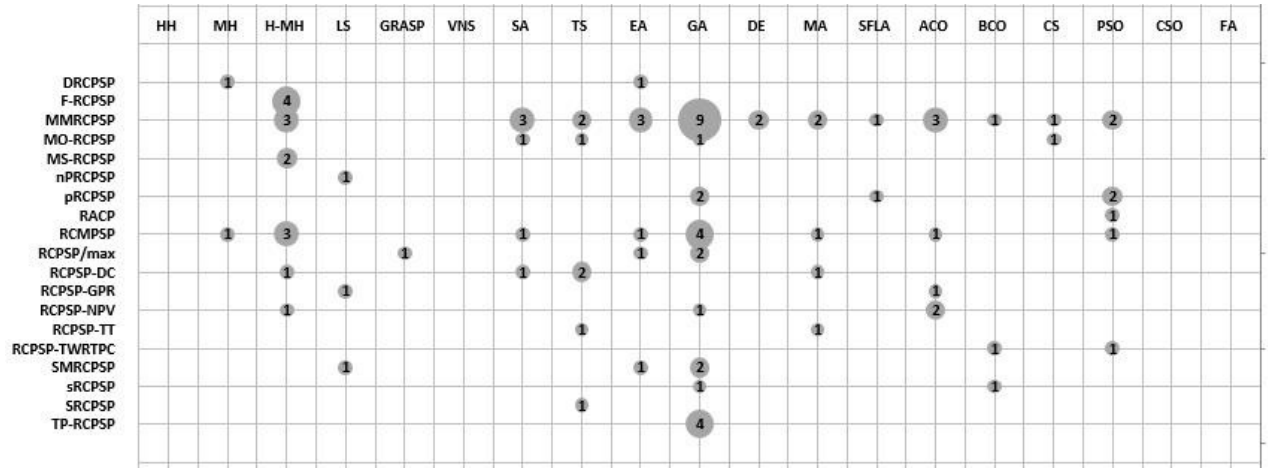

Fig. 5 Mapping of modern heuristic algorithms on RCPS classes of problems

According to the year-based distributions, preferred algorithms are GA (52 studies) and PSO (18 studies), followed by EA (13 studies) and ACO (12 studies). Fewer attempts for developing RCPSP solutions included: derivations of CSO, CS, FA. Compared to other classes of algorithms, the SI-MH appear to be a recent class of solving algorithms, having a debut in the 2000-2004 period. Several independent studies present directions for future interest: a) despite the specific identified algorithms, 2 studies have been depicted addressing solving approaches based on learning strategies b) 1 agent-based solution method.

According to the RCPSP solution space, a solution framework consists of both solution method and the problem definition addressed. Fig.4. maps the distribution of general modern metaheuristics (HH, MH, H-MH), the specific algorithms belonging to the E-MH, SI-MH classes, as well as T-MH class (LS: local search, GRASP: greedy randomized adaptive search, VNS: variable search neighborhood, SA: simulated annealing, TS: tabu search) on RCPS problems. 19 specific problem classes have been identified in the extracted list of entries, based on existing classification schemes [17]. Additionally, 91 studies addressed a general class of the RCPSP, while 62 studies did not address the specific RCPSP. 4 classes of algorithms, where found of not addressing any RCPS problem (xH, HH, Ni-MH, xH). The frequency distribution presents the MMRCPSP (multi-mode RCPSP) (14.2%) and the RCMPS (mult-project RCPSP) (6.2%) as the most addressed problems. Solution methods for the MMRSPSP are popular within E-MH (17 studies) and SI-MH (7 studies). In terms of general heuristic optimization classes, H-MH (14 studies) algorithms prove an increased popularity in addressing specific RCPS problems (F-RCPSP, MMRCPSP, MS-RCPSP), comparable to the T-MH class.

V. Conclusions

While current studies that seek to provide a representation for the RCPS problem space are more oriented on taxonomy construction, the current work adopts the structured process of SM studies to provide an overview and decomposition on the evolution of solution methods and their applicability to specific RCPS problems. Several contributions are to be claimed: 1) providing a framework under which the SMs can be extended to other fields, specifically validation of SM applicability to the RCPSP 2) validation of the solution methods and problems classification based on an extensive database of studies 3) trend identification and decomposition based on existing solution evolution. To reduce bias in assessment we recommend a further evaluation of quality metrics, an optional step in conducting SMs (opposite to SLRs, where quality assessment is mandatory to validate study selection and filtering). A second proposed improvement addresses construction of initial search strings based on words synonymy or derived attributes (i.e. “strategies”, “methods” when referring to “algorithms”). For a complete validation and for the purpose of transforming a SM in a work of reference for the RCPSP, computational comparison is required to evaluate algorithms performance, based on specific setups. Several existing RCPSP libraries (PSPLIB, Peterson set) provide project descriptions (number of activities, types of activities and resources) on which proposed algorithms are tested for computational parameters (average/min/std. deviation, computational time etc), in different scenarios (number of iterations). Therefore, the current study provides the input for a further SLR, being a successful candidate for a meta-analysis, that would provide a more solid background in algorithmic benchmarking.

***Abstract*—We study the problem of minimizing total completion time in 2-stage flowshop with availability constraint. This problem is NP-hard in the strong sense even if both machines are always available. With availability constraint, although a bulk of research papers have studied the makespan minimization problem, there is no research done on the total completion time minimization. This paper is the first attempt to tackle this problem. We focus on the case that there is a single unavailable interval on the first machine only. We show that several special cases can be solved optimally or approximated within a constant factor. For the general case, we develop some lower bounds and dominance rules. Then we design and implement a branch and bound algorithm. We investigate the effectiveness of different lower bounds and the dominance rules by computational experiments. We also study how the start time and the duration of the unavailable interval affects the efficiency of the branch and bound algorithm.**

I. Introduction

SCHEDULING with machine availability constraint has attracted more and more research effort since early nineties. Machine availability constraint is prevalent in all real industrial settings. A machine may be unavailable due to breakdown, preventive maintenance, or processing unfinished jobs from a previous scheduling horizon. With the machine availability constraint, many classical problems have to be reconsidered. While some of the problems can still be easily solved, many of them become more complicated and new optimal algorithms/heuristics need to be designed. Many papers have been devoted to various scheduling problems with machine availability constraint, see the survey papers by Lee, Lei and Pinedo ([18]), Sanlaville and Schmidt ([21]), Schmidt ([22]), Ma, Chu and Zuo ([20]), etc.

For flowshop scheduling with availability constraint, most research is done for two-stage flowshop problems([20]): there are two machines, machine 1 and machine 2. Each machine may have one or more unavailable intervals; There are n jobs, 1, 2, ..., n. Each job j, $1 \leq j \leq n$, has two operations a_j and b_j which have to be processed on machine 1 and on machine 2, respectively. The operation b_j cannot start on machine 2 before a_j finishes on machine 1. We want to find a schedule of the jobs so that some objectives are optimized. The bulk of flow shop research in the last decades has been focused on the minimization of the maximum of the job completion time, i.e. the length or makespan of a schedule. However, Gupta and Dudek [8] pleaded that criteria in which the costs of each job are reflected have a better economic interpretation than the makespan objective has. This paper deals with the minimization of the sum of the job completion times in a two-machine flow shop.

Based on the effect of the availability constraint to the disrupted job's processing, researchers discuss three cases, namely resumable, nonresumable, and semiresumable. Resumable and nonresumable cases are defined by Lee in [16]. In the resumable case, preemption is allowed thus jobs can be resumed after being interrupted by the unavailable interval. In the nonresumable case, a job has to be restarted if interrupted by the interval. Semiresumable case is defined by Lee in [19] and is between the resumable case and nonresumble case. In this case, a job doesn't have to be restarted from scratch, instead, a fraction of the job needs to be reprocessed after the machine is available.

A. Literature Review

Almost all research papers about flow shop scheduling with availability constraint are with respect to makespan criterion ([20]). Lee ([17]) showed that if there is only one unavailable interval, either on the first machine or on the second machine,the problem is NP-hard in the ordinary sense. If there are an arbitrary number of unavailable intervals on the first machine but the second machine is always available, or there there are an arbitrary number of unavailable intervals on the second machine but the first machine is always available, the problem becomes strongly NP-hard ([15]) in either case. Furthermore, for the former case, Johnson's rule gives a 2-approximation regardless of the number of unavailable intervals; On the other hand, for the latter case, there is no polynomial time constant approximation for any constant even if there are only two unavailable intervals on the second machine and the first machine is always available. Many heuristics, meta-heuristics and exact methods are developed for the general problem, see the surveys [18],[21], [22], [20] and the references therein for more details.

For the problem of minimizing the total completion time with availability constraint, we are not aware of any research so far. On the other hand, when both machines are available, the problem has attracted a lot of attention because of its

notorious intractability. A lot of research effort has been focused on finding the exact solution using branch and bound algorithm. In the following, we will review related literature.

The first research on this problem was done by Ignall and Schrage ([13]) in 1965. They gave two lower bounds and developed a branch-and-bound algorithm. For the experiments, they limited the number of jobs to be 10. In 1967, Conway et. al ([3]) showed that it is sufficient to study permutation schedules, i.e. a schedule in which both machines have the same job sequence with no unnecessary idle time between operations. By using local search and other heuristics to generate a good initial upper bound for the branch and bound algorithm, Kohler and Steiglitz ([14]) further improved the algorithm by Ignall and Schrage. They did the experiments on instances of size 10 to 50 jobs. For most instances of more than 15 jobs, only suboptimal solutions is obtained within preset time limit. In 1976, this problem was shown to be NP-Hard in the strong sense by Gary, John and Sethi([6]).

Since 1990s, the problem was studied again by a group of research papers, including [23], [10], [5], [4], [1], [12]. These papers try to improve the lower bounds by using Lagrangian relaxation ([23], [10]) or networking formulation ([1]), and/or propose some dominance rules ([5],[4]), consequently improve the performance of the branch-and-bound procedure and solve bigger problems. Della Croce et al.'s ([4]) branch-and-bound algorithm can solve up to 45 (30) job problems when processing times are uniformly distributed in the [1,10] ([1,100]) range. In 2004, using a lower bound scheme based on a network formulation, the branch and bound algorithm by Akkan and Karabati ([1]) can solve problems with up to 60 (45) jobs, where processing times are uniformly distributed in the [1,10] ([1,100]) range. At about the same time, Hoogeveen et al. ([12]) also used improved lower bounds by LP to solve instances of 40 jobs within reasonable time.

Very few papers studied the constant approximation algorithms or solvable cases. The first one is by Gonzales and Sahni ([7]) who showed that SPT (Shortest Processing Time first) rule gives an m-approximation for m stage flowshops. Thus for 2-stage flowshop, SPT is a 2-approximation. Later, Hoogeveen and Kawaguvhi ([9] refined this bound for 2-stage flowshop and they showed that the approximation ratio of SPT is $2\beta/(\alpha+\beta)$, where $\alpha = \min\{a_j, b_j\}$, $\beta = \max\{a_j, b_j\}$. They also studied some special cases. Specifically, they showed that

1) if $a_j = a$ for all jobs j, the problem remains NP-hard in the strong sense and SPT rule gives $4/3$- approximation schedule and the bound is tight.
2) if $b_j = b$ for all jobs j, then SPT rule generates an optimal schedule.
3) if $a_j \geq b_j$ for all jobs j, scheduling the jobs in non-decreasing order of a_j gives an optimal schedule.
4) if $a_j \leq b_j$ for all jobs j, the problem can be solved optimally in $O(n^3)$ time.

B. New Contributions

Our paper is the first attempt to tackle the total completion time minimization problem in the 2-stage flowshop with availability constraint. Given the complexity of the problem, we focus on the case that there is a single unavailable interval on the first machine. We consider the resumable case only. We first show that SPT still provides a 2-approximation if the single unavailable interval starts early so that no a_j can finish before it. We also show that some other special cases can be solved or approximated within a constant factor.

For the general case, we give some lower bounds and dominance rules and develop a branch and bound algorithm. We investigate the effectiveness of different lower bounds and the dominance rules by computational experiments. We also study how the start time and the duration of the unavailable interval affects the efficiency of the branch and bound algorithm.

C. Organization

The paper is organized as follows. We first give some preliminary results in Section II. In Section III, we give a mathematical formulation of the problem and develop five lower bounds of the optimal solution. In Section IV, we develop some dominance rules and a branch and bound algorithm. Then we give analysis of the experimental results. Finally, we conclude in section V.

II. Preliminary results

Let us first introduce some notations. To indicate the machine unavailability constraint, most literature extends the $\alpha \mid \beta \mid \gamma$ notation, by adding two new components. In the α field, h_{ik} represents the problem with k unavailable intervals on the ith machine. So h_{11} and h_{21} represents the problem with one unavailable interval on the first machine and on the second machine respectively. The second component is in the β field, we use $r-a$, $nr-a$ and $sr-a$ to denote resumable, nonresumable and semiresumable availability constraints, respectively. Thus, our problem, minimizing the total completion time with a single unavailable interval on machine 1, can be denoted as $F2, h_{11} \mid r-a \mid \sum C_j$.

Like the classical model, one can show that there is an optimal schedule that is a permutation schedule. So we only consider permutation schedules. Let S be a permutation schedule of the jobs, for job j, we use $C_{a,j}(S)$, $C_{b,j}(S)$ to denote the completion time of the first operation a_j and the second operation b_j in S, respectively. The completion time of job j in S, is denoted by $C_j(S)$ which is equal to $C_{b,j}(S)$. We use $[j]$ to denote the job scheduled in position j on both machines, and use $C_{a,[j]}(S)$ and $C_{b,[j]}(S)$ to represent the completion of $a_{[j]}$ and $b_{[j]}$ in S, respectively. If it is clear from the context, S may be omitted.

We frequently sort the jobs, for convenience, we use SPT_a, SPT_b, SPT to denote the rule that schedules the jobs in non-decreasing order with respect to a_j, b_j, and $(a_j + b_j)$ respectively.

From [7], we know that SPT is a 2-approximation algorithm when both machines are available. When there is a single

unavailable interval, we show in the following that the performance of SPT depends on the start time of the interval.

Lemma 2.1: Let $[s,t]$ be the unavailable interval for $F2,h_{11} \mid r-a \mid \sum C_j$, if $s \geq \sum_{j=1}^{n} a_j$ or $s < \min\{a_j\}$, SPT is a 2-approximation.

Proof: First, if $s \geq \sum_{j=1}^{n} a_j$, then all a_j-s can finish before the unavailable interval, thus the interval has no effect on the jobs at all. By [7], SPT is a 2-approximation.

Now, let us consider the case $s < \min\{a_j\}$. Suppose the jobs are indexed so that $(a_j + b_j) \leq (a_{j+1} + b_{j+1})$ for $1 \leq j \leq n-1$. We denote $P1$ to be the problem of scheduling of n jobs with processing time $(a_j + b_j)$ on a single machine with the unavailable interval $[s,t]$. Then one can easily show that the optimal schedule S_1 for $P1$ is obtained by SPT rule, and the completion time of j-th job will be $C_{[j]}(S_1) = t + \sum_{k=1}^{j}(a_k + b_k)$.

Let S be the schedule generated by SPT rule for $F2,h_{11} \mid r-a \mid \sum C_j$. Apparently, we have

$$C_j(S) \leq C_{[j]}(S_1) = t + \sum_{k=1}^{j}(a_k + b_k).$$

Now, consider the relaxed flowshop problem $P2$ where a_j and b_j can be concurrently executed and the completion time is the time when both a_j and b_j finish. Let S_2 be the optimal schedule for this relaxed flowshop problem. We must have that

$$C_{[j]}(S_2) \geq \tfrac{1}{2}(t + \sum_{k=1}^{j}(a_{[k]} + b_{[k]})) \geq \tfrac{1}{2}(t + \sum_{k=1}^{j}(a_k + b_k)).$$

Let S^* be the optimal schedule for $F2,h_{11} \mid r-a \mid \sum C_j$. Then we have

$$C_{[j]}(S^*) \geq C_{[j]}(S_2) \geq \frac{1}{2}(t + \sum_{k=1}^{j}(a_k + b_k)) \geq \frac{1}{2}C_{[j]}(S).$$

Thus, $\sum_{j=1}^{n} C_j(S) \leq \sum_{j=1}^{n} 2C_{[j]}(S^*)$. This completes the proof. ∎

Unfortunately, if s is arbitrary, SPT may generate a schedule that has a very large approximation ratio.

Lemma 2.2: For $F2,h_{11} \mid r-a \mid \sum C_j$ with a single unavailable interval $[s,t]$, if $s \geq a_1$ where $a_1 + b_1 = \min\{a_j + b_j\}$, SPT can generate a schedule whose approximation ratio is n in the worst case.

Proof: Given an instance I of the problem with a single unavailable interval $[s,t]$. Let I' be the corresponding instance of $F2 \mid\mid \sum C_j$ which is obtained from I by removing the unavailable interval. Let C_{opt} and C'_{opt} be the minimum total completion time for I and I', respectively. It is obvious that $C'_{opt} \leq C_{opt}$.

Let S be the schedule generated by SPT rule for instance I and S' be the SPT schedule for I'. For convenience, suppose the jobs are indexed in non-decreasing order of $(a_j + b_j)$, $1 \leq j \leq n$. Let i be the last job such that $C_{a,i}(S) \leq s$. Since $a_1 \leq s$, $i \geq 1$. It is clear that for $j \leq i$, we have $C_j(S) = C_j(S')$; for all $j > i$, we have $C_{a,j}(S) = C_{a,j}(S') + (t-s)$, so $C_j(S) = C_{b,j}(S) \leq C_{b,j}(S') + (t-s)$. Thus,

$$\begin{aligned}\sum_{j=1}^{n} C_j(S) &\leq \sum_{j=1}^{i} C_j(S') + \sum_{j=i+1}^{n}(C_j(S') + (t-s)) \\ &\leq \left(\sum_{j=1}^{n} C_j(S')\right) + (n-i)(t-s).\end{aligned}$$

On the other hand, since $\sum_{j=1}^{n} a_j > s$, at least one job must finish after t in any schedule. Thus the completion time of the last job in the optimal schedule is

$$C_{[n]}(S^*) \geq ((t-s) + \sum_{j=1}^{n}(a_j + b_j))/2 \geq \tfrac{(t-s)}{2} + \tfrac{C_n(S')}{2}.$$

For j-th job in S^*, $j \neq n$, we have that $C_{[j]}(S^*) \geq C_j(S')/2$. Thus we have $\sum_{j=1}^{n} C_j(S^*) \geq \sum_{j=1}^{n} C_j(S')/2 + (t-s)/2$ and

$$\begin{aligned}\sum_{j=1}^{n} C_j(S) &\leq \left(\sum_{j=1}^{n} C_j(S')\right) + (n-i)(t-s) \\ &\leq (2\left(\sum_{j=1}^{n} C_j(S^*) - (t-s)\right) + (n-i)(t-s) \\ &\leq 2\sum_{j=1}^{n} C_j(S^*) + (n-i-1)(t-s) \\ &\leq (n-i+1)\sum_{j=1}^{n} C_j(S^*).\end{aligned}$$

Since we assume $i \geq 1$, $\sum_{j=1}^{n} C_j(S) \leq nC_{opt}$. ∎

Next, we show that for some special cases in terms of a_j-s and/or b_j-s, we can use SPT_a or SPT_b to solve the problem optimally or get a good approximation.

Lemma 2.3: SPT_a generates a schedule whose total completion time is minimum for

(a) $F2,h_{11} \mid r-a, b_j = b \mid \sum C_j$; and
(b) $F2,h_{11} \mid r-a, a_j \geq b_j \mid \sum C_j$

Proof: First consider case (a): $F2,h_{11} \mid r-a, b_j = b \mid \sum C_j$. Let S be an arbitrary schedule and suppose that the jobs are scheduled in the order of 1, 2, $\cdots$. Define $C_0 = 0$, then the completion time of job i in S is

$$C_i(S) = \max(C_{i-1}, C_{a,i}) + b,$$

where

$$C_{a,i} = \begin{cases} \sum_{j=1}^{i} a_j, & \text{if } \sum_{j=1}^{i} a_j \leq s \\ \sum_{j=1}^{i} a_j + (t-s), & \text{if } \sum_{j=1}^{i} a_j > s. \end{cases}$$

Apparently scheduling the jobs in SPT_a minimizes the total completion time.

Now we consider case (b): $F2,h_{11} \mid r-a, a_j \geq b_j \mid \sum C_j$. Suppose that $a_1 \leq a_2 \leq \cdots \leq a_n$. Since $a_j \geq a_{j-1} \geq b_{j-1}$, in the schedule generated by SPT_a, b_j can be scheduled immediately after a_j completes, thus minimizing the total completion

time is the same as minimizing the total completion time of the a_j-s which is obtained by SPT_a rule.

■

Lemma 2.4: SPT_b generates a schedule for $F2, h_{11} \mid r - a, a_j = a \mid \sum C_j$ whose total completion time is at most $7/3$ times that of the optimal schedule.

Proof: Given an instance I of problem $F2, h_{11} \mid r - a, a_j = a \mid \sum C_j$ with the unavailable interval $[s, t]$, let C_{opt} be its minimum total completion time for I. Let S be the schedule generated by the SPT rule. Let I' be the instance of $F2 \mid a_j = a \mid \sum C_j$ obtained from I by removing the unavailable interval. Let C'_{opt} be the minimum total completion time for I'. Apparently, we have $C'_{opt} \leq C_{opt}$. Let S' be the SPT schedule for I'. From [9], we know that $\sum_{j=1}^{n} C_j(S') \leq \frac{4}{3} C'_{opt} \leq \frac{4}{3} C_{opt}$. Let $i = \lfloor \frac{s}{a} \rfloor$. Then only i jobs can finish before t on the first machine in any schedule which implies that $C_{opt} > (n-i)t$. Thus we have $C_j(S) = C_j(S')$ for $1 \leq j \leq i$. For $j > i$, its completion time in S is increased by at most the length of the interval compared with that in S', thus, $C_j(S) \leq C_j(S') + (t - s)$. So we have

$$\begin{aligned}\sum_{j=1}^{n} C_j(S) &\leq \left(\sum_{j=1}^{n} C_j(S')\right) + (n-i)(t-s) \\ &\leq \tfrac{4}{3} C'_{opt} + C_{opt} \\ &\leq \tfrac{4}{3} C_{opt} + C_{opt} \\ &\leq \tfrac{7}{3} C_{opt},\end{aligned}$$

and this completes the proof. ■

III. Mathematical Formulation

Our problem can can be formulated as follows: $\min \sum_{j=1}^{n} C_{b,j}$ subject to

$$C_{a,j} \geq a_j \quad \forall j \tag{1}$$

$$C_{b,j} \geq C_{a,j} + b_j \quad \forall j \tag{2}$$

$$C_{a,i} \geq C_{a,j} + a_i \bigvee C_{a,j} \geq C_{a,i} + a_j \quad \forall i, j,\ i \neq j \tag{3}$$

$$C_{b,i} \geq C_{b,j} + b_i \bigvee C_{b,j} \geq C_{b,i} + b_j \quad \forall i, j,\ i \neq j \tag{4}$$

$$C_{a,j} \leq s \bigvee C_{a,j} > t \quad \forall j \tag{5}$$

The schedule is a permutation schedule. (6)

The first four constraints are the same as the classical model. Constraint (1) says that the processing of any job on first machine cannot start before time 0; and the constraint (2) specifies the second operation of any job can't start before the first operation finishes; and the constraints (3) and (4) show that a machine can not process more than one job at a time. The constraint (5) is unique to our model, it says that the completion time of the first operation is either before or after the breakdown. An additional redundant constraint is (7) or (8), which will be used when we develop lower bounds.

$$C_{b,j} \geq \left(\min_{1 \leq k \leq n} a_k\right) + b_j \quad \forall j \tag{7}$$

$$C_{b,j} \geq \left(\min_{1 \leq k \leq n} a_k\right) + (t - s) + b_j \quad \text{if } \min_{1 \leq k \leq n} a_k > s \ \ \forall j \tag{8}$$

A. Lower Bounds

Let C_{opt} denote the minimum total completion time of the jobs. Based on the formulation, we can develop several lower bounds for C_{opt} by relaxing some of the constraints. Quite a few lower bounds were developed in previous literature for the classical flowshop model, see [5] and the references therein. With breakdown, those lower bounds either need to be modified or not work at all. In the following, we will examine those lower bounds.

1) LB1: This lower bound corresponds to the first lower bound of Ignall and Schrage [13]. The first lower bound from [13] is obtained by relaxing the constraint (4) so that the second machine can simultaneously process as many jobs as needed. Thus, the jobs should be scheduled in SPT_a order on the first machine, and b_j-s can be scheduled immediately without any delay after a_j finishes. With breakdown, the same idea still works, except that we have to count the number of a_j-s that are scheduled after the breakdown.

Suppose $a_1 \leq a_2 \leq \cdots \leq a_n$ and k is the smallest integer such that $\sum_{j=1}^{k+1} a_k > s$ where s is the start time of the unavailable interval. It is easy to see that there are at least $(n - k)$ jobs finish after the breakdown on the first machine in any schedule. Thus

$$LB1 = \left(\sum_{j=1}^{n} \sum_{i=1}^{j} a_i\right) + (n-k)(t-s) + \sum_{j=1}^{n} b_j.$$

2) LB2: This corresponds to the second lower bound of Ignall and Schrage [13], which is obtained by relaxing the constraints (1) and (3). Thus, the jobs should be scheduled in SPT_b order subject to constraint (7). Again, with breakdown, we need to do a modification. If $\min\{a_i\} \leq s$, then the lower bound is not affected by the breakdown; otherwise, constraint (8) should be satisfied. Assume $b_{i_1} \leq b_{i_2} \leq \cdots \leq b_{i_n}$, then we have that

$$LB2 = \begin{cases} n \min\{a_i\} + \sum_{j=1}^{n} \sum_{p=1}^{j} b_{i_p}, & \text{if } \min a_i \leq s \\ n(\min\{a_i\} + (t-s)) + \sum_{j=1}^{n} \sum_{p=1}^{j} b_{i_p}, & \text{otherwise.} \end{cases}$$

3) LB3: this corresponds to the lower bound in [23], which is obtained by applying Lagrangian relaxation to constraint (2) to the classical model. The bound from [23] is based on the assumption that $C_{a,[j]} = \sum_{i=1}^{j} a[i]$ which is true for classical model but not true with breakdown. However, we can still use it to get lower bounds for partial schedules whose completion time on the first machine passes the unavailable interval. For the details on how to calculate/estimate the lower bound, see [23].

From the analysis, we can see LB4 givens a stronger bound than both LB1 and LB2.

4) LB4: This corresponds to LB_{DNT2} in [5] which dominates the first two lower bounds in classical model. We can adapt this bound for our model.

First note that with breakdown, it is still the case that for any schedule S and the j-th job in S, $C_{a,[j]}(SPT_a) \leq C_{a,[j]}(S)$,

where SPT_a represents the schedule generated by SPT_a rule. If we relax the constraint (3), then the problem is equivalent to a single machine problem with each job j has a release time a_j or $a_j + (t-s)$ if $a_j > s$, and processing time b_j. A lower bound of the new problem is given by schedule the jobs using $SRPT$ (Shortest Remaining Processing Time First). As with the classical model, it is still true that $C_{b,[j]}(SRPT) \leq C_{b,[j]}(S)$ for S and j.

Use similar argument as in [5], we can show that for any schedule S,

$$\sum_{j=1}^{n} C_j(S) \geq \sum_{j=1}^{n} \max\left(C_{a,[j]}(SPT_a) + b_{[j]}(S), C_{b,j}(SRPT)\right) = \left(\sum_{j=1}^{n} C_{b,j}(SRPT)\right) + \Delta,$$

where

$$\Delta = \sum_{j=1}^{n} \max(0, b_j(S) - (C_{b,[j]}(SRPT) - C_{a,[j]}(SPT_a))),$$

and Δ is minimized by sorting both b_j-s of S and $(C_{b,[j]}(SRPT) - C_{a,[j]}(SPT_a))$ in non-decreasing order. By the analysis, it is easy to see that LB4 generates a bound that is better than both LB1 and LB2.

5) LB5-Lower Bound by Linear Programming: If we know that the number of first operations that finish before breakdown in the optimal schedule is K, then we can modify the formulation from [12] as follows. Let w_j be the time that $b_{[j]}$ has to wait after $a_{[j]}$ finishes and $w_1 = 0$. Thus we have

$$C_{b,[j]} = C_{a,[j]} + b_{[j]} + w_j \text{ for each position } j = 1, \ldots, n.$$

Then the problem is to minimize

$$\sum_{j=1}^{n} (C_{a,[j]} + w_j + b_{[j]})$$

subject to

$$a_{[k]} + w_k \geq b_{[k-1]} + w_{k-1} \; \forall k = 2, \ldots, n, \text{ and } k \neq K+1 \quad (9)$$

$$a_{[K+1]} + w_{[K+1]} + (t-s) \geq b_{[K]} + w_K \quad (10)$$

$$\sum_{i=1}^{K} a_{[i]} \leq s \quad (11)$$

Let x_{ij} be the binary variable such that $x_{ij} = 1$ means job i is the j-th job in the schedule and $x_{ij} = 0$ otherwise. Then the problem can be formulated as to

minimize

$$\sum_{j=1}^{n} (n-j+1) \sum_{i=1}^{n} x_{ij} a_i + \sum_{j=1}^{n} w_j + \sum_{j=1}^{n} b_j + (n-K)(t-s)$$

subject to

$$\sum_{j=1}^{n} x_{ij} \geq 1, \forall i = 1, \ldots, n$$

$$\sum_{i=1}^{n} x_{ij} \leq 1, \forall j = 1, \ldots, n$$

$$\sum_{i=1}^{n} x_{ik} a_i + w_k - \left(\sum_{i=1}^{n} x_{ik-1} b_i + w_{k-1}\right) \geq 0, \forall k \neq K+1$$

$$\sum_{i=1}^{n} x_{ik} a_i + w_k + (t-s) - \left(\sum_{i=1}^{n} x_{ik-1} b_i + w_{k-1}\right) \geq 0, \; k = K+1$$

$$\sum_{j=1}^{K} \sum_{i=1}^{n} x_{ij} a_i \leq s$$

$$x_{ij} \in \{0,1\} \text{ for } i = 1, \ldots n; j = 1, \ldots, n$$

$$w_j \geq 0 \text{ for } j = 2, \ldots, n$$

The problem is that we don't know the magic number K. However, we can find its minimum possible value of $K_{\min}$ and its maximum possible value $K_{\max}$ by sorting the first operations in SPT_a and LPT_a (longest processing time first by a_js) respectively. Let $LP(k)$ be the lower bound for our problem with a specific $K = k$. Then the lower bound for our problem is $\min_{k=K_{\min}}^{K_{\max}} LP(k)$.

IV. Branch and Bound Algorithm

Our branch-and-bound procedure builds the search tree in a depth-first-search fashion. It starts with the root node at level 0. Each node at level k of the tree corresponds to an initial partial schedule in which k jobs have been put in the first k positions. For this node, at most $(n-k)$ child nodes will be created, one for each unscheduled job. The size of the search tree can be reduced by applying lower bounding technique and dominance rules at each node.

A. Upper Bound

To get an initial upper bound, we first generate some random schedules. We also generate the neighbors of these random schedules which are obtained by local interchanges. Then, we pick the best among these schedules and the schedules obtained by applying SPT, SPT_a, SPT_b. The upper bound is updated any time a leaf of the search tree results in a better schedule. At each internal node, we also calculate the upper bound using SPT, SPT_a, SPT_b based on the partial schedule, the upper bound is updated if a better schedule is obtained.

B. Lower Bound of a Partial Schedule

The LB1, LB2, LB3, LB4 and LB5 mentioned in previous section assume that no jobs have been scheduled yet. All of them can be adjusted if some jobs have been scheduled. However, it will be too expensive to calculate LB5 at each node. So we only calculate LB5 at the root node, and enhance the lower bound based on the partial schedule using the technique from [9]. All other lower bounds will be calculated at each node. If the maximum lower bound is greater than the current upper bound, the node will be cut from the search tree.

C. Dominance Rules

For the aim of improving the performance of the branch and bound algorithm, dominance rules can be used to reduce the size of the search space.

Given a (partial) schedule S, we use $C_A(S)$, $C_B(S)$ to represent the completion time of the last operation on machine 1 and 2 in S, respectively. Let $TC(S)$ be the total completion time of the jobs in S. The earliest available time for the remaining jobs on the second machine, denoted by $r(S)$, is $\max(C_B(S), C_A(S) + \min_{i\notin S} a_i)$ or $\max(C_B(S), C_A(S) + \min_{i\in S} a_i + (t-s))$ if $s < C_A(S) + \min_{i\notin S} a_i \leq t$.

We have the following dominance rules that can be applied to cut the branches of the search tree.

Lemma 4.1: Dominance rule 1. Given two partial schedule S_1 and S_2 of the same set of jobs. If $TC(S_1) \leq TC(S_2)$ and $C_B(S_1) \leq r(S_2)$, then to find the optimal schedule of all jobs, there is no need to consider the schedules based on S_2.

It is easy to see that the above lemma is true. Given a schedule S, a particular schedule that can be checked to see if it dominates S is the schedule resulting from Johnson's rule. If $C_A(S) \leq s$, we check the schedule generated by Johnson's rule for the same set of jobs. Otherwise, $C_A(S) > t$, we check the schedule that schedules the jobs in the same way as S before t, and schedule the remaining jobs after t using Johnson's rule. In both cases, the schedules being checked are guaranteed to have a makespan not greater than that of S.

Lemma 4.2: Dominance rule 2 ([4]). Given two partial schedules of the same set of jobs, S_1 and S_2, then S_2 can be pruned if both of the following inequalities hold:

$$TC(S_1) \leq TC(S_2)$$

and

$$(C_B(S_1) - C_B(S_2))q \leq TC(S_2) - TC(S_1),$$

where q is the number of unscheduled jobs.

The Lemma is obviously true, actually it holds no matter how many breakdowns on the first machine, as long as there is no breakdown on the second machine. The rule can be applied to a schedule S by checking any adjacent schedules of S. Adjacent schedule can be obtained by swapping any two jobs i and j or by inserting j before or after i, etc.

Lemma 4.3: Dominance rule 3. Given a partial schedule S and an unscheduled job i such that $a_i \leq b_i$. If for any other unscheduled job j , we have $a_i \leq a_j$ and $b_i \leq b_j$, and $C_A(S) + a_i + a_j \leq s$ or $C_A(S) + \min_{k\notin S} a_k > s$ then there exists an optimal schedule that job i is the first among all the unscheduled jobs.

Proof: A similar rule for the classical model without availability constraint is given by Croce et. al ([4]) (Dominance rule D2). One can prove the lemma by adapting the proof from [4]. ■

It should be noted that this dominance rule holds only if $C_A(S) + a_i + a_j \leq s$ or $C_A(S) + \min_{k\notin S} a_k > s$. For example, consider $a_1 = a_2 = a_3 = 2$, $b_1 = 2$, $b_2 = 3$ and $b_3 = 4$. Suppose the unavailable interval is $[5, 11]$. At the beginning, S is empty, the conditions are satisfied for $i = 1$, thus by Lemma 4.3, we know there must exist an optimal schedule starting with job 1. So we don't need to consider the schedules that start with job 2 or 3. On the other hand, if the unavailable interval is $[3, 9]$, neither $C_A(S) + a_i + a_j \leq s$ nor $C_A(S) + \min_{k\notin S} a_k > s$ holds for $i = 1$. So it is not clear that there exists an optimal schedule starting with job 1. It turns out the the optimal schedule starts with the last job 3, not job 1.

Lemma 4.4: Dominance rule 4. Given a partial schedule π and two unscheduled jobs i and j, such that $a_i \leq a_j$, $b_i \geq b_j$. Let $L = s - C_A(\pi)$, and π_1 and π_2 be sequences of unscheduled jobs. Let $S_1 = \pi i \pi_1 j \pi_2$ and $S_2 = \pi j \pi_1 i \pi_2$. Then S_1 dominates S_2 if one of the following cases is true,

(a) $0 < L \leq a_i \leq a_j$, and

$$\begin{aligned}&\max(C_A(\pi) + a_i + (t-s), C_B(\pi)) + b_i \\ &\leq \max(C_A(\pi) + a_j + (t-s), C_B(\pi)) + b_j;\end{aligned}$$

(b) $L \leq 0$ or $L > a_i$, and

$$\begin{aligned}&\max(C_A(\pi) + a_i, C_B(\pi)) + b_i \\ &\leq \max(C_A(\pi) + a_j, C_B(\pi)) + b_j.\end{aligned}$$

Proof: If we could show (1) $C_{b,i}(S_1) + C_{b,j}(S_1) \leq C_{b,i}(S_2) + C_{b,j}(S_2)$, and (2) $C_{b,k}(S_1) \leq C_{b,k}(S_2)$ for any $k \neq i, j$, then both the makespan and the total completion time of S_1 are less than or equal to that of S_2, thus the lemma is true.

We consider case (a) first. Apparently, for any $k \in \pi$, we have $C_{a,k}(S_1) = C_{a,k}(S_2)$ and $C_{b,k}(S_1) = C_{b,k}(S_2)$. For job i in S_1 and job j in S_2, the condition $0 < L \leq a_i \leq a_j$ means that neither a_i not a_j can finish before the unavailable interval given the partial schedule π. So for S_1, we have $C_{a,i}(S_1) = C_A(\pi) + a_i + (t-s)$, $C_{b,i}(S_1) = \max(C_{a,i}(S_1), C_B(\pi)) + b_i$.

Similarly for S_2, we have $C_{a,j}(S_2) = C_A(\pi) + a_j + (t-s)$, $C_{b,j}(S_2) = \max(C_{a,j}(S_2), C_B(\pi)) + b_j$.

Since $a_i \leq a_j$, we have $C_{a,i}(S_1) \leq C_{a,j}(S_2)$. The condition $\max(C_A(\pi) + a_i + (t-s), C_B(\pi)) + b_i \leq \max(C_A(\pi) + a_j + (t-s), C_B(\pi)) + b_j$ implies

$$C_{b,i}(S_1) \leq C_{b,j}(S_2).$$

Consequently, for any $k \in \pi_1$, it must be true that $C_{a,k}(S_1) \leq C_{a,k}(S_2)$ and $C_{b,k}(S_1) \leq C_{b,k}(S_2)$. Therefore $C_B(\pi i \pi_1) \leq C_B(\pi j \pi_1)$.

Clearly, $C_{a,j}(S_1) = C_{a,i}(S_2)$. Since $b_i \geq b_j$, we have $C_{b,j}(S_1) = \max(C_{a,j}(S_1), C_B(\pi i \pi_1) + b_j \leq C_{b,i}(S_2) = \max(C_{a,i}(S_1), C_B(\pi j \pi_1)) + b_i$ Thus, for any $k \in \pi_2$, $C_{a,k}(S_1) = C_{a,k}(S_2)$ and $C_{b,k}(S_1) \leq C_{b,k}(S_2)$.

For case (b), given the partial schedule π, if $L \leq 0$, then all the remaining jobs including i and j have to be scheduled after the unavailable interval. If $L \geq a_i$, then a_i can finish before the unavailable interval, but a_j may or may not finish before the unavailable interval. Either way, the inequality

$$\max(C_A(\pi)+a_i, C_B(\pi))+b_i \leq \max(C_A(\pi)+a_j, C_B(\pi))+b_j$$

guarantees that $C_{b,i}(S_1) \leq C_{b,j}(S_2)$. We can use similar argument as case (a) to prove that $C_{b,k}(S_1) \leq C_{b,k}(S_2)$ for any $k \neq i, j$, thus the lemma is true. ■

D. Experimental Results

The instances are generated as follows. For processing times, we use three distributions, $[1, 10]$, $[1, 50]$, $[1, 100]$. It is known that the distribution $[1, 100]$ generates the most difficult type of problem instances. The $[1, 10]$ distribution is the easiest and also the most practical distribution. The number of jobs n takes on values 10, 15, 20, 25, 30, 35. The start time s of the unavailable intervals are generated from four uniform distributions, $[0, \frac{1}{4}A]$, $[\frac{1}{4}A, \frac{1}{2}A]$, $[\frac{1}{2}A, \frac{3}{4}A]$, $[\frac{3}{4}A, A]$, where $A = \sum_{j=1}^{n} a_j$. The duration of the unavailable intervals, $(t-s)$, takes the values of 1% 20%, 40%, 60%, 80%, 100% of A. For each combination of n and a processing time distribution, we generate 25 sets of n jobs; then for each set of n jobs, we generate 16 instances by combining different distribution of s and $(t - s)$.

We pre-process the jobs in SPT, SPT_a, SPT_b and Johnson's rule and keep this order so that they can be accessed at each node of the tree. We set the termination criteria of the branch and bound algorithm by limiting the number of the nodes explored to be 5000000.

1) Comparison of Lower Bounds At the Root Node: From previous discussion, when $min_{1 \leq i \leq n} a_i < s$, the LB2 bound doesn't put much consideration of the unavailable interval on the first machine, so its is expected to be the worst lower bound. $LB3$ can only be applied for partial schedules passing the unavailable interval. We also know that LB4 dominates LB1 and LB2. LB5 is generated by linear programming.

Experiments show that at the root node, LB5 always gives the best lower bound, and LB4 is very close to LB5. On average, LB1 is not that bad. The performance of LB2 can vary a lot from instance to instance. Table I shows the ratios of the LB5 with LB1, LB2, and LB4 for the instances with $n = 35$. For each distribution of the processing times, we list the minimum, maximum, average ratios and the standard deviation.

We also notice that the gap of LB5 at the root and the optimal solutions is very small. Table II shows the value of LB5 at the root compared with the optimal solution (or the best solution found if optimal not found) for the instances with $n = 35$. We can see on average, LB5 is within 1% of the optimal (best) solution.

2) Lower Bounds at the Internal Node: Although LB5 is very good and close to the optimal solution, but its computation takes a lot of time, thus we cannot afford to compute at other nodes. So we use the method from [12] to enhance LB5 based on the partial schedule at each node. For each instance, we record the number of nodes it explores before it finds the optimal solution or reach the maximum node limit, 5000000. For each of the lower bound LB1, . . ., LB5, We also record the number of nodes such that the lower bound is maximum. We observed that LB4 provides the best lower bound at internal nodes for almost all instances. Fig.1 shows 125 instances of 35 jobs. For each instance, among all the nodes explored, the figure shows the number of times when each of LB3, LB4 and LB5 equals to $\max(LB3, LB4, LB5)$. We can clearly see that $LB4$ provides the best lower bounds at the majority of the nodes in the search tree, and $LB3$ provides good lower bound only for a very small portion of the nodes in the tree.

3) Dominance Rule: To find out the effectiveness of the dominance rules, we run experiment with and without applying dominance rules. For each instance, we compare the number of nodes explored by the algorithm in both cases. We compute the ratio of the number of nodes with dominance rules and the number of nodes without dominance rules. Table III lists minimum, maximum, and average ratio for different processing time distribution when $n = 20$. We can see on average, the number of the nodes with dominance rules is only 10% of the number of nodes with no dominance rules, i.e 10 times speed up of the algorithm.

4) Unavailable Interval: Fig. 2 shows how the starting time of the unavailable interval affects the size of the search tree. In the figure, we show the number of nodes explored for 120 instances of $n = 20$. The instances are divided into 4 groups of 30 instances whose unavailable interval starting times are drawn from the distribution $[0, \frac{1}{4}A]$, $[\frac{1}{4}A, \frac{1}{2}A]$, $[\frac{1}{2}A, \frac{3}{4}A]$, $[\frac{3}{4}A, A]$, respectively. The figure suggests that the search tree size is getting bigger as the unavailable interval starts later. We can also see that the LB3 plays a bigger role when the unavailable intervals starts before $\frac{1}{4}A$.

Fig. 3 shows how the length of the unavailable interval affects the size of the search tree. The effect is not that obvious.

5) Problems Size Solved: Our algorithm is implemented in C++, and Gurobi is used for linear programming. Within the maximum number of nodes 5000000, we were able to solve the instances of 30 jobs. When $n = 35$, we can solve the majority of the instance if the processing time distribution is from $[1, 10]$. For the other two distributions, $[1, 50]$ and $[1, 100]$, we can only solve some of the instances. For example, for the 125 instances we used from Table I and Table II, the number of solved instances are 88, 28, 19, respectively. On the other hand, from the Table II, we know that the best solutions found by the branch and bound algorithm are actually very close to the optimal solution.

V. Conclusion

In this paper, we studied the problem of minimizing total completion time subject to the constraint that there is a

single unavailable interval on the first machine. We show that some special cases can be solved optimally or within a constant factor; and for the general case, SPT rule gives an n-approximation. We performed computational experiments to investigate the effectiveness of different lower bounds and the dominance rules. It is observed that at the root node, LB5 provides the best lower bound with the expense of time, LB4 can provide almost good lower bounds but more efficiently at the root node and gives the best lower bounds at most internal nodes. The dominance rules speeds up the algorithm dramatically. We also observed that the earlier the the unavailable interval starts, the more efficient the algorithm is; on the other hand, the duration of the unavailable interval does not affect the efficiency of the branch and bound algorithm very much.

Computer Science & Systems

CSS is a FedCSIS conference area aiming at integrating and creating synergy between FedCSIS events that thematically subscribe to more technical aspects of computer science and related disciplines. The CSNS area spans themes ranging from hardware issues close to the discipline of computer engineering via software issues tackled by the theory and applications of computer science and to communications issues of interest to distributed and network systems. Events that constitute CSNS are:

- AIPC'16—1st International Workshop on Advances in Image Processing and Colorization
- CANA'16—9th Computer Aspects of Numerical Algorithms
- CPORA'16—1st Workshop on Constraint Programming and Operation Research Applications
- IWCPS'16—3rd International Workshop on Cyber-Physical Systems
- MMAP'16—9th International Symposium on Multimedia Applications and Processing
- WSC'16—8th Workshop on Scalable Computing

1st International Workshop on Advances in Image Processing and Colorization

IMAGE Processing and Colorization are two fields which have shown a stable growth in the last decades. They have different impact in computer science and other research areas, e.g. biology, remote sensing, and medicine. Image processing is very important in medical applications, robotics, and other industrial applications. Recently, the study of "colorization" begins to attract attention. The colorization technique can colorize a monochrome image by giving a number of color pixels. Colorization is a computerized process of adding color to a black and white print, movie and TV program. Image Colorization has a great impact on different applications. Image processing and Colorization can also be combined in many applications. Different tools, from machine learning and mathematics, are greatly influencing the research areas in image processing and Colorization. Recently, bio-inspired optimization techniques have been used to improve the image processing techniques, segmentation and classification.

The purpose of the "Advances in Image Processing and Colorization" session is to bring scientists, researcher scholars, and students from academia and practitioners present ongoing research activities about both theoretical advances and applications of Image Processing and Colorization and to allow the exchange of new ideas and application experiences to face to face.

TOPICS

Topics of interest include but are not limited to:

- Bio-inspired based image classification,
- Bio-inspired based image segmentation,
- Thermal image processing,
- Biometric identification and authentication,
- Face and iris recognition,
- Bio-inspired based face and iris recognition,
- New colorization approach,
- Colorization image coding techniques,
- Color embedding,
- Applications of image colorization,
- Video colorization,
- Physics-based colorization,
- Interactive colorization method,
- Colorization using optimization techniques,
- Colorization for monochrome Image,
- Color to gray and back.

***Abstract*—The security of data over the internet is a crucial thing specially if this data is personal or confidential. The transmitted data can be intercepted during its journey from device to another. For that reason, we are willing to develop a simple method to secure data. Data encryption is one method to secure the messages but the intruders can still try to crack it, in order to overcome this, steganography has been used to hide the data into a cover media(i.e. audio, image or video). Recently steganography attracts many researchers as a hot topic. This paper proposes an advanced technique for encrypting data using Advanced Encryption System (AES) and hiding the data using Haar Discreet Wavelet Transform (HDWT). HDWT aims to decrease the complexity in image steganology while providing less image distortion and lesser detectability. One-forth of the image carrying the details of the image in a region and other three regions carrying a less details of the image then the cipher text is concealed at most two Least Significant Bits (LSB) positions in the less detailed regions of the carrier image, if the message doesn't fit in the first LSB only it will use the second LSB. This proposed algorithm covers almost all type of symbols and alphabets.**

I. Introduction

STEGANOGRAPHY is a data hiding technique that has been mainly used in information security applications. It is similar to watermarking and cryptography techniques, but these three techniques are different in some aspects. Firstly, watermarking mainly tracks illegal copies or claims of the ownership of digital media. It is not geared for communication. Secondly, cryptography scrambles the data with the mixture of permutation(s) and substitution(s) so that unintended receivers cannot perceive the processed information. However, the fact that information has been embedded into a medium (i.e., watermarking) and communication has been carried out (i.e., cryptography) is known to everyone, or at least it is acceptable to reveal such a fact. Finally, steganography transmits information by embedding messages into innocuous looking cover objects, such as digital images, to conceal the very existence of communication. As a result, steganography is the art and science of data smuggling since its goal is to hide the presence of communication [1].

Each image hiding system consists of an embedding process and an extraction process. An innocuous-looking original image is used as the cover-image to conceal the secret data. The secret data are embedded into the cover-image by modifying the cover-image to form a stego-image. Cryptography [2], [3] and steganography [4] are the two important aspects of communications security. Although cryptography is a primary method of protecting valuable information by rendering the message unintelligible to outsiders [3], steganography is a step ahead by making the communication invisible. A possible formula of the process may be represented as: $Stegomedium = Covermedium + Embeddedmessage + Stegokey$

In this paper, an advanced technique for encrypting data is proposed using AES and hiding the data using Haar DWT technique, carrying the details of the image in a region and other three regions carrying a less details of the image then the cipher text is concealed at most two LSB positions. Extensive experiments show the effectiveness of the proposed method. The results obtained also show significant improvement than the method proposed in [5]. The remainder of the paper is organized as follows. Section II briefly describes the related work. In Section III, the related main knowledge is described. Section IV, discusses the features of the proposed technique. The performance is analyzed. Experimental results are given in Section V. Finally, Section VI concludes this paper.

II. Related Work

A few steganography approaches are briefly reviewed here.In [6], Tiegang et al. proposed a new image encryption algorithm based on hyper-chaos, which uses a new image total shuffling matrix to shuffle the pixel positions of the plain-image and then the states combination of hyper-chaos is used to change the grey values of the shuffled-image. In [7], Chin-Chen et al. proposed a new steganographic method to increase the message load in every block of the stego-image while keeping the stego-image quality acceptable. In [8], B. T. NilanjanDey, et al, proposed a method for hiding multiple images in an image based on DWT and DCT. In [9], Chen Po-Yueh et al. proposed a new steganography technique which embeds the secret messages using the DWT in the frequency domain to divide the image into 4 sub bands, and it will embed the secret data in the LSB of the lowest priority band and it wouldn't use the low frequency sub band that holds the most

details to preserve the quality of the image, and it have 2 modes and 5 cases because of the demands of the capacity or quality.

In [10], Chiang-Lung et al. proposed method adopts the complementary embedding strategy to reduce the loss of statistical property of the stego-image in spatial domain. In [11], Chi-Kwong Chan et al. proposed a data hiding method by simple LSB substitution with an optimal pixel adjustment process. The image quality of the stego-image can be greatly improved with low extra computational complexity. In [12], KokSheik et al. presented a novel Mod4 steganographic method in discrete cosine transform (DCT) domain. Mod4 is a blind steganographic method.

In [13], M. Juneja et al., proposed a secure methods of information security using steganography, the first method embeds In the LSB of the blue components partial green components of random positions in the edges of the green component, the second method is an adaptive method that uses the data of the MSB of the red, green and blue components to embed the message in the random pixels across smooth areas, the third method is a hybrid feature detection filter that predicts the edges in noisy conditions.

In [5], Avval et al, proposed steganography technique to embed audio into the edges of a color image, this technique uses the chaotic map to select the random edge pixels to embed the bits and to choose which random LSB bit location in the selected pixel. In [14], Hemalatha S. et al. proposed a method to hide multiple secret keys and images in a color image using integer wavelet transform (IWT). In [11], T. Garima, proposed an approach to encrypt message using RSA 1024 algorithm then it will be embedded in a cover image by modifying the LSB technique. In [15], L. S. Ahmed et al., proposed a method of encrypting the message by a substitution cipher then it will be embedded using LSB insertion techniques to achieve high capacity to be embedded and security of the steganography method. In [10], Liu Lung et al. proposed a jpeg steganographic using complementary embedding technique, this method is achieved by dividing the quantized DCT coefficients and the secret bits into two parts according to a predefined partition ratio. The two parts of DCT coefficients are used to embed the corresponding parts of secret bits with different embedding algorithms. Specifically, the secret bits are embedded by subtracting one from one part of coefficients, and adding one to the other part of coefficients.

III. The steganography

A. 2D-Haar-wavlet Transform

Wavelet transform has the capability to offer some information on frequency-time domain concurrently. In this transform, time domain is passed through high-pass and low-pass filters to extract high and low frequencies respectively. This process is repeated for a number of times and each time a section of the signal is drawn out. DWT analysis splits signal into two classes (i.e. Approximation and Detail) by signal decomposition for different frequency bands and scales. DWT employs two function sets: scaling and wavelet which associate with low and high pass filters orderly. Decomposition follows the manner of dividing time separability. Meanly, only half of the samples in a signal are sufficient to represent the whole signal, doubling the frequency separability.

Haar wavelet operates on data by calculating the sums and differences of adjacent elements. This wavelet operates first on adjacent horizontal elements and then on adjacent vertical elements. One important feature of the Haar wavelet transform is that the transform is equal to its inverse. Each transform computes the data energy in relocated to the top left hand corner.

Figure 1 shows the image Lena after one Haar wavelet transform

Fig. 1: 2D Haar Wavelet Transform Example

After each transform is performed the size of the square which contains the most important information is reduced by a factor of 4 as seen in Figure 2.

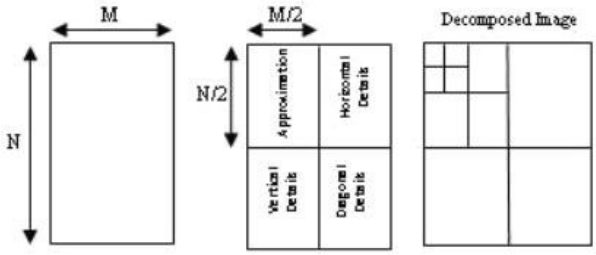

Fig. 2: Detailed 2D Haar Wavelet Transform

B. AES encryption technique

The cipher takes a plaintext block size of 128 bits, or 16 bytes. The key length can be 16, 24, or 32 bytes (128, 192, or 256 bits). Data block of 4 columns of 4 bytes is state key expanded to array of words. Ordering of bytes within a matrix is by column. The cipher consists of rounds, where the number of rounds depends on the key length: 10 rounds for a 16-byte key, 12 rounds for a 24-byte key, and so on, each transformation takes one or more 4 X 4 matrices as input and produces a 4 X 4 matrix as output (the cipher text).The key expansion function generates N + 1 round keys, each of which is a distinct 4 X 4 matrix. Each round key serves as one of the inputs to the Add Round Key transformation in each round.

C. LSB substitution technique

The wide used technique of hiding messages into the image without affecting the whole image is the LSB technique that uses the least significant bit of each pixel to embed the message into it. Figure 3 shows how the pixel can be illustrated from the most important bit to the least important bit. The basic concept of LSB substitution is to embed the message in the least important bit (least significant bit) of the pixel the equation for the LSB is

$$X_i^{'} = X_i - X_i mod 2^k + m_i \tag{1}$$

in this equation the $X_i^{'}$ is the i^{th} pixel value of the stego image, X_i is the i^{th} pixel of the image (cover image) and m_i denotes the decimal value of the i^{th} block in confidential data. K denotes the number of LSB places. we will use or substitute from the pixel. In the process of extracting the message from the image pixel is to copy the least significant bit directly, and this process is showed in the following equation (2):

$$m_i = x_i^{'} mod 2^k \tag{2}$$

This technique is easy and fast but it have drawback if the message have a great size, it will affect the image and it can be noticeable.

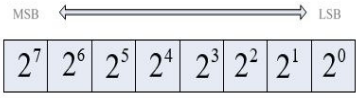

Fig. 3: The places of the bits in the pixel

IV. Proposed Approach

In this research the proposed approach includes two main process: Embedding process and Extracting process.

A. Embedding process

As seen in Algorithm 1, we started first by reading the cover image C and the message to be embedded M. The cipher message S is extracted by applying the AES encryption technique on message M. After performing the AES technique on the message, it is ready to be concealed in the image. Suppose that the 8-bit gray level cover image of size M_CxN_C as :

$$C = \{x_{i,j} | 1 \leqslant i \leqslant M_c, 1 \leqslant j \leqslant N_c, x_{i,j} \in \{1, 2, 3..., 255\}\} \tag{3}$$

S is the n-bit secret message represented as:

$$S = \{S_i | 1 \leqslant i \leqslant n, S_i \in \{0, 1\}\} \tag{4}$$

From Algorithm 1, the embedding steps will be as follows:

1) Apply the DWT on the cover image and get the four sub-bands obtained are denoted LL, HL, LH and HH.
2) Get three bits iteratively from the cipher message and distribute only one bit from the three bits in every one LSB of the three sub bands HH, HL and LH respectively, if the cipher message require more LSB, our algorithm will move cursor to the second LSB of each pixel in the three sub bands. This improves the capacity and permits high capacity with no effect on the pixel value. As the embedding process is done on the sub bands that don't contain details of the image.
3) Perform the inverse DWT on the result of step 2, by performing this step the resulted matrix is H, some pixels of H are not integers ranging from 1-255 due to LSB substitution. So we obtain (K-matrix) that contains the possible non-integer situation (0.0, 0.25, 0.5 and 0.75).
4) Round the matrix H to obtain the stego image E, in order to reconstruct the secret message we will use the k-matrix for reconstruction.
5) Send the Stego image to the receiver with the k-matrix in the description file or tag with the total number of message bits too.

Algorithm 1 Proposed Approach

1: input=gray scale cover image C and message to be embedded M
2: output= StegoImage
3: $S =$ Encrypt M using AES technique
4: $IfSize(S) >$ total first three bit of LSB in C
5: Then get another cover Image AC and go to step 4
6: D = Apply the DWT on C
7: Embed S in the coefficient of D
8: Inverse D
9: obtain (K-matrix) that contains the possible non-integer situation (0.0, 0.25, 0.5 and 0.75)
10: Calculate inverse 2D-DWT on each block to get the stego image.

B. Extraction process

In order to extract the original image the following steps are followed:

1) Extract the k-matrix of the file tag of E.

$$K = \{K_{i,j} | 1 \leqslant M_F \leqslant n, 1 \leqslant j \leqslant N_F, K_{i,j} \in \{00, 01, 10, 11\}\} \tag{5}$$

Transform all elements of k into (0.0, 0.25, 0.5 and 0.75).
2) Obtain the H by performing DWT which is calculated as H=E+K-matrix.
3) Obtain the total number of the message from the file tag of E, extract 3 bits iteratively from the LSB of the three sub bands HHH, HHL and HLH. After completing the first LSB and there are more bits of the message is still not extracted (bits extracted message size of E != 0) Get the remaining bits from the second LSB in the same way as the last step. Extracting the two LSB of the remaining bits, example [A,B]
4) After extracting the whole bits perform the inverse AES on the encrypted bits to obtain the original message.

V. Results and Discussion

The proposed approach is applied on 512x512 8-bit grayscale images Jet, Boat, Baboon and Lena. The messages

are generated randomly with size upto maximum hiding capacity. To measure the quality, a parameter is developed to compute the quality of the image this parameter is called PSNR and defined as follows:

$$PSNR = 10\log_{10}(255^2/MSE) \tag{6}$$

The root mean square error (RMSE) has been used as a standard statistical metric to measure model performance in meteorology, air quality, and climate research studies. The mean absolute error (MAE) is another useful measure widely used in model evaluations, denotes the mean error and it's the deference between the original image and the stego image as seen in Figure 5, and the equations to compute the MAE and MSE are:

$$MSE = \frac{1}{MXN}\sum(a-b)^2 \tag{7}$$

Where a denotes the pixel in the original image and b denotes the pixel in the stego image, with high PSNR means a high quality, this means that while the dB is low this means that the image has been modified or there is a noise or distortion.

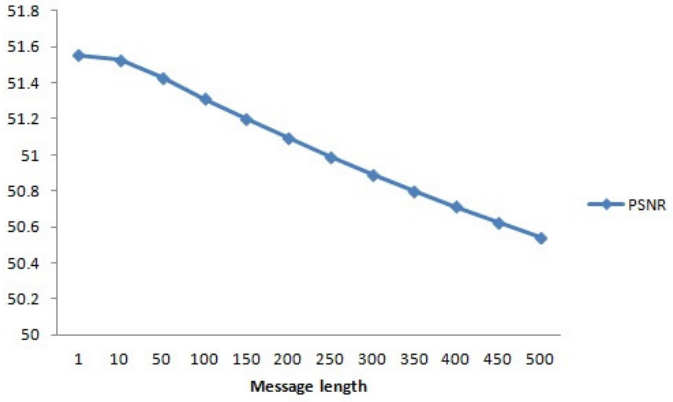

Fig. 4: PSNR Results

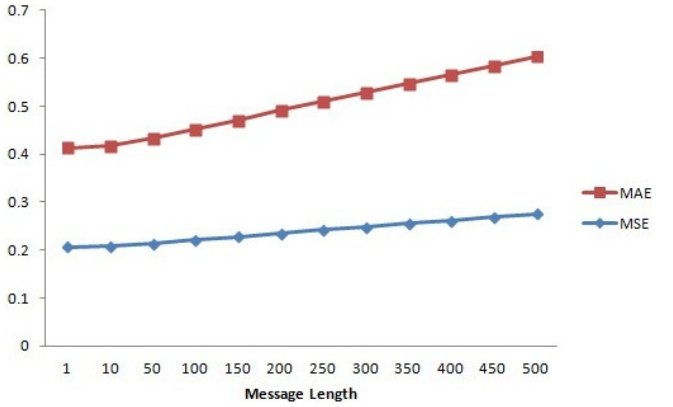

Fig. 5: MSE and MAE Results

Verification of the results has been done for various length of message (LM) and calculates error for all different messages the proposed technique works fine show in Figure 5. When compare our technique with scheme [5]. It gets results better than other method. Result of PSNR for other method between 75, 80 but PSNR of our method smaller than it as seen in Figure 4.

VI. Conclusion

There are demands of the algorithms of steganography to progress with the capacity or with quality, so with this method we aimed at the capacity demand to store as high as possible messages in the image with reduced effect of the quality of the image, and made it even harder to get the message by encrypting it before storing the message in the cover image, with this method the message is secured and hidden, and the cover image can take much more message size to hide. As the main goal of steganography is to hide and secure the message.

***Abstract*—This paper presents an approach based on Artificial Bee Colony (ABC) to optimize the parameters of membership functions of Sugeno based Adaptive Neuro-Fuzzy Inference System (ANFIS). The optimization is achieved by Artificial Bee Colony (ABC) for the sake of achieving minimum Root Mean Square Error of ANFIS structure. The proposed ANFIS-ABC model is used to build a system for predicting the wind speed. To ensure the accuracy of the model, a different number of membership functions has been used. The experimental results indicates that the best accuracy achieved is 98% with ten membership functions and least value of RMSE which is 0.39.**

I. Introduction

ADAPTIVE Neuro-Fuzzy Inference Systems (ANFIS)[1] can be used for energy planning. Its learning techniques is to adjust the parameters of FIS membership functions that best represent the given input/output data. An adaptive neuro fuzzy control [2] is applied to optimize the use of wind energy in smart grids. In [3] the ANFIS have have applied for wind power prediction. Also, the authors in [4] predicted the wind speed using soft computing models formulated on a back propagation neural network (BPNN) and an adaptive neurofuzzy inference system (ANFIS). The adaptive neuro-fuzzy inference system (ANFIS) has been applied to estimate optimal power coefficient value of the wind turbines by [5]. In [6] the fuzzy modeling techniques and artificial neural networks have applied to estimate annual energy output of a wind turbine. the authors in [7] have demonstrated an online fuzzy neural network controller for output maximization in a wind energy conversion system. An on-line training recurrent fuzzy neural network (RFNN) controller for wind generation system with a high-performance model reference adaptive system (MRAS) observer for the sensorless control of an induction generator (IG) have presented [8]. In [9,10] ANFIS have applied for wind speed profiling and for wind power prediction. In [11] the wind speed is predicted using fuzzy logic and artificial neural network.

The artificial bee colony (ABC) algorithm is relatively a new swarm intelligence based optimizer [12][13]. Some good properties of ABC has been revealed in[14][16]. Especially, the number of controlling parameters in ABC is less than that of other population-based algorithms, which makes it easier to be implemented. Moreover, the optimization performance of ABC is comparable and sometimes superior to the state-of-the-art meta-heuristics.That is why ABC has aroused interest and has been successfully applied to different kinds of optimization problems [17][19].

This paper presents an application of ANFIS-ABC to predict the wind speed. Where the ABC algorithm is applied to search the optimal parameters of ANFIS structure. The best parameters of membership functions are adjusted again using ABC.

Section II presents an outline of ANFIS structure. Section III introduces the proposed ANFIS-ABC structure. Section IV demonstrates the experimental results. Section V shows the implementation and results of building a wind speed prediction system. Section VI introduces future work and conclusion.

II. ANFIS

ANFIS is an adaptive fuzzy inference system [1]. The architecture of ANFIS is shown in Fig (1). The first two stages of the fuzzy inference process are fuzzifying the inputs and applying the fuzzy operator. The output of Sugeno membership functions are either linear or constant. The rule in a Sugeno fuzzy model has two main components, the antecedent and the consequent parts and has the form
If x_1 is A_{i1} and x_2 is A_{i2}, then y_i is f_i(x)
where x_1, x_2 are the input variables to the ANFIS. A_{i1},...,A_{in} are the linguistic variables of input membership function for the ith rule ($i = 1,2,...,n$) and y_i is the consequent part of ith rule. The fuzzy set A_{ij} at layer one uses a Gaussian membership function for each input variable and it has the form shown in Eq(1)

$$A_{ij}(x) = e^{-(\frac{x_j - m_{ij}}{\sigma_{ij}})^2} \quad (1)$$

where m_{ij} and σ_{ij} are the center and the width of the fuzzy set A_{ij} respectively. The parameters of this layer are the *antecedent parameters*. The output of the fuzzy inference system with n rules is calculated by weighting the real

values of consequent parts of all rules with the corresponding membership grade is shown in Eq(2,3,4)

$$\hat{y} = \sum_{i=1}^{n} (\bar{w}_i f_i) = \frac{w_i}{\sum_{i=1}^{n} (w_i)} \tag{2}$$

where

$$w_i = \prod_{j=1}^{n} A_{ij}(x_i) \tag{3}$$

and

$$y_i = f_i(x) = a_i x_1 + b_i x_2 + c_i \tag{4}$$

where a_i, b_i and c_i are the set of *consequent parameters*.

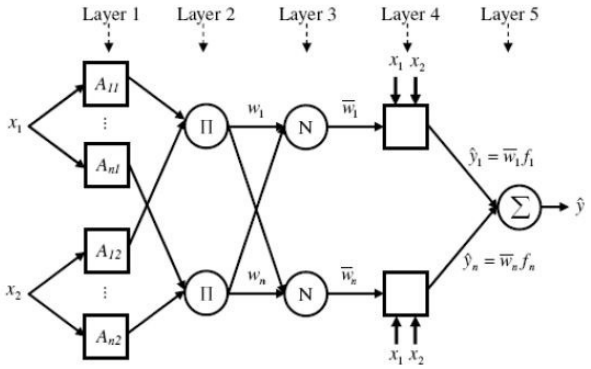

Fig. 1: Sugeno-Type Fuzzy Inference

III. Proposed ANFIS-ABC

In Artificial Bee Colony (ABC), the colony contains three groups: employed bees, onlookers and scouts. The first half of the colony consists of employed bees and the second half contains onlookers. Employed bees search for food sources and share the information about these sources to recruit onlookers. The food sources found by all employed bees are selected and exploited by onlookers according to the probability proportional to the quality of food sources. Scouts are generated from a few employed bees, which abandon their food sources through a predetermined number of cycles called *limit* and search new ones. The position of each food source is a possible solution to an optimization problem, and its fitness is the profitability of that food source. The number of food sources equals to the number of employed bees. Initially, a population containing SN solutions is generated randomly. SN is the number of food sources, which is half of the population size (NP). Let X_i= x_{i1},x_{i2},...,x_{iD} represents the ith food source in the population, where D is the number of optimization parameters. The population is subject to repeated cycles, C=1,2,..., maximum cycle number (MCN), of the search processes of the employed bees, onlookers and scouts. in ABC, the fitness function is defined as Eq(5)

$$fit(X_i) = \begin{cases} \frac{1}{1+f(X_i)} & if \;\; f(X_i) \geq 0 \\ 1 + abs(f(X_i)) & if \;\; f(X_i) < 0 \end{cases} \tag{5}$$

where $f(X_i)$ is the value of objective function of X_i, $fit(X_i)$ is the fitness value of X_i. The probability of a food source being selected by an onlooker can be represented by Eq(6)

$$p(X_i) = \frac{fit(X_i)}{\sum_{n=1}^{SN} fit(X_n)} \tag{6}$$

Afetr discovering or selecting the food source X_i by an employed bee or an onlooker, they exploit a neighboring food source V_i. V_i is determined by changing only one parameter of X_i, where $v_{ij} \neq x_{ij}$, while the rest of V_i keep the same value as X_i, v_{ij} is generated by Eq (7)

$$v_{ij} = x_{ij} + \phi_{ij}(x_{ij} - x_{kj}) \tag{7}$$

where $k \in$ 1,2,..,SN is a random chosen inde and k must be different from from i, $j \in$ 1,2,...,D , ϕ_{ij} is a random number between [-1 , 1]. After determining a new candidate food source in the neighborhood of its currently associated food source using Eq (7) by an employed bee or onlooker , a greedy selection method is used to distinguish between the new food source and the old one. if the abandoned food source is X_i, a scout produces a new food source according to Eq (8)

$$v_{ij} = x_{minj} + rand(0,1)(x_{maxj} - x_{minj}) \tag{8}$$

where x_{minj} and x_{maxj} are the lower and upper bounds of the variable x_{ij}, respectively.

ABC is a possible technique to optimize the parameters of ANFIS. In ANFIS-ABC, ANFIS parameters are considered as one food source that represent a possible solution, and parameters that affect the ANFIS training can be taken as the dimensions of each food source.

Two parameters in ANFIS are to be optimized which are the linguistic hedges p that affect the membership function values and the consequent parameters k that accilerates the performances value.

Denote X as a food source, and let p denotes the set of linguistic hedges of each input where $p \in \{verylow, low, medium, ...\}$. Each linguistic hedge p is presented by gaussian membership function $\mu^{gaussian}$ whose parameters are center m and the width σ as shown in Eq (1). The number of linguistic hedges per input equals the number of ANFIS rules R. Then an algebraic representation of the antecedent parameters is shown in Eq (9).

$$X = \left\{ \mu_{jr}^{gaussian} | r \in R; j \in J \right\} \tag{9}$$

where J is a set of inputs and R is a set of rules that forms ANFIS-ABC.

Let k be denoted as the consequent parameters of each food source. The consequent parameters k of each rule output presents the parameters of a linear membership function μ^{linear} whose the number of parameters equals J+1. Then an algebraic representation of the length of the dimension formed by k is shown in Eq(10).

$$X = \left\{ \mu_{r}^{linear} | r \in R \right\} \tag{10}$$

Because the dimensions of one food source in the ANFIS-ABC has two parameters, then an algebraic representation of that one food source is presented in Eq(11).

$$X = \left\{ (\mu_{jr}^{gaussian}, \mu_{r}^{linear}) | j \in J; r \in R \right\} \quad (11)$$

Fig (2) shows The coding of antecedent and consequent parameters in each food source. The same as ABC, the ANFIS-

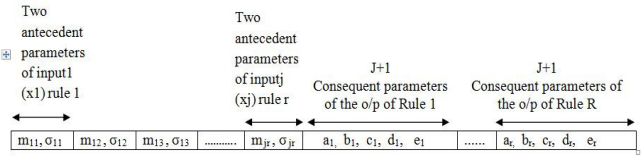

Fig. 2: The coding of ANFIS-ABC source

ABC consists of a number of food sources. Then an algebraic representation of the dimension of each food source in the ANFIS-ABC is represented in Eq (12).

$$X_i = \left\{ (\mu_{ijr}^{gaussian}, \mu_{ir}^{linear}) | j \in J; r \in R \right\} \quad (12)$$

where i=1,2,...N and N is the number of food sources. ANFIS-ABC requires an objective function to minimize which is the root mean square error (RMSE) of ANFIS structure. Eq(13) shows the RMSE calculation.

$$RMSE = \sqrt{\frac{\sum_{i=1}^{s} (\hat{y}_i - y_i)^2}{s}} \quad (13)$$

where y_i is the observed value for the ith observation and $\hat{y}_i$ is the predicted output from fuzzy model, and s is the number of training data pairs. Fig (3) shows the whole ANFIS-ABC model. Fig (4) shows the antecedent part of ANFIS-ABC

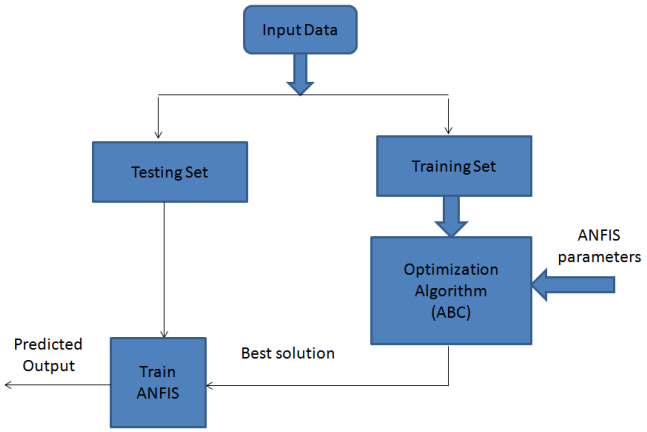

Fig. 3: ANFIS-ABC Structure

parameters and the process of generating a firing strength for each output rule. Fig (5) shows the consequent part of ANFIS-ABC and generating the final crisp output. Fig (6) shows how the objective function (RMSE) of the ANFIS-ABC model is calculated and then converted into fitness value. Fig (7) shows

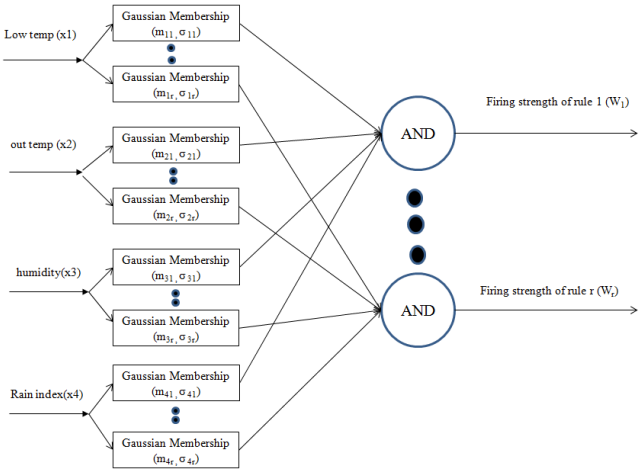

Fig. 4: Antecedent Part of ANFIS-ABC

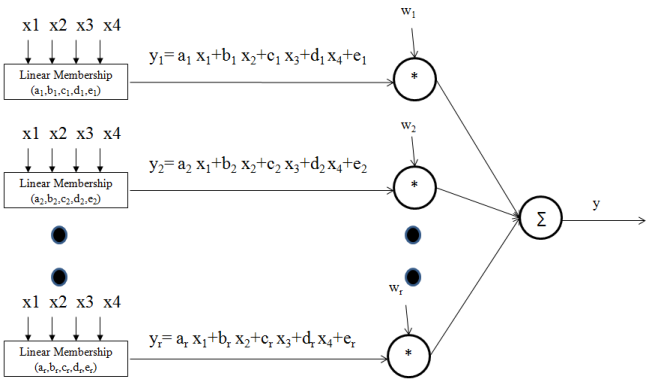

Fig. 5: Consequent Part of ANFIS-ABC

the proposed ANFIS-ABC structure and The main steps of ANFIS-ABC are outlines below as in algorithm 1:

IV. Experimental Results

Seventy percent of the data set is used in training ANFIS-ABC model. The parameters initialization and the achieved results are discussed in this section.

A. Data set description

Each instance of the data set consists of four inputs and only one output. The four inputs are the low temperature, the out temperature, the humidity and the rain index and are represented as ($In1$, $In2$, $In3$ and $In4$). The output value indicates the wind speed. Only 70% of the dataset is used in training the model which constitutes 2128 records out of 3040 records.

B. ANFIS parameters

The ANFIS model parameters are shown in table I. The ANFIS-ABC model was trained four times with different number of rules. In this training procedure, the ANFIS-ABC algorithm is used to optimise both the antecedent parameters

Algorithm 1: Pseudocode of the ANFIS-ABC algorithm

1: set the training dataset to be 70% of the whole data.
2: Initialize ANFIS structure parameters: J, R, Type of Input/Output membership functions.
3: Present the values of ABC parameters: D, SN, MCN, $limit$, $cycle$=1.
4: Form the ANFIS-ABC food sources using Eq (12) and Initialize The ANFIS-ABC food sources using eq (8).
5: ANFIS-evalute(foodsources).
6: **repeat**
7: Produce new solutions food sources for the employed bees using Eq (7) and ANFIS-evalute(foodsources), then apply greedy selection process employed bees'phase.
8: calculate the probability values for food sources using Eq(6).
9: Produce new food sources for the onlookers from the food source X_i selecetd depending on $p(X_i)$ using Eq (7) and ANFIS-evalute(foodsources), then apply the greedy selection process onlookers' phase.
10: Determine the abandoned food source for the scout, if exists, and replace it with a new randomly produced solution using Eq(8) scout's phase.
11: Memorize the best food source achieved so far.
12: $cycle$=$cycle$+1.
13: **until** $cycle$=Maximum Cycle Number (MCN)

Algorithm 2: ANFIS-evalute

1: Build ANFIS structure
2: Input Fuzzification.
3: Calculate firing strength.
4: Calculate summed crisp output.

TABLE II: ABC Parameters

ABC Parameters	
Number of Optimization Parameters (D)	J * R * 2 + R (J+1)
Number of Food Sources (SN)	120
Number of Employed Bees (Ebees)	60
Number of Onlookers (Onbees)	60
limit (L)	round(0.6*D*Ebees)
Maximum Cycle Number (MCN)	300

and the consequent parameters. A Gaussian membership function is used in the input layer and linear membership function is used in the output layer. The number of variables in each food source will depends on the number of parameters of membership function for each input and output. The consequent part of each z_i Suegno ANFIS rule will take the form k_1*$In1$+ k_2*$In2$ + k_3*$In3$ + k_4*$In4$ + k_5. where k_1, k_2, k_3, k_4 and k_5 are the consequent parameters of each rule output.

C. ABC parameters

the ABC parameters are initialized as shown in table II

D. Training ANFIS-ABC system with different number of membership functions

The system has been trained using different number of rules, hence different number of membership functions per input/output. The objective of the training is to obtain the parameters of membership functions that achieve least mean square error value. The results are shown in table III. It is worth to note that the increase in the number of membership functions does not improve the value of RMSE. The case of using four membership functions shows a slight improvement.

V. Wind Speed Prediction System

The optimized ANFIS parameters obtained by ABC are used to build and test a system for wind speed prediction. Thirty percentage of the data is used for testing the prediction

TABLE III: Results of Training ANFIS-ABC model

Training ANFIS-ABC Model

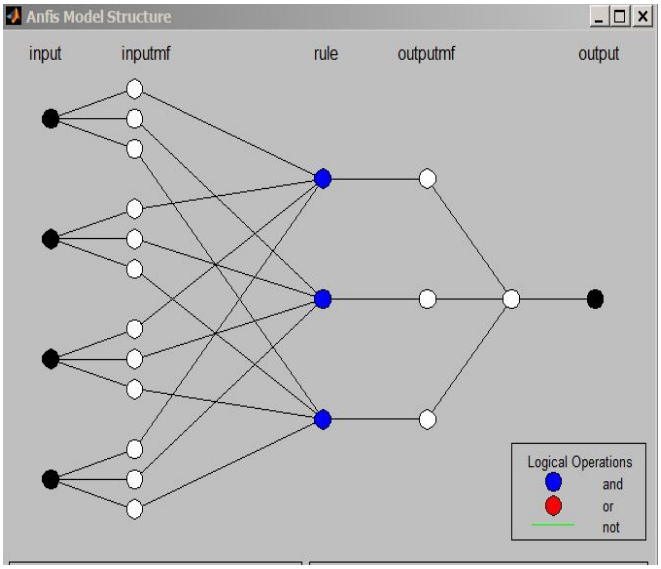

Fig. 8: ANFIS-ABC Structure with three rules

Fig. 9: Wind Prediction with three rules

system. Different number of membership functions are used along with 4 input parameters (low temeperature, out temperature, humidity and rain index). The accuracy of the resulting system is discussed below.

A. Wind Speed Prediction with 3 Membership Functions

Three membership functions means three linguistic variables low,medium and high for the measurements of the values of each input parameter. Fig 8 shows the ANFIS(ABC) structure and Fig 9 shows the generated system which can be used to predict the wind speed (output) by enter four input values corresponding to the input parameters. The average testing error is 0.29 which indicates accuracy with 71%. Fig (4,5) show the ANFIS-ABC structure and output with three rules.

B. Wind Speed Prediction with 4 Membership Functions

Four membership functions means four linguistic variables very low, low, medium and high for the measurements of the values of each input parameter. Fig 10 shows the ANFIS(ABC) structure and Fig 11 shows the generated system which can be used to predict the wind speed (output) by enter four input values corresponding to the input parameters. The average testing error is 0.30 which indicates accuracy with 70%.

C. Wind Speed Prediction with 5 Membership Functions

Five membership functions for each input means five linguistic variables very low, low, medium, high and very high for the measurements of the values of each input parameter. Fig 11 shows the ANFIS(ABC) structure and Fig 12 shows the generated system which can be used to predict the wind speed (output) by enter five input values corresponding to the input parameters. The average testing error is 0.29 which indicates accuracy with 71%.

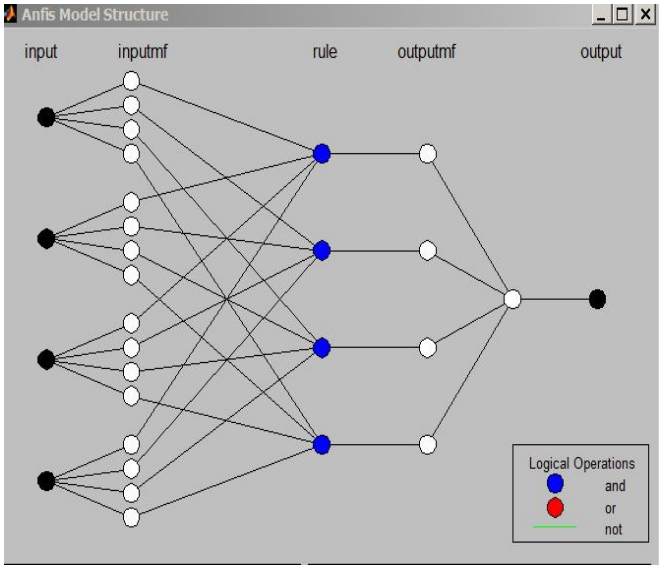

Fig. 10: ANFIS-ABC Structure with four rules

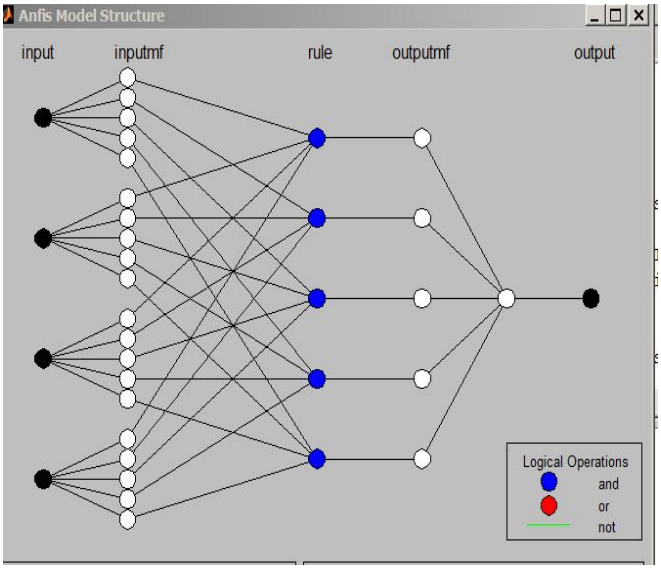

Fig. 12: ANFIS-ABC Structure with five rules

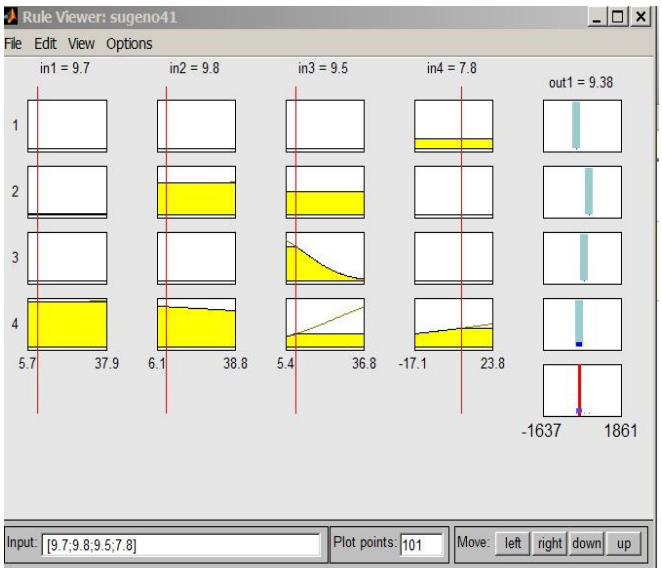

Fig. 11: Wind Prediction with four rules

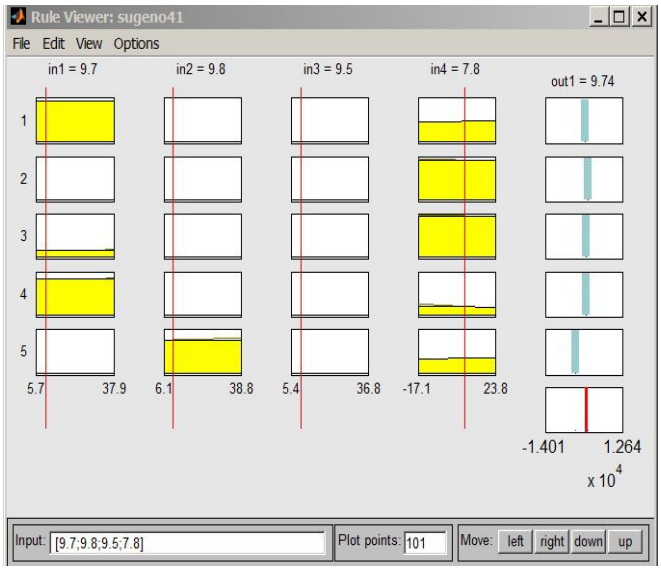

Fig. 13: Wind Prediction with five rules

D. Wind Speed Prediction with 10 Membership Functions

Ten membership functions for each input means Ten different classes for the measurements of the values of each input parameter. Fig 14 shows the generated system which can be used to predict the wind speed (output) by enter four input values corresponding to the input parameters. The average testing error is 0.29 which indicates accuracy with 71%. from the above discussion, It is deduced that the best achieved accuracy is 70% with four membership functions. The increase of membership functions does not improve the accuracy significantly. Table IV shows the summary of achieved results.

VI. Conclusion and Future Works

A new approach for optimising the Sugeno adaptive neuro-fuzzy inference system (ANFIS) in prediction problems has been proposed in this paper. The ABC technique is integrated into the process of ANFIS in order to achieve the optimal solution for ANFIS. This was achieved by simultaneously optimising the ANFIS performance based on a criteria which is enhancing the accuracy based on lower error rate. The experimental results indicated that ANFIS-ABC provides a promised accuracy in prediction problems. However, an algorithm that can result in a complete balance of accuracy and interpretability would be more adaptable for real applications.

TABLE IV: Results of Testing ANFIS-ABC

Results of Testing ANFIS-ABC			
Num of Membership Functions	MAE	MAPE%	Accuracy%
3	0.43	2.6%	97.4%
4	0.33	2.4%	97.6%
5	0.3	1.9%	98.1%
10	0.29	1.8%	98.2%

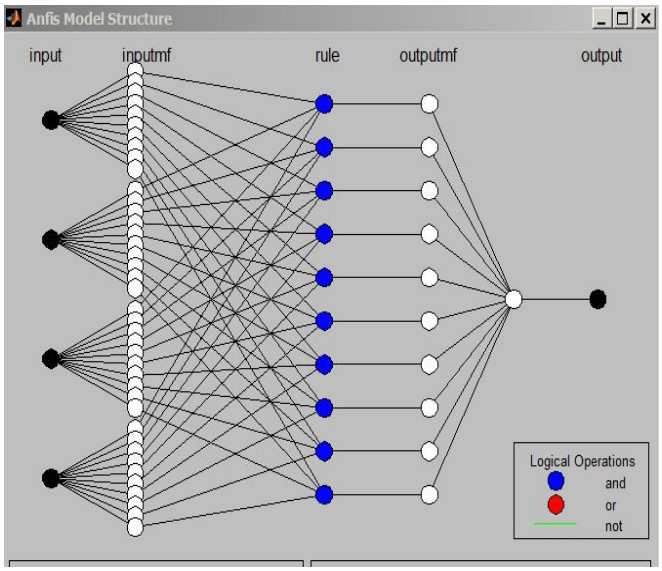

Fig. 14: ANFIS-ABC Structure with ten rules

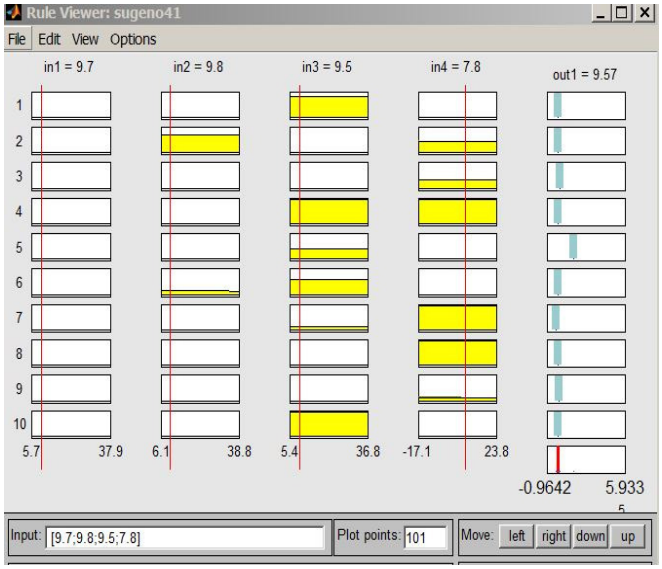

Fig. 15: Wind Prediction with ten rules

Thus, problems based on this approach are the subject of further work by integrating other swarm algorithms.

9th Computer Aspects of Numerical Algorithms

NUMERICAL algorithms are widely used by scientists engaged in various areas. There is a special need of highly efficient and easy-to-use scalable tools for solving large scale problems. The workshop is devoted to numerical algorithms with the particular attention to the latest scientific trends in this area and to problems related to implementation of libraries of efficient numerical algorithms. The goal of the workshop is meeting of researchers from various institutes and exchanging of their experience, and integrations of scientific centers.

TOPICS

- Parallel numerical algorithms
- Novel data formats for dense and sparse matrices
- Libraries for numerical computations
- Numerical algorithms testing and benchmarking
- Analysis of rounding errors of numerical algorithms
- Languages, tools and environments for programming numerical algorithms
- Numerical algorithms on coprocesors (GPU, Intel Xeon Phi, etc.)
- Paradigms of programming numerical algorithms
- Contemporary computer architectures
- Heterogeneous numerical algorithms
- Applications of numerical algorithms in science and technology

***Abstract*—In this article we evaluate some strategies of parallelizing nested loops on Intel Xeon Phi on the example of the WZ factorization for dense matrices. We employ both parallelism and vectorization to accelerate nested loops on manycore coprocessor.**

For random dense square matrices with the dominant diagonal we report the execution time and the performance of the nested loops. Numerical experiments show that the vectorization that is efficiently exploiting SIMD vector units do not always improve the application performance on the coprocessor.

I. Introduction

MANYCORE computers with shared memory are used to solve the computational science problems. One of the machines with manycore architecture is Intel Xeon Phi [8], [9], which is based on Intel's Many Integrated Core (MIC). Intel Xeon Phi has got over 60 cores, hardware threading capabilities and wide vector units (VPU).

To implement parallel programs on manycore systems with shared memory, in particular on Intel Xeon Phi, programmers can use the OpenMP standard [12] as for the traditional multicore processors. The programming model provides a set of directives to explicitly define parallel regions in applications. The compiler translates these directives. One of its most interesting features in the language is the support for the nested parallelism.

In the scientific applications, loops are an important source of the parallelism — nested loops, in particular. Parallelizing nested loops require the programmer to make a decision about applying some strategies of the parallelization and the vectorization.

The research of the parallelization of nested loops have been undertaken by different scientists.

In the work [10], the authors study five different models for the nested parallel loops execution on shared-memory manyprocessors and show a simulation-based performance comparison of different techniques using a real application. The possibility to take advantage of the parallelism in nested parallel loops with the use of good scheduling and synchronization algorithms is described.

An automatic mechanism to dynamically detect the best way to exploit the parallelism when having nested parallel loops is presented in the study [5]. This mechanism takes into account the number of threads, the size of the problem, the number of iterations in a loop and it was implemented inside the IBM XL runtime library. That paper examined (among others) an LU kernel, which decomposes the matrix $\mathbf{A}$ into the matrices: $\mathbf{L}$ (a lower triangular matrix) and $\mathbf{U}$ (an upper triangular matrix).

An algorithm for finding good distributions of threads to tasks is provided and the implementation of the nested parallelism in OpenMP is discussed in the paper [1].

The focus of [7] was to investigate the possibility of dynamically choosing, at runtime, the loop which utilizes the available threads the best.

One of the direct methods of solving a dense linear system is to factorize the matrix into some simpler matrices — it is its decomposition into factor matrices of a simpler structure or of some specific properties — and then solving simpler linear systems. The most known factorization is the LU factorization (mentioned above). Another form of the factorization is the WZ factorization. In the work [2] we investigated four strategies of parallelizing nested loops on multicore architectures on the example of the WZ factorization [3], [6], [11]. We dealt with the following parallelism strategies for nested loops: *outer*, *inner*, *nested* and *split*.

For random dense square matrices with the dominant diagonal we reported the execution time, the performance, the speedup of the WZ factorization for these four strategies of parallelizing nested loops and we investigated the accuracy of such solutions. The *outer* and *split* approaches achieved the best speedup.

The goal of this paper is to study parallelized nested loops on Intel Xeon Phi. We research only two strategies, namely: *outer* and *split* due to their best results for multicore architectures. The efficient parallelizing of a nested loop is very difficult on Intel Xeon Phi because we must employ both a large number of threads and wide vector units available in Intel Xeon Phi. For the thread-level parallelism we use OpenMP [12], [4].

The OpenMP standard supports the loop parallelism. For the OpenMP standard, it is done by the utilization of the directive `#pragma omp parallel for`, which provides a shortcut for specifying a parallel region that contains a single `#pragma omp for`. We scale nested loops to a large number of threads and choose a good load balancing. The division of the work among threads is controlled with the

978-83-60810-90-3/$25.00

`schedule` clause.

We provide enough work for the coprocessor and we also try to efficiently exploit 512-bit vectors on Intel Xeon Phi using adequate pragmas.

The paper deals with the following issues: In Section II it describes the main characteristics of the Intel Xeon Phi architecture. Section III provides some information about some strategies of parallelizing nested loops and their application to the original WZ factorization. Section IV presents the results of our experiments. The time, the speedup, the performance of the WZ factorization for different strategies on Intel Xeon Phi are analyzed. Section V is a summary of our experiments.

II. Intel Xeon Phi architecture

Intel Xeon Phi [9] coprocessors are one of the state-of-the-art architectures which goal is to execute parallel codes. Intel Xeon Phi is a manycore coprocessor created on the basis of the Intel MIC (Many Integrated Cores) technology. The first generation the Intel MIC architecture is based on the Knights Corner chips. Many redesigned Intel CPU cores are connected by a bi-directional 512-bit ring bus. The cores are enriched with 64-bit instructions and the L1 and L2 cache memories. Each of the cores contains a vector processing unit (VPU), which together with 32 512-bit vector registers allows to process many data with the use of one instruction (SIMD instructions).

A single Intel Xeon Phi has 61 cores of 1,238 GHz frequency and it serves 244 threads and communicates through PCI-Express 2.0.

Intel Xeon Phi enhances the performance of applications written in the C/C++ and Fortran languages. The Intel company offers a set of programming tools assisting programming processes such as compilers, debuggers, libraries, that allow creating parallel applications (e. g. Pthread, OpenMP, Intel Cilk plus, MPI). Intel Xeon Phi is able to use standard parallel programming models such as OpenMP.

The Intel Xeon Phi coprocessors can work in two executing modes: the native mode or the offload mode (for one Intel Xeon Phi).

In the native mode the task is executed directly by a coprocessor, which makes it a separate computing node. The compilation of the source code for the accelerator architecture demands so-called cross-compiling, which produces a file executable on Intel Xeon Phi. The native application can be started by hand on the coprocessor or by the *micnativeloadex* tool which automatically copies the program together with necessary files and then starts it.

III. Nested loops parallelization

An application with nested loops can be performed in parallel in different ways depending on compilers, hardware and run-time system support available. Nested loops require a programmer to take a decision concerning details of the parallelism. Nested loops can have a few levels of the parallelism. The outermost loop contains other loops. Next, each of these loops may also consist of loops. It is a reason for the increased complexity of the implementation.

Frequently, the parallelization is applied to the outer loop levels and the vectorization to the inner levels. If you are certain that the vectorization is a safe alternative (gives the same results as the non-vectorized code) in a particular loop where the compiler itself does not vectorize, using `#pragma simd` often provides the best and the most predictable benefits.

In this work we deal with the following parallelization strategies for the nested loops:

1) *outer*;
2) *split*.

All variables used in a parallel region are by default `shared`; in each strategy we declare explicitly all variables as `private` or `shared` for all directives respectively. Using the `private` clause, we specify that each thread has its own copy of variables.

To ensure a good load balancing for all threads we use the `schedule` clause, which specifies how the iterations of the loop are assigned to the threads. In the directive `#pragma omp parallel for` in the clause `schedule` we set values `static` or `dynamic`. We research the impact of this clause on the efficiency.

A. Outer

Outer — the simplest parallelization strategy of nested loops is the parallel execution of the outermost loop (not counting the loop which cannot be parallelized). This approach gives good results if the number of iterations in a loop is big and the iteration's granularity is coarse enough.

Figure 1 presents a listing of the outer strategy for the WZ factorization. The outermost k-loop cannot be parallelized. However, we can parallelize the i-loop. In this simple parallelization strategy the loop is divided equally between threads using both the static and dynamic scheduler.

Figure 2 also presents a listing of the outer strategy for the WZ factorization with the use of the vectorization. Again the outermost k-loop cannot be parallelized, however, we can parallelize the i-loop. The loop is divided equally between threads. The inner loop is vectorized. The compiler is unable to automatically vectorize the inner loop due to the vector dependences. To vectorize this code we use `#pragma simd`.

B. Split

The second (and final) strategy consists in the division of the i-loop into two separate loops and we denote it by *split*. Figure 3 shows a listing of the *split* strategy for the WZ factorization. The first loop is parallelized. The second loop is a nested loop and we execute only its outer loop in parallel.

Figure 4 also shows a listing of the *split* strategy for the WZ factorization. Here, the first loop is parallelized. The second loop is a nested loop and we execute its outer loop in parallel and we vectorize it at the same time. For the OpenMP standard, it is done by the utilization of the directive `#pragma omp parallel for simd`, which provides a shortcut for

```
for (k=1; k<=n/2-1; k++) {
  k2=n-k+1;
  det=a[k2,k]*a[k,k2]-a[k,k]*a[k2,k2];
#pragma omp parallel for default(none) private(i,j) shared(w,k,k2,n,a,det) \
schedule(static/dynamic)
  for (i=k+1; i<=(k2-1); i++) {
    w[i,k]=(a[k2,k] * a[i,k2] - a[k2,k] * a[i,k])/det;
    w[i,k2]=(a[k,k2] * a[i,k]-a[k,k] * a[i,k2])/det;
    for (j=k+1; j<=k2-1; j++)
        a[i,j]=a[i,j] - w[i,k]*a[k,j] - w[i,k2] * a[k2,j];
  }//for i
}//for k
```

Fig. 1. A fragment of the WZ factorization algorithm — the outer strategy with the static or dynamic scheduler without the vectorization

```
for (k=1; k<=n/2-1; k++) {

schedule(static/dynamic)
  for (i=k+1; i<=(k2-1); i++) {
    w[i,k]=(a[k2,k]*a[i,k2]-a[k2,k2]*a[i,k])/det;
    w[i,k2]=(a[k,k2]*a[i,k]-a[k,k]*a[i,k2])/det;
  }
#pragma omp parallel for simd default(none) shared(k2,k,a,w) private(i,j) \
schedule(static/dynamic)
  for (i=k+1; i<=(k2-1); i++) {
    for (j=k+1; j<=k2-1; j++)
      a[i,j]=a[i,j]-w[i,k]*a[k,j]-w[i,k2]*a[k2,j];
  }
}//for k
```

Fig. 4. A fragment of the WZ factorization algorithm — the split strategy with the static or dynamic scheduler with the parallelization of the first loop and with the parallelization and the vectorization of the second outer loop

specifying a parallel region that contains a single `#pragma omp for simd`.

Figure 5 shows a listing of another version of the *split* strategy for WZ factorization. The first loop is parallelized. The second loop is a nested loop and we execute the outer loop in parallel and we vectorize the inner loop using `#pragma simd`.

IV. Numerical experiments

In this section we show how we tested the time and the performance of the parallelized nested loops for Intel Xeon Phi. Our intention was to investigate different nested loops parallelization strategies for nested loops on manycore architectures. We examined 10 versions of the parallelized nested loops:

1) *outer*:
   - *static* (Figure 1),
   - *dynamic* (Figure 1),
   - *static+simd* (Figure 2),
   - *dynamic+simd* (Figure 2);
2) *split*:
   - *static* (Figure 3),
   - *dynamic* (Figure 3),
   - *static+forsimd* (Figure 4),
   - *dynamic+forsimd* (Figure 4)
   - *static+simd* (Figure 5),
   - *dynamic+simd* (Figure 5).

The input matrices were generated (by the authors). They were random, dense, square matrices with a dominant diagonal of even sizes (1000, 2000, ..., 12000).

A. Test environment

The tests were carried out using a computing node of the following parameters:

- Platform: Intel Server Chassis R2000WTXXX, Intel Server Board S2600WT2.
- CPU: 2×Intel Xeon E5-2670 v3 (2x12 cores, 2.3 GHz).
- Memory: 128 GB DDR4 2133MT/s (8×Crucial CT16G4RFD4213).
- Network card: FDR InfiniBand ConnectX-3 Mellanox AXX1FDRIBIOM (FDR 56GT/S).
- Coprocessor: Intel Xeon Phi Coprocessor 7120P.
- Software: Intel Parallel Studio XE 2016 Cluster Edition for Linux (Intel C++ Compiler, Intel Math Kernel Library, Intel OpenMP).

The algorithms were implemented with the use of the C language and with the use of the double precision. Our codes were compiled by INTEL C Compiler (icc) with the optimization flag `-O3` and with the cross-compiling option `-mmic`. Additionally, all algorithms were linked with the OpenMP library. To run the native executable on the co-processor, the `micnativeloadex` command was used. We set the number of threads using the environment variable `OMP_NUM_THREADS`.

B. The run-time

All the processing times are reported in seconds. The time was measured with the OpenMP function `open_get_wtime()`. They were tested in the double precision.

In Figures 6 and 7 we have compared the average running time of the four versions of the *outer* strategy on Intel Xeon Phi.

Figure 6 shows the dependence of the time on the number of threads for the matrix of the size 12000 on Intel Xeon Phi.

Figure 7 shows the dependence of the time on the matrix size for 240 threads on Intel Xeon Phi.

In Figures 8 and 9 we have compared the average running time of the six versions *split* strategy on Intel Xeon Phi.

```
for (k=1; k<=n/2-1; k++) {
  k2=n-k+1;
  det=a[k2,k]*a[k,k2]-a[k,k]*a[k2,k2];
#pragma omp parallel for  default(none) private(i) shared(k2,k,w,n,a,det) \
schedule(static/dynamic)
   for (i=k+1; i<=(k2-1); i++) {
     w[i,k]=(a[k2,k]*a[i,k2]-a[k2,k2]*a[i,k])/det;
     w[i,k2]=(a[k,k2]*a[i,k]-a[k,k]*a[i,k2])/det;
    }
#pragma omp parallel for default(none) shared(k2,k,a,w) private(i,j) \
schedule(static/dynamic)
   for (i=k+1; i<=(k2-1); i++) {
#pragma simd
     for (j=k+1; j<=k2-1; j++)
       a[i,j]=a[i,j]-w[i,k]*a[k,j]-w[i,k2]*a[k2,j];
   }
}//for k
```

Fig. 5. A fragment of the WZ factorization algorithm — the split strategy with the static or dynamic scheduler with the parallelization of the first loop and the second loop and with the vectorization of the second outer loop and with vectorization of the inner loop

Figure 8 shows the dependence of the time on the number of threads for the matrix of the size 12000 on Intel Xeon Phi.

Figure 9 shows the dependence of the time on the matrix size for 240 threads on Intel Xeon Phi .

Figure 10 shows the dependence of the time on the number of threads for the matrix of the size 12000 on Intel Xeon Phi comparing the best of the *outer* and *split* strategies.

Figure 11 shows the dependence of the time on the matrix size for 240 threads on Intel Xeon Phi comparing the best of the *outer* and *split* strategies.

Using obtained results we conclude that:

- The *outer* strategy gives better results without the vectorization.
- For the *split* strategy the best results were obtained for the *static+forsimd* version (Figure 4).
- The *split* strategy achieves better execution time than the *outer* strategy.
- The worse execution time was achieved for the *outer* strategy in the *static+simd* version (Figure 2).
- The choice of the scheduler usually makes small differences in the execution time.
- If the size of the matrix is increased, then the runtime is increased too and it may become more profitable to use a big number of threads.
- Our approaches (both *outer* and *split* strategies) are scalable to a large number of threads.

C. The performance

Figures 12 and 13 compare the performance (in Gflops) results obtained for both the *outer* and the *split* strategies — in double precision on Intel Xeon Phi. The performance is based on the number of floating-point operations in the WZ factorization, namely:

$$\sum_{k=1}^{\frac{n}{2}-1}\left(3+\sum_{i=k+1}^{n-k}\left(8+\sum_{j=k+1}^{n-k}4\right)\right)=\frac{4n^3-7n-18}{6}.$$

Figure 12 shows the dependence of the performance (of the best algorithms of both strategies) on the size of the matrix for 240 threads.

Figure 13 shows the dependence of the performance (of the best algorithms of both strategies) on the number of threads for the matrix size of 12000.

We can see that the best performance (about 11 Gflops) is achieved by the *split* strategy for the matrix of the size 12000 for 240 threads, and worst (less than 2 Gflops) is for the *outer* strategy for the smallest sizes. The performance increases fast with the growth of the number of threads.

V. Conclusion

In this paper we examined several practical aspects of the nested parallel loop execution on Intel Xeon Phi. Our approach exploits the thread-level and SIMD parallelism of the Intel Xeon Phi coprocessor. We used different strategies for executing nested parallel loops on the examples of the WZ factorization.

Both the *outer* and the *split* algorithms exploited the available number of threads. The *split* strategy achieves the best performance. The performance of 11 Gflops was achieved for 240 threads on Intel Xeon Phi. The implementation of the *split* strategy presented in this paper achieves high performance results, which has a direct impact on the solution of linear systems. Using the split strategy can help programmers with loop parallelization in multithreading environments.

This paper is another example of the successful use of OpenMP for solving scientific applications on Intel Xeon Phi.

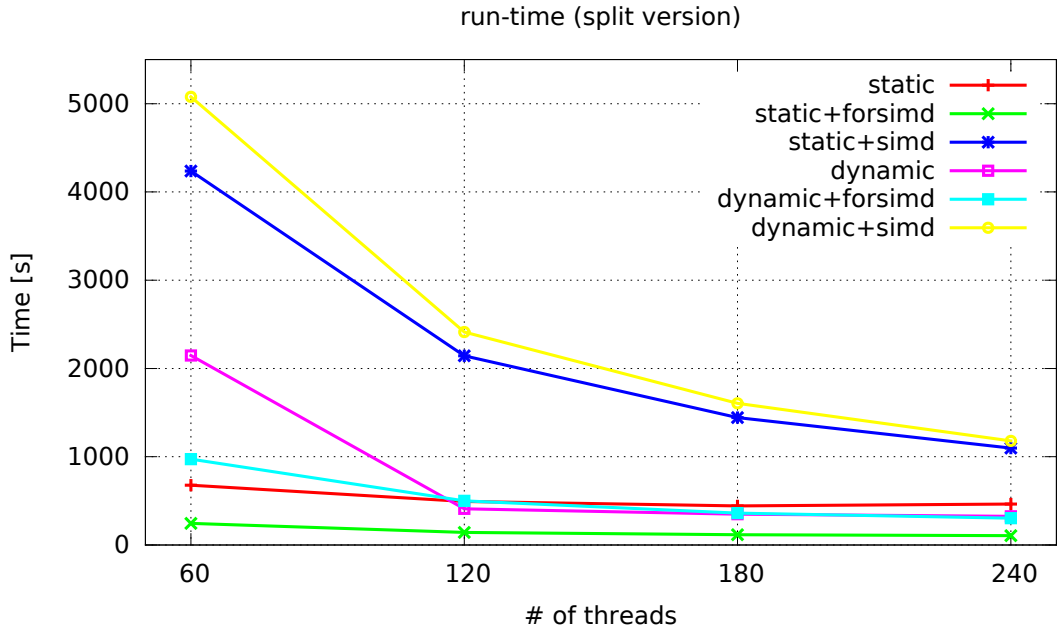

Fig. 8. The average running time of the WZ matrix decomposition as a function of the number of threads — for the *split* strategy using the double precision on Intel Xeon Phi for the matrix of the size 12000.

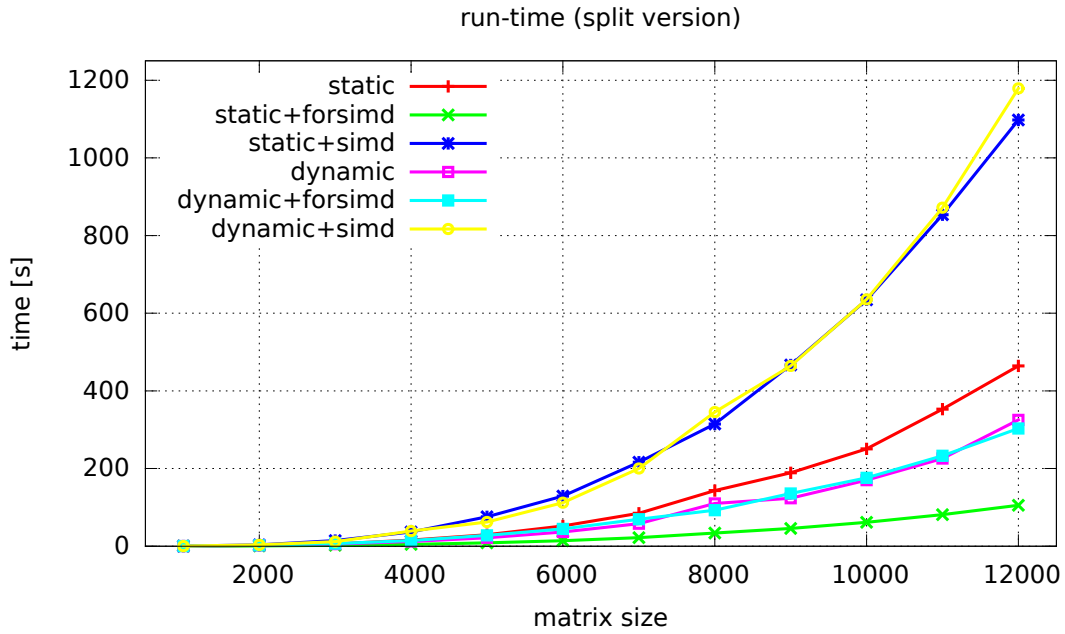

Fig. 9. The average running time of the WZ matrix decomposition as a function of the matrix size — for the *split* strategy for 240 threads on Intel Xeon Phi

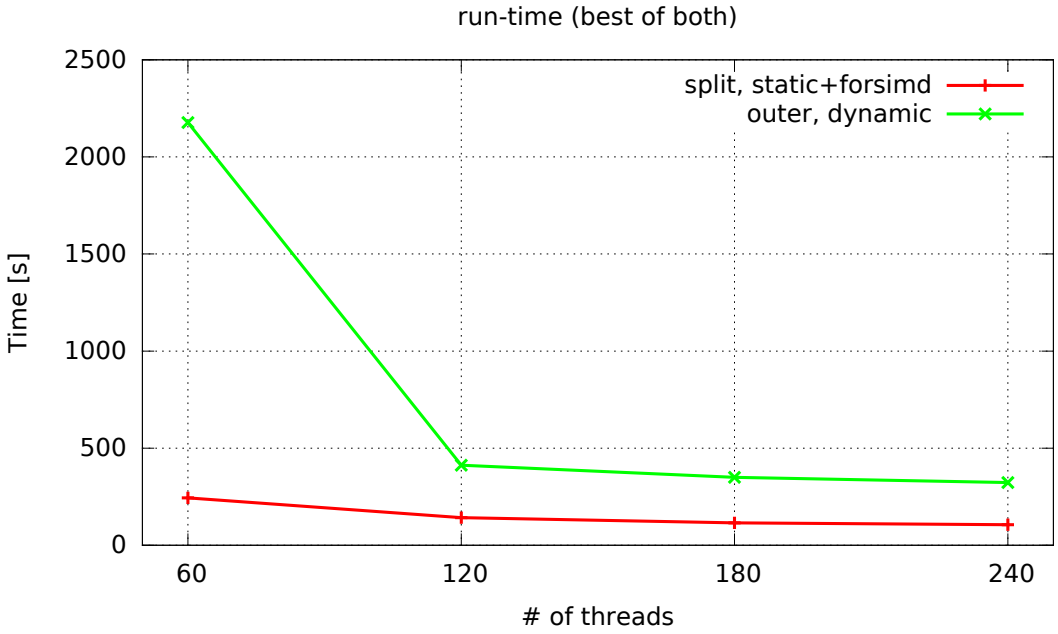

Fig. 10. The average running time of the WZ matrix decomposition as a function of the number of threads — the best of the *split* and *outer* strategies for the matrix of the size 12000

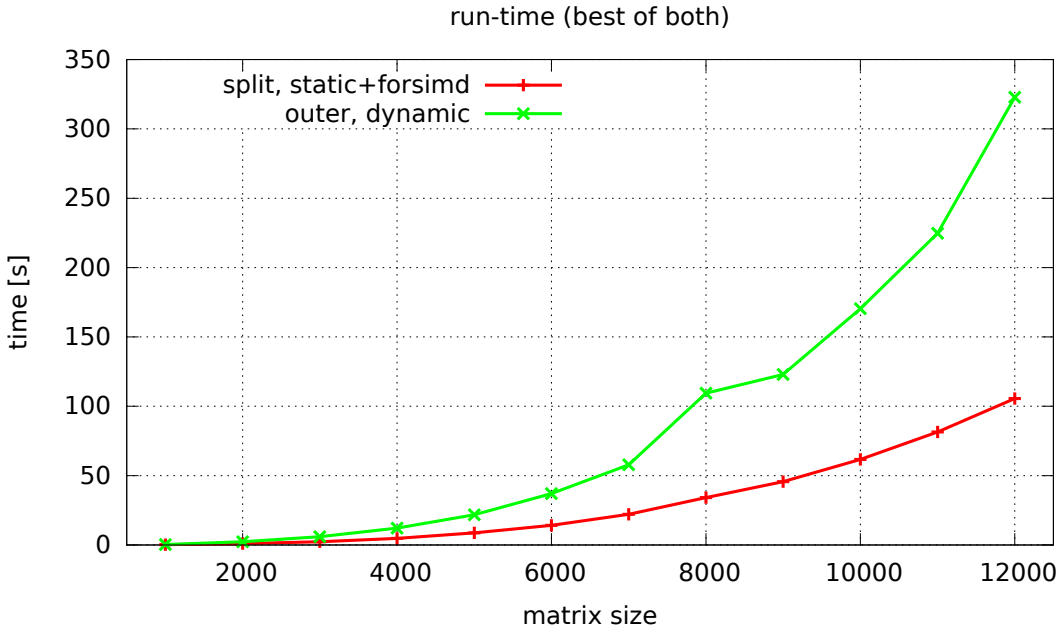

Fig. 11. The average running time of the WZ matrix decomposition as a function of the matrix size — the best of the *split* and *outer* strategies for 240 threads

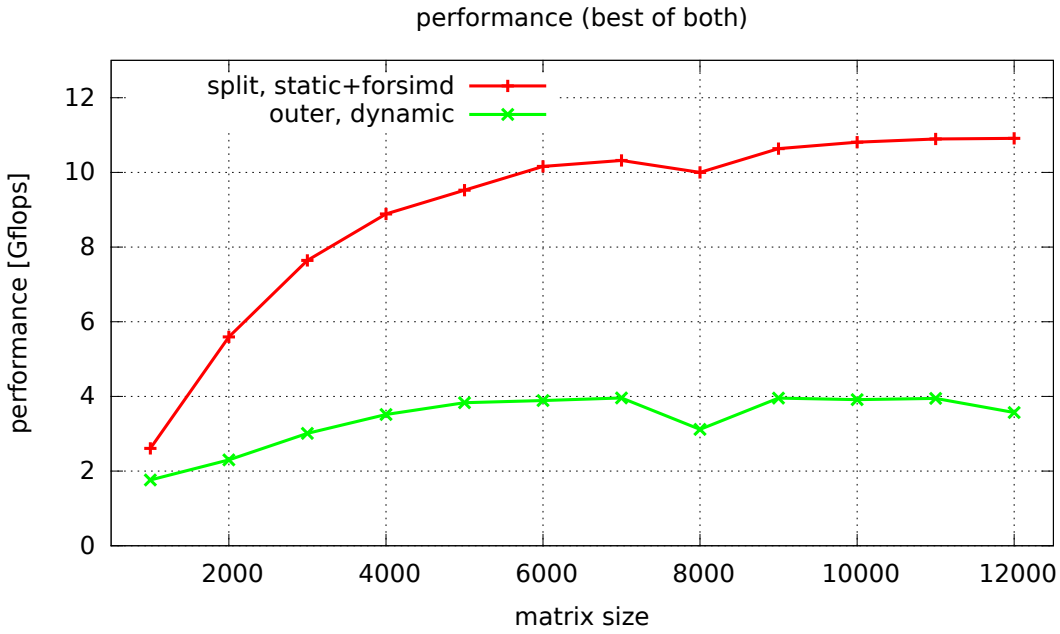

Fig. 12. The performance results for nested loops — for 240 threads for the best of both strategies as a function of the matrix size

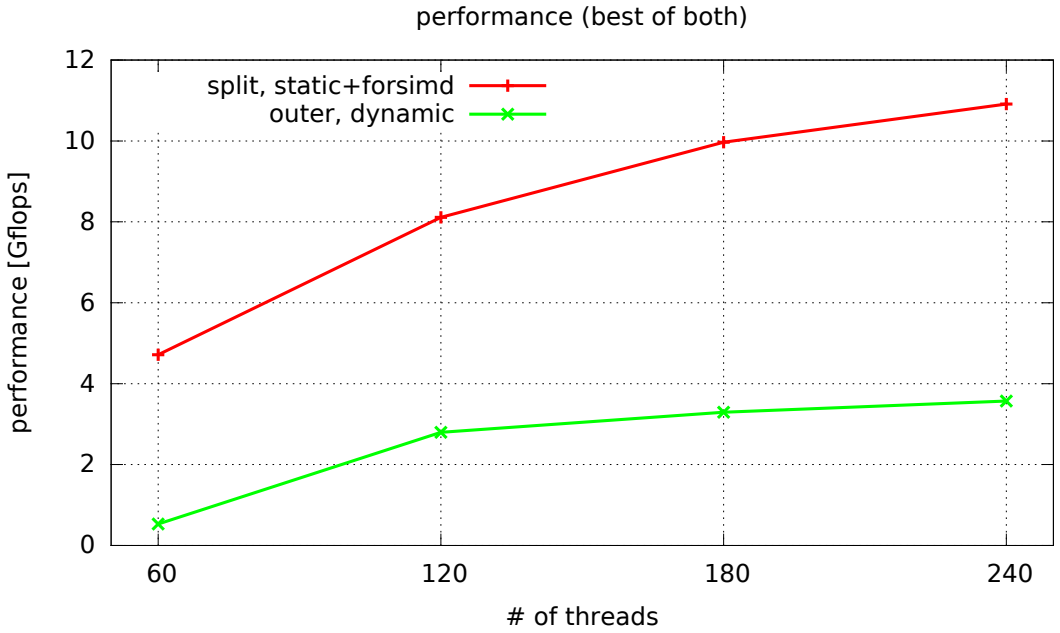

Fig. 13. The performance results for nested loops — for the matrix of the size 12000 for the best of both strategies as the function of number of threads

This paper is also example that the vectorization is not always the only key to achieving high performance on Intel Xeon Phi architecture.

The achieved results provide the basis for the further research on optimization of nested loops using the loop tiling technique in such a way that a data element used once is reused as soon as possible. Another field of further research is the use of thread affinity strategies which allow improving the performance and the scalability of our solution.

***Abstract*—We employ Intel Xeon Phi as a high-performance coprocessor to solve Markov chains. Matrices arising from Markov models are very sparse with short rows. In this paper, the authors research two storage formats of Markov chain transition matrices on Intel Xeon Phi. In this work CSR and HYB (modification ELL) formats for such matrices are studied. Numerical experiments results for transition matrices of Markov chains from wireless networks and call-center models show that HYB format in offload version is more effective than CSR format. The obtained performance for HYB format is even `1.45` times better in comparison to multi-threaded CPU (dual Intel Xeon E5-2670) with the use of the CSR format (SpMV from the MKL library on CPU).**

I. Introduction

MARKOV chains are a tool for modeling various natural complex systems as well as computer systems and networks. Lately, they have been used to model wireless networks [3], [5], [6] and they often appear in computational biology [10] as well as in modeling call-centers [9].

In Markov modeling the models are very large because of exponential explosion of the states number, which happens due to the fact that complex systems usually consist of a certain number of subsystems and the states' space size of the whole complex system is usually exponentially dependent on the number of subsystems.

Any Markov chain can be described in terms of linear algebra with the use of a square matrix. A transition rate matrix $\mathbf{Q}$ (describing a Markov chain which models a system or a phenomenon) has some particular properties. It is a huge one and very sparse (with short rows). Sparse matrices are stored in special data structures and special algorithms are used to process these structures optimally. We can find descriptions of many such storage schemes in the literature (e.g. [14], [4], [2]).

The problem of efficiency of the sparse matrix-vector multiplication operation (SpMV) on Intel Xeon Phi was considered in [13], [12], [8]. In paper [13], the performance of the Intel Xeon Phi coprocessor for SpMV is investigated. One of the studied aspects in this work is CSR format for the sparse matrices. The authors showed that this format is not suited for Intel Xeon Phi for very sparse matrix (with short rows) in particular. The use of OpenMP based parallelization on Intel MIC (Intel Many Integrated Core Architecture) was evaluated in [8]. An efficient implementation of SpMV on the Intel Xeon Phi coprocessor by using a specialized ELLPACK-based format with load balancing is described in [12]. This implementation outperforms the implementation using CSR format even for matrices with very short rows.

The aim of this work is to shorten the computation time for the transition matrices from Markovian models of complex systems on Intel Xeon Phi by way of application of two data structures to store sparse matrices. Namely, CSR format will be used as in the works of [13], [8] and HYB format (as ELLPACK modification) similar as in the work [12]. HYB format was analyzed on GPU [7] and was much more effective than CSR for Markov chains.

Sparse matrix-vector multiplication (SpMV) operation on Intel Xeon Phi is implemented for these formats using the thread-level and the SIMD parallelism. Next, these SpMV's implementations are employed to the explicit fourth-order Runge-Kutta method. The numerical experiments were conducted for two groups of transition rate matrices, namely for a model of a call-center and a model of a wireless network on Intel Xeon Phi. A comparative analysis is also done with the CSR format from the Intel MKL library (Intel Math Kernel Library) on multithread CPU (dual Intel Xeon E5-2695).

The structure of the article is the following. Section II gives characteristics of the sparse matrix storage, chiefly CSR and HYB formats. Sections III and IV contain a description of the explicit fourth-order Runge-Kutta method and some details of its implementation on Intel Xeon Phi in particulary sparse matrix-vector multiplication operation (SpMV). Section V analyzes Intel Xeon Phi's performance on this kernel for two data structures (CSR and HYB). Section VI presents conclusions.

II. Storage of a sparse matrix

In the literature [14], a lot of ways which represent sparse matrices and enable their effective storage and processing have been suggested.

One of the formats to store any sparse matrices is *Compressed Sparse Row* (CSR). The operations on matrices stored in this format are part of Intel MKL library in version on Intel MIC architecture [11]. In this format, the information about $\mathbf{A}$ matrix, where $\mathbf{A}$ is a sparse matrix of $m \times n$ size and nz nonzero elements, is stored in three one-dimentional arrays:

- $data[\cdot]$, of nz size stores values of nonzero elements (in increasing order of row indices);
- $col[\cdot]$, of nz size stores column indices of nonzero elements (in order conforming to the data array content);

978-83-60810-90-3/$25.00

- $ptr[\cdot]$, of $m+1$ size, stores indices of beginnings of successive rows in $data$ array — that is $data[ptr[i]]$ is the first nonzero element of i-th row in $data$ array, similar, $col[ptr[i]]$ is the column number of this element.

Hybrid format (HYB) comprises of two other formats of sparse matrix storage in the memory disregarding its weaknesses and simultaneously making use of its advantages: COO format (*Coordinate format*) and ELLPACK package format (ELL).

ELLPACK [1] package format (ELL) is a sparse matrix format which is helpful in vector architecture. It is useful for matrices in which the number of the elements in almost every row is the same, especially when many rows reach maximum length in a given matrix or approach it, it becomes useless when the number of elements in a row is dispersed, e.g. when there are many rows which are longer than the mean. In this format the sparse matrix is stored in two two-dimensional arrays.

In HYB format the matrix is stored in two two-dimensional arrays (ELL) and three one-dimensional arrays (COO):

- $ell\_data[\cdot]$ stores values of nonzero elements as two-dimensional rectangular array of $M \times MNNZ$ size, where M is the number of rows in the matrix and $MNNZ$ denotes the mode of number of nonzero elements in a row. The rows with fewer nonzero elements than $MNNZ$ are aligned to the left and filled with zero (meaningless) values in the remaining part, while the longer rows are cut off.
- $ell\_indices[\cdot]$ stores column indices of a matrix elements placed appropriately in $ell\_data[\cdot]$. The size and the structure of this array is the same as $ell\_data[\cdot]$.
- $coo\_data[\cdot]$ stores nonzero elements values, which were cut off from $ell\_data[\cdot]$.
- $coo\_col[\cdot]$ stores column indices of nonzero elements from $coo\_data[\cdot]$ (in the same order as $coo\_data[\cdot]$).
- $coo\_row[\cdot]$ stores row indices of nonzero elements from $coo\_data[\cdot]$ (in the same order as $coo\_data[\cdot]$).

III. Parallel Runge-Kutta algorithm

General form explicit fourth-order Runge-Kutta method in parallel version is presented as Algorithm 1.

The implementation of the Algorithm 1 contains our implementation of SpMV operation and vector addition. We use the OpenMP standard and the `for` directives to parallelize all operations. We use a `static` scheduler for the distribution of the matrix rows and the values of vector. The SpMV operation is a simple task to assign a row block to a single thread in a parallel execution. The idea of vectorization is to process all the nonzero elements in row at once. Since the Intel Xeon Phi architecture has 32 512-bit registers, the matrices should have at least 8 values in each row to fully utilize the register. For one-row block we use a pragma compilator `#pragma simd` which enforces vectorization of the inner loops. This vectorization is not effective because our matrices have got short rows — shorter than 8 elements (see table I).

Algorithm 1 The parallel algorithm which determines the transient probabilities vector, where $*$ operation denotes parallel sparse matrix-vector multiplication and $+$ operation denotes parallelized and vectorized vector addition

Require: Q^T — transition rate matrix, pi_0 — initial probability vector, h — step, t — time
Ensure: vector of transient probabilities pi_t in the time t

$lk \leftarrow t/h$
$pi_t \leftarrow pi_0$
for $k = 1$ to lk **do**
  $k_1 \leftarrow Q^T * pi_t$
  $k_2 \leftarrow Q^T * (pi_t + \frac{h}{2} k_1)$
  $k_3 \leftarrow Q^T * (pi_t + \frac{h}{2} k_2)$
  $k_4 \leftarrow Q^T * (pi_t + h k_3)$
  $pi_t = pi_t + \frac{h}{6} \cdot (k_1 + 2k_2 + 2k_3 + k_4)$
end for
return pi_t

IV. Numerical experiment

In this section we tested the time, the speedup and the performance of the explicit fourth-order Runge-Kutta method (RK4). The programs were implemented in C++ language and three implementations of this algorithm were created:

- MKL-CSR version — it is a version using parallelism and vectorization offered by the function of the Intel MKL library in the version of Intel MIC architecture, where the sparse matrix was stored in CSR format.
- CSR version — it is a version, where the sparse matrix was stored in CSR format; all vector and matrix operations were implemented by the authors.
- HYB version — it is a version, where the sparse matrix was stored in HYB format; all vector and matrix operations were implemented by the authors.

The impact of the program execution mode (native and offload) and the various numbers of threads were tested.

For each version, the program was compiled by using the Intel C++ compiler (`icc`) with a compiler flag `-O3`, which resulted in automatic computing vectorization, `-openmp`, `-mmic` (enabling the cross compilation needed for a native execution on Intel Xeon Phi). Additionally, during development, we used the flag `-vec-report2` to verify whether the RK4 kernel was successfully vectorized. In every case, alignment of the memory data was used as vectorization support; the data were aligned with 64 bytes limit, which was recommended by the documentation. `-mkl` option was also used to allow introducion of parallelism in MKL-CSR version. Intel MKL library was applied to measure the elapsed time.

In the table I, the properties of matrices used during the test are given: WF1, WF2 describe wireless networks, CC1, CC2 describe the call-center.

The matrices we tested are very sparse, however, the pattern varies in dependence on the model (table I). L_i, $1 \leq i \leq n$, denoted the number of nonzero elements per row. CC matries

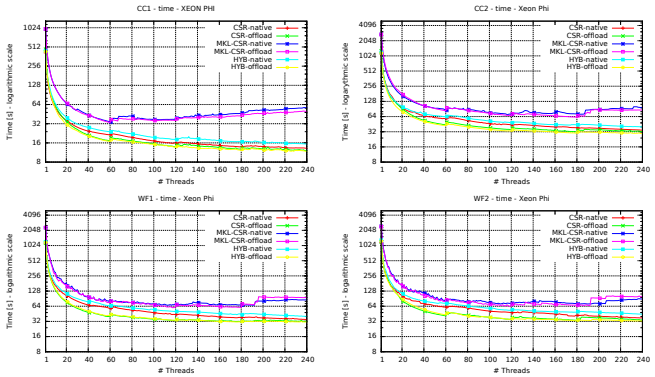

Fig. 1. Runtime of explicit fourth-order Runge-Kutta method on Intel Xeon Phi for CC1, CC2, WF1 and WF2 matrices

have similar number of nonzero elements per row (3—6). WF matrices have different number of elements per row.

TABLE I
THE PROPERTIES OF THE TESTED MATRICES

No	Name	n	nz	$\frac{nz}{n}$	$\min L_i$	$\max L_i$
1.	CC1	335421	1996701	5.95	3	6
2.	CC2	937728	5588932	5.56	3	6
3.	WF1	962336	4434326	4.61	1	12
4.	WF2	1034273	4660479	4.51	1	11

All tested matrices have very short rows; the mean number of elements in a row is between 4.51 and 5.95 elements. The input arrays size is long enough and we provide enough work for each thread.

The tests were carried out using computing node of the following parameters:

- Platform: Intel Server Chassis R2000WTXXX, Intel Server Board S2600WT2
- CPU: 2xIntel Xeon E5-2670 v3 (2x12 cores, 2.3 GHz)
- Memory: 128 GB DDR4 2133MT/s (8xCrucial CT16G4RFD4213)
- Network card: FDR InfiniBand ConnectX-3 Mellanox AXX1FDRIBIOM (FDR 56GT/S)
- Coprocessor: Intel Xeon Phi Coprocessor 7120P (16GB, 1.238 GHz, 61 cores)
- Software: Intel Parallel Studio XE 2016 Cluster Edition for Linux (Intel C++ Compiler, Intel Math Kernel Library, Intel OpenMP)

V. RESULTS

In this section we evaluate the time, the speedup and the performance of our approach to the problem of the different ways of sparse matrices storage, two execution modes for various numbers of threads.

A. Time

Fig. 1 presents execution time of RK4 algorithm. It is obvious that independently of the models and matrices size, the version using MKL library routines is the slowest. In case of our implementations offload versions are the fastest but there is no clear difference between CSR and HYB formats. Our implementations (in offload version) always perform about two times faster than MKL-CSR version, for a similar number of threads (except CC1 matrix, when execution time for 240 threads in HYB-offload version and CSR-offload is even four times faster than MKL-CSR-offload version).

For every solution, the time for the first 60 threads decreases most rapidly (with 1 thread per core activated). The gain with the use of a large number of threads per core is meaningless.

We obtain the best time for each matrix for HYB-offload version. Basing on the received charts, it seems that for MKL-CSR version the size matrix is essential; for CC1 matrix execution time increases with 60 threads and for the remaining matrices with 3 times bigger size, the time increases with 180 threads. In case of our implementations, execution time is even independent of the matrix size and model.

B. Speedup

Fig. 2 shows the speedup of RK4 method on Intel Xeon Phi with respect to a sequential version running on one thread of Intel Xeon Phi. The speedup for CC1 matrix gives a bit different charts in comparison with other matrices. It is due to a small matrix size in relation to others. For the number of threads from 1 to 60, HYB-native and CSR-native implementations give the lowest speedup, for other version the results are similar.

For more than 60 threads we can see that the speedup of the MKL-CSR version decreases. Moreover, for over 140 threads it gives the poorest results. With 60 to 240 threads (2-4 threads per core) we can see that CSR-offload and HYB-offload perform the best (with minimal superiority of the first implementation).

CC1 matrix achieves maximum speedup (which is 40) for CSR-offload version with 240 threads. The other matrices (CC1, WF1, WF2) have similar sizes and their speedup charts look similar. The lowest speedup is obtained for the CSR-native and HYB-native versions with 1 to 180 threads (1-3 threads per core).

The remaining implementations give similar results. The difference appears when we start over 180 threads (4 threads per core). HYB-offload and CSR-offload have the best speedup while MKL-CSR (native and offload version) clearly decrease. The best achieved speedup is 44 for CC2 matrix in MKL-CSR-offload version with 180 threads. For WF matrices the lowest speedup is 39 for WF1 and almost 40 for WF2 in MKL-CSR-offload version.

C. Performance

Fig. 3 presents the performance of RK4. Each of the figure's bars shows maximum performance obtained for a given stored matrix in a given format and for the program executed in the given mode. In comparison we also present the performance of RK4 method on CPU where all matrix and vector operations were realized with the use of the kernels from MKL library (denoted MKL-CSR-CPU).

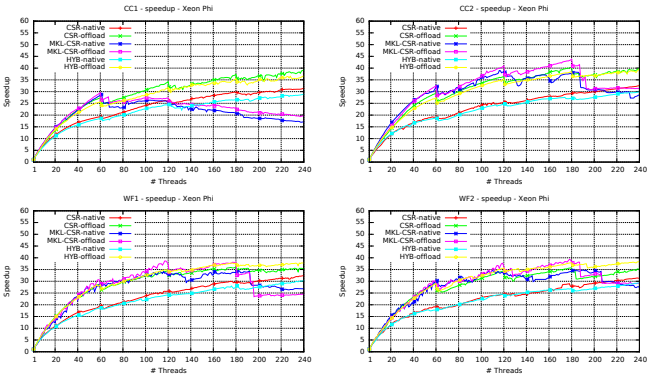

Fig. 2. Speedup of explicit fourth-order Runge-Kutta method on Intel Xeon Phi with respect to a sequential version running on one thread Intel Xeon Phi for CC1, CC2, WF1 and WF2 matrices

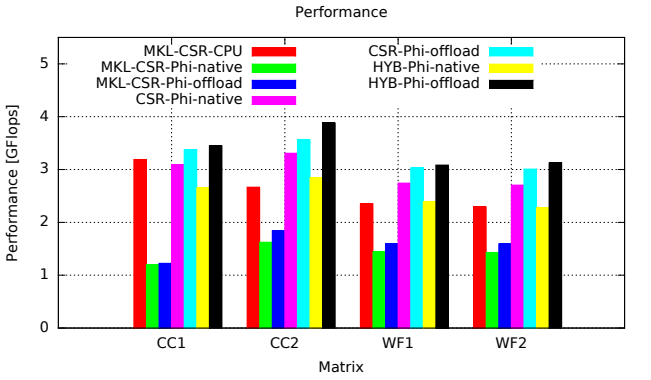

Fig. 3. Performance of explicit fourth-order Runge-Kutta method on Intel Xeon Phi

The results analysis shows a clear difference between the performance of our implementations as opposed to MKL-CSR version on Intel Xeon Phi. We can also notice that independently of the matrix size and storage format (MKL-CSR, CSR, HYB) we obtained better performance when starting the application in offload version. The biggest differences between native and offload modes occurred for HYB format. In case of our implementations we achieved the best results for every matrix in HYB-Phi-offload version. Moreover it was from 1.9 to 2.8 times more efficient than MKL-CSR-Phi-offload version due to the fact that our implementations is less general and enables better control over multithreading and vectorization.

The matrices generated for call-center model achieve better performance than the matrix from wireless network models. Despite the size, is connected with slightly higher matrix density and more regular pattern (tab. I).

Our implementations also have better performance in relation to MKL-CSR-CPU; with small matrix CC1 the differences become insignificant, but for the bigger matrices our approach is clearly favourable even up to 50% for HYB-Phi-offload version.

VI. Conclusion

In this article we investigated the use of two sparse matrices format storage in context of Markov chain problems for accelerating on the Intel Xeon Phi. Our approach exploits the thread-level parallelism and vectorization for SpMV operation and the thread-level parallelism and vectorization for the vector addition.

Based on the conducted experiments, we can clearly state that the Intel MKL library for Intel MIC architecture performed worse than our own CSR and HYB implementations.

Our implementations significantly outperform the optimized implementation routine SpMV from Intel MKL library using the CSR format on Intel Xeon Phi. The CSR and HYB versions are scalable to a large number of threads and they use all the cores on Intel Xeon Phi. We achieve the best performance for HYB format offload version.

Our implementation can still be improved. In future works we will employ thread affinity strategies which allowe to improve the performance and scalability of our approach.

***Abstract*—The block subspace projection preconditioned conjugate gradient method for analysis of natural vibration frequencies and modes applying to large problems of structural mechanics is proposed. It is oriented at the usage in finite element analysis software operated on multi-core desktop computers with restricted amount of core memory as an alternative approach to widespread block Lanczos method and subspace iteration method. We focused our attention on achievement of high computational stability and parallelization of proposed algorithm. The solution of real-life large problems confirms the reliability of proposed approach.**

I. Introduction

THE block Lanczos method as well as various versions of subspace iteration method widely is used for extraction of natural vibration frequencies and modes in modern engineering software applying to the problems of structural mechanics

$$\mathbf{K}\mathbf{v}_i - \lambda_i \mathbf{M}\mathbf{v}_i = 0 \ , \tag{1}$$

where **K** and **M** are the sparse symmetric stiffness and mass matrices arising when the finite element method is applied to problems of structural mechanics, $\{\lambda_i, \mathbf{v}_i\}$ – eigenpair for i-th mode, $i \in [1, n]$, $n << N$, n – number of required eigenmodes, N – dimension of problem (1).

The Lanczos method as well as subspace iteration (SI) approach produces the inverse iterations

$$\mathbf{K}\mathbf{v}_i^{k+1} = \mathbf{M}\mathbf{v}_i^k \ , \tag{2}$$

where $\mathbf{v}_i^k$ is an approximation of eigenvector $\mathbf{v}_i$ on iteration step k (k = 1, 2, … until converges). For large problems solved on desktop and laptop computers with restricted amount of core memory the lower triangular matrix **L** of factorized stiffness matrix $\mathbf{K} = \mathbf{L}\cdot\mathbf{D}\cdot\mathbf{L}^T$ is stored block-by-block on disk. Therefore, on each iteration step k mentioned above eigenvalue solvers must read twice the lower triangular matrix **L** from disk. Taking into account that size of matrix **L** for large design models (N = 3 000 000 – 6 000 000 equations) achieves 6 – 20 GB and more, performance of such eigenvalue solver drastically decreases.

Unlike mentioned Lanczos and SI approaches, the preconditioned conjugate gradient (PCG) method [8], [12] uses only RAM. However, for poorly conditioned problems, which are the most of problems of structural mechanics (see [7]), we have to construct an efficient preconditioning, because the conventional SSOR, symmetrical Gauss-Seidel, ICCG0 preconditioners result in unacceptable slow convergence. We found that the aggregation multilevel preconditioning [1], [2] and incomplete Cholesky factorization by value, realized in technique of sparse matrices [4], demonstrate a stable convergence for solution of linear equation sets (static analysis) as well as for extraction of natural vibrations frequencies and modes (modal analysis) for considered class of problems.

Achieving of stable convergence of the conjugate gradient method for solving the eigenvalue problem (1) is much more difficult than in solving systems of linear algebraic equations. Most likely, for this reason, in modern commercial FEA software mainly used eigenvalue solvers based on inverse matrix iteration (2) [9]. In present article, we propose the block subspace projection preconditioned conjugate gradient (BSPPCG) method for solution of problem (1).

II. Block Subspace Projection Preconditioned Conjugate Gradient Method

A. State of problem

To achieve the computational stability of PCG method at solution of poorly conditioned problems of structural mechanics, the aggregation multilevel preconditioning and shift technique have been used [1]. A little later, an aggregation multilevel preconditioning was replaced by an incomplete Cholesky factorization by value implemented in technique of sparse matrix [4].

Article [5] presents a block version of PCG method, where several vectors in block are iterated simultaneously. The Gram-Schmidt orthogonalization provides orthogonality of vectors in the block between themselves as well as their orthogonality to the eigenmodes, converged earlier. The shift technique is used for acceleration of convergence.

This work was not supported by any organization

A very interesting idea of local block PCG (LOBPCG) method was proposed in [10]. The approximations on the next iteration step are presented as:

$$\begin{cases} \mathbf{v}_i^{k+1} = \sum_{j=1}^{m} \alpha_j^k \mathbf{z}_j^k + \sum_{j=1}^{m} \tau_j^k \mathbf{v}_j^k + \sum_{j=1}^{m} \gamma_j^k \mathbf{p}_j^k \\ \mathbf{p}_i^{k+1} = \sum_{j=1}^{m} \alpha_j^k \mathbf{z}_j^k + \sum_{j=1}^{m} \gamma_j^k \mathbf{p}_j^k \end{cases}, \quad i \in [1, m], \quad (3)$$

where m is a dimension of subspace $span\{\mathbf{z}_1^k,\ldots, \mathbf{z}_m^k, \mathbf{v}_1^k,\ldots, \mathbf{v}_m^k, \mathbf{p}_1^k,\ldots, \mathbf{p}_m^k\}$, $\mathbf{z}_j^k = \mathbf{B}^{-1}\mathbf{r}_j^k$, $\mathbf{B}$ – preconditioning operator, $\mathbf{r}_j^k = \lambda_j^k \mathbf{M}\mathbf{v}_j^k - \mathbf{K}\mathbf{v}_j^k$ – residual vector, $\mathbf{p}_j^k$ – conjugate direction vector, $j = 1, \ldots, m$. The projection matrix $\mathbf{Q} = \{\mathbf{Z}\ \mathbf{V}\ \mathbf{P}\}$ has dimension $N \times 3{\cdot}m$ and consists of $N \times m$ submatrices $\mathbf{Z} = \{\mathbf{z}_1^k,\ldots, \mathbf{z}_m^k\}$, $\mathbf{V} = \{\mathbf{v}_1^k,\ldots, \mathbf{v}_m^k\}$ and $\mathbf{P} = \{\mathbf{p}_1^k,\ldots, \mathbf{p}_m^k\}$. In matrix form:

$$\begin{aligned} &\mathbf{V}^{k+1} = \mathbf{Q}\cdot\mathbf{q}, \quad \mathbf{q} = \{\mathbf{q}_1,\ldots,\mathbf{q}_m\}, \\ &\mathbf{q}_j = \{\boldsymbol{\alpha}_j^k\ \boldsymbol{\tau}_j^k\ \boldsymbol{\gamma}_j^k\}^T, \quad j \in [1, m] \end{aligned}, \quad (4)$$

where $\boldsymbol{\alpha}_j^k = \{\alpha_{1,j}^k, \ldots, \alpha_{m,j}^k\}$, $\boldsymbol{\tau}_j^k = \{\tau_{1,j}^k, \ldots, \tau_{m,j}^k\}$, $\boldsymbol{\gamma}_j^k = \{\gamma_{1,j}^k, \ldots, \gamma_{m,j}^k\}$ and iteration number k is omitted for matrices $\mathbf{Q}$, $\mathbf{q}$. Subscript j denotes a number of eigenmode in expansion (6).

Let us substitute (7) in (1) and multiple at left by $\mathbf{Q}^T$:

$$\mathbf{k}\mathbf{q} - \mathbf{m}\mathbf{q}\boldsymbol{\Lambda} = 0, \quad (5)$$

where $\mathbf{k} = \mathbf{Q}^T\mathbf{K}\mathbf{Q}$, $\mathbf{m} = \mathbf{Q}^T\mathbf{M}\mathbf{Q}$ and $\boldsymbol{\Lambda}$ is a diagonal matrix with approximations of eigenvalues on iteration step k. The approximation of eigenmodes $\mathbf{v}^{k+1}$ on the next iteration step follows from (4) after substitution of $\mathbf{q}$, which is obtained from solution of reduced eigenproblem (5). The conjugate direction vector is derived as

$$\mathbf{P}^{k+1} = \mathbf{Q}'^T\mathbf{q}', \quad (6)$$

where $\mathbf{Q}' = \{\mathbf{Z}\ \mathbf{P}\}$ and $\mathbf{q}' = \{\boldsymbol{\alpha}^k\ \boldsymbol{\gamma}^k\}^T$. Then, the Rayleigh quotient is used for approximation of eigenvalues on iteration step k+1 and evaluation of residual vectors $\mathbf{r}_j^k$ is produced after it.

The proposed approach in the form of [10] is little suitable to analysis of real-life problems of structural mechanics, since the columns in matrix $\mathbf{Q}$ become the linearly dependent as soon as the first eigenpair begins to converge. The authors of current article obtained the computational instability even for simple test problem – simply supported beam. The clear explanation of this fact is in [11]: the second expression in (3) is a linear combination between vectors $\mathbf{z}_j^k$ and $\mathbf{p}_j^k$. Therefore, the first expression in (3) is possible to rewrite as

$$\mathbf{v}_i^{k+1} = \sum_{j=1}^{m} \alpha_j^k \mathbf{z}_j^k + \sum_{j=1}^{m} \tau_j^k \mathbf{v}_j^k + \sum_{j=1}^{m} \beta_j^k \mathbf{v}_j^{k-1}, \quad i \in [1, m]. \quad (7)$$

For instance, let vector $\mathbf{v}_1$ begins to converge. Then, basis vectors $\mathbf{v}_1^k$ and $\mathbf{v}_1^{k-1}$ are almost linearly dependent, because $\mathbf{v}_1^{k-1}$, $\mathbf{v}_1^k$ as well as $\mathbf{v}_1^{k+1}$ tends to the same eigenvector $\mathbf{v}_1$ – an exact solution. In [11] for stabilization of computational process was suggested to remove the vectors $\mathbf{z}_j^k$, $\mathbf{v}_j^k$, $\mathbf{p}_j^k$ of subspace $span\{\mathbf{z}_1^k,\ldots, \mathbf{z}_m^k, \mathbf{v}_1^k,\ldots, \mathbf{v}_m^k, \mathbf{p}_1^k,\ldots, \mathbf{p}_m^k\}$, as soon as the corresponding vector $\mathbf{v}_j^k$ converges.

The drawbacks of such approach are:

- For some problems of structural mechanics it turns out that the iterative process is falling apart even before the error

$$err_i = \left\|\mathbf{r}_i^k\right\|_2 \Big/ \left[\lambda_i^k \left\|\left(\mathbf{v}_i^k\right)^T \mathbf{M}\mathbf{v}_i^k\right\|_2\right] \quad (8)$$

is still enough small ($err_j \le tol$) to recognize the convergence of vector $\mathbf{v}_j^k$.

- The dimension of subspace m must be not less than the number of required eigepairs n ($m \ge n$). Such an approach results in enormous computational efforts if it is required a large number of eigenpairs (n = 100 – 200 and more). In addition, it is required a significant amount of core memory for allocation of matrix $\mathbf{Q}$.

The proposed in given article eigenvalue block subspace projection PCG (BSPPCG) solver uses the idea (3) of LOBPCG, but possesses the high computational stability and requires essentially less computational efforts when large number of eigenpairs is required. That allows us to recommend this solver for use in FEA software intended for analysis of problems of structural mechanics on widespread desktop and laptop computers as well as on shared memory workstations.

B. Algorithm of BSPPCG method

1. Set $m \in [8, 32]$, $m\%np = 0$; prepare linearly independent start vectors $\mathbf{V}^0=\{\mathbf{v}_1^0,\ldots,\mathbf{v}_m^0\}$, $\mathbf{P}^0=\{\mathbf{p}_1^0,\ldots,\mathbf{p}_m^0\}$, $nconvmodes = 0$;
2. **do** $k = 1, 2, \ldots$, **until** $nconvmodes < n$.
3. **parallel loop for** $j = 1, \ldots, m$
   $(\mathbf{v}_j^k)^T{\cdot}\mathbf{M}{\cdot}\mathbf{v}_j^k = \mathbf{I}$ (normalization procedure)
   $\lambda_j^k = [(\mathbf{v}_j^k)^T\ \mathbf{K}\ \mathbf{v}_j^k]/[(\mathbf{v}_j^k)^T\ \mathbf{M}\ \mathbf{v}_j^k]$
   $\mathbf{r}_j^k = \lambda_j^k\mathbf{M}\mathbf{v}_j^k - \mathbf{K}\mathbf{v}_j^k$
   $\mathbf{B}\ \mathbf{z}_j^k = \mathbf{r}_j^k \rightarrow \mathbf{z}_j^k$
   end of parallel loop for
4. **do** j=1, m
   if($err_j \le tol$)
   $nconvmodes$++;
   put $\{\lambda_j, \mathbf{v}_j\}$ as final results,
   prepare new start vectors $\mathbf{v}_j^k$ and $\mathbf{p}_j^k$,
   orthogonalize $\mathbf{v}_j^k$ against converged modes
   and put to blocks $\mathbf{V}^k$, $\mathbf{P}^k$.
   $\lambda_j^k = [(\mathbf{v}_j^k)^T\ \mathbf{K}\ \mathbf{v}_j^k]/[\ [(\mathbf{v}_j^k)^T\ \mathbf{M}\ \mathbf{v}_j^k]$
   $\mathbf{r}_j^k = \lambda_j^k\mathbf{M}\mathbf{v}_j^k - \mathbf{K}\mathbf{v}_j^k$
   $\mathbf{B}\ \mathbf{z}_j^k = \mathbf{r}_j^k \rightarrow \mathbf{z}_j^k$, put $\mathbf{z}_j^k$ to $\mathbf{Z}^k$.

end if
end do
5. **paralel loop for** $s = 1, 3m$
loop for $p = s, 3m$ (s, p – columns of matrix $\mathbf{Q}$)
$\mathbf{m}_{sp} = \mathbf{Q}_p{}^T\mathbf{M}\mathbf{Q}_s$ – evaluation of matrix $\mathbf{m}$
end loop for
end of parallel loop for
6. **if**(Chol($\mathbf{m}$): $\mathbf{m} = \mathbf{l}\cdot\mathbf{l}^T$)
paralel loop for $s = 1, 3m$
loop for $p = s, 3m$ (s, p – columns of matrix $\mathbf{Q}$)
$\mathbf{k}_{sp} = \mathbf{Q}_p{}^T\mathbf{K}\mathbf{Q}_s$ – evaluation of matrix $\mathbf{k}$
end loop for
end of parallel loop for
else
Gram-Schmidt orthogonalization of all columns in $\mathbf{Q}$ and normalization $\mathbf{Q}^T\mathbf{M}\mathbf{Q} = \mathbf{I}$
paralel loop for $s = 1, 3m$
loop for $p = s, 3m$ (s, p – columns of matrix $\mathbf{Q}$)
$\mathbf{m}_{sp} = \mathbf{Q}_p{}^T\mathbf{M}\mathbf{Q}_s$ – evaluation of matrix $\mathbf{m}$
$\mathbf{k}_{sp} = \mathbf{Q}_p{}^T\mathbf{K}\mathbf{Q}_s$ – evaluation of matrix $\mathbf{k}$
end loop for
end of parallel loop for
Chol($\mathbf{m}$): $\mathbf{m} = \mathbf{l}\cdot\mathbf{l}^T$
end if
7. solve reduced eigenproblem $\mathbf{kq} - \mathbf{mq}\Lambda = 0$
8. obtain $\mathbf{V}^{k+1}$ and $\mathbf{P}^{k+1}$ using (4), (6).
9. parallel orthogonalization of $\mathbf{V}^{k+1}$ and $\mathbf{P}^{k+1}$ against converged eigenmodes.
end do

Algorithm 1. BSPPCG method

We accept the fixed dimension of subspace m, which is multiple to available number of threads np ($m\%np = 0$) for achievement a load balance between threads (point 1). Then, we prepare linearly independent start vectors $\mathbf{V}^0$ and set $\mathbf{p}_j^0 = \emptyset$, $j \in [1, m]$, where $\emptyset$ is a zero vector, and number of converged modes set to sero: $nconvmodes = 0$.

The iteration loop **do** $k = 1, 2, \ldots$ runs until $nconvmodes < n$, where n is the number of required modes (point 2).

In parallel loop (point 3) for each mode j we produce the normalization of $\mathbf{v}_j^k$, obtain the current approximation of eigenvalue λ_j^k, residual vector $\mathbf{r}_j^k$ and vector $\mathbf{z}_j^k$ from solution of linear equation set arising when preconditioning operator $\mathbf{B}$ is introduced for acceleration of convergence. On first iteration, the projection matrix $\mathbf{Q}$ contains only submatrices $\mathbf{Z}$ and $\mathbf{V}$ because submatrix $\mathbf{P}$ is zero. On all subsequent iterations, $\mathbf{Q}$ comprises $\mathbf{Z}$, $\mathbf{V}$ and $\mathbf{P}$ submatrices.

Iteration loop **do** j=1, m (point 4) checks of convergence. If convergence of j-th mode is achieved, we store the eigenpair $\{\lambda_j, \mathbf{v}_j\}$ to structure of data containing the final results, increment $nconvmodes$ and prepare the new linearly independent start vectors in addresses of vectors $\mathbf{v}_j^k$ and $\mathbf{p}_j^k$. In each starting vector $\mathbf{p}_j^k$ we put only one element equal to unit, all remaining elements are zero. Due to such an action, all new vectors $\mathbf{p}_j^k$ are linearly independent. All remaining elements of each vector $\mathbf{p}_j^k$ are zero. In such a way, we avoid the linear dependency between columns of projection matrix $\mathbf{Q}$. Then, we orthogonalize the new starting vectors $\mathbf{v}_j^k$ against converged modes and compute the λ_j^k, $\mathbf{r}_j^k$ and $\mathbf{z}_j^k$ corresponding to new starting vectors $\mathbf{v}_j^k$. Vectors $\mathbf{z}_j^k$, corresponding to new starting vectors, replace columns j in submatrix $\mathbf{Z}$, corresponding to converged vectors on current iteration step k.

The reduced matrix $\mathbf{m}$ is evaluated in **parallel loop for** $s = 1, 3m$. The sparse matrix $\mathbf{M}$ is multiplied by columns $\mathbf{Q}_s$ of matrix $\mathbf{Q}$ in parallel region: $\mathbf{w}_s = \mathbf{K}\cdot\mathbf{Q}_s$. The number of threads in team is np. In second loop (**loop for** $p = s, 3m$) we calculate the element $\mathbf{m}_{sp}$ as a dot product of column $\mathbf{Q}_p{}^T$ and previously obtained vector $\mathbf{w}_s$. Matrix $\mathbf{m}$ is symmetrical therefore p starts with s.

Chol($\mathbf{m}$) denotes the Cholesky factorization of matrix $\mathbf{m}$ and $\mathbf{l}$ is a lower triangular matrix. (point 6). We consider the matrix $\mathbf{m}$ as a weighted Gram matrix of subspace $span\{\mathbf{z}_1{}^k,\ldots,\mathbf{z}_m{}^k, \mathbf{v}_1{}^k,\ldots,\mathbf{v}_m{}^k, \mathbf{p}_1{}^k,\ldots,\mathbf{p}_m{}^k\}$. Therefore, if Cholesky factorization completes successfully, the columns of matrix $\mathbf{Q}$ are linearly independent and basis vectors are OK. Otherwise, if Cholesky factorization of $\mathbf{m}$ is failed, the columns of matrix $\mathbf{Q}$ are almost linearly dependent, and we produce the Gram-Schmidt orthogonalization of all columns in $\mathbf{Q}$ and normalization $\mathbf{Q}^T\mathbf{M}\mathbf{Q} = \mathbf{I}$. After this, we prepare reduced matrices $\mathbf{k}$, $\mathbf{m}$ using multithreaded parallelization and repeat Cholesky factorization of $\mathbf{m}$.

We apply procedures from LAPACK of Intel math kernel library (Intel MKL) [13] for solution of the generalized algebraic eigenproblem (5).

Submatrices $\mathbf{V}^{k+1}$ and $\mathbf{P}^{k+1}$ (point 8) is derived using (4), (6). We apply the multithreaded version of *dgemm* procedure from Intel MKL for multiplication of dense matrices.

The Gram-Schmidt orthogonalization provides orthogonality of vectors in the submatrices $\mathbf{V}^{k+1}$ and $\mathbf{P}^{k+1}$ to the converged eigenmodes (point 9). The columns in $\mathbf{V}^{k+1}$ as well as in $\mathbf{P}^{k+1}$ can be independently orthogonalized against converged eigenmodes, therefore, this algorithm can be easily parallelized. Also, orthogonalization, made in point 4, can be easily parallelized. Unlike these algorithms, the Gram-Schmidt orthogonalization procedure applied to all columns of matrix $\mathbf{Q}$ (point 6) has a strongly sequential nature and cannot be successfully parallelized.

We emphasize the fundamental differences between proposed method and LOBPCG.

1. BSPPCG method keeps constant the dimension of subspace m, which does not depend on number of required

eigenmodes. This allows us to reduce the amount of core memory and computing time and makes proposed approach applicable for solution of large problems on desktops and laptops.

2. As soon as the vectors converge, we immediately remove them from the block and replace with new starting vectors. In many cases, this allows us to keep a linear independence of the columns in matrix **Q**.

3. If in spite of everything, linear dependencies between base vectors still appears, we make the full reortogonalization of columns of the matrix **Q**.

4. We apply an efficient preconditioning for considered class of problems – incomplete Cholesky factorization by value developed in technique of sparse matrices [4].

III. Numerical Results

We consider example "stadium" taken from computational practice of SCAD Soft IT Company, developer of the SCAD FEA software, one of the most popular software used in the CIS countries for structural analysis and design, certified according to the regional norms.

We use computer with 16-core processor AMD Opteron 6276, 2.3/3.2 GHz, 64 GB DDR3 RAM, OS Windows Server 2008 R2 Enterprise SP1, 64 bit. The large amount of RAM allows us on application of incomplete Cholesky factorization for preparation of preconditioning with very small value of drop parameter $\psi = 10^{-16}$ [4] and keep all data in core memory. In addition, 16 processor cores provide the opportunity to explore the speed-up of method when we increase the number of cores. The tolerance is accepted as $tol = 10^{-3}$ – see (8).

The design model of stadium comprises 4 033 620 equations and consists of several types of finite elements: spatial frames, triangular and quadrilateral flat shell finite elements, elastic supports and rigid links One hundred eigenpairs are extracted (n = 100). The large number of almost multiple natural vibration frequencies occurs due to local vibration modes of bars in spatial trusses.

For accepted values of ψ, tol the number of iterations is 121 and number of reorthogonalizations, when Cholesky factoring of matrix **m** was failed, is 20. If there is at least one reorthogonalization, that means that LOBPCG method in version [10] would fail, since the columns of the matrix **Q**, which are basis vectors, are linearly dependent. Reorthogonalization of columns in matrix **Q** allows us to successfully continue a computation process. The shortest computational time is achieved on 16 threads.

Table I presents the total time of eigenvalue analysis of considered problem using proposed BSPPCG method, shifted block PCG (SBPCG) method [5] and shifted block Lanczos (SBLANC) method [3]. Method SBLANC solves this problem in core memory using PARFES [6], [7] – one from fastest for today sparse direct solvers on shared memory computers.

TABLE I
COMPARISON OF COMPUTATIONAL TIME FOR DIFFERENT METHODS. COMPUTER A, PROBLEM 1.

Method	Total time, s
BSPPCG	6 466
SBPCG	20 708
SBLANC (core mode)	6 228

The proposed BSPPCG demonstrates the solution time, which is slightly bigger than solution time of SBLANC method. The SBPCG method solves this problem considerably slower.

***Abstract*—Nowadays, recursive filters (RFs) are frequently used in several research fields. More in particular, Gaussian RFs offer a more efficient way for computing approximate Gaussian filters and Gaussian-based convolutions. The use of such recursive filters introduces many sources of errors. Among them, here we consider the filter truncation error, that is the error due to the transition from the starting filter operator to the RF approximating it. Since input and output signals have infinite dimensions, the analysis of the related filter operator involves infinite matrices. In this paper, starting from a summary of the comprehensive mathematical background, we consider the case of the first-order Gaussian recursive filter. Then, taking into account the matrix form of the related operator, we perform the error analysis and provide theoretical results that estimate the filter truncation error.**

I. Introduction

IN RECENT years, recursive filters have been frequently used in several fields. For example Gaussian RFs are usually involved in image processing [1], [2] and are also implemented for solving three-dimensional variational analysis schemes in data assimilation [3]. Moreover, they have been recently constructed specifically for the electrocardiogram denoising [4], [5], [6]. The idea of recursive filters is to approximate a given filter, or for example the convolution with the impulse response of such a filter, in a more efficient way. More in particular, among RFs, the Gaussian RFs are very efficient implementations that approximate Gaussian-based convolutions. Gaussian RFs can be constructed in several ways but, in this work, we deal just with the kind derived by Deriche [7] and Young and van Vliet (see [8], and the references therein). As is well known, Gaussian RF based algorithms, applied to a signal with compact support, generate unbounded distortions in the output signal boundary entries (a detailed explanation is in [8]). This is known as edge effect and, to the aim of removing it, theoretical tools (named boundary conditions) and implementative improvements have been proposed in literature [8], [9]. Here we are not interested in edge effects and only focus on the error due to the the transition from the starting filter operator to the RF approximating it. We refer to this error as the filter truncation error. In this work, we are interested in studying the filter truncation error for the case of the first-order Gaussian recursive filter. The aim is to investigate on the quality of the approximation supplied by that filter. We underline that input and output signals have infinite dimensions, hence the analysis of the related filter operator will involve infinite matrices.

The paper is organized as follows. In Section 2, we give some mathematical preliminaries about the first-order Gaussian RF and also provide its matrix formulation. In Section 3, the analysis of the filter operator structure is carried out. In Section 4, we report the error analysis and provide an upper bound for the filter truncation error. Finally, conclusions in Section 5 close the paper.

II. Mathematical background

Let:

$$s^{(0)} = \{s_j^{(0)}\}_{j\in\mathbf{Z}} = (\dots, s_{-2}^{(0)}, s_{-1}^{(0)}, s_0^{(0)}, s_1^{(0)}, s_2^{(0)}, \dots)$$

be a input signal. $s^{(0)}$ can be thought of as a complex function defined on the set of integers, that is an element of the set of sequences of complex numbers $\mathbf{C}^{\mathbf{Z}}$. Let g denote the Gaussian function with zero mean and standard deviation σ. Let:

$$\delta_j = \begin{cases} 1 & \text{if } j = 0 \\ 0 & \text{if } j \neq 0 \end{cases} \tag{1}$$

be the *unit-sample*. The Gaussian filter is a filter whose impulse response to the unit-sample, i.e. the output of such a filter when the input is δ, is the Gaussian function g, or an approximation to it. Applying the Gaussian filter to the input $s^{(0)}$ gives rise to a response that can be simply expressed by the discrete Gaussian convolution:

$$s_j^{(g)} = \left(g * s^{(0)}\right)_j = \sum_{t=-\infty}^{+\infty} g_{j-t} s_t^{(0)}, \qquad \forall\, j \in \mathbf{Z}, \tag{2}$$

where:

$$g_t \equiv g(t) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{t^2}{2\sigma^2}\right). \tag{3}$$

The expression in (2) can be conveniently rewritten by changing the index t of the summation in $t - j$, and by making use of the symmetry $g_t = g_{-t}$. We have:

$$s_j^{(g)} = \sum_{t=-\infty}^{+\infty} g_t s_{j+t}^{(0)}, \qquad \forall\, j \in \mathbf{Z}. \tag{4}$$

The entries $s_j^{(g)}$ of $s^{(g)}$ can be efficiently approximated by means of Gaussian RFs and K-iterated Gaussian RFs.
A K-iterated n-order Gaussian RF filter computes the output

978-83-60810-90-3/$25.00

signal $s^{(K)}$, i.e. the K-iterate approximation of $s^{(g)}$, whose entries solve the infinite sequences of equations:

$$p_j^{(k)} = \beta s_j^{(k-1)} + \sum_{t=1}^{n} \alpha_t p_{j-t}^{(k)}, \qquad \forall\, j \in \mathbf{Z}, \tag{5}$$

$$s_j^{(k)} = \beta p_j^{(k)} + \sum_{t=1}^{n} \alpha_t s_{j+t}^{(k)}, \qquad \forall\, j \in \mathbf{Z}. \tag{6}$$

The filter iteration counter k goes from 1 to K (number of filter iterations). For $K = 1$, the filter merely becomes an n-order Gaussian RF filter. Equations in (5) and (6) are conveniently referred to as the advancing and backing filters, respectively: when a Gaussian RF is implemented as an algorithm, the index j must be treated in increasing order in the former and decreasing in the latter [8]. The values α_t and β are called *smoothing coefficients* and satisfy the constraint:

$$\beta = 1 - \sum_{t=1}^{n} \alpha_t.$$

In a general setting they depend on σ, n and K. In the following we consider just the first-order Gaussian RF with one-iteration only ($n = 1, K = 1$), for which equations (5) and (6) take the simplified form:

$$p_j = \beta s_j^{(0)} + \alpha p_{j-1}, \qquad \forall\, j \in \mathbf{Z}, \tag{7}$$

$$s_j = \beta p_j + \alpha s_{j+1}, \qquad \forall\, j \in \mathbf{Z}. \tag{8}$$

The smoothing coefficients are given by:

$$\alpha = 1 + E_\sigma - \sqrt{E_\sigma(E_\sigma + 2)} \tag{9}$$

and:

$$\beta = \sqrt{E_\sigma(E_\sigma + 2)} - E_\sigma, \tag{10}$$

with $E_\sigma = \sigma^{-2}$. The behaviour of α and β, as σ varies, is shown in Figure 1. Using Taylor expansion arguments, we can observe that, for small σ, it is:

$$\alpha = \frac{1}{2}\sigma^2 - \sigma^4 + \mathcal{O}\big(\sigma^6\big), \quad (\text{for} \quad \sigma \to 0),$$

while, for large σ, it is:

$$\alpha = 1 - \sigma^{-1}\sqrt{2} + \mathcal{O}\big(\sigma^{-2}\big), \quad (\text{for} \quad \sigma \to +\infty).$$

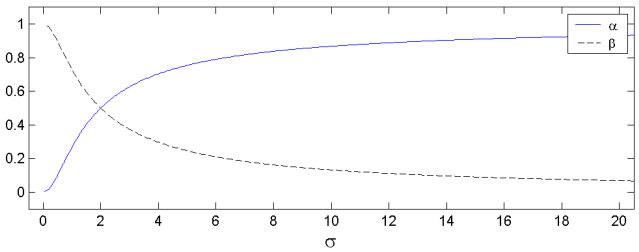

Fig. 1. Blue solid line: α. Black dashed line: β

By adapting the discussion in [3] to the case of the infinite dimension signals:

$$s^{(0)} = \big\{s_j^{(0)}\big\}_{j\in\mathbf{Z}}, \quad p = \big\{p_j\big\}_{j\in\mathbf{Z}} \quad \text{and} \quad s = \big\{s_j\big\}_{j\in\mathbf{Z}},$$

we can rewrite, in matrix form, the advancing filter (7) as:

$$Lp = s^{(0)}, \tag{11}$$

and the backing filter (8) as:

$$Us = p. \tag{12}$$

L and U are (bi)infinite matrices (matrices with infinite rows and columns, see [10] for notation and conventions), whose nonzero entries are:

$$L_{i,i} = \frac{1}{\beta}, \qquad L_{i,i-1} = -\frac{\alpha}{\beta}, \qquad \forall\, i \in \mathbf{Z}, \tag{13}$$

$$U_{i,i} = \frac{1}{\beta}, \qquad U_{i,i+1} = -\frac{\alpha}{\beta}, \qquad \forall\, i \in \mathbf{Z}. \tag{14}$$

Moreover L and U are both Toeplitz, bidiagonal matrices and U is the transpose of L, in the sense that:

$$U_{i,j} = L_{j,i}, \qquad \forall\, i, j \in \mathbf{Z}. \tag{15}$$

The products in (11) and (12) can be thought of as multiplications of infinite matrices. Given two infinite matrices:

$$A = \big\{A_{i,j}\big\}_{i,j\in\mathbf{Z}} \qquad \text{and} \qquad B = \big\{B_{i,j}\big\}_{i,j\in\mathbf{Z}},$$

the matrix product $C = AB$ has entries expressed as the series:

$$C_{i,j} = A_i B^j = \sum_{k=-\infty}^{+\infty} A_{i,k} B_{k,j},$$

where A_i and B^j are sequences denoting a row of A and a column of B, respectively. Now, substituting in equation (11) the expression of p given in (12), we deduce that the output s and the input $s^{(0)}$ of the first-order Gaussian RF satisfy:

$$Ds = s^{(0)}, \quad \text{with} \quad D = LU. \tag{16}$$

Then, to obtain the operator form for such a filter, we need just to invert the matrix D in (16). For infinite matrices, many definitions of inverse are given. Here, we mean the matrix A^{-1} as the inverse of an infinite matrix A, if and only if:

$$AA^{-1} = A^{-1}A = I,$$

where $I_{i,j} = \delta_{i-j}$, with δ_j as in (1). If D has inverse D^{-1}, from (16) it trivially results:

$$s = D^{-1}s^{(0)}. \tag{17}$$

Equation (17) proves that the infinite matrix:

$$F \stackrel{\text{def}}{=} D^{-1} = (LU)^{-1} \tag{18}$$

acts as the operator related to first-order Gaussian recursive filter. In the next section we will provide the structure of D and F.

III. FILTER OPERATOR

We need the following results: the first lemma provides a formula, equivalent to (7) and (8), which expresses the output entries s_j in terms of the input entries $s_j^{(0)}$, without using p_j values; the second lemma makes explicit the expression of the entries of the infinite matrix product LU.

Lemma III.1. *(Filter output entries representation) Let s, p_j and $s_j^{(0)}$ be as in* (7) *and* (8)*. If $\beta = 1-\alpha$ and $|\alpha| < 1$, then the output entries s_j are given by the series:*

$$s_j = \sum_{t=-\infty}^{+\infty} c_t s_{j+t}^{(0)}, \qquad \forall\, j \in \mathbf{Z}, \tag{19}$$

with:

$$c_t \equiv \frac{\beta}{1+\alpha}\alpha^{|t|}, \qquad \forall\, t \in \mathbf{Z}. \tag{20}$$

Proof. Let k be a positive integer. Combining the equation (7) in itself repeatedly, with indices j, $j-1, \ldots, j-(k-1)$, we obtain inductively:

$$p_j = \beta \sum_{m=0}^{k-1} \alpha^m s_{j-m}^{(0)} + \alpha^k p_{j-k}, \qquad \forall\, j \in \mathbf{Z},$$

and, since $|\alpha| < 1$, for $k \to +\infty$ it is:

$$p_j = \beta \sum_{m=0}^{+\infty} \alpha^m s_{j-m}^{(0)}, \qquad \forall\, j \in \mathbf{Z}, \tag{21}$$

Similarly, combining the equation (8) in itself, with indices j, $j+1, \ldots, j+(k-1)$, we get:

$$s_j = \beta \sum_{l=0}^{k-1} \alpha^l p_{j+l} + \alpha^k s_{j+k}, \qquad \forall\, j \in \mathbf{Z},$$

and, for $k \to +\infty$ it is:

$$s_j = \beta \sum_{l=0}^{+\infty} \alpha^l p_{j+l}, \qquad \forall\, j \in \mathbf{Z}. \tag{22}$$

Hence, using (21) with $j+l$ in (22), we obtain:

$$\begin{aligned} s_j &= \beta \sum_{l=0}^{+\infty} \alpha^l \left(\beta \sum_{m=0}^{+\infty} \alpha^m s_{j+l-m}^{(0)} \right) \\ &= \sum_{l=0}^{+\infty} \sum_{m=0}^{+\infty} \beta^2 \alpha^{l+m} s_{j+l-m}^{(0)}, \qquad \forall\, j \in \mathbf{Z}. \end{aligned} \tag{23}$$

Observing that, as l, m vary in $0, 1, \ldots$, $t = l - m$ varies in $\mathbf{Z}$, we can simplify the representation in (23) by collecting the coefficients of $s_{j+l-m}^{(0)} = s_{j+t}^{(0)}$, for each fixed t. Then, by means of a suitable change of indices in (23), we get:

$$s_j = \sum_{t=-\infty}^{+\infty} \left(\sum_{m=0}^{+\infty} \beta^2 \alpha^{|t|+2m} \right) s_{j+t}^{(0)}, \qquad \forall\, j \in \mathbf{Z}.$$

Finally, the thesis follows using $\beta = 1-\alpha$ and because of:

$$\sum_{m=0}^{+\infty} \beta^2 \alpha^{|t|+2m} = \beta^2 \alpha^{|t|} \sum_{m=0}^{+\infty} \alpha^{2m} = \frac{\beta^2}{1-\alpha^2}\alpha^{|t|} = c_t.$$

□

Lemma III.2. *(D structure) Let L and U be with entries as in* (13) *and* (14)*, respectively. Then $D = LU$ is a Toeplitz, tridiagonal, symmetric, infinite matrix, with entries:*

$$D_{i,j} = \begin{cases} \frac{1+\alpha^2}{\beta^2} & \text{if } \; j = i \\ -\frac{\alpha}{\beta^2} & \text{if } \; j = i \pm 1 \\ 0 & \text{if } \; j = i \pm m, \quad m \geq 2 \end{cases} \tag{24}$$

Proof. We need just to prove (24). Since $L_{i,k} = 0$ for $k < i-1$ and $k > i$, $\forall\, i, j \in \mathbf{Z}$ it is:

$$D_{i,j} = \sum_{k=-\infty}^{+\infty} L_{i,k} U_{k,j} = L_{i,i-1} U_{i-1,j} + L_{i,i} U_{i,j}.$$

Then recalling (13) and (15), it holds:

$$D_{i,j} = L_{i,i-1} L_{j,i-1} + L_{i,i} L_{j,i} = -\frac{\alpha}{\beta} L_{j,i-1} + \frac{1}{\beta} L_{j,i}. \tag{25}$$

Putting $j = i$ in (25), we obtain:

$$D_{i,i} = -\frac{\alpha}{\beta} L_{i,i-1} + \frac{1}{\beta} L_{i,i} = \left(-\frac{\alpha}{\beta}\right)^2 + \left(\frac{1}{\beta}\right)^2 = \frac{1+\alpha^2}{\beta^2}.$$

For $j = i-1$, it is:

$$D_{i,i-1} = -\frac{\alpha}{\beta} L_{i-1,i-1} + \frac{1}{\beta} L_{i-1,i} - \frac{\alpha}{\beta}\frac{1}{\beta} + \frac{1}{\beta} \cdot 0 = -\frac{\alpha}{\beta^2},$$

and for $j = i+1$, it is:

$$D_{i,i+1} = -\frac{\alpha}{\beta} L_{i+1,i-1} + \frac{1}{\beta} L_{i+1,i} = \frac{1}{\beta}\left(-\frac{\alpha}{\beta}\right) = -\frac{\alpha}{\beta^2}.$$

Finally, for $j = i \pm m$, with $m \geq 2$, we have:

$$L_{j,i-1} = L_{i\pm m,i-1} = 0$$

and:

$$L_{j,i} = L_{i\pm m,i} = 0.$$

Hence, from (25), we obtain:

$$D_{i,j} = D_{i,i+m} = L_{i,i-1} L_{i\pm m,i-1} + L_{i,i} L_{i\pm m,i} = 0,$$

and this completes the proof. □

Using the result in Lemma III.1 we can derive the structure of the operator $F = D^{-1}$. Notice that, from (17) and (18), it is:

$$s_j = \left(F s^{(0)}\right)_j = F_j s^{(0)} = \sum_{k=-\infty}^{+\infty} F_{j,k} s_k^{(0)}.$$

With the substitution $k = j + t$ we obtain the expression:

$$s_j = \sum_{t=-\infty}^{+\infty} F_{j,j+t} s_{j+t}^{(0)}, \tag{26}$$

which has the same form of the result in (19). This suggests that the F entries are given by the coefficients in (20). Starting from this remark, we deduce the form of F.

Theorem III.1. *(F structure) Let L and U be with entries as in* (13) *and* (14)*, respectively. Then $F = (LU)^{-1}$ is a Toeplitz, symmetric, infinite matrix, with entries:*

$$F_{i,j} = \frac{\beta}{1+\alpha}\alpha^{|j-i|}, \qquad \forall\, i, j \in \mathbf{Z}. \tag{27}$$

Proof. By comparing the series in (26) and (19), for each fixed $j \in \mathbf{Z}$, we get:

$$\sum_{t=-\infty}^{+\infty} F_{j,j+t} s^{(0)}_{j+t} = \sum_{t=-\infty}^{+\infty} c_t s^{(0)}_{j+t}.$$

Therefore, by taking for all $t \in \mathbf{Z}$, the input signal $s^{(0)}$ as the time shifted unit-sample with nonzero entry $s^{(0)}_{j+t}$, it follows:

$$F_{j,j+t} = c_t, \qquad \forall\, t \in \mathbf{Z}.$$

Then, recalling (20) we obtain the thesis:

$$F_{i,j} = F_{i,i+(j-i)} = c_{j-i} = \frac{\beta}{1+\alpha}\alpha^{|j-i|}, \qquad \forall\, i,j \in \mathbf{Z}.$$

□

Another proof that F actually acts as the inverse of D, can be obtained by verifying, by direct computation, that $DF = I$. To do this, observe that from Lemma III.2, we have:

$$(DF)_{i,j} = \sum_{k=-\infty}^{+\infty} D_{i,k} F_{k,j} = \sum_{k=i-1}^{i+1} D_{i,k} F_{k,j}.$$

So, for $j = i + m$, it is:

$$(DF)_{i,i+m} = D_{i,i-1}F_{i-i,i+m} + D_{i,i}F_{i,i+m} + D_{i,i+1}F_{i+1,i+m},$$

and by exploiting (24) and (27), we get:

$$(DF)_{i,i+m} = \frac{-\alpha\alpha^{|m+1|} + (1+\alpha^2)\alpha^{|m|} - \alpha\alpha^{|m-1|}}{\beta(1+\alpha)}. \quad (28)$$

For $j = i$, that is $m = 0$, (28) becomes:

$$(DF)_{i,i} = \frac{-\alpha^2 + (1+\alpha^2) - \alpha^2}{\beta(1+\alpha)} = \frac{1-\alpha^2}{\beta(1+\alpha)} = 1.$$

For $j > i$, that is $m \geq 1$, (28) becomes:

$$(DF)_{i,i+m} = \frac{-\alpha\alpha^{m+1} + (1+\alpha^2)\alpha^{m} - \alpha\alpha^{m-1}}{\beta(1+\alpha)} = \alpha^m \frac{-\alpha^2 + (1+\alpha^2) - 1}{\beta(1+\alpha)} = 0.$$

For $j < i$, that is $m \leq -1$, (28) becomes:

$$(DF)_{i,i+m} = \frac{-\alpha\alpha^{-m-1} + (1+\alpha^2)\alpha^{-m} - \alpha\alpha^{-m+1}}{\beta(1+\alpha)} = \alpha^{-m} \frac{-1 + (1+\alpha^2) - \alpha^2}{\beta(1+\alpha)} = 0.$$

IV. Error analysis

In this section we are interested in studying the error occurring when the Gaussian filter is substituted by the first-order Gaussian RF, namely the filter truncation error. Let $\|\cdot\|$ denote the sup-norm, defined for signals f as:

$$\|f\| = \sup_{k \in \mathbf{Z}} |f_k|,$$

and for infinite matrices A as:

$$\|A\| = \sup_{f \in \mathbf{C}^{\mathbf{Z}}, \|f\|=1} \|Af\| = \sup_{i \in \mathbf{Z}} \sum_{j \in \mathbf{Z}} |A_{i,j}|.$$

Let denote by:

$$\tau_j = s^{(g)}_j - s_j, \quad (29)$$

the difference between the output entries of the Gaussian filter and the first-order Gaussian RF. We refer to:

$$\tau = \left\| \{\tau_j\}_{j \in \mathbf{Z}} \right\| \quad (30)$$

as the filter truncation error (f.t.e.). Before giving an upper bound for τ, let us indicate by V the infinite Gaussian matrix, with entries:

$$V_{i,j} = g_{j-i}, \qquad \forall\, i,j \in \mathbf{Z}, \quad (31)$$

where g_t values are as in (3). Now, using the operator V, the equation (4) is compactly represented as:

$$s^{(g)} = V s^{(0)}. \quad (32)$$

Therefore, combining (17), (18), (29) and (32), we get:

$$\{\tau_j\}_{j \in \mathbf{Z}} = s^{(g)} - s = V s^{(0)} - F s^{(0)} = (V - F) s^{(0)}, \quad (33)$$

that is the f.t.e. is simply obtained as the product of the filter operators difference and the input signal. Starting from (33) we can proof the following main result.

Theorem IV.1. *(Filter truncation error) Assume that $\|s^{(0)}\| \leq S$ and let V be the same as in* (31)*. Then, for the f.t.e. defined in* (29) *and* (30)*, it holds that:*

$$\tau \leq \kappa \cdot S, \quad (34)$$

with:

$$\kappa = \|V - F\| = \sum_{t=-\infty}^{+\infty} |g_t - c_t| \quad (35)$$

and g_t and c_t as in (3) *and* (20)*, respectively.*

Proof. Immediate by construction. The proof of (34) is as follows. From (30) and (33) it is:

$$\tau = \|(V - F)s^{(0)}\| \leq \|V - F\| \cdot \|s^{(0)}\| = \kappa \cdot S.$$

To complete the proof, we need just to prove (35). From (20) and (27) we deduce that $\forall\, i,t \in \mathbf{Z}$ it is:

$$F_{i,i+t} = \frac{\beta}{1+\alpha}\alpha^{|(i+t)-i|} = \frac{\beta}{1+\alpha}\alpha^{|t|} = c_t.$$

Then, changing the summation index j in $i + t$, and by using (31), we get the thesis:

$$\begin{aligned} \kappa = \|V - F\| &= \sup_{i \in \mathbf{Z}} \sum_{j \in \mathbf{Z}} |V_{i,j} - F_{i,j}| \\ &= \sup_{i \in \mathbf{Z}} \sum_{t \in \mathbf{Z}} |V_{i,i+t} - F_{i,i+t}| = \sup_{i \in \mathbf{Z}} \sum_{t \in \mathbf{Z}} |g_t - c_t| \\ &= \sum_{t \in \mathbf{Z}} |g_t - c_t| = \sum_{t=-\infty}^{+\infty} |g_t - c_t|. \end{aligned} \quad (36)$$

□

The previous result proves that, without considering the order of magnitude S of the input signal, the factor κ behaves

like a physical limit in the accuracy provided by the first-order Gaussian RF in approximating the Gaussian convolution. Then, for investigating on the f.t.e., and completing the error analysis, we can limit our discussion to the behaviour of κ. Recalling (3), (9), (10) and (20), we deduce that coefficients g_t and c_t depend on σ and t, making κ dependent just on σ. We remark that if $g_t - c_t$ was of constant sign, for example $g_t - c_t \geq 0,\ \forall\, t \in \mathbf{Z}$, then we would simply have:

$$\kappa = \sum_{t=-\infty}^{+\infty} g_t - \sum_{t=-\infty}^{+\infty} c_t = \sum_{t=-\infty}^{+\infty} g_t - 1 \leq \frac{1}{\sigma\sqrt{2\pi}}, \qquad (37)$$

where the last inequality arises from:

$$\sum_{t=-\infty}^{+\infty} g_t \leq 1 + \frac{1}{\sigma\sqrt{2\pi}}.$$

This bound can be easily proved exploiting the monotonicity properties of the Gaussian function:

$$g_t \leq \int_{t-1}^{t} g(x)dx, \qquad \forall t = 1, 2, \ldots,$$

and the symmetry $g_t = g_{-t}$. Indeed, we have:

$$\sum_{t=-\infty}^{+\infty} g_t = g_0 + 2\sum_{t=1}^{+\infty} g_t \leq \frac{1}{\sigma\sqrt{2\pi}} + 2\sum_{t=1}^{+\infty}\int_{t-1}^{t} g(x)dx$$
$$= \frac{1}{\sigma\sqrt{2\pi}} + 2\int_{0}^{+\infty} g(x)dx = \frac{1}{\sigma\sqrt{2\pi}} + 1.$$

However, in general, the coefficients $g_t - c_t$ change sign as t varies. An example of this fact is in Figure 2, where $g_t - c_t$ values are obtained for $\sigma = 100$. Consequently, (37) cannot

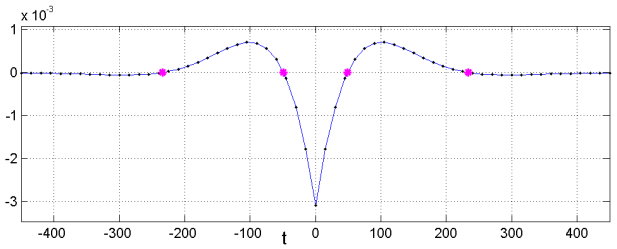

Fig. 2. Behaviour of $g_t - c_t$ for $\sigma = 100$ and $t = -450, \ldots, 450$

be proved and κ is not bounded by $1/(\sigma\sqrt{2\pi})$. In fact, the behaviour of κ, as σ varies in $[0.05, 50\,000]$, is shown in Figure 3. The figure highlights that κ takes its minimum values $\kappa_{min} = 0.05$ for $\sigma \approx 0.47$ and, except for values of σ in a small interval ($[0.37, 0.60]$), is always greater than 0.25. Moreover, we observe the following asymptotic behaviours:

- for small values of σ, κ seems to be unbounded and to increase like $1/\sigma$. This trend is consistent with (37) and is easily proved. Observing that $\alpha > 0$ implies:

$$c_0 = \frac{\beta}{1+\alpha} = \frac{1-\alpha}{1+\alpha} < 1,$$

for $\sigma < 1/\sqrt{2\pi} = 0.398$, it is:

$$\frac{1}{\sigma\sqrt{2\pi}} - 1 \leq g_0 - c_0 = |g_0 - c_0| \leq \kappa;$$

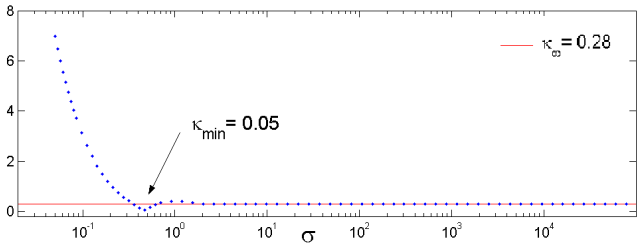

Fig. 3. Behaviour of κ for 75 values of σ increasing exponentially in the interval $[0.05, 50\,000]$

- for σ large enough, ($\sigma > 3.4$), κ becomes indeed constant and takes nearly the asymptotic value:

$$\kappa_\infty = \lim_{\sigma\to\infty} \kappa \approx 0.28.$$

This is the empirical evidence that (37) does not hold true for all σ. The value κ_∞ can be found observing that, for large σ, κ can be accurately approximated by the integral:

$$\int_{-\infty}^{+\infty} |g(t) - c(t)|dt,$$

where g is the Gaussian function, and c is the function:

$$c(t) = \frac{\beta}{1+\alpha}\alpha^{|t|}, \qquad \forall\, t \in \mathbf{R}.$$

To compute the integral, we need to establish when $g - c$ changes sign. Figure 2 shows that, for $\sigma = 100$, $g - c$ has 4 zeros (two pairs: $\pm t_1$, $\pm t_2$) and that changes sign 4 times. That is what actually happens for each large enough σ. Indeed, using the approximations:

$$\alpha \approx 1 - \frac{\sqrt{2}}{\sigma},\ \beta \approx \frac{\sqrt{2}}{\sigma},\ \frac{1}{1+\alpha} \approx \frac{1}{2},\ 1 - \frac{\sqrt{2}}{\sigma} \approx \exp\left(-\frac{\sqrt{2}}{\sigma}\right),$$

we obtain:

$$c(t) \approx \frac{\sqrt{2}}{\sigma}\frac{1}{2}\left(1 - \frac{\sqrt{2}}{\sigma}\right)^{|t|} \approx \frac{1}{\sigma\sqrt{2}}\exp\left(-\sqrt{2}\frac{|t|}{\sigma}\right) = \tilde{c}(t).$$

Solving $g(t) = \tilde{c}(t)$ for $x = \frac{|t|}{\sigma}$, we get:

$$\frac{1}{\sigma\sqrt{2\pi}}\exp\left(-\frac{x^2}{2}\right) = \frac{1}{\sigma\sqrt{2}}\exp\left(-\sqrt{2}x\right),$$

from which, taking the logarithms:

$$-x^2 - \ln\pi = -2x\sqrt{2},$$

and so:

$$x_1 = \sqrt{2} - \sqrt{2 - \ln\pi} = 0.489, \quad \text{and} \quad t_1 = x_1\sigma,$$

and:

$$x_2 = \sqrt{2} + \sqrt{2 - \ln\pi} = 2.339, \quad \text{and} \quad t_2 = x_2\sigma.$$

Finally, the value κ_∞ is achieved exploiting the symmetry and the sign of $|c-g|$. We have:

$$\kappa_\infty = 2\int_0^{+\infty} |g(t)-\tilde{c}(t)|dt = 2\int_0^{x_1\sigma} \big(\tilde{c}(t)-g(t)\big)dt+$$
$$+2\int_{x_1\sigma}^{x_2\sigma} \big(g(t)-\tilde{c}(t)\big)dt + 2\int_{x_2\sigma}^{+\infty} \big(\tilde{c}(t)-g(t)\big)dt = 0.28,$$

where, after changing the variable of integration t in $x = t/\sigma$ and specifying computations, one can see that the values of the integrals are no longer dependent on σ. In conclusion, our analysis has pointed out that, except for a small subinterval of σ values, the bound κ of the filter truncation error is never significantly small. Then we can state that the first-order Gaussian RF, when used in a single iteration, does not offer a good approximation of the Gaussian convolution.

V. Conclusions

In this work, we have given mathematical preliminaries and definitions about Gaussian RFs by focusing on the first-order Gaussian RF. For this filter we have studied the related matrix operator, by providing a complete description of its structure. Then, we have studied the associated filter truncation error and, exploiting the structure operator, we have given a theoretical error upper bound. This result has been used to investigate about the quality of the approximation supplied by that filter and has allowed to conclude that, in general, this filter is not very accurate.

***Abstract*—3D Electrical Capacitance Tomography provides a lot of challenging computational issues that have been reported in the past by many researchers. Image reconstruction using deterministic methods requires execution of many basic operations of linear algebra. Due to significant sizes of matrices used in ECT for image reconstruction and the fact that best image quality is achieved by using algorithms of which significant part is FEM and which are hard to parallelize or distribute. In order to solve these issues a new set of algorithms had to be developed.**

I. Introduction

ELECTRICAL Capacitance Tomography (ECT) is a relatively new imaging technique that can be used for non-invasive visualization in industrial applications in 2D, 3D and even 4D dynamic mode. ECT is performing the task of imaging of materials with a contrast in dielectric permittivity by measuring capacitance from a set of electrodes (Fig. 1). Among other non-invasive imaging techniques, ECT is characterized by much higher temporal resolution than Magnetic Resonance Imaging, Computed Tomography etc.

Unfortunately to achieve best image quality in 3D image reconstruction complex algorithms have to be used, especially ones that use large sensitivity matrices, Finite Element Method as well as neural networks approach [3].

In this article the authors have focused on accelerating non-linear image reconstruction algorithms, that are based on Finite Element Method and use sparse matrices to store data. We show that it is indeed possible to parallelize such algorithm and achieve significant speed-up, as well as develop them in such a way, to be able to use them in a distributed, heterogeneous computational system.

A. Image reconstruction in ECT

The scheme of image synthesis in Electrical Capacitance Tomography is called image reconstruction. It is based on solving the so called inverse problem, in which the spatial distribution of electric permittivity from the measured values of capacitance C is approximated. We can distinguish two types of image reconstruction algorithms. Firstly there are linear algorithms, which, because of higher temporal resolution, are used for monitoring fast-varying industrial process applications, like oil-gas flows in pipelines [1] or gravitational flows and discharging of silo [9] and non-linear algorithms, which allow reconstructing images with higher quality. Afterwards, reconstructed images can be analysed using either state of the art algorithmic approach, such as fuzzy-logic based classification [1] or by using a novel method of applying crowdsourcing [2], in order to determine, for example, flow characteristics.

II. Non-linear reconstruction algorithms

Non-linear three-dimensional image reconstruction in 3D capacitance tomography is a complex numerical problem, saturated with linear algebra transformations. During this iterative calculation process a set of parameters is determined, that is necessary for proper reconstruction of three-dimensional tomographic image optimization. The general idea of the algorithm is presented in Figure 2. One of the three key stages of the iterative process of reconstruction is a forward problem involving setting up a simulated vector based on a given spatial distribution of dielectric permittivity. The accuracy of the forward problem solution has a significant impact on the quality and speed of image reconstruction, and depends on the method of its determination. Most often forward problem is determined numerically using the Finite Element Method (FEM) based on a numerical model of a capacitance sensor. The authors have focused primarily on developing methods for accelerating the

Fig. 1. Object and 3D reconstruction obtained using Electrical Capacitance Tomography

calculations using algorithms developed specifically for use with sparse matrices (CULA library, CUSP). This made it possible to develop proprietary paralel computing algorithms (as a set of functions and procedures), dedicated to specific processing of tomographic data. Developed methods allow reconstructing three-dimensional images by using relatively fast methods of solving sparse matrix equations (AMG method - Algebraic Multi Grid, the Jacobi method and the Conjugate Gradient algorithm), which are computed on graphic processors.

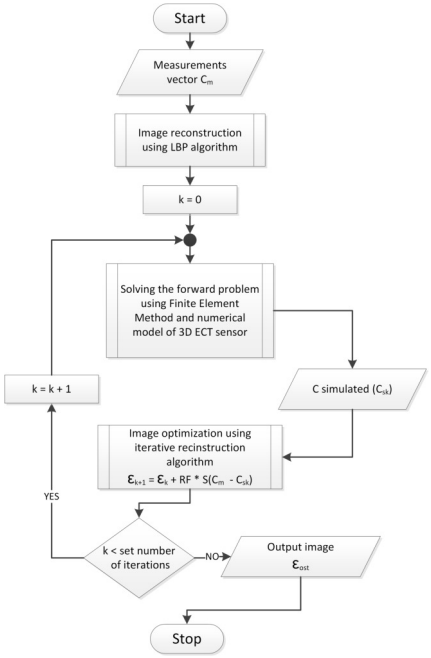

Fig. 2. General non-linear reconstruction algorithm in ECT

A. Finite Element Method

Image reconstruction algorithms using the Finite Element Method are often used in 3D Electrical Capacitance Tomography because of the possibility of obtaining a more accurate solution to the forward problem than linear algorithms, which in turn can improve spatial resolution of resulting 3D images. A major drawback of this method, however, is its large computational complexity. The authors have developed a number of proprietary software algorithms, which are designed to significantly reduce the time of image reconstruction using the Finite Element Method, through the implementation of parallel computing for sparse matrices and calculations in a heterogeneous and distributed environments.

Main idea of the developed algorithm is to obtain the solution (electric field distribution) given in the form of equation:

$$\boldsymbol{\varphi} = \boldsymbol{Y}^{-1}\boldsymbol{F} \tag{1}$$

where:

$\boldsymbol{\varphi}$ - is a sought distribution of the electric field - represented by the spatial distribution of nodal potential - partial solution of the forward problem in capacitance tomography;

$\boldsymbol{Y}$ - is a transformation matrix, built according to the geometric dependencies of sensor model mesh and Neumann boundary conditions;

$\boldsymbol{F}$ - is the extortion vector, defining the given Dirichlet boundary conditions

The first step of the algorithm is to pre-process the input data and store it as a set of sparse matrices. Then, in order to obtain $\boldsymbol{Y}$, matrix decomposition is performed as described by the equation:

$$\boldsymbol{Y} = \boldsymbol{A}^{\boldsymbol{T}}\boldsymbol{B}\boldsymbol{A} \tag{2}$$

where:

$\boldsymbol{A}$ - shape functions gradients matrix

$\boldsymbol{B}$ - matrix of normalized mesh volumes

$\boldsymbol{A}^{\mathrm{T}}$ - transposed shape functions gradients matrix

The next step of the algorithm is processing of the input data matrix and selecting the rows corresponding to each electrode - known potential in nodes describing the electrode. Then the matrix is preconditioned using either Jacobi or Algebraic Multi-Grid method. This makes it possible to solve the equation (1) using a Conjugate Gradients Method. Once this is done the resulting matrix is supplemented with data from the Dirichlet boundary conditions. The last step of the algorithm is to determine the vector of simulated measurements using Gauss' law described by the formula:

$$C_{eg} = \frac{\iiint_{\Omega} \varepsilon\,(x,y,z)\; grad[\varphi(x,y,z)]d\Omega}{\varphi_e - \varphi_g} \tag{3}$$

where:

C_{eg} – Capacitance between electrodes e and g

ε(x,y,z) – distribution of electric permitivity

φ(x,y,z) – distributon of potential

φ_e – electric potential on electrode e

φ_g – electric potential on electrode g

x,y,z – cartesian coordinates

B. Computations using sparse matrices

The operation of multiplying three matrices, represented by the formula (2), is an integral part of the Finite Element Method for 3D ECT. This action, however, is characterized by high computational complexity. Moreover, the stiffness matrices $\boldsymbol{Y}$, generated by numerical models of 3D ECT sensors, are too large to fit entirely in RAM of graphics cards. However, the number of non-zero elements is relatively small in relation to the dimensions. Thus, it is possible to treat them as sparse matrices to reduce memory usage.

There are many formats for storing sparse matrices. Among them the most common formats are CSC (Compressed Sparse Column) and CSR (Compressed Sparse Row). The authors decided to use CSR format because it allows, in most cases, for optimal access to the data stored in GPU memory. Reading and writing data is usually done in a row-major manner, which is optimal for most architectures of CPUs and GPUs. Saving sparse matrix in the CSR format is, for the same reason, not optimal for multiplication, as there needs to be a way of quickly accessing the columns of the matrix without causing

uncoalesced reads/writes from GPU memory. This situation arises when data must be read in a manner that does not comply with optimal memory access for specific hardware and cannot be obtained in one transaction. The impact of this phenomenon on the speed of computations is highly dependent on the hardware architecture of the GPU, however, it is always significant.

In order to significantly reduce this problem the authors have introduced a hybrid format, called Hybrid Compressed Sparse Row-Column (H-CSRC), comprised of both the records of CSR and CSC. Depending on the needs, data can be accessed in either row or column-major manner, while minimizing memory operation and maintaining compatibility with other algorithms.

Multiplication of three sparse matrices has been implemented as a single operation. This approach allows for optimal use of local and private memory on the GPU, in order to increase the speed of calculations. In this algorithm, it is necessary to use the local memory, shared by thread groups, to minimize the number of global memory accesses.

In 3D ECT it is particularly important to optimize each of the algorithms for the speed of execution. Hence the authors have developed a special version of three matrix multiplication algorithm, which takes into account all the specific properties of the matrix calculations in the 3D ECT, as defined by equation (2). There are three main properties of the input data, specific to the ECT, that allow for further optimizations:

- Items in the matrix $\boldsymbol{B}$ have a non-zero values on the main diagonal only. In addition, they repeat in sets of three, which is due to the specificity of the input data.
- The output array is symmetrical along its main diagonal, which, using proper element indexing, can reduce the number of operations almost by half.
- Due to the nature of the calculations, the amount of output elements and their position, does not change during the execution of the program, assuming the immutability of input data distribution. Hence this can be determined before the execution of the program and put into the algorithm as a map of elements to instantly skip the input matrix elements, which are known a priori to not produce results.

C. Parallelization

The first variant of image reconstruction algorithm using the Finite Element Method is the reconstruction in the local system. As it constitutes a platform for further modifications it was necessary to design and implement a solution, that would be also applicable in multi-GPU [4], as well as distributed systems. To ensure efficient 3D image reconstruction the proposed algorithm includes data caching solutions. This issue is particularly important in the case of heterogeneous systems. In most 3D ECT systems measurement data is collected with higher frequency than it can be reconstructed. Moreover, because of the asynchronous nature of the developed solution, based on the commissioning of tasks to local GPUs using CUDA technology, as well as remote computing nodes, delays can accumulate, therefore there is a need for their elimination by buffering systems. All the algorithms have been designed, implemented and optimized from the start as a solution suited to multi-GPU and distributed systems. Due to the specific nature of the computations the most optimal solution is to start a separate thread for each GPU in the system, that are synchronised when reading the results.

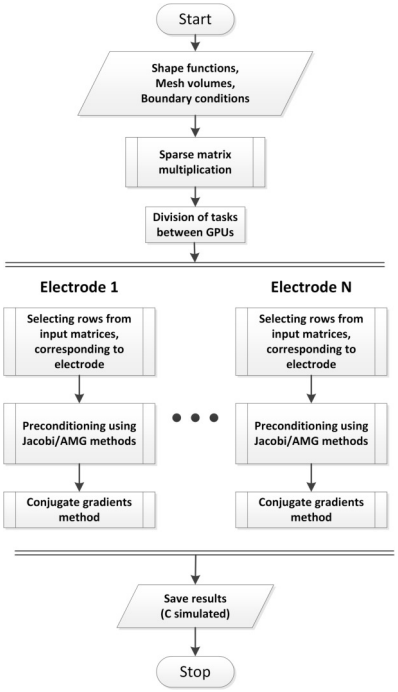

Fig. 3. Algorithm for calculating solution to forward problem using multiple GPUs

All the algorithms, developed by the authors, were designed to function in systems with multiple GPUs. Thus a natural direction for obtaining a further acceleration of computations is to perform non-linear 3D image reconstruction in a distributed system, which tends to have a higher degree of heterogeneity than the local systems.

The main idea of the developed algorithm is, that each GPU inside the compute calculates the solution to forward problem for one or more electrodes, by assigning to each GPU calculations specific to the selected electrode of the system, where all the GPU compute the result of a single image reconstruction (Fig. 3). This approach allows for more precise control of tasks allocation. This in turn enables its use in distributed systems with a high degree of heterogeneity. This solution also allows for potential reduction in overall system response time, since all nodes perform calculation for a single output image. Therefore, the task of caching is greatly simplified, and the image can be displayed on the screen without introducing delays larger than the reconstruction time for a single image. The disadvantage of this solution is, however, that it limits the scalability of a distributed system, since the total number of graphics processors cannot be greater than the number of electrodes.

III. RESULTS

The research conducted on ECT algorithms [6] has shown that, although, dynamic development of GPU computing performance and its recent application for image reconstruction in ECT has significantly improved calculations time, in modern systems a single GPU is not enough to perform many tasks [7]. As a result multiple GPUs have to be used to accelerate calculations [5]. Thus, the authors are proposing a distributed, multi-node, multi-GPU heterogeneous system with a software layer that will allow use of multiple computers with fast GPUs to perform calculations across network connection [5]. The developed system, based on the proprietary KISDC networking platform [8], is designed to fully exploit parallel performance of all devices that the nodes are equipped with. Such architecture is very scalable and makes it possible to increase computation performance by adding new network nodes. Reconstruction algorithm verification tests were conducted using real measurement data, recorded during the research under Ministry of Education grant number 4664/B/T02/2010/38, using semi-industrial installation. Due to the nature of calculations using the graphics processors, the stability of execution times is lower than for algorithms executed on the CPU. Therefore, all of the results shown in this paper represent the worst case scenario - the lowest number of reconstructed images per second, achieved during testing.

All the results achieved with GPUs were compared with the performance of algorithms executed on the CPU, implemented using optimized BLAS libraries (Basic Linear Algebra Subprograms), compiled with Intel compiler and optimized for the tested CPU architecture.

A. Non-linear algorithms - local system

Reconstruction tests using non-linear algorithms and multiple graphics processors at the same time were carried out using NVIDIA Tesla C2070 card and NVIDIA Tesla S1070-400 computing server, which has four graphics cores (Table I). Verification of developed solutions in this case was performed for 1, 2, and 4 GPUs. The division of tasks between the graphics processors was done by creating a new thread for each GPU. As a result, it was possible to separate the control flow of the application from computations, thus allowing for asynchronous commission of tasks to the GPUs. Tests were performed for 10 iterations of non-linear reconstruction algorithm. The test results are presented as the number of images obtained per second.

TABLE II
RESULTS OF NON-LINEAR IMAGE RECONSTRUCTION [IMAGES/SECOND]

Elements in image vector	4 GPUs	2 GPUs	GPU	CPU (BLAS)
8488	0.035	0.024	0.015	0.003
20499	0.021	0.012	0.007	0.002
60896	0.007	0.004	0.002	0.001
87172	0.005	0.003	0.002	<0.001
157264	0.003	0.002	0.001	<0.001

All the tests were performed using the developed task division algorithm, by assigning each GPU calculations for a specific set of electrodes (Fig. 3). Moreover, verification was conducted using an optimized version of this algorithm, which enables asymmetric division of compute jobs between the units. Based on the known efficiency parameters, each GPU was assigned with solving the forward problem for appropriate number of electrodes. For example, by using two GPUs - Tesla C2070 card and a single GPU from Tesla S1070 accelerator, the C2070 card computes solution for 18 electrodes, and the S1070 GPU for the remaining 14. The results for this configuration are shown in Table II and in Figure 4.

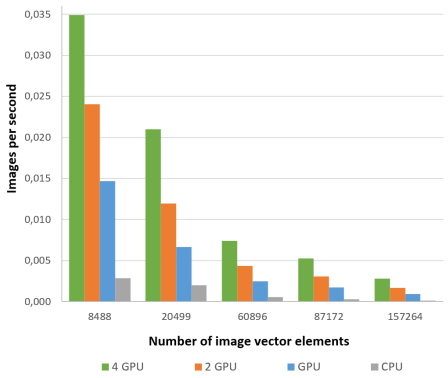

Fig. 4. Speed of non-linear reconstruction

As can be seen from Table II and Fig. 4, the use of multiple GPUs allowed to accelerate a non-linear image reconstruction by up to seventeen times for the two graphics processors and 28-fold in the case of four GPU compared to calculations using traditional algorithms executed on a CPU.

B. Non-linear algorithms - distributed system

Image reconstruction tests in distributed environment were performed using two HPC nodes code named: Dave and Hal. Their full specification is shown in Table I. In this case verification was performed for a total of 6 GPUs - four in HPC Hal (Tesla C2070 + Tesla S1070) and two in HPC Dave (2x Nvidia GTX 570). As it was in the case with computations in the local system all the tests were performed using task allocation based on number of electrodes. The data was sent between the nodes using KISDC networking layer, developed specifically by the authors for use in distributed

TABLE III
RESULTS OF DISTRIBUTED NON-LINEAR IMAGE RECONSTRUCTION [IMAGES/SECOND]

Elements in image vector	Local system 4 GPUs	Distributed system 4+2 GPUs	Speed-up
8488	0.0349	0.0381	1.09
20499	0.0210	0.0198	0.94
60896	0.0074	0.0086	1.16
87172	0.0053	0.0059	1.12
157264	0.0028	0.0034	1.20

image reconstruction in 3D ECT. All the results for these tests are presented in Table III and in Figure 5.

Using the distributed system for image reconstruction purposes the authors were able to speed-up the computations compared to local system by up to 20%. There was however one exception - for the image vector size of 20499. In this case the computations on a distributed system were slower than in local environment. This was caused by a combination of overheads resulting from synchronisation and network delays. Moreover, because of the specifics of GPU computations it is common to come across a combination of input data sizes and algorithm logic that will cause overall slow-down in specific cases. Nevertheless, the authors are sure that further work on the developed algorithms will result in even better results in the future.

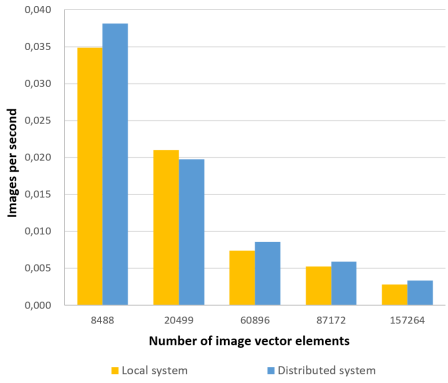

Fig. 5. Speed of non-linear reconstruction

IV. CONCLUSION

As a part of the research authors have developed a flexible, distributed computing system, intended for tomographic image reconstruction process. For both the linear and non-linear reconstruction algorithms parallel architecture developed by the authors is designed in such a way that it can be scaled to any number of computing nodes, assuming that the network medium is not a limiting factor. Performance tests have shown that the practical application of parallel algorithms executed on GPU allows for a 28-fold increase in the rate of performing calculations in the case of non-linear algorithms, compared to the optimized, sequential versions of algorithms.

Further research will also address challenges of calculations in heterogeneous and distributed environments. This work will be aimed at reducing delays, and therefore the response time of the system, due to the transmission of data over the network, as well as overall optimizations to increase the stability of the proposed solution. In addition, the authors are carrying out further work on the system, and the concept of complete reconstruction, utilizing both linear and non-linear algorithms, on the remote nodes. Ultimately, this will enable the transfer of all calculations to remote servers, connected to the data acquisition system over the Internet, thereby allowing monitoring and control of the industrial processes using smartphones or other mobile devices.

***Abstract*—Because the numerical solution of initial value problems (IVPs) of systems of ordinary differential equations (ODEs) can be computationally intensive, several parallel methods have been proposed in the past. One class of modern parallel IVP methods are the peer methods proposed by Schmitt and Weiner, some of which are publicly available in the software package EPPEER released in 2012. Since they possess eight independent stages, these methods offer natural parallelism across the method suitable for the typical numbers of CPU cores in modern multicore workstations. EPPEER is written in FORTRAN95 and uses OpenMP as parallel programming model.**

In this paper, we investigate the influence of the locality of memory references on the scalability of method- and system-parallel explicit peer methods. In particular, we investigate the interplay between the linear combination of the stages and the function evaluations by applying different program transformations to the loop structure and by evaluating their performance in detailed runtime experiments. These experiments point out that loop tiling is required to improve cache utilization while still allowing the compiler to vectorize along the system dimension.

To show that for certain classes of right-hand-side functions a stage-parallel execution is not optimal, and to enhance the scalability of the peer methods to core numbers larger than the number of stages of a method, system-parallel implementations have been derived. Runtime experiments show that there are IVPs for which these new implementations outperform stage-parallel implementations on numbers of cores less than or equal to the number of stages. Moreover, by exploiting the ability to utilize higher core numbers, higher speedups than the number of stages have been reached.

I. Introduction

THIS paper considers a class of parallel solution methods for initial value problems (IVPs) of systems of ordinary differential equations (ODEs), defined by

$$\mathbf{y}'(t) = \mathbf{f}(t, \mathbf{y}(t)), \quad \mathbf{y}(t_0) = \mathbf{y}_0, \quad t \in [t_0, t_e], \qquad (1)$$

where $\mathbf{f} : \mathbb{R} \times \mathbb{R}^n \to \mathbb{R}^n$ is the *right-hand-side function* defining the ODE system, $t \in \mathbb{R}$ is the *independent variable*, usually denoting "*time*", $\mathbf{y} : \mathbb{R} \to \mathbb{R}^n$ is the *solution function* to be computed within the *integration interval* $[t_0, t_e] \subset \mathbb{R}$, and $\mathbf{y}_0$ is the initial value, i.e., the value of $\mathbf{y}$ at time t_0.

Many ODE IVPs do not have an analytical solution and must be solved numerically. The classical numerical approach, which is also used by the class of methods considered in this paper, applies a time-stepping procedure that starts at t_0 and walks through the integration interval, computing a new approximation value $\mathbf{y}_m \approx \mathbf{y}(t_m)$ at each time step $m = 1, 2, \ldots$ until t_e is reached. A detailed treatment of the subject can be found in [1].

Because the numerical solution of ODE IVPs often is computationally intensive, several methods with potential for parallelism have been proposed. Usually, these methods are classified as exploiting *parallelism across the method*, *parallelism across the system*, and *parallelism across time* (also called *parallelism across the steps*), see [2] for an overview of classical parallel ODE methods.

This paper considers the explicit parallel two-step peer methods provided as part of the EPPEER software package [3]. Peer methods have been introduced by Schmitt and Weiner in 2004 [4]. The explicit methods included in EPPEER, which has been released in 2012, are described in [5], [6], [7]. These methods possess up to 8 independent stages, which can be computed in parallel on different cores. Hence, they are an example for methods providing parallelism across the method, which can be exploited without a (possibly difficult) parallelisation of the right-hand-side function. However, as the authors of EPPEER note, additional parallelisation across the system is possible for larger numbers of cores, but this functionality is currently not part of the EPPEER package and has not been investigated yet.

In their tests of the parallel performance of the explicit two-step peer methods, the authors of EPPEER notice that near-optimal speedups are possible for expensive right-hand-side functions, while the speedups observed for cheap right-hand-side functions were less satisfactory [6], [8]. They attribute this behavior to a part of the time step where a linear combination of vectors is computed [6], [8].

In this paper, we investigate the reasons for the lower performance of cheap right-hand-side functions in detail and identify the locality of memory references of the linear combination but also the interplay between the locality of the linear combination and the locality of the function evaluations as the main performance limiters. As part of this investigation, we apply several different program transformations to the loop structure of the peer methods and evaluate their effect on locality and scalability using runtime experiments on two

978-83-60810-90-3/$25.00

different hardware architectures. In particular, we make use of loop tiling to exploit both temporal and spatial locality while still enabling the compiler to vectorize the loops over the system dimension. In addition to the parallelization over the stages, we also investigate system-parallel implementations. The goal of this is not only to enable the use of larger numbers of processor cores, but primarily to compare the locality behavior and the scalability of a system-parallel and a stage-parallel execution on small numbers of cores. In particular, we are interested in the question whether a system-parallel or a stage-parallel execution is more efficient for IVPs with a cheap right-hand-side function.

The rest of the paper is structured as follows: Section II discusses related work. Section III describes the mathematical structure of peer methods. Section IV investigates the influence of the loop structure on locality and scalability. Section V considers the interplay of the function evaluations and the system-parallel execution. The last two sections conclude the article.

II. Background and Related Work

A. Parallel ODE Methods

The numerical solution of ODE IVPs can be computationally intensive. Therefore, many solution methods with potential for parallelism have been proposed. Most of the fundamental work on parallel ODE methods dates back to the 1980s and 1990s; an overview and further references can be found in [2].

Parallelism across time is generally difficult to obtain for IVPs because there needs to be an information flow from the initial value at t_0 to the end of the integration interval t_e. There are, however, promising approaches based on the Picard iteration, e.g., Parareal methods [9]. Most of the parallel ODE methods proposed concentrate on *parallelism across the method*, i.e., they provide a small number of independent coarse-grained computational tasks inherent in the computational structure of the method, for example, independent stages. Examples are Parallel Adams–Bashforth (PAB) and Parallel Adams–Moulton (PAM) methods [10], which belong to the class of *general linear methods* [1], parallel iterated RK (PIRK) methods [2], and extrapolation methods [1], [2]. Basically, all IVP methods possess a natural potential for *parallelism across the ODE system*, because usually the equations of the ODE system can be distributed to different processor cores. Of course, this approach is only feasible for reasonably large ODE systems.

One implementation strategy aiming at parallelism across the system is the use of parallel linear algebra operations which are parallelized along the system dimension. The project Odeint [11], for example, which is part of the Boost C++ library, contains several IVP methods and allows the use of different sequential or parallel state vector types. Another example of this type of parallelism is the PETSc library [12], which targets partial differential equations (PDEs), but also contains several ODE IVP solvers. One disadvantage of this approach is that parts of the code outside the linear algebra operations are not parallelized, and parallel performance tuning cannot be applied to the IVP solver as a whole.

System-parallel implementations covering all parts of a time step have been investigated in [13] for embedded RK methods and in [14] for PIRK methods.

Waveform relaxation methods [2] are specially tailored for a system-parallel execution of large ODE systems as they arise in the simulation of electrical circuits. They use the Picard iteration to decouple the equations of the ODE system and thus avoid synchronization and communication between cores. However, similar to Parareal methods, they have to deal with a possibly slow convergence of the Picard iteration.

The subject of this paper are explicit parallel two-step peer methods, which show similarities in their computational structure to PIRK methods and Parallel Adams methods. It investigates the locality and scalability of these methods when exploiting either method or system parallelism.

B. Performance Optimization

Computer systems are becoming more and more complex and make use of parallelism at various levels. To hide the increasing complexity, modern CPUs and compilers contain many mechanisms and techniques that aim at providing most of the available performance of the hardware in a transparent way to the application programmer. For example, CPUs contain multiple execution units, which can work in parallel, and they use dynamic instruction scheduling and *simultaneous multithreading* (SMT) to increase the utilization of the execution units. Modern compilers try to automatically unroll and vectorize loops to make use of SIMD (*single instruction multiple data*) extensions such as SSE and AVX [15].

Practically all modern CPUs used in high-performance computing possess a deep memory hierarchy with usually two or three levels of cache to temporarily store and reuse data read from or written to the external, slower main memory, thus hiding most part of the latency time that would otherwise be needed to access the main memory. In multi-core CPUs, the higher cache levels are often shared between several cores. To obtain maximum performance on a hardware platform with memory hierarchy, it is crucial to optimize the locality of memory references.

In the field of compiler design, efficient use of the memory hierarchy is tried to be achieved by reordering compute intensive loops in the source code. Loop tiling is considered as one of the most successful techniques. An important analytical model are *cache miss equations* [16], which can be used to estimate the effects of loop transformations. To analyze the dependencies of loops and to perform loop transformations, often the polyhedral model is used, e.g., [17]. A simple, but insightful visual model for the performance of computer programs on modern multi-core architectures is the *roofline model* [18]. A generalization of the roofline model to cover deep memory hierarchies is the *execution cache memory (ECM) model* [19].

To overcome the limits of static code analysis, some compiler-based approaches introduce source code annotations

[15] or propose domain specific languages (DSLs), which are then extended by *autotuning* techniques, e.g., [20]. Autotuning tries to determine the best configuration from a search space of possible code variants and parameters (e.g., block sizes for loop tiling, loop unroll factors, or number of threads). In [21], an online autotuning approach for system-parallel PIRK methods has been investigated.

III. Explicit Parallel Peer Methods in EPPEER

In this section, we will explain the computational structure of the explicit parallel two-step peer methods and describe their implementation in EPPEER. Then, we will investigate locality and scalability of the unmodified EPPEER code by several runtime experiments.

A. Computational Structure

Similar to classical RK methods, the explicit two-step peer methods in EPPEER use a time-stepping procedure to solve the IVP and compute s stages $\mathbf{Y}_{m,i}$, $i = 1, \ldots, s$, at each time step from t_{m-1} to t_m with $t_m = t_{m-1} + h_{m-1}$ for $m = 1, 2, \ldots$ [7]. However, in contrast to classical RK methods, all s stages have the same accuracy and stability properties and, to compute the stages, the s stages and the s function values of the previous time step are used:

$$\mathbf{Y}_{m,i} = \underbrace{\sum_{j=1}^{s} b_{ij} \mathbf{Y}_{m-1,j}}_{\mathbf{S_Y}} + \underbrace{h_m \sum_{j=1}^{s} a_{ij} \mathbf{f}(t_{m-1,j}, \mathbf{Y}_{m-1,j})}_{\mathbf{S_f}}, \quad (2)$$

where $t_{m-1,j} = t_{m-1} + h_{m-1} c_j$ for $j = 1, \ldots, s$, and a_{ij}, b_{ij}, and c_j, $i, j = 1, \ldots, s$ with $c_s = 1$ are the coefficients of the particular peer method. Therefore, these methods are a subclass of general linear methods (GLMs) [1].

Because only values from the previous time step are used, the s stages of the current time step do not depend on each other and can be computed in parallel on different cores, thus exhibiting parallelism across the method. In EPPEER, three methods with $s = 4, 6, 8$ are included which can use up to s cores. These methods have been introduced in [6]. In addition, four FSAL methods (first same as last: last stage of the previous time step is reused as the first stage of the current time step) with $s = 3, 5, 7, 9$, which have been introduced in [5], are included, which can use up to $s - 1$ cores.

Since all s stages have the same properties, in particular the same order $O(h_m^s)$, there is no determined value for $\mathbf{y}_m \approx \mathbf{y}(t_m)$. Instead, any stage value can be used as new approximation to the solution function.

Due to the two-step character, a starting procedure is required to generate $s-1$ stages in addition to the initial value $\mathbf{y}_0$ before the first time step can be performed with the peer method to compute $\mathbf{Y}_{1,i}$. Currently, EPPEER uses an explicit RK method (DOPRI 5(4)) to compute the start values. However, a parallel starting procedure has been proposed in [22].

B. Implementation

The following section introduces the implementation of the original EPPEER package. The source code of this implementation can be seen in Listing 1. Each time step of a peer method consists of two basic parts: The linear combination and the function evaluation.

EPPEER implements those two basic parts by three consecutive loop nests: The first and the second loop nest perform the linear combination. For this purpose the first loop nest initializes an $s \times n$ accumulation matrix for the computation of $\mathbf{Y}_{m,i}$ with zeroes, i.e.,

$$\text{for } i = 1, \ldots, s: \quad \mathbf{Y}_{m,i} \leftarrow \mathbf{0} \quad (3)$$

and uses this matrix to accumulate and add the second sum of Eq. (2), $\mathbf{S_f}$:

$$\text{for } i = 1, \ldots, s: \quad \mathbf{Y}_{m,i} \leftarrow \mathbf{Y}_{m,i} + \underbrace{h_m \sum_{j=1}^{s} a_{ij} \mathbf{F}_{m-1,j}}_{\mathbf{S_f}}, \quad (4)$$

where

$$\mathbf{F}_{m-1,j} = \mathbf{f}(t_{m-1,j}, \mathbf{Y}_{m-1,j}) \quad (5)$$

are stored function values computed in the previous time step. After that the second loop nest accumulates and adds the first sum of Eq. (2), $\mathbf{S_Y}$:

$$\text{for } i = 1, \ldots, s: \quad \mathbf{Y}_{m,i} \leftarrow \mathbf{Y}_{m,i} + \mathbf{S_Y}. \quad (6)$$

The third and final loop nest performs the function evaluation to compute $\mathbf{F}_{m,j}$, needed in the next time step, using Eq. (5).

The outermost loop of each loop nest iterates over the stages of the peer method, where the ith iteration of the outer loop computes the argument vector $\mathbf{Y}_{m,i}$ for stage i. Thus, we will refer to these loops as "stage loops". The iterations of the stage loops are independent of each other. That is why the stages

can be computed in parallel for each loop nest. This is a major advantage of the peer methods. The EPPEER package takes this advantage by parallelizing each stage loop with OpenMP.

The stage loops of the first and the second loop nest contain inner loops, which also iterate over the stages in order to compute the linear combinations $\mathbf{S_f}$ and $\mathbf{S_Y}$, respectively, for the stage i corresponding to the current iteration of the outer stage loop. Thus, we will refer to these loops as "combination loops".

The combination loops perform operations on vectors of dimension n and, thus, contain an innermost loop, which iterates over the system dimension and which we therefore call "system loop". Instead of explicitly implementing these system loops as FORTRAN `do` loops, EPPEER uses the FORTRAN vector notation, thus making it easy for the compiler to generate vectorized code for these loops.

C. Performance

In this section, we use the results of runtime experiments to analyze the scalability of the original EPPEER package with the number of cores. The first target system for these experiments is an 8 core Intel Xeon E5-2630V3 (Haswell-EP) CPU. However, the Haswell-EP CPU has two features which might alter the scalability in an unexpected way: Turbo Boost (on-demand increase of clock frequency) and Hyper Threading (2-way simultaneous multithreading (SMT) per core). To avoid potential negative influences of these features on our measurement results, we disabled both features for all measurements. Our second target system is an Intel Xeon Phi 31S1 coprocessor. The Xeon Phi does not have a turbo mode, but it provides 4-way SMT per core, which cannot be disabled. However, to ensure that each thread runs on a separate physical core, we make use of the OpenMP runtime environment to distribute the threads evenly among the cores until the number of threads exceeds the total number of cores. On both target systems, the Intel FORTRAN compiler in version 16.0.2 was used with optimization level 2 (`-O2`) to compile the EPPEER package. All computations were performed using double precision. For profiling purposes we use PAPI in Version 5.4.1. PAPI is a powerful profiling library, which can read the values of CPU-internal performance counters, which can count, for example, the number of cache misses or the number of load/store operations.

We chose two different ODE systems as test problems: The first one is the 2D Brusselator *brus*. It models an oscillating chemical reaction-diffusion system using a two dimensional grid as spatial discretization. The resulting access pattern to the grid points is a five-point 2D stencil. Therefore, *brus* is a sparse problem and its right-hand-side function $\mathbf{f}$ has a time complexity of $\Theta(n)$. For all measurements with *brus*, we chose a vector size of 500 000 elements, where each vector element is a double precision floating point number, requiring 8 bytes of storage space. Thus, a vector corresponds to a grid of 500×500 cells, where each cell contains two double values, so that one vector requires 3.81 MB of storage space. The second test problem is the N-body problem *mbod*, which is also known as the many body problem. It simulates the movement of particles, which interact with each other by the gravitational force. Since the gravitational field of a particle influences every other particle, the N-body problem is a dense problem and its right-hand-side function $\mathbf{f}$ has a time complexity of $\Theta(n^2)$. To obtain the experimental results shown in the following, a scene consisting of 2000 particles was used, where each particle added 6 equations to the ODE system, resulting in a vector size of 12 000 elements (93.75 KB). Table I shows the speedups observed in our experiments.

TABLE I
SPEEDUPS MEASURED WITH THE EPPEER PACKAGE.

		Speedups for different #threads				
Hardware	**Problem**	1	2	3	4	8
Haswell-EP	*brus*	1	1.839	2.006	2.232	2.311
Haswell-EP	*mbod*	1	1.961	2.582	3.779	7.047
Xeon Phi	*brus*	1	1.941	2.619	3.609	6.702
Xeon Phi	*mbod*	1	1.966	2.594	3.804	7.133

Similar to the authors of the EPPEER package, our measurements with the *mbod* problem show a very good scalability. The use of 8 threads yields an almost ideal speedup of 7.0 on Haswell-EP and a speedup of 7.1 on the Xeon Phi. In contrast, the best speedups measured for the *brus* problem are only 2.3 and 6.7 on the Haswell-EP and the Xeon Phi, respectively (on both systems obtained using 8 threads). Thus, obviously, the scalability of the peer methods is influenced by the IVP to be solved.

Interestingly, Table I shows a smaller efficiency when 3 threads are used, which is caused by the following: It is not possible to distribute s equally sized tasks among p threads evenly if $s \bmod p \neq 0$. In our case it is impossible to distribute the 8 stages equally among 3, 5, 6 and 7 threads. This load imbalance forces some of the threads to idle while all other threads complete their last remaining task.

One apparent difference between the two test problems is the access pattern of the right-hand-side function $\mathbf{f}(t_{m,j}, \mathbf{Y}_{m,j})$ to the argument vector $\mathbf{Y}_{m,j}$ and the resulting time complexity. While the dense *mbod* problem has a time complexity of $\Theta(n^2)$, the time complexity of the sparse *brus* problem is only $\Theta(n)$. We can therefore expect that for *brus* the time needed to perform the function evaluations constitutes a smaller fraction of the runtime of a time step than for the *mbod*. In fact, further measurements (Figure 1) have shown that on average evaluating the right hand side of *mbod* takes about 97 % of the total runtime of a time step, whereas the linear combination only takes the remaining 1 to 2 %. In contrast, for *brus*, less than 18 % of the total runtime of a time step is required to compute the function evaluations, but nearly 75 % are needed to perform the linear combination to compute the argument vectors $\mathbf{Y}_{m,j}$.

In total, the results of the runtime experiments show that the scalability depends on the IVP to be solved. For sparse and computationally inexpensive systems like *brus*, computing the linear combinations takes a major part of the runtime (see Figure 1 (b)) and can therefore be expected to have

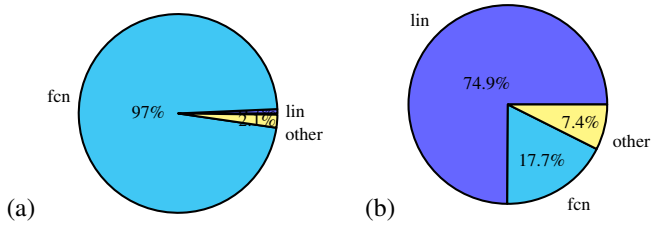

Fig. 1. Average runtime fractions of the linear combination (lin), the function evaluation (fcn) and other parts of the code for (a) *mbod* and (b) *brus*.

a significant influence on scalability. Since the arithmetic intensity, i.e., the ratio of the number of arithmetic instructions to the number of memory instructions, of this part of the time step is low, we can expect the performance of the linear combination to be bound by the performance of the cache and memory subsystem. Moreover, the working set of one time step, i.e., the amount of data accessed in a time step, amounts to four $s \times n$ matrices, which corresponds to 122.1 MB in our experiments and, thus, is significantly larger than the cache size of typical workstations today. We can therefore expect that many expensive accesses to the main memory are required in the experiments with *brus*.

However, for dense and computationally intensive systems like *mbod*, the evaluation of the right-hand-side function of the ODE system dominates the runtime. Since the function evaluations are independent of each other, this leads to the high scalability observed. For the problem size we used, the working set of one time step amounts to 2.92 MB, that means all data accessed during one time step fits completely in the 20 MB L3 cache of the Haswell-EP. The 512 KB L2 cache of a Xeon Phi core can not store the whole working set of a time step, but, to perform the stage-parallel function evaluation efficiently, it is only important that it can store two n-vectors (93.75 KB each) to hold the argument of the function evaluation and its result. The reason for this is that to compute the gravitational force acting on one body the interacting forces with all other $N-1$ bodies are accumulated. Thus, to compute all entries of the function result $\mathbf{f}(t_{m,j}, \mathbf{Y}_{m,j})$, half of the argument vector $\mathbf{Y}_{m,j}$ is read $n/2$ times.[1] Since all important data fits in the cache and the arithmetic intensity is higher than that of *brus*, we can expect the performance of the *mbod* problem to be bound by the compute performance of the processor used. Therefore, improving the locality of memory references further would probably not improve the already high scalability.

In the following, we therefore focus on the sparse case, where an improvement of the scalability is more important and where we can expect to be able to improve the scalability by an improvement of the locality behavior. As test problem we consider only *brus* from now on.

[1] *mbod* is a first order system derived from a second order system by substitution.

IV. Loop Structure of the Linear Combination

A. Variants of the Loop Structure

After the identification of the linear combination as the major fraction of the runtime for sparse ODE systems in the previous section, this section focuses solely on the improvement of the loop structure of the linear combination, possible loop transformations, and their influence on the resulting locality and scalability. The interplay with the evaluation of the right-hand-side function (the third loop nest in the original EPPEER package) will be considered afterwards in Section V.

The data access pattern of the original stage-parallel EPPEER loop structure (referred to as "Ver-0" in the following) is illustrated in Figure 2 for a method with 8 stages and one thread per stage. Only the first two threads are shown, because the data access pattern is similar for all threads: to compute the argument vector $\mathbf{Y}_{m,i}$ of their stage i, the whole two $s \times n$ matrices Y_{m-1} and F_{m-1} are read, and after each loop nest the result of the computations within the loop nest are written back to memory. Hence, in total there are $2s+1$ write accesses to each element of the matrix Y_m: initialization with zero, accumulation of sum $\mathbf{S_Y}$ and accumulation of sum $\mathbf{S_Y}$. Though the stages are computed in parallel by different threads, in most current shared-memory computers several threads share parts of the memory subsystem (e.g., shared higher level caches, main memory modules connected to a socket) so that they compete for these limited resources and may quickly reach their limits.

Since the system dimension is the stride-1 dimension, the innermost loops of Ver-0 iterate over the stride-1 dimension, which leads to high spatial locality and allows the compiler to vectorize the loads and stores using sequential SIMD load/store instructions.

The first improvement of the loop structure we consider can be seen in Listing 2 and will be referred to as "Ver-1" in the following. Ver-1 adopts the parallelization across the stages from Ver-0, but it contains two modifications. First, it eliminates the zero initialization of Y_m by peeling off the first iteration of the combination loop. This saves one pass over the matrix Y_m and, thus, many expensive memory accesses. Moreover, the first and the second loop nest of Ver-0 are fused, which both contribute to the computation of $\mathbf{Y}_{m,i}$, to a single loop nest. This loop fusion is legal, because the only dependencies between those two loop nests are the write accesses to the matrix Y_m accumulating the sums in Eq. 2. That is why changing the order of the loops, and thus the order of the accumulation, only influences the round-off error. An advantage of this new fused loop structure is that only s write accesses to each element of Y_m are necessary.

Trying to overcome some disadvantages of Ver-0 and Ver-1, Ver-2 (Listing 3) parallelizes the linear combinations across the system dimension. This version is based on an earlier version of the EPPEER package. It is obtained by interchanging the loops of each loop nest of Ver-0 so that the outermost loop iterates over the system dimension and the two inner loops iterate over the stages. To enable this interchange,

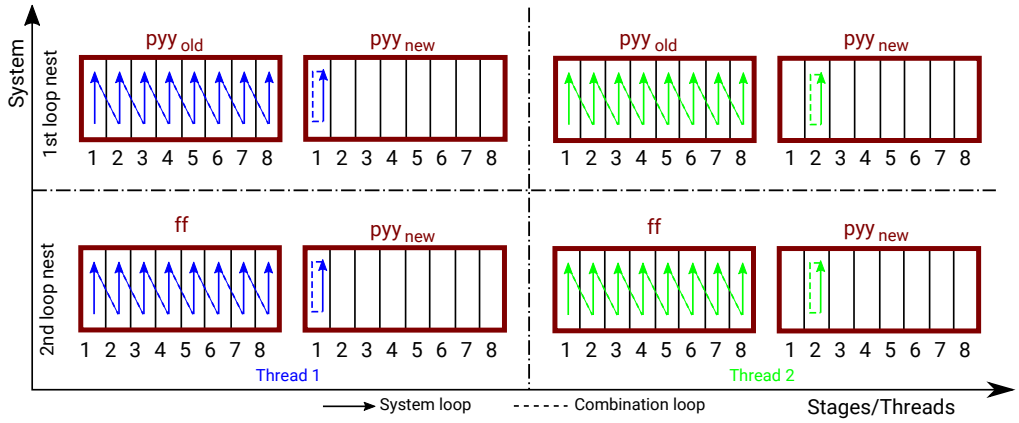

Fig. 2. Data access pattern of the original EPPEER package (Ver-0).

```

Listing 3. Ver-2: System parallel execution.

the previously innermost system loops, which were defined implicitly using vector notation, had to be transformed into an explicit FORTRAN do loop. As a result, a higher temporal locality for the write accesses to the elements of the matrix Y_m is generated. The compiler can now keep the temporary partial sums in a register during the s^2 iterations over the stages by the inner loops of each loop nest, so that now each element of Y_m needs only be written to main memory twice.

Even more important, the amount of data accessed by each thread is reduced significantly: While in Ver-0 and Ver-1 each thread needs to read all elements of the matrices Y_{m-1} and F_{m-1} to compute the stage(s) assigned to it, in Ver-2 it reads only the range of elements of Y_{m-1} and F_{m-1} assigned to it and it writes only the corresponding range of elements of Y_m. Hence, if there are p threads, each thread only reads at most $2s\lceil\frac{n}{p}\rceil$ elements and writes at most $s\lceil\frac{n}{p}\rceil$ elements, whereas in Ver-0 and Ver-1 each thread reads $2sn$ elements and writes at most $\lceil\frac{s}{p}\rceil$ elements.

While Ver-1 can use only as many threads as the peer method used has stages, an additional benefit of the system parallel execution is that more threads can participate in the computation of the linear combination.

Unfortunately, the new loop structure of Ver-2 also has disadvantages. Since the iteration over the stride-1 dimension is performed by the outermost loop, the reads of the matrix elements in the innermost loops have a large stride of n. Hence, the higher temporal locality comes at the expense of lower spatial locality. Further, the compiler cannot vectorize the loads and stores using sequential SIMD load/store instructions. However, there are SIMD gather or scatter instructions, which make a vectorization of strided memory accesses possible. Although all modern Intel CPUs since Haswell support AVX2 gather instructions, our Haswell-EP still emulates those instructions by microcode. Thus, gather instructions still have a low throughput on Haswell-EP.

In order to derive a loop structure with high temporal as well as spatial locality, we can make use of loop tiling (Ver-3, Listing 4). Ver-3 also makes use of both optimizations from Ver-1 (elimination of the zero initialization phase and loop fusion) yielding a similar loop structure as in Ver-1. However, in contrast to Ver-1, it has an outer parallel tile loop, which iterates over the system dimension in larger steps dividing the system into tiles of a user-defined size. Inside the tile loop run the stage loop and the combination loop. The innermost loop is the intra-tile loop, which iterates over the elements of the

TABLE II
RUNTIME COMPARISON FOR 100 TIME STEPS ON HASWELL-EP AND XEON PHI WITH GRID SIZE 500×500

		Runtime for different #threads				
Hardware	**Version**	1	4	8	60	120
Haswell-EP	Ver-0	10.73	4.98	5.02	-	-
Haswell-EP	Ver-1	8.64	4.00	3.45	-	-
Haswell-EP	Ver-3	2.53	0.95	0.76	-	-
Xeon Phi	Ver-0	50.01	13.06	6,69	-	-
Xeon Phi	Ver-3	19.54	4.90	2.47	0.39	0.29

corresponding tile, i.e., the stride-1 dimension. The resulting memory access pattern is illustrated in Figure 3. Only the same amount of data needs to be accessed as in Ver-2, but, since the tile loop now contains the stage loop and the combination loop, an iteration of the tile loop computes the linear combination for one tile for all the stages. This provides a blocking effect across the stages: Assuming the tile size is small enough so that the data accessed in one iteration of the tile loop fits in the cache, the final values of the elements of Y_m have to be sent to main memory only once. Since the innermost loop iterates over the stride-1 dimension, there also is a high spatial locality, so that cache lines can be reused once they have been loaded into the cache, and efficient SIMD vectorization is possible. Because of that, choosing a good tile size for Ver-3 is important.

B. Performance of the Loop Structure Variants

In this section we will analyze how the different versions so far scale with the amount of active cores. For this purpose we have measured the runtimes of the different versions on the Haswell-EP and on the Xeon Phi. The runtimes measured are given in Table II. The scaling behavior is shown in Figures 4 and 6 in terms of the inverted runtime (reciprocal of the runtime) as a function of the number of threads. As in a speedup diagram, a linear growth of the inverted runtime corresponds to a good scalability, but, in contrast to a speedup diagram, there is no need to chose a sequential reference runtime.

We can divide the versions so far into two groups: The first group consists of the original EPPEER version (Ver-0) and Ver-1, which both only utilize stage parallelism, while the second group consists of Ver-2 and Ver-3, which both only utilize system parallelism for the linear combination.

Because the peer methods part of EPPEER possess at most 8 stages, the stage-parallel variants use up to 8 cores only. Furthermore, there is a load imbalance when 3, 5, 6, or 7 threads are used. Ver-1 of the first group, which improves the original EPPEER version by removing the zero initialization and fusing the two loop nests, is about 1.6 times faster than the original EPPEER version.

In contrast to the stage-parallel variants, the system-parallel variants can potentially use more than 8 cores and are not affected by the load imbalance. The cause of this is the system dimension offering a higher degree of parallelism. Ver-2 uses system parallelism without loop tiling. That is why it eventually became up to 3 times faster than the best stage-parallel variant on the Haswell-EP. However, when Ver-2 was used on less than 4 cores, it was slower than the stage-parallel variants.

Unlike Ver-2, Ver-3 achieves system parallelism with an efficient memory access pattern by utilizing loop tiling. Preparatory runtime measurements had shown that a tile size of about 128 was best for almost all problem sizes. For the following experiments, therefore 128 was used as tile size for Ver-3. Figure 5 shows the normalized runtime of Ver-3 with different tile sizes for a grid size of 500×500 and 700×700 and for one core and eight cores on the Haswell-EP. For both problem sizes and both core numbers there is a runtime minimum between tile size 64 and 256.

Because of its more efficient memory access pattern, Ver-3 was about three times faster than Ver-2 running on the same amount of cores on the Haswell-EP. Ver-3 was also about 8 times faster than the best stage-parallel variant, if both used the same amount of cores. This suggests Ver-3 also having a more cache friendly memory access pattern than the stage-parallel variants.

On the Xeon Phi also Ver-3 obtains the best runtime. On this processor we could observe a reduction of the runtime for up to 120 threads, where for large numbers of threads Ver-3 clearly outperforms Ver-2.

To measure the locality behavior, we measure the normalized runtime (Figures 7 and 8), i.e., the runtime per time step divided by the number of equations, n, on the Haswell-EP. Since the right-hand-side of *brus* has costs $\Theta(n)$, an increase in the normalized runtime usually indicates working sets falling out of a cache level. As we can see, the normalized runtime of Ver-3 is significantly lower than that of the other versions, and it does not increase as strongly when the problem size exceeds a certain threshold, which depends on the number of threads.

In addition, we measured the L3 cache misses and the total amount of store and load operations. The measurements confirm that Ver-3 has a smaller L3 cache miss rate in relation to the total load/store operations than both stage-parallel versions (see Figure 9). Furthermore, this plot shows also that the L3 cache miss rate is much lower on small problem sizes.

V. Interplay with the Function Evaluation and Fully System-Parallel Execution

In the last section we have only focused on optimizing the linear combination without modifying the loop nest, which evaluates the problem function. In this section, however, we will improve the problem function evaluation and the

interaction of the problem function with the linear combination.

The runtime experiments of the previous section have confirmed that an optimized system-parallel tiled loop variant of the linear combination such as Ver-3 outperforms stage parallel variants, because it requires less memory references and can efficiently exploit temporal and spatial locality. However, up until now all implementation variants evaluated the problem function using parallelism across the stages.

Unfortunately, combining the system-parallel linear combination with a stage-parallel function evaluation has several disadvantages: The stage-parallel function evaluation can use as many cores as there are stages only. Furthermore both a system parallel linear combination and method parallel function evaluation have different memory access patterns, which causes a data redistribution and reduces locality. That is why we modify the loop nest containing the problem function to adopt system parallelism. However, up to now the problem function has been evaluated by a single function call that computed the temporal derivatives for every element of a given vector, which is not suited for system parallelism.

Therefore, we implemented two new versions of the *brus*

Listing 6. Blockwise function evaluation.

problem with a modified signature and a modified internal structure: The first new version (*element* version) calculates the temporal derivatives for one single element of the problem vector per call. Yet again, this design has two major disadvantages: The *element* version has to perform the boundary checks of the stencil for each call, and the compiler is not able to vectorize this function efficiently. Moreover the temporal derivatives of the two substances contained in a grid cell have some computations in common, which the *element* version has to compute redundantly twice. We can avoid all those inefficiencies if we do not call the right-hand-side function once per element, but once for a range of elements, and optimize the internal structure of the function accordingly. This results in the implementation of the *block* version. Finally, we have adapted the loop nest evaluating the problem functions to the *element* version in Listing 5 and to the *block* version in Listing 6. Since the *element* version cannot provide any blocking itself, we have added a simple 1D-blocking scheme to the loop nest.

Inverted runtimes measured for the two new variants of *brus* are shown in Figures 10 and 11. Here, the grid size used is 500×500, the number of stages is set to 8, and 200 is used as block size for the *block* version. As expected, both new versions introduced in this section are faster. The *block* version has the best runtime. The *element* version first starts slower than the original implementation, because this version invokes the function evaluation n times, each time performing a test whether the current index corresponds to a boundary point or not. This leads to a high overhead. But for large numbers of cores, the higher locality of the *element* version can compensate this. In particular, it can obtain speedups higher than the number of stages available.

Hence, all in all, the best runtime for *brus* is obtained by the system-parallel linear combination with loop tiling, loop

fusion and loop peeling combined with the system-parallel blockwise function evaluation.

VI. Conclusions

In this paper, we have considered the influence of locality on the scalability of method- and system-parallel explicit peer methods. In particular, we have focused on improving the scalability for large sparse ODE systems with cheap function evaluation costs. After confirming that the linear combination to compute the argument vectors requires the major part of the runtime for such ODE systems, we have considered several transformations of the loop structure, analyzed their memory access pattern and measured the resulting runtimes and scalability on a Haswell-EP and on a Xeon Phi processor. As expected, the results of the runtime experiments confirmed that a system-parallel computation of the linear combination leads to a better performance than a stage-parallel computation because less memory references are required and a more cache-efficient data access pattern can be employed. A further performance improvement is possible when also the function evaluation can be performed in a system-parallel way, so that no data-redistribution is necessary.

***Abstract*—Finding an optimal block size for a given sparse matrix forms an important problem for storage formats that partition matrices into uniformly-sized blocks. Finding a solution to this problem can take a significant amount of time, which, effectively, may negate the benefits that such a format brings into sparse-matrix computations. A key for an efficient solution is the ability to quickly iterate, for a particular block size, over matrix nonzero blocks. This work proposes an efficient parallel algorithm for this task and evaluate it experimentally on modern multi-core and many-core high performance computing (HPC) architectures.**

I. Introduction

STORAGE formats prescribe a way how sparse matrices are stored in a computer memory. Many designed formats are based on partitioning of matrices into blocks where

1) blocks have a uniform size,
2) this size is not fixed for a given format and may be chosen for each matrix individually.

We call such formats *uniformly-blocking formats* or, shortly, *UB formats*.

Considering a particular sparse matrix A and a particular UB format, we thus face a problem of finding an optimal block size (whatever this means). Typically, we want to find a block size that will provide highest performance of sparse matrix-vector multiplication (SpMV) performed with A. Generally, this task cannot be accomplished until the matrix is fully assembled or at least until its structure of nonzero elements is fully known, which implies that matrices cannot be assembled in UB formats directly (there are usually other reasons as well). Instead, one needs to

1) assemble A in some suitable (not-parametrized) simple storage format,
2) find an optimal block size for A,
3) transform A in memory from its original storage format to a given UB format.

The second and third steps form an important problem related to a given UB format. If the solution of this problem takes too long, it might effectively negate the benefits that a UB format brings into subsequent computations with A.

To find an optimal block size, there is usually no option other than

1) to form some set of possibly-optimal block sizes,
2) to evaluate an optimization criterion for all of them.

Note that this approach generally gives a pseudooptimal block size instead of an optimal one. For sake of simplicity, we do not distinguish between these two cases and call them both optimal throughout this text.

Evaluation of an optimization criterion for a given UB format, given matrix A, and a particular tested block size typically involves gathering some information about all nonzero blocks of A. We therefore need to examine all these nonzero blocks. Such a procedure can be described briefly as follows: *for all nonzero blocks of A, perform some calculations that contribute to the evaluation of an optimization criterion*. Thus, in fact, we need to *iterate over nonzero blocks of A*.

When an optimal block size is found, this iterative process has to be run once again within the third step mentioned above, i.e., during the final transformation of A to a given UB format.

This paper addresses the problem of fast iteration over nonzero blocks of a sparse matrix. We propose an efficient scalable parallel algorithm for a solution to this problem and evaluate it experimentally on modern multi-core and many-core HPC architectures, where matrices frequently emerge in multi-threaded programs. (In distributed-memory environments, objects of our concern are "local" matrices formed by nonzero elements mapped to particular application processes.)

II. Case Study

As an illustrative case study, we work throughout this text with the *adaptive-blocking hierarchical storage format*

Algorithm 1: Transformation of A to the ABHSF

Input: A: sparse matrix
Input: $\mathcal{S} = \{s_1, s_2, \ldots\}$: set of possibly-optimal block sizes
Data: M_{opt}, M, s_{opt}, i: auxiliary variables

```
M_opt ← 0
for i ← 1 to |S| do
    M ← 0
    for each nonzero block B of size s_i of A do
        find a space-optimal way W to store B in memory
        considering ⌈log2 s_i⌉ bits for in-block indexes;
        calculate the contribution c(B, W) of B stored in W
        to the memory footprint of A;
        M ← M + c(B, W)
    end
    if i = 1 or M < M_opt then
        s_opt ← s_i
        M_opt ← M
    end
end
for each nonzero block B of size s_opt of A do
    store B in memory in the ABHSF format
end
```

(ABHSF) [1], [2]. This format partitions A into uniform square blocks of size s and stores each block in memory in a space-optimal way. The optimization criterion of ABHSF is represented by the total memory footprint of A which is being minimized. This is a very common optimization criterion for storage formats in general (not only UB formats), since the performance of SpMV is limited by bandwidths of memory subsystems on modern HPC architectures [3].

Many UB formats work with in-block row and column indexes. Optimal (space-optimal) block sizes are then typically those that employ most or all of the available indexing bits. In case of the ABHSF and byte-padded in-block indexes, setting $s = 256$ is almost generally optimal or at least close to being optimal [1]. (Such a choice eliminates the discussed optimization problem, however, it does not eliminate the need to iterate over nonzero blocks of A; this process is still required for transformation of A into the ABHSF.)

On the other hand, if we really want to minimize the memory footprint of A stored in the ABHSF, we need to use the minimum possible number of bits for in-block indexes, i.e., $\lceil \log_2 s \rceil$. In such cases, any block size s can be generally optimal. Let $\mathcal{S} = \{s_1, s_2, \ldots\}$ denotes some set of possibly-optimal block sizes. The transformation of A into the ABHSF can then be written as Algorithm 1.

Algorithm 1 iterates over nonzero blocks of A exactly $|\mathcal{S}|+1$ times. Therefore, we want $|\mathcal{S}|$ to be

1) large enough to find the best possible block size,
2) small enough to prevent long algorithm running times.

One way to get close to both these outcomes is to consider only block sizes

$$\mathcal{S} = \{2^k : 1 \leq k \leq k_{\max}\}, \tag{1}$$

which implies maximum utilization of all k bits for in-block indexes. The $k_{\max}$ parameter, which corresponds to $|\mathcal{S}|$, determines the upper bound for tested block sizes. In practice, setting $k_{\max} = 10$ is typically sufficient, which implies 11 iterations over nonzero blocks of A while testing block sizes $s = 2, 4, 8, \ldots, 1024$ within Algorithm 1.

III. Notation

Let A be an $m \times n$ sparse matrix, where $a_{i,j}$ denotes the value of an element of A located in its ith row and jth column. As a mathematical object, A can be written as

$$A = \begin{pmatrix} a_{1,1} & \cdots & a_{1,n} \\ \vdots & \ddots & \vdots \\ a_{m,1} & \cdots & a_{m,n} \end{pmatrix}. \tag{2}$$

However, within computer programs, we typically work only with nonzero elements of sparse matrices (or, even only with nonzero elements from a single triangular part if a matrix exhibits some kind of symmetry). An element of A is determined by its value, row index, and column index; let us write it as a triplet $(i, j, a_{i,j})$. As a data structure, we can consider A as a *set of matrix nonzero elements*:

$$A = \big\{(i, j, a_{i,j}) : 1 \leq i \leq m,\ 1 \leq j \leq n,\ a_{i,j} \neq 0\big\}. \tag{3}$$

Moreover, nonzero elements stored in memory are accessible in some order, which is typically prescribed by a given storage format. If this order matters, we can consider A as a *sequence of matrix nonzero elements*:

$$A = \big((i_l, j_l, a_{i_l,j_l})\big)_{l=1}^{nnz}, \quad a_{i_l,j_l} \neq 0, \tag{4}$$

where nnz denotes the number of nonzero elements of A.

In the text below, we use forms (2), (3), and (4) interchangeably, while preferring the particular one in dependence on the actual context. For the sake of simplicity, we also consider partitioning into square blocks only; the generalization for rectangular blocks is straightforward.

Partitioning A into square blocks of size s yields an $M \times N$ block matrix, where $M = \lceil m/s \rceil$ and $N = \lceil n/s \rceil$. For indexing block rows and columns, we use capital letters I and J, respectively. A block is called nonzero if it contains at least one nonzero matrix element.

A matrix element $(i, j, a_{i,j})$ belongs to a block with indexes

$$I = \lfloor (i-1)/s \rfloor + 1 \quad \text{and} \quad J = \lfloor (j-1)/s \rfloor + 1. \tag{5}$$

By using $\backslash$ for integer division, we can rewrite (5) as

$$I = (i-1) \backslash s + 1 \quad \text{and} \quad J = (j-1) \backslash s + 1. \tag{6}$$

Element's in-block indexes can be found correspondingly as $\big[(i-1) \mod s\big] + 1$ and $\big[(j-1) \mod s\big] + 1$.

Note that the calculations of block indexes and local in-block indexes for nonzero matrix elements involve integer division and modulo, which are relatively expensive arithmetic operations [4]. When possibly-optimal block sizes are chosen according to (1), both integer division and modulo can be substituted by much faster *logical shift* and *bitwise AND* operations.

Algorithm 2: Iteration over nonzero blocks of A: variant 1

```
Input: A: sparse matrix
Input: s: block size
Data: B: nonzero elements of a single block
Data: I, J: indexes
1  for I ← 1 to ⌈m/s⌉ do
2      for J ← 1 to ⌈n/s⌉ do
3          B ← {}
4          for all (i, j, a_{i,j}) ∈ A do
5              if (i − 1)\s + 1 = I and (j − 1)\s + 1 = J then
6                  B ← B ∪ {(i, j, a_{i,j})}
7              end
8          end
9          if B ≠ {} then
10             process block B with indexes I and J
11         end
12     end
13 end
```

Algorithm 3: Iteration over nonzero blocks of A: variant 2

```
Input: A: sparse matrix
Input: s: block size
Data: B_{I,J}: nonzero elements of a block in Ith block row and
      Jth block column
Data: I, J: indexes
1  for I ← 1 to ⌈m/s⌉ do
2      for J ← 1 to ⌈n/s⌉ do B_{I,J} ← {}
3  end
4  for all (i, j, a_{i,j}) ∈ A do
5      I ← (i − 1)\s + 1
6      J ← (j − 1)\s + 1
7      B_{I,J} ← B_{I,J} ∪ {(i, j, a_{i,j})}
8  end
9  for I ← 1 to ⌈m/s⌉ do
10     for J ← 1 to ⌈n/s⌉ do
11         if B_{I,J} ≠ {} then
12             process block B_{I,J} with indexes I and J
13         end
14     end
15 end
```

IV. Algorithms

Let us now analyse the problem of iteration over the nonzero blocks of A. In the most generic case, we have, at the outset, no knowledge which blocks of A are nonzero and which nonzero elements of A belong to these blocks. There are basically two ways to find this out:

1) to iterate over all blocks of A and for each block find its nonzero elements;
2) to iterate over all nonzero elements of A, find for each of them the corresponding block (6), and save the information that the element belongs to this block.

Pseudocodes for these two options are provided as Algorithms 2 and 3, respectively. Processing of blocks is application-dependent; it might, e.g., represent the calculation of blocks contributions to the optimization criterion (line 5–7 of Algorithm 1) or the storage of blocks in memory (line 15).

Algorithm 2 have low memory requirements; its auxiliary space is

$$S_2(A, s) = O(s^2),$$

since, at a given time, only nonzero elements for a single block need to be kept in memory. The drawback of this algorithm is its high time complexity

$$T_2(A, s) = \Theta(m \cdot n \cdot nnz/s^2).$$

As for Algorithm 3, its time complexity is considerably lower, namely

$$T_3(A, s) = \Theta(m \cdot n/s^2 + nnz).$$

However, the auxiliary space of Algorithm 3 is

$$S_3(A, s) = O(m \cdot n/s^2 + nnz),$$

since one needs to save the information about all nonzero elements for each nonzero block. Moreover, an implementation of this algorithm would likely require some complex dynamic data structure, which might introduce problems with memory fragmentation and expensive insertion/look-up operations.

Whenever working with sparse matrices, we generally want to avoid algorithms with $\Omega(nnz)$ auxiliary space as much as possible. Within many running instances of HPC programs, matrices are the largest objects in a computer memory and their sizes determine an extent of underlying computational problems. Any $\Omega(nnz)$ auxiliary space algorithm (such as Algorithm 3) thus, in effect, considerably limits the size of a problem being solved.

To avoid the high time complexity of Algorithm 2 as well as the high auxiliary space of Algorithm 3, we propose another solution for iteration over nonzero block of A that works as follows:

1) The nonzero elements of A are reordered such that the nonzero elements of each block are laid out consecutively (grouped together) in memory. In other words, *the nonzero elements are sorted with respect to blocks*.
2) A single iteration over nonzero elements is performed while elements of each nonzero block are identified and processed.

The pseudocode of such a solution is provided as Algorithm 4. Its time complexity and auxiliary space is dominated by the sorting step (line 1). Let us assume that we use an in-place randomized quicksort with time complexity $O\big(nnz \cdot log_2(nnz)\big)$ and auxiliary space $O\big(\log_2(nnz)\big)$. The overall time complexity of Algorithm 4 then will be

$$T_4(A, s) = O\big(nnz \cdot \log_2(nnz)\big)$$

and its auxiliary space

$$S_4(A, s) = O\big(\log_2(nnz)\big)$$

as well.

Algorithm 4 reduces both the time complexity of Algorithm 2 and the auxiliary space of Algorithm 3, however, at the following price: it requires A to be provided in such a format that facilitates reordering/sorting its nonzero elements. There is

Algorithm 4: Iteration over nonzero blocks of A: variant 3

Input: A: sparse matrix
Input: s: block size
Data: I, I', J, J', l, l_1: indexes

1 $\left((i_l, j_l, a_{i_l,j_l})\right)_{l=1}^{nnz} \leftarrow$ sort A with respect to blocks
2 $l_1 \leftarrow 1$
3 $I \leftarrow (i_1 - 1) \backslash s + 1$
4 $J \leftarrow (j_1 - 1) \backslash s + 1$
5 **for** $l \leftarrow 2$ to nnz **do**
6 $\quad I' \leftarrow (i_l - 1) \backslash s + 1$
7 $\quad J' \leftarrow (j_l - 1) \backslash s + 1$
8 $\quad$ **if** $I' \neq I$ **or** $J' \neq J$ **then**
9 $\quad\quad$ process block with indexes I and J that contains nonzero elements $\left((i_q, j_q, a_{i_q,j_q})\right)_{q=l_1}^{l-1}$
10 $\quad\quad l_1 \leftarrow l$
11 $\quad\quad I \leftarrow I'$
12 $\quad\quad J \leftarrow J'$
13 $\quad$ **end**
14 **end**
15 process block with indexes I and J that contains nonzero elements $\left((i_q, j_q, a_{i_q,j_q})\right)_{q=l_1}^{nnz}$

practically only one candidate—the *coordinate* storage format (COO) [5], [6]; it consists of three arrays containing row indexes, column indexes, and values of nonzero elements. At the same time, it does not prescribe any particular ordering for these arrays.

To require A to be initially in COO is not as restrictive in practice as it might seem, since:

1) any sparse matrix can be easily and quickly transformed into COO regardless of its original storage format,
2) COO is the most convenient format for assembling sparse matrices (newly generated nonzero elements are simply appended to the corresponding COO arrays).

A scenario where matrices are first assembled in COO and then transformed to another, computationally more suitable, storage format (such as some UB format) is thus perfectly viable for HPC programs.

To sort the nonzero elements with respect to blocks, we can define sorting keys by using the pairs of I and J block indexes calculated by (5). For example, if we want blocks to be sorted lexicographically, we can calculate sorting keys as $I \cdot N + J$. Again, note that choosing (1) for possibly-optimal block sizes implies faster calculation of sorting keys and therefore, in effect, likely faster sorting step within Algorithm 4.

A. Parallelization

Parallelization of (expensive) Algorithms 2 and 3 is straightforward. In Algorithm 2, we can parallelize the inner-most loop (line 4) while synchronizing concurrent updates of B at line 6. In Algorithm 3, we can parallelize the loops over blocks (lines 1–2 and 9–10) as well as the loop over nonzero matrix elements (line 4) while using thread-local I and J indexes and synchronizing concurrent updates to $B_{I,J}$ at line 7.

Parallelization of Algorithm 4 is a bit more complex; we propose its multi-threaded variant as Algorithm 5. Note that

Algorithm 5: Parallel iteration over nonzero blocks of A

Input: A: sparse matrix
Input: s: block size
Input: T: number of threads
Data: I, I', J, J', l, l_1, t: thread-private indexes
Data: $tb[]$: thread-shared integer array of size $T + 1$

1 $\left((i_l, j_l, a_{i_l,j_l})\right)_{l=1}^{nnz} \leftarrow$ sort A in parallel with respect to blocks
2 $tb[1] \leftarrow 1$
3 $tb[T + 1] \leftarrow nnz + 1$
4 **for all** threads **do in parallel**
5 $\quad t \leftarrow$ current thread number (between 1 and T)
6 $\quad$ **if** $t > 1$ **then**
7 $\quad\quad l \leftarrow \lceil nnz \cdot (t - 1) \rceil \backslash T + 1$
8 $\quad\quad I \leftarrow (i_1 - 1) \backslash s + 1$
9 $\quad\quad J \leftarrow (j_1 - 1) \backslash s + 1$
10 $\quad\quad l \leftarrow l + 1$
11 $\quad\quad$ **while** $l \leq nnz$ **do**
12 $\quad\quad\quad I' \leftarrow (i_1 - 1) \backslash s + 1$
13 $\quad\quad\quad J' \leftarrow (j_1 - 1) \backslash s + 1$
14 $\quad\quad\quad$ **if** $I' \neq I$ **or** $J' \neq J$ **then break**
15 $\quad\quad\quad l \leftarrow l + 1$
16 $\quad\quad$ **end**
17 $\quad\quad tb[t] \leftarrow l$
18 $\quad$ **end**
19 $\quad$ perform barrier to synchronize threads
20 $\quad l_1 \leftarrow tb[t]$
21 $\quad I \leftarrow (i_{l_1} - 1) \backslash s + 1$
22 $\quad J \leftarrow (j_{l_1} - 1) \backslash s + 1$
23 $\quad$ **for** $l \leftarrow tb[t] + 1$ to $tb[t + 1] - 1$ **do**
24 $\quad\quad I' \leftarrow (i_l - 1) \backslash s + 1$
25 $\quad\quad J' \leftarrow (j_l - 1) \backslash s + 1$
26 $\quad\quad$ **if** $I' \neq I$ **or** $J' \neq J$ **then**
27 $\quad\quad\quad$ process block with indexes I and J that contains nonzero elements $\left((i_q, j_q, a_{i_q,j_q})\right)_{q=l_1}^{l-1}$
28 $\quad\quad\quad l_1 \leftarrow l$
29 $\quad\quad\quad I \leftarrow I'$
30 $\quad\quad\quad J \leftarrow J'$
31 $\quad\quad$ **end**
32 $\quad$ **end**
33 $\quad$ process block with indexes I and J that contains nonzero elements $\left((i_q, j_q, a_{i_q,j_q})\right)_{q=l_1}^{tb[t+1]-1}$
34 **end**

we cannot simply parallelize the main loop of Algorithm 4 (line 5), since its uniform splitting would generally cause threads to start with nonzero elements that are not, in sequence (4), first within corresponding blocks. Algorithm 5 therefore splits the load among threads such that:

1) an amortized number of nonzero elements processed by each thread is nnz/T, where T denotes the number of threads;
2) all nonzero elements of each particular block are processed by a single thread only.

Such splitting is calculated at lines 2–18 of Algorithm 5 and stored into an auxiliary array $tb[]$. Each thread can then process its exclusive portion of nonzero elements independently of other threads (lines 20–33). Threads are required to be indexed from 1 to T; if not, some mapping from thread IDs to such indexing must be provided.

Fig. 1: Strong scalability of Algorithm 5 with the *do-nothing processor* measured for different architectures, different matrices, and different block sizes.

V. Experiments

We have conducted an extensive experimental study to evaluate Algorithm 5. Within this study, we worked with matrices from the University of Florida Sparse Matrix Collection (UFSMC) [7]. Matrices that we used are listed in Appendix; their characteristics can be found at the UFSMC web pages[1]. We tried to choose matrices emerging in a wide range of scientific and engineering disciplines and thus having different properties, such as:

- different types of elements—real, complex, integer, binary;
- different sizes and shapes—square, rectangular;
- different kinds of symmetries—unsymmetric, symmetric, Hermitian;
- different numbers of nonzero elements—from $1.1 \cdot 10^7$ of the kim2 matrix to $6.4 \cdot 10^8$ of the arabic-2005 matrix;
- different densities, i.e., relative counts $nnz/(m \cdot n)$, of nonzero elements—from $5.12 \cdot 10^{-7}$ of the nlpkkt240 matrix to $1.11 \cdot 10^{-2}$ of the TSOPF_RS_b2328 matrix;
- different patterns of nonzero elements.

The matrices were read on the input from files downloaded from the UFSMC. All these files stored nonzero elements of matrices in the *reverse lexicograhical order* (RLO) and in the same order, we stored the elements in memory in the COO format as the first step of our benchmark program.

The measurements were performed on the following two shared-memory HPC architectures:

1) nodes of the Salomon supercomputer operated by IT4Innovations National Supercomputing Center in Ostrava, Czech Republic, having two 12-core Intel Xeon E5-2680v3 CPUs and 128 GB RAM per node;
2) Intel Xeon Phi coprocessor type 7120P with 16 GB RAM.

Benchmark codes were written in C++ and we used the GNU g++ compiler version 5.1.0 on Salomon and Intel icpc compiler version 16.0.1 for Intel Xeon Phi builds.

Parallelization was implemented with OpenMP. As for sorting (line 1 of Algorithm 5), we used AQsort[2]—an OpenMP-based multi-threaded variant of in-place quicksort that can work with multiple arrays, such as the arrays of the COO storage format in our case.

A. Processors

Lines 27 and 33 of Algorithm 5 contain processing of found nonzero blocks. Within this study, we invoked two different block *processors* at these points. The first one did nothing useful at all, which allowed us to evaluate the algorithm itself

Fig. 3: Aggregated runtime of Algorithm 5 with the *do-nothing processor* run 10 times in a row for block sizes $s = 2, 4, 8, \ldots, 1024$, measured for 26 matrices from the UFSMC, different architectures and the optimal number of threads.

without any application-dependent computations; we call this processor a *do-nothing processor*.[3]

The second processor was designed for the problem of finding an optimal block size when storing A in the ABHSF; we call it the *ABHSF-opt processor*. This processor calculated and summed the contributions of blocks to the overall memory footprint of A.

B. Scalability

First, we measured the strong scalability of Algorithm 5; the results for 4 different matrices and 2 different block sizes are shown in Fig. 1. In all cases, parallelization led to a considerable reduction of runtime required for the iteration over nonzero blocks of A. This runtime was dominated by the sorting phase of the algorithm (see Section V-C for details), thus, consequently, the overall scalability of Algorithm 5 was determined by the scalability of AQsort within our study. The maximum number of threads, i.e., 24 for Salomon nodes and 122 for Intel Xeon Phi, was chosen experimentally; beyond these points, runtime of AQsort started to grow significantly.

[3]A processor that would do anything at all might be optimized away by the compiler. We therefore designed the do-nothing processor such that it summed the number of nonzero elements of blocks, which also allowed us to verify that the algorithm correctly iterated over all nonzero blocks of A.

C. Algorithm Phases

The second experiment evaluated the contributions of the *sorting* and *iterations* phases of Algorithm 5 to its *overall* runtime; the results are presented by Fig. 2. The set of tested block sizes was selected according to (1) while setting $k_{\max} = 10$. The sorting phase of Algorithm 5 clearly dominates the overall algorithm runtime. The runtime of the iteration phase (with the *do-nothing* processor in this case) is practically negligible. We can also notice that larger block sizes yielded slightly faster sorting due to lower number of distinct sorting keys (less nonzero elements need to be swapped in memory).

Fig. 5: Runtime of Algorithm 5 (*Overall*) and its two phases (*Sorting* and *Iteration*) with the *do-nothing processor*, measured for different architectures, different matrices, different block sizes, and the optimal number of threads.

D. Multiple Block Sizes

Within the problem of finding an optimal block size, we need to iterate over nonzero blocks of matrices multiple times while testing different block sizes. In the next experiment, we therefore run Algorithm 5 ten times in a row, while testing block sizes $s = 2, 4, 8, \ldots, 1024$ as proposed in Section II. We used 26 matrices from the UFSMC (listed in Appendix) and, for each one, measured the aggregated runtime of all 10 algorithm runs. The results are presented by Fig. 3, which shows runtimes as a function of the number of matrix nonzero elements.

We can observe that the relation of runtime and nnz was roughly linear. Though, for a constant T, the time complexity of Algorithm 5 is $O\big(n \cdot \log_2(n)\big)$, modern implementations of parallel quicksorts yield in practice such a linear growth of runtime on modern multi-core and many-core architectures (details are beyond the scope of this text).

E. Initial Ordering Effects

Fig. 2 shows the runtimes for sorting of nonzero elements of matrices from the RLO to the block-aware ordering. However, when we are looking for an optimal block size from $\mathcal{S}$ for a given matrix, we initially need to sort its nonzero elements from the input ordering (the RLO in our case) only once for the tested block size s_1. Then, for all other tested block sizes $s_k : k > 1$, the sorting algorithm takes as an input nonzero elements sorted with respect to the block size s_{k-1}.

Within our study, we considered block sizes $s_k = 2^k$, which implies $s_k = 2 \cdot s_{k-1}$ for $k > 1$. Moreover, we defined sorting keys according to the lexicographical ordering of blocks. Consequently, for $k > 1$, the nonzero elements were on the input of Algorithm 5 partially sorted, which should result in shorter sorting times. We performed an experiment to verify this assumption; the results are shown in Fig. 4. They clearly indicate that AQsort was able to take the advantage of such partially sorted data; the amount of spared time was significant, especially on Salomon CPU-based nodes.

F. Block Sizes Effects

Recall that in the previous text, we made an assumption that setting block sizes $s_k = 2^k$ should provide faster runs of Algorithm 5 due to the possibility of calculation of block indexes I and J by using cheap logical and bitwise operations. However, if we need to test block sizes other than the powers of 2, we cannot avoid integer division (6). To evaluate the

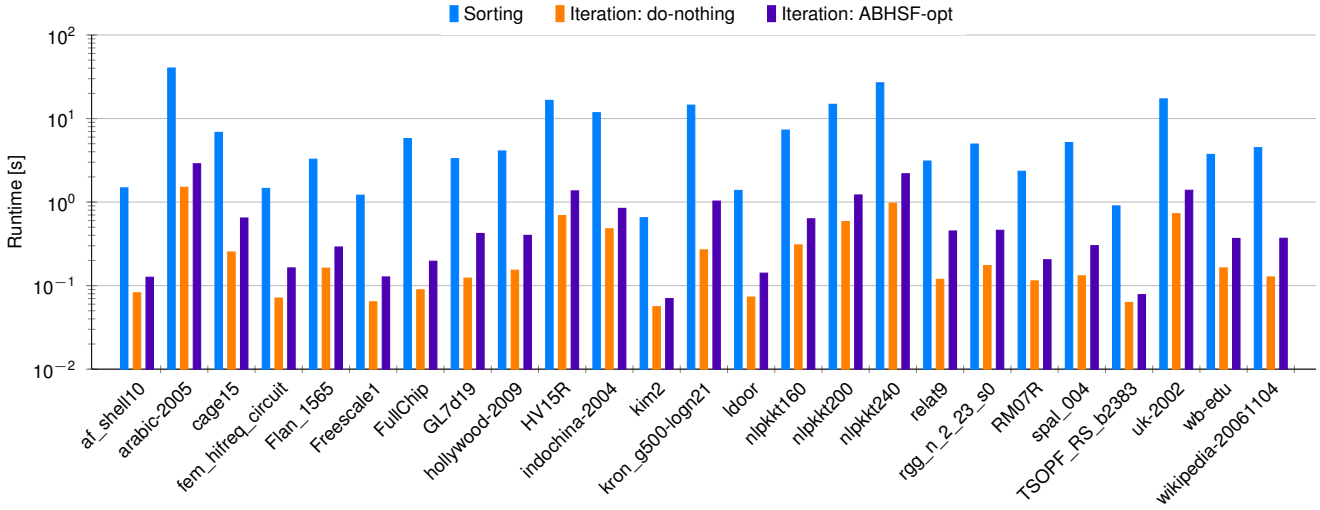

Fig. 6: Aggregated runtime of sorting and iteration phases of Algorithm 5 run 10 times in a row for block sizes $s = 2, 4, 8, \ldots, 1024$, measured for different matrices on a Salomon node using 24 threads. The iteration phases were measured for both the *do-nothing* and *ABHSF-opt* processors.

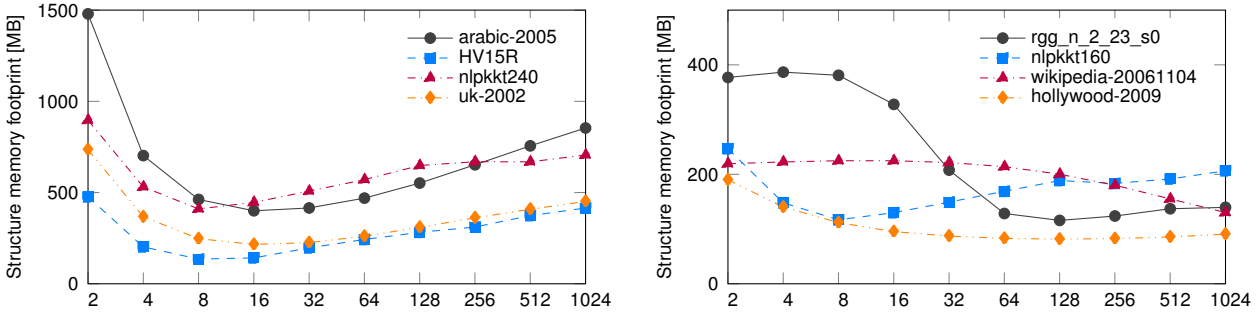

Fig. 7: Matrix structure memory footprints for different matrices stored in the ABHSF and different block sizes.

difference between both cases, we measured runtimes of Algorithm 5 and both its phases (sorting and iteration) for several block sizes of both classes $s = 2^k$ and $s \neq 2^k$; the results are presented in Fig. 5.

The conclusion is obvious—the way of deriving block indexes for the nonzero elements had a tremendous impact on the algorithm. Its runtime grew by almost a factor of 4 and 7 on Salomon nodes and Intel Xeon Phi, respectively, when using integer division instead of bitwise/logical operations.

G. ABHSF

Up to now, we presented measurements that used the *do-nothing processor* designed to evaluate Algorithm 5 itself. However, in practice, we iterate over nonzero blocks of sparse matrices to do something useful and the question is how the algorithm runtime will change in such cases. To answer this question, we substituted the *do-nothing processor* with the *ABHSF-opt* processor introduced in Section V-A and used Algorithm 5 for finding optimal block sizes for all tested matrices. The results of this experiment are presented in Fig. 6. They show aggregated runtimes of all 10 sorting phases as well as 10 iteration phases, and, for comparison, we show results for both types of block processors. We can observe that with the *ABHSF-opt processor*, the iteration phase took considerably longer times in comparison with the *do-nothing* processor. However, the overall runtime of the whole algorithm was still dominated by its sorting phase.

In regard to memory footprints of sparse matrices, we can usually focus only on *matrix structure memory footprints*, i.e., memory footprints of the information describing the structure of nonzero elements (compression of the values of nonzero elements pays off only for special kinds of matrices where same values emerge many times). For illustration, we show in Fig. 7 the relation between block sizes and the matrix structure memory footprints of selected matrices stored in the ABHSF. For most of the tested matrices, we have found only a single minimum, which typically corresponded to block sizes of 8 or 16 (left side of Fig. 7 and the nlpkkt160 matrix). However, we have also observed few "pathological" cases with different behavior (right side of Fig. 7). For example, the minimum

TABLE I: Matrix structure memory footprints in MB for selected matrices stored in the COO and CSR storage formats with 32-bit indexes and the ABHSF with optimal block sizes.

uk-2002	2274.4	1207.9	215.7
wikipedia-20061104	300.5	162.2	130.1

for the wikipedia-20061104 matrix was not even found within the whole tested range $s = 2, 4, 8, \ldots, 1024$; such a result might indicate that the ABHSF is not a suitable format for this matrix.

We also present in Table I the comparison of the matrix structure memory footprints for selected matrices and 3 storage formats—COO, the *compressed sparse row* (CSR) format, and the ABHSF. CSR is likely the most commonly used format for sparse matrices, together with its *compressed sparse column* (CSC) counterpart (they are also often abbreviated as CRS and CCS). The measurements revealed that storing sparse matrices in the ABHSF can result in substantial memory savings.

VI. Related Work

We have proposed an algorithm for the purpose of storing matrices in a file system in the ABHSF [2, Algorithm 1]. This algorithm served as a starting point for the development of Algorithm 4 that was generalized for any UB format.

For examples of designed UB formats, see, e.g., [1], [5], [8]–[21]

VII. Conclusions

The contribution of this paper is an efficient scalable parallel algorithm for fast iteration over nonzero blocks of sparse matrices. This algorithm is a building block of a process of transformation of sparse matrices into UB storage formats. We have presented an extensive experimental study with the proposed algorithm using matrices from the UFSMC that came from different scientific and engineering disciplines and thus featured different characteristics. Measurements conducted on modern multi-core and many-core HPC architectures revealed that if the set of tested block sizes is chosen properly, the process of finding an optimal block size takes up to tens of seconds even for very large matrices.

The remaining question is whether or not it pays off to transform matrices into UB formats. The answer to this question is highly application-dependent. For instance, if a matrix is used within an iterative linear solver or an eigensolver, we would first need to know how many SpMV operations are applied to a given matrix and how much time this operation takes. In our future work, we want to focus on the ABHSF and undertake a research that should tell how many SpMV-based iterations need to be done with a given matrix to reduce the overall application runtime when considering matrix storage in this format.

An Iteration Space Visualizer for Polyhedral Loop Transformations in Numerical Programming

Marek Palkowski, Wlodzimierz Bielecki
West Pomeranian University of Technology in Szczecin
ul. Zolnierska 49, 71-210 Szczecin, Poland
Email: mpalkowski@wi.zut.edu.pl, wbielecki@wi.zut.edu.pl

***Abstract*—An iteration space visualizer is presented to analyze parallelism in loop nests including parallelism in tiled code of numerical programs. The tool visualizes exact data dependences available in arbitrarily nested loops as well as tiles generated with TRACO by means of the transitive closure of a loop nest dependence graph. Various graphical operations such as rotation, zooming, coloring and filtering allow for a detailed examination of dependences, iteration space slices, and shapes of generated tiles. The visualizer is a built-in TRACO module which collects results generated with TRACO and it is launched automatically when TRACO finishes code generation. The visualizer helps high-performance application developers discover parallelism available in loop nests and analyze tiled code produced by means of the polyhedral model.**

I. Introduction

AUTOMATIC parallelization in numerical programs has been the topic of research for many decades. In the majority of cases, the techniques focus on two basic steps: dependence analysis and program transformations. Despite the great steps forward in this area, sophisticated dependences, the construction of loop transformations, and statement instance mappings are beyond what the programmer is able to see at first glance [1].

This paper focuses on a graphical support for the automatic parallelizer and optimizer, TRACO, – the source-to-source compiler based on the transitive closure of a dependence graph to transform affine loop nests. A proposed visualizer assists both experts and non-expert programmers to understand the results generated with TRACO [2] and code generated by it.

The TRACO visualizer is based on Python scripts which use wrappers to the Integer Set Library (ISL) [3] and matplotlib [4]. ISL allows users to manipulate on sets and maps while matplotlib is a plotting library to produce 2-D figures and 3-D interactive projections. The tool collects and visualizes data generated by TRACO, for example, dependences, code fragments to be executed in parallel, and shapes of tiles.

The remainder of the paper is organized as follows. The next section discusses the basics of the polyhedral model, iteration space dependence graph and operations to manipulate maps and sets. Section 3 briefs algorithms implemented in TRACO. Section 4 explores visualizing functions and theirs capabilities. Section 5 introduces related work. The last section concludes the paper.

II. Background

In this paper, we deal with affine loop nests where, for given loop indices, lower and upper bounds as well as array subscripts and conditionals are affine functions of surrounding loop indices and possibly of structure parameters (defining loop index bounds), and the loop steps are known constants.

To implement algorithms, we have chosen the dependence analysis proposed by Pugh and Wonnacott [5], where dependences are represented by dependence relations. A dependence relation is a tuple relation of the form [*input list*]→[*output list*]: *formula*, where *input list* and *output list* are the lists of variables and/or expressions used to describe input and output tuples, and *formula* describes the constraints imposed upon input and output lists and it is a Presburger formula built of constraints represented by algebraic expressions and using logical and existential operators [5].

Standard operations on relations and sets are used, such as intersection (∩), union (∪), difference (-), domain (dom *R*), range (ran *R*), relation application (S'= *R*(*S*): $e' \in S'$iff exists *e* s.t. $e \rightarrow e' \in R$, $e \in S$). In detail, the description of these operations is presented in [5], [3].

The positive transitive closure for a given relation *R*, R^+, is defined as follows [6] $R^+ = \{e \rightarrow e' : \ e \rightarrow e' \in R \vee \exists e'' s.t. \ e \rightarrow e'' \in R \wedge e'' \rightarrow e' \in R^+\}$. It describes which vertices e' in a dependence graph (represented by relation *R*) are connected directly or transitively with vertex *e*. Transitive closure, R^*, describes the same connections in a dependence graph (represented by R) that R^+ does plus connections of each vertex with itself.

In sequential loop nests, the iteration i executes before j if i is *lexicographically less* than j, denoted as $i \prec j$, i.e., $i_1 < j_1 \vee \exists k \geq 1 : i_k < j_k \wedge i_t = j_t, for \ t < k$.

An ultimate dependence source is a source that is not the destination of another dependence. Set including all dependence sources,S_{UDS} is calculated as follows: $S_{UDS} = domain(R) - range(R)$, where a dependence relation *R* describes all the dependences in a loop nest.

An (iteration-space) slice is defined as follows. Given a dependence graph defined by a set of dependence relations, a slice *S* is a weakly connected component of this graph, i.e., a maximal sub-graph such that for each pair of vertices in the sub-graph there exists a forward or backward path.

Let IS denotes the loop nest iteration space. A function is called a schedule if it maps each iteration of IS onto another

978-83-60810-90-3/$25.00

space so that all data dependences available in the loop nest are preserved. The schedule that maps every $x \in IS$ to the first possible time step allowed by the dependences is called the free schedule.

III. The TRACO Compiler

TRACO allows us to generate parallel code. Parallelization is based on extracting synchronization-free slices or producing and applying the free-schedule. An approach to extract synchronization-free slices takes two steps [2]. First, for each slice, a representative statement instance is defined (it is the lexicographically minimal statement instance from all the ultimate sources of a slice). Next, slices are reconstructed from their representatives and code scanning these slices is generated.

In order to find representatives of slices, we build a relation, R_{USC} that describes all pairs of the ultimate dependence sources being transitively connected in a slice. The relation is constrained with the intersection of the sets $R*(e)$ and $R*(e') : (R*(e) \cap R*(e'))$ which guarantees that vertices e and e' are transitively connected, i.e., they are the sources of the same slice.

Next, set, S_{repr}, containing representatives of each slice is found as S_{repr} = S_{UDS} - range(R_{USC}). Then the remaining sources of this slice can be found by applying the relation (R_{USC})* to set S_{repr}. A set, representing slice elements, is formed by applying R* to the sources of a slice. To generate code, we apply the CLooG library [7] or ISL [3] to the set comprising statement instances of independent slices.

To parallelize loop nests which expose a single synchronization-free slice, time partitioning is applied. The algorithm, presented in paper [8], allows us to generate the free schedule and next fine-grained parallel code; all statement instances of a time partition can be executed in parallel, while partitions are enumerated sequentially.

Given relations R, representing all dependences in a loop nest, we calculate R^k, where $R^k = \underbrace{R \circ R \circ ... R}_{k}$, "$\circ$" is the composition operation. Given set *UDS* comprising all loop nest statement instances that are ready to execution at time *k*=0, each vertex, belonging the set S_k = $R^k(UDS)$ - $R^+ \circ R^k(UDS)$, is connected in the dependence graph, defined by relation *R*, with some vertex(ices) represented by set *UDS* with a path of length *k*. Hence at time *k*, all the statement instances belonging to the set S_k can be scheduled for execution and it is guaranteed that *k* is as few as possible.

Tiling is a very important iteration reordering transformation for both improving data locality and extracting loop nest parallelism. TRACO allows users generate parallel tiled code by means of algorithms based on the transitive closure of a dependence graph [2]. First, we form rectangular set *TILE*(***II***,***B***) including iterations belonging to a parametric tile as follows *TILE*(***II***, ***B***) = $\{[\boldsymbol{I}] \mid \boldsymbol{B}*\boldsymbol{II} + \boldsymbol{LB} \leq \boldsymbol{I} \leq \min(\boldsymbol{B}*(\boldsymbol{II}+\mathbf{1}) + \boldsymbol{LB} - \mathbf{1}, \boldsymbol{UB})$ AND $\boldsymbol{II} \geq 0\}$, where vectors ***LB*** and ***UB*** include the lower and upper loop index bounds of an original loop nest, respectively; diagonal matrix ***B*** defines the size of a rectangular original tile; elements of vectors ***I*** and ***II*** represent the original loop nest indices and the identifiers of tiles, respectively; **1** is the vector whose all elements are equal to 1.

TRACO, instead of program transformations represented by a set of affine functions, one for each statement, uses the transitive closure of a loop nest dependence graph to carry out corrections of original rectangular tiles so that all dependences of the original loop nest are preserved under the lexicographic order of target tiles. This may lead to changing shapes of original rectangular tiles; target tiles can be of an arbitrary shape which is affected with dependences available in a loop nest. Recognizing shapes from a mathematical representation of target tiles can be difficult. The visualizer helps recognize what are tile shapes. After code generation, the visualizer forms a graphical representation of the iteration space, dependences, and target tiles.

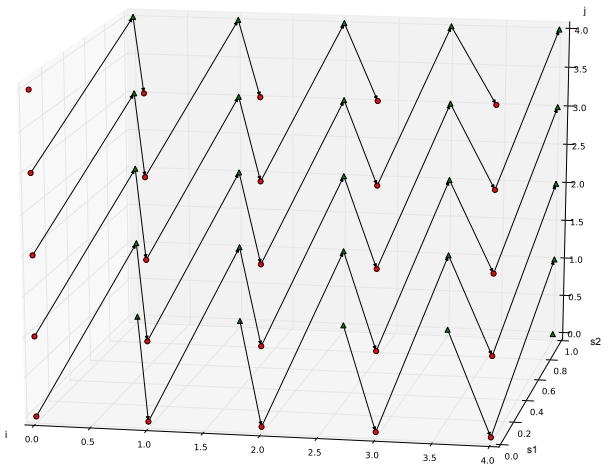

Fig. 1. Iteration space and dependences of Example 1 (n=4); statement instances are marked with the red circles and green triangles.

IV. Applying the TRACO Visualizer

Let us consider the example from paper [9] presented below:

```
// Example 1.
for(i=0; i<=n; i++)
 for(j=0; j<=n; j++){
  a[i][j] = a[i][j] + b[i-1][j];//s1
  b[i][j] = a[i][j-1 * b[i][j]; //s2
}
```

Figure 1 shows the iteration space and dependences for Example 1 generated with the visualizer. Analyzing this figure, we can discover that coarse-grained parallelism represented with synchronization-free slices is available in the considered loop nest (9 threads when n=4), but slices are load imbalanced. We also can see that there exist fine-grained parallelism, i.e., exist time partitions: for each value of index j, we can execute all instances of statement s2 in parallel for all values of index i, then all instances of statement s1. Visualization helps to

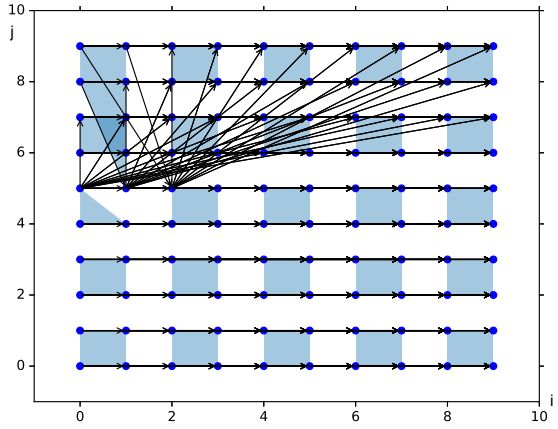

Fig. 2. Dependences, tiles of the size 2x2, and slices for Example 2.

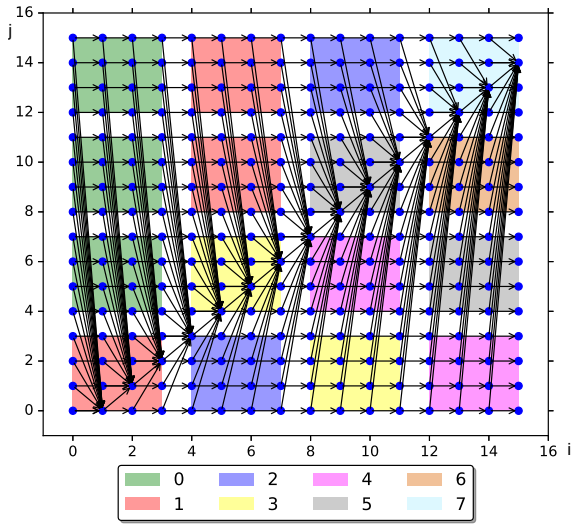

Fig. 3. Dependences, tiles of the size 4x4 and the schedule for Example 3.

discover parallelism available in Example 1 and what is the type of parallelism.

For Example 2 below

```
// Example 2.
for(i=0; i<=9; i++)
 for(j=0; j<=9; j++)
  a[j+4][j+1]=a[i+2*j+1][i+j+3];
```

Figure 2 depicts the iteration space with dependences. The loop tiling algorithm, implemented in TRACO, moves iteration [1,5] from tile [0,2] to tile [0,4] because it is the destination of the dependence whose source belongs to iteration [0,8]. For this example, TRACO is able to find three independent slices whose elements are tiles.

The iteration space with dependences for Example 3 is illustrated in Figure 3. Original rectangular tiling is preserved for this example. The figure shows tiles which are executed according to the free schedule. Time partitions are marked by different colors starting with the three independent green tiles.

```
// Example 3.
for(i=0; i<=15; i++)
 for(j=0; j<=15; j++)
    a[i][j] = a[i+1][i]+a[i+1][j];
```

Figure 4 illustrates dependences and tiles for the loop nest below in the 3D space.

```
// Example 4
for(k=0; k<=15; k++)
 for(i=0; i<=15; i++)
  for(j=0; j<=15; j++)
   a[i][j][k] =  a[i+1][j-1][k];
```

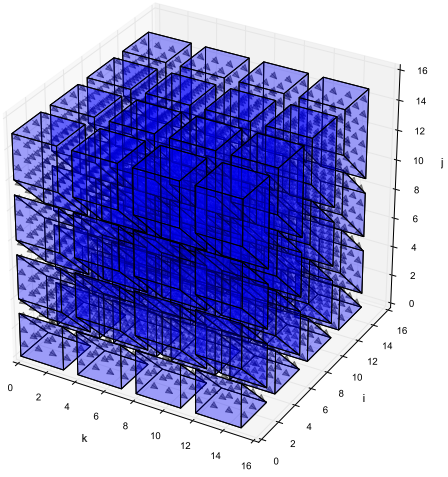

Fig. 4. Dependences and tiles of the size 2x2 for Example 4.

We use also a 3D projection to visualize 2D tiles for the arbitrary nested loops of Example 5, see Figure 5. The third axis indicates numbers of statements in the loop nest.

```
// Example 5
for(i=0; i<=15; i++){
 for(j=0; j<=15; j++)
  a[i][j] = a[i+1][j-1];
 for(j=0; j<=i; j++)
  b[i][j] = b[i][j+1]+a[i][0]; }
```

Figure 6 presents four independent slices whose elements are tiles for Example 6, the Planckian distribution. A 3D-projection reveals synchronization-free parallelism after appropriate rotating.

```
// Example 6 - Planckian distribution, loop=n=7
for ( l=1 ; l<=loop ; l++ )
  for ( k=0 ; k<n ; k++ ){
    y[k] = u[k] / v[k];
    w[k] = x[k] / ( exp( y[k] ) -1.0 );
  }
```

Summing up, we can conclude that visualization allows the programmer to find suitable loop transformations and discover available parallelism or code optimization.

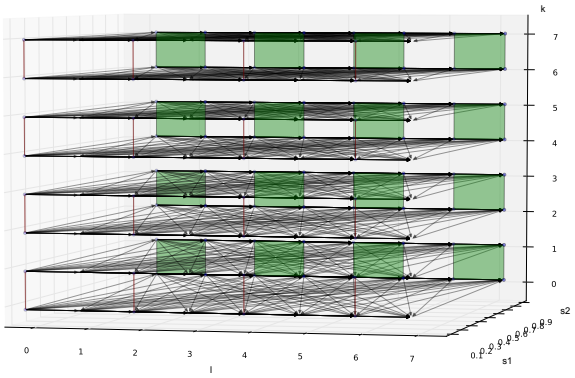

Fig. 6. Dependences and tiles of the size 2x2 for Example 6.

V. Related Work

Popular polyhedral libraries and compilers provide interface to visualization. The PolyLib tool [10] projects loop iteration domains by means of the VisualPolylib. LooPo [11] visualizes loop dependences before and after automatic parallelization. The 3D iteration space visualizer [12], [1] allows programmers to visualize and manipulate 3D dependence graphs, and to select a desired iteration space to start automatic parallelization search based mainly on unimodular transformations.

Clint [13] translates manipulations back to the polyhedral representation and ultimately transforms code to match visualization. This tool seems to be the most advanced visualizer and corresponds to extended versions of classical loop transformations (reordering, shifting, interchange, fusion, splitting, index set splitting, grain, reversal, skewing, tiling etc.).

The islplot[1] and Linpy tools [14] are based on islpy[2], a Python wrapper around Sven Verdoolaeges isl [3], the library for manipulating sets and relations of integer points bounded by linear constraints. Both the libraries are based on the matplotlib framework. Given the fact that TRACO is implemented also by means of the islpy interface, we considered these libraries for the presented approach. Islplot allows us to draw 2D maps and sets directly from islpy classes. However, domains of unions in isplot are drawn as separated figures. Therefore, we draw 2D polygons of tile points building convex hulls by means of Jarvis' March. Moreover, islplot is not integrated with matplotlib in 3D and provides only one function to draw sets in WebGL. Hence, for solids we used the interface provided by LinPy, which allows us to build the Polyhedron object from its constraints.

[2]https://documen.tician.de/islpy/

VI. Conclusion

Visualization of results of a dependence analysis and TRACO transformations carried out assists the development of parallel numerical programs. The approach complements analytical methods used in traditional automatic parallelizing compilers. Furthermore, the tool is helpful to investigate the use of interactive visualization for learning parallelization and the polyhedral model. In future, we plan to provide more interactive functions to the visualizer using event handling and object picking provided by matplotlib. We are going also to use the approach in order to design algorithms of arbitrary shaped tiles.

***Abstract*—Many storage formats for sparse matrices have been developed. Majority of these formats can be parametrized, so the algorithm for finding optimal parameters is crucial. For overall efficiency, it is important to reduce the execution time of this preprocessing. In this paper, we propose a new algorithm for the determination of the number of nonzero blocks of the given size in a sparse matrix. The proposed algorithm requires relatively a small amount of auxiliary memory. Our approach is based on the Morton reordering and bitwise manipulations. We also present a parallel (multithreaded) version and evaluate its performance and space complexity.**

I. Introduction

COMPUTATIONS with sparse matrices are widespread in scientific projects. Many storage formats for sparse matrices have been developed. The most straightforward approach is to accompany values of nonzero elements with their row and column indexes, which forms the *coordinate* format (COO, for details see Sec. I-C). If the local matrix nonzero elements are ordered lexicographically, then row indexes in COO can be substituted by the number of nonzero elements of each row. Such idea is represented by the *compressed sparse row* (CSR, for details see Sec. I-D) format. Due to matrix sparsity, the memory access patterns in common formats (like COO or CSR) are irregular and the utilization of cache suffers from low spatial and temporal locality, hence other (so called advanced) formats are used in practice. These advanced formats are usually parametrized,

A. General notation

We consider a matrix A of order $n \times n$, $A = (a_{i,j})$. The number of its nonzero elements is denoted by N. Matrix A is considered *sparse* if it is worth (for performance or any other reason) not to store this matrix in memory in a dense array. In the following text:

- We assume that indexes of all vectors and matrices start from zero.
- We assume that $1 \ll n \leq N \ll n^2$.
- The number of nonzero elements in submatrix B of matrix A is denoted by $\eta(B)$, so $\eta(A) = N$
- For any submatrix C, if $\eta(C) = 0$ then the submatrix C is called zero submatrix, otherwise it is called nonzero submatrix.
- If all elements in A have the same probability N/n^2 to be nonzero (independently on other elements) then A has a *uniform distribution* of nonzero elements.
- The parameter th denotes the number of threads used for the execution of an algorithm.

B. Banded matrices

Citing from Golub and Van Loan [1]:

Definition 1:

If all matrix elements are zero outside a diagonally bordered band whose range is determined by constants k_1 and k_2:

$$a_{i,j} = 0 \quad \text{if} \quad j < i - k_1 \quad \text{or} \quad j > i + k_2, \quad k_1, k_2 \geq 0.$$

Then the quantities k_1 and k_2 are called the left and right half-bandwidth, respectively. The bandwidth of the matrix (denoted by $\omega(A)$) is $k_1 + k_2 + 1$.

Definition 2: If $\omega(A) \ll n$, then A is *banded*.

C. The Coordinate (COO) format

The coordinate (COO) format is the simplest format for storing sparse matrices (see [2], [3]). The matrix A is represented by three linear arrays $values$, $xpos$, and $ypos$. The array $values[0, \ldots, N-1]$ stores the nonzero values of A, arrays $xpos[0, \ldots, N-1]$ and $ypos[0, \ldots, N-1]$ contain column and row indexes, respectively, of these nonzero values. The ordering of elements in this format is not prescribed.

D. The Compressed Sparse Row (CSR) format

The most common format for storing sparse matrices is the *compressed sparse row* (CSR) format (see [2]–[7]). The matrix A stored in the CSR format is represented by three linear arrays: $values$, $addr$, and ci. The array $values[0, \ldots, N-1]$ stores the nonzero elements of A, the array $addr[0, \ldots, n]$ contains indexes of initial nonzero elements of rows of A. The array $ci[0, \ldots, N-1]$ contains column indexes of nonzero elements of A.

E. Hierarchical formats

Many hierarchical formats are based on the idea of partition the matrix into square disjoint *blocks* of size $2^c \times 2^c$ rows/columns, where $c \in N^+$ is a formal parameter. In the further text, we will denote them as basic hierarchical format (BHF), for details see [6], [8], [9]. Coordinates of the upper left corners of these blocks are aligned to multiples of 2^c. Thus, indexes of nonzero elements are separated in two parts, indexes of blocks and indexes inside the blocks. Every such a region has *block row* and *block column* indexes. Let $B(c)$ denote the number of nonzero blocks for matrix A. The minimal number of nonzero blocks is equal to $B(c)_{min} = \lceil \frac{N}{2^{2c}} \rceil$, if all nonzero blocks contain only nonzero elements (i.e., are 100% dense). The maximal number of nonzero blocks is equal to $B(c)_{max} = \min\left(N, \lceil \frac{n}{2^c} \rceil^2\right)$, if each nonzero block contains exactly one nonzero element or if the whole matrix A is covered by nonzero blocks. This idea is for example behind formats: COOCOO format [10], ABHSF [8], [9], multilevel format [11], and so on. For all these formats, the optimal value of bits for each level should be computed. For this decision, the information about number of blocks $B(c)$ for given c is required.

F. Our requirements for an algorithm

Our assumptions and the requirements for an algorithm for computation of the number of nonzero blocks are as follows:

- The algorithm should be execution efficient (even in the multithreaded environment).
- Since, we are processing large sparse matrices, we assume that the space complexity (memory footprint) of the sparse matrix A is significant. We define an *in-place* algorithm as an algorithm that needs auxiliary data structures with space complexity strictly lower than the number of matrix nonzero elements. By in-place computation we mean an algorithm with $o(N)$ space complexity, in contrast to $O(N)$. It is the typical situation in HPC (high performance computing) that the matrix typically represents the largest object stored in the main memory. Hence, the algorithm should be also space-efficient, i.e., space complexity of all its temporary data should be much lower than space complexity of the matrix. When the computation of the number of nonzero blocks of a matrix cannot be performed in-place, then there might not be enough free memory to make this computation at all.
- In real situation, we don't need to compute the number of nonzero blocks for all c from $[1, \ldots, \lceil \log n \rceil]$ because some block sizes from this interval are simply too small or too large for the given purpose. Thus, we need to compute the number of nonzero blocks only for c from the given interval $[c\_min, \ldots, c\_max]$.

G. Overview of state-of-the-art

As far as we know, there are only two algorithms for the computation of the number of nonzero blocks (e.g., in [10]), both of them are based on sets. There are two main reasons for such low number:

- Authors rarely present algorithms for preprocessing of matrices, which are necessary for assessment of the suitability of their formats for a given application [6]. We have not found a case where format authors provided efficient parallel implementations of algorithms for the computation of the number of nonzero blocks in non-experimental forms.
- Register blocking formats (like SPARSITY [12] or [13] or CARB [5], [14]) store a matrix as a set of small dense blocks. Blocks can be linear (horizontal, vertical, or diagonal) or rectangular, a usual range of size is from 2 to 20. Since the block-size is not limited to the power of 2 and optimization criteria are more complex, a special transformation algorithm is used.
- Some formats (e.g., [11], [15]–[17]) skip this computation and use "typically good" values of the block-size.

The idea behind the two found solutions is to evaluate the number of blocks $B(c)$ for all values of parameter c from $[c\_min, \ldots, c\_max]$ using a set. We will consider four implementations of such an algorithm using different data-structure for implementation of the set.

1) First algorithms based on sets: All nonzero elements are mapped to block coordinates. These block coordinates are mapped to index $i \in \langle 0, \ldots, \lceil n/2^c \rceil^2 \rangle$ and put into set U. Finally, the cardinality of U is determined. It is equal to the number of blocks $B(c)$.

Algorithm 1 Determination of the number of blocks $B(c)$

```
 1: procedure NumberOfBlocks1(I,c)
Input: In = a matrix in the CSR format
Input: c = the parameter (logarithm of block size)
Output: B = the number of blocks
 2:     B ← 0;  d ← 2^c;  p ← ⌈n/d⌉;
 3:     construct the set U;
 4:     U = ∅;
 5:     for y ← 1, In.n do
 6:         for j ← In.addr[y], In.addr[y+1] − 1 do
 7:             x ← In.ci[j];
 8:             i ← ⌊y/d⌋ · p + ⌊x/d⌋;
 9:             put the element i into U;
10:     B ← |U|;
11:     return B;
```

The time complexity of Algorithm 1, $T_1(n, N)$, consists of

- t_1 = time complexity of creating an empty set U at codeline (4),
- $t_2 = N \cdot t_{\text{ins}}$ = time complexity of inserting N elements at codeline (9) into the set U,
- t_3 = time complexity of computing the cardinality of U at codeline (10).

The time complexity depends on the data structure used for implementing the set U. Let $d = 2^c$ and $p = \lceil n/d \rceil$. Let us consider four basic implementations:

1) a bit array (of size of $p^2 = \lceil n/d \rceil^2 = \lceil n/2^c \rceil^2$ bits): Then

- t_1 is proportional to the range of indices i: $t_1 = O(p^2)$,
- $t_2 = N \cdot O(1) = O(N)$,
- t_3 is also proportional to the range of indices i: $t_3 = O(p^2)$.

The total time complexity is $T_1(n, N) = O(N + p^2) = O(N + \lceil n/2^c \rceil^2)$ and the space complexity is $O(p^2) = O(\lceil n/2^c \rceil^2)$. These complexities are high (especially for small values of c) which makes this approach inefficient.

2) A linked list:

- $t_1 = N \cdot O(1) = O(N)$,
- $t_2 = N \cdot O(B(c)_{max})$,
- $t_3 = O(B(c)_{max})$.

The total time complexity is $T_1(n, N) = O(N \cdot B(c)_{max})$ and the space complexity is $O(B(c)_{max})$. This complexity is high which makes this approach inefficient.

3) A balanced binary search tree:

- $t_1 = O(1)$,
- t_2 is proportional to N and to the logarithm of the size of binary representation of index i: $t_{\text{ins}} = O(2 \log p) = O(\log(n/2^c)) = O(\log n - c)$,
- $t_3 = O(B(c)_{max})$.

The total time complexity is $T_1(n, N) = O(B(c)_{max} + N(\log n - c))$ and the space complexity is $O(B(c)_{max})$, hence the approach is quite execution efficient, but space inefficient (especially for small values of c).

4) A hash table of size l (we assume a closed hashing scheme):

- $t_1 = O(l)$,
- $t_2 = N \cdot O(1)$ in ideal case,
- $t_3 = O(l)$.

We must carefully choose the value of parameter l to satisfy the no-collision assumption during the insertion of elements, this parameter should be greater than $B(c)_{max}$. Then, the total time complexity is $T_4(n, N) = O(N + l) = O(N + B(c)_{max})$ and the space complexity is $O(B(c)_{max})$, hence the approach is execution efficient, but space inefficient (especially for small values of c).

2) An improved algorithm: We can improve Algorithm 1 as follows: The matrix A is divided into disjoint horizontal strips whose height is equal to 2^c. Then the cardinality of set U (i.e., the number of blocks) is determined in each strip separately. The value of $B(c)_{max}$ is decreased to $\lceil \frac{n}{2^c} \rceil$ that occurs if the whole strip is covered by nonzero regions.

Algorithm 2 Determination of the number of blocks $B(c)$ (improved)

```
1:  procedure NumberOfBlocks2(In,c)
Input: In = a matrix in the CSR format
Input: c = the parameter (logarithm of block size)
Output: B = the number of blocks
2:      B ← 0;  old ← −1;
3:      d ← 2^c;
4:      create the set U;
5:      U = ∅;
6:      for y ← 1, In.n do
7:          if ⌊y/d⌋ > old then
8:              B ← B + |U|;
9:              U = ∅;
10:             old ← ⌊y/d⌋;
11:         for j ← In.addr[y], In.addr[y + 1] − 1 do
12:             x ← In.ci[j];
13:             i ← ⌊x/d⌋;
14:             put the element i into U;
15:     B ← B + |U|;
16:     return B;
```

The time complexity of Algorithm 2, $T_2(n, N)$, consists of:

- $t_1 = p \cdot t_{\text{init}}$ = time complexity of creating empty sets at codelines (5) and (9),
- $t_2 = N \cdot t_{\text{ins}}$ = time complexity of inserting N elements at codeline (14),
- $t_3 = p \cdot t_{\text{enum}}$ = time complexity of determining the cardinality of the set at codelines (8) and (15).

Four basic implementations of the set data type provide the following time complexities:

1) a bit array (of size of $\lceil n/d \rceil = \lceil n/2^c \rceil$ bits):
   - $t_{\text{init}} = O(p)$,
   - $t_{\text{ins}} = O(1)$,
   - $t_{\text{enum}} = O(p)$,

   $T_2(n, N) = O(N + p^2)$ and the space complexity is $O(p)$. So, the space complexity decreased compared to same implementation of the set data type in Algorithm 1, but the time complexity remains high, especially for small values of c.
2) a linked list:
   - t_{init} remain the same as in the previous case,
   - $t_{\text{enum}} = t_{\text{ins}} = O(B(c)_{max})$ drops due to $B(c)_{max}$ decrease.

   The total time and the space complexities remain the same compared to the same implementation of the set data type in Algorithm 1.
3) a balanced binary search tree:
   - t_{init} remains the same as in the previous case,
   - $t_{\text{ins}} = O(\log p) = O(\log(n/2^c)) = O(\log n - c)$.
   - $t_{\text{enum}} = O(B(c)_{max})$ drops due to $B(c)_{max}$ decrease.

The total time complexity remains the same compared to the same implementation of the set data type in Algorithm 1.

4) a hash table with the open hashing scheme (the size of the hash table is equal to l). It is much easier to satisfy the no collision assumption by insertion of elements (with lesser value of l).
   - t_{ins} is the same,
   - t_{init} and t_{enum} drops due to $B(c)_{max}$ and l decrease.

   The total time complexity remains the same.

3) The summary of state-of-the-art algorithms: None of the algorithm and implementation satisfies the requirements describe in Sec. I-F. The improved algorithm reduces memory requirements which allows implementations to be space efficient. On the other hand, existing algorithms are execution inefficient (especially for small values of c). The situation is getting worse for multithreaded execution. If each strip is computed in parallel then every thread has independent instance of the set and memory requirements will be th-times higher. If single strip is computed by multiple threads then the only one (shared) set is used, but every access is a critical section, hence the speedup would be minimal.

II. Our new approach

A. Main idea

In our approach, we utilize reordering of nonzero elements according to so-called Morton order (for details see [18]). Morton ordering is a mapping from an i-dimensional space onto a linear list of numbers. If we want to convert a certain set of integer coordinates to a Morton code, we have to interleave the binary representations of each coordinate. Here is an example of transformation from 3D coordinates into Morton code.

$$(x, y, z) = (5, 9, 1)_{10} = (0101, 1001, 0001)_2$$

Interleaving the bits results in: $(010\ 001\ 000\ 111)_2 = (1095)_{10}$-th cell along the co called Z-curve. For the determination of the number of blocks, we use the following lemma.

Lemma 1: Morton codes for all elements inside the block of size 2^c that is aligned to multiple of 2^c are the same except $2 \cdot c$ least significant bits.

The proof of Lemma 1 is obvious (based on the construction of Morton code). Hence, we can design an algorithm based on this lemma: in a sorted sequence of nonzero elements, we count differences in Morton codes of two adjacent items (more exactly: the positions of highest bit set in the result of logical XOR of two adjacent items). We call this algorithm Morton-based (see Algorithm 3).

Algorithm 3 Determination of the number of blocks $B(c)$ (new)

```
 1: procedure NumberOfBlocks3(In,c)
Input: A = a matrix in the COO format
Input: c = the parameter (logarithm of block size)
Output: B = the number of blocks
 2:     for j ← 1, c_max do
 3:         number[j] ← 1;
 4:     add to every nonzero element its Morton code;
 5:     sort nonzero elements on its Morton code;
 6:     old ← A[0].Morton;
 7:     for i ← 1, N do
 8:         new ← A[i].Morton;
 9:         diff ← XOR(new, old);
10:         old ← new;
11:         k ← round_up(Highest1(diff)/2);
12:             ▷ Highest1 = the index of the position of the
    highest bit set
13:         for j ← 1, k do
14:             number[j] ← number[j] + 1;
15:     return number[];
```

The time complexity of Algorithm 3, $T_3(n, N)$, consists of:

- $t_1 = N$ = time complexity of generating Morton codes at codeline (4),
- $t_2 = N \log N$ = time complexity of sorting. We assume the sorting algorithm with complexity $O(i \log i)$ for a array of length i.
- $t_3 = N \cdot c\_max$ = time complexity of for-cycle at codeline (7) mainly inner loop at codeline (13).

Overall time complexity is $T_3(n, N) = N(c\_max + \log N)$, so this algorithm is efficient, but requires additional space for Morton codes proportional to N. To avoid this, we propose two solutions:

1) Morton codes are not stored explicitly. They can overwrite COO storage format (arrays $xpos$ and $ypos$). After determination of the number of blocks, the coordinates (original values in these arrays) will be restored from Morton codes.
2) Computation of Morton code can be included in a compare function of sorting algorithm at codeline (5) in Algorithm 3.

B. Example of algorithm usage

Let us assume a very small example of a sparse matrix with $n = 8$ and $N = 12$. Instead of the values of the matrix elements, we deal only with binary flags indicating the existence of nonzero elements.

$$\mathbf{M^{(0)}} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}$$

The steps of the new algorithm are as follows:

Step 1: (codeline 4) For each nonzero element, the Morton code is computed. Morton codes (for elements in lexicographic order) = { 000000, 010101, 000011, 010110, 001100, 001111, 011010, 110011, 101000, 111100, 101011, 111111 }.

Step 2: (codeline 5) The whole sequence is sorted according to Morton codes.

Step 3: (codeline 7-14) We count difference in Morton codes of adjacent items. Morton codes (for elements the highest different bit set is marked) ={ 000000, 0000$\bar{1}$1, 00$\bar{1}$100, 0011$\bar{1}$1, 0$\bar{1}$0101, 0101$\bar{1}$0, 01$\bar{1}$010, $\bar{1}$01000, 1010$\bar{1}$1, 1$\bar{1}$0011, 11$\bar{1}$100, 1111$\bar{1}$1 }. The counters (in variable $numbers$) are increased according to the position of the highest bit set (e.g., 0000$\bar{1}$1 $\Rightarrow$ increase $numbers[1]$ by one, 00$\bar{1}$100 $\Rightarrow$ increase $numbers[1]$ and $numbers[2]$ by 1, etc.).

Step 4: (codeline 15) After traversing the example sequence, the counters are set to $B(c = 1) = numbers[1] = 7$, $B(2) = 4$, $B(3) = 1$.

C. Parallelization

1) SW technologies: The OpenMP API specification [19] is defined by a collection of compiler directives, library routines and environment variables extending the C, C++ and Fortran languages. These can be used to create portable parallel programs utilizing shared memory. The core of OpenMP is the so called *fork-join model* execution model. An application employing OpenMP usually begins as a single thread program and during execution uses multiple threads or even other devices to perform parallel tasks.

The OpenMP API provides a relaxed-consistency, shared memory model. All threads have access to the memory and each may have its own temporary view of the memory (which represents cache or other local storage used for caching). Each thread also have access to thread private memory, which cannot be accessed by any other thread. A single access to a variable is not guaranteed to be atomic with respect to other accesses of that variable, since it may be implemented with multiple load or store instructions. If multiple threads write without synchronization to the same memory unit, the data race occurs.

2) Multithreaded execution: The parallel (multithreaded) version of the algorithm is represented by Alg. 4. We simply make all steps (described in Sec. II-B) parallel:

Step 1 (Computation of Morton codes): The parallelization of this step is straightforward.

Step 2 (Sorting of Morton codes): The parallelization of this step is straightforward by using any parallel in-place sort (e.g., `sort` method from `std::algorithm` [20] or AQsort [21])

Step 3 (Counting the differences): The whole sequence of sorted Morton codes is partitioned into th disjoint chunks of consecutive elements. Each chunk contains approximately the same number of elements. Each thread counts the differences in the assigned chunk independently. After this computation, local (thread private) instances of $l\_number[]$ are summed up to the global values ($number[]$).

Algorithm 4 Determination of the number of blocks $B(c)$ (new, parallel version)

```
1:  procedure NumberOfBlocks4(In,c)
Input: A = a matrix in the COO format
Input: c = the parameter (logarithm of block size)
Output: B = the number of blocks
2:      parallel add to every nonzero element its Morton code;
3:      parallel sort nonzero elements on its Morton code;
4:      len = N/th;
5:      start of parallel block
6:      tid = get_tid_of_current_thread();
7:      if tid = 0 then
8:          old ← A[0].Morton;
9:          start ← 1;
10:         for j ← 1, c_max do
11:             l_number[j] ← 1;
12:     else
13:         old ← A[tid · len − 1].Morton;
14:         start ← tid · len;
15:         for j ← 1, c_max do
16:             l_number[j] ← 0;
17:     for i ← start, (tid + 1) · len − 1 do
18:         new ← A[i].Morton;
19:         diff ← XOR(new, old);
20:         old ← new;
21:         k ← round_up(Highest1(diff)/2);
22:         for j ← 1, k do
23:             l_number[j] ← l_number[j] + 1;
24:     end of parallel block
25:     parallel reduction(+) of l_number into number;
26:     return number[];
```

D. Modification of algorithm suitable for the CSR format

Our algorithms (see Alg. 3 and 4) require the input storage format that allows to reorder/sort its nonzero elements. Hence, we use the COO format. This format is used in HPC, but the CSR format is more frequent (see for example [22], [23]). For the CSR format, we propose the following modification.

Step 1 The whole matrix is partitioned into 2D disjoint regions (=chunks of consecutive rows). Starting row of each

region are aligned to multiple of 2^{c_max}.

Step 2 For each region all nonzero elements in this region are extracted and their Morton codes are stored into a temporary array. These regions are proceeded by Alg. 3.

Step 3 The results for all regions are summed up to the global values.

The parallelization of this algorithm is easy: each region can be computed independently by a different thread. For good load balancing in OpenMP API even for matrices with non-uniform distribution (e.g., for banded matrices), so-called dynamic scheduling strategy is used.

TABLE I: Characteristics of the testing matrices and their abbrevation in the further text.

III. Evaluation of the results

A. Testing matrices

We have used 10 testing matrices from various application domains from the University of Florida Sparse Matrix Collection [24]. Table I shows the characteristics of the testing matrices.

B. Used HW and SW

The execution times were measured on a server with following HW and SW parameters:

- 2 × CPU Intel Xeon Processor E5-2620 v2 (15MB L3 cache per CPU),
- CPU cores: 6 per CPU, 12 in total,
- Memory size: 32 GB RAM, total max. memory bandwidth: 51.2 GB/s,
- Peak single precision floating point performance 0.48 Tflops (using base clocks),
- OS Linux, C++ compiler (g++) version 4.8.3 with switches `-O3 -march=native -mavx -fopenmp`.

We measure elapsed wall clock times using OpenMP function `omp_get_wtime()`.

C. Evaluation of results

1) Comparison of sequential algorithms: Tables II and III show the comparison of measured times for different algorithms for the determination of the number of blocks. From this table, we can conclude that our Morton-based algorithm is always faster for larger matrices. The reason is the following: the time complexity of classical algorithm is $O(n^2+N)$, hence for smaller matrices (with small order) both components are approximately the same and algorithm is execution-efficient. On the other hand, for larger matrices in the complexity of the classical algorithm the component n^2 become dominant and algorithm is execution-inefficient. For small matrices the initial overhead of the Morton-based algorithm is significant. For larger matrices, this overhead become negligible and this algorithm is execution-efficient.

Matrix	CL($th=1$)	CL($th=12$)	NEW($th=1$)	NEW($th=12$)
m1	2834	265.9	3.56	0.348

m8	14.4	2.39	0.388	0.130
m9	0.128	0.128	0.157	0.157
m10	0.309	0.325	0.154	0.154

TABLE III: Measured times in seconds for the determination of the number of blocks ($c\_max = 16$): CL denotes the classical (improved) algorithm, NEW denotes the Morton-based algorithm.

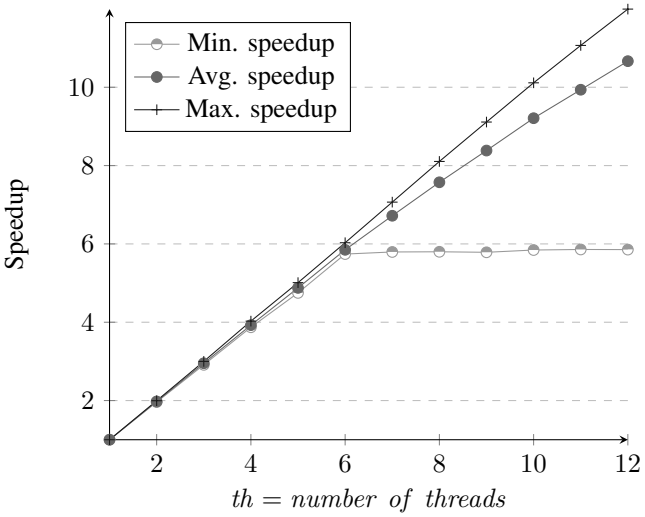

Fig. 1: Speedups for classical (improved) algorithm with $c\_max = 8$.

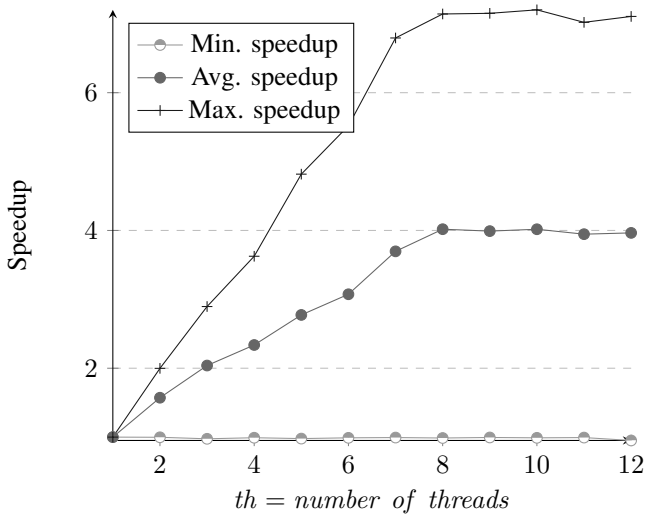

Fig. 2: Speedups for classical (improved) algorithm with $c\_max = 16$.

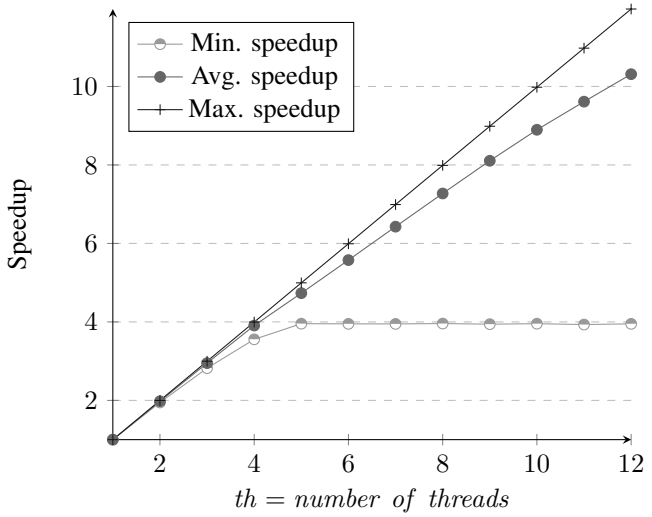

Fig. 3: Speedups for Morton-based algorithm with $c\_max = 8$.

2) Comparison of parallel algorithms: Tables II and III show the comparison of measured times for different algorithms for the determination of the number of blocks. From Fig. 1, 2, 3, and 4 we can conclude that both algorithms scale very well (speedup is equal to the number of threads) for $c\_max = 8$. For $c\_max = 16$, the scalability is getting worse since parallelization is based on regions (see Section I-G3 and II-D). For small matrices (with small order), the parameter 2^{c_max} is comparable with the order of the matrix. In this case, the load-balance is not good and majority of threads is idle and the speedup is almost independent on the number of threads.

IV. Conclusions

This paper presents the design of a new algorithm for the for the calculation of the number of blocks in sparse matrices. This

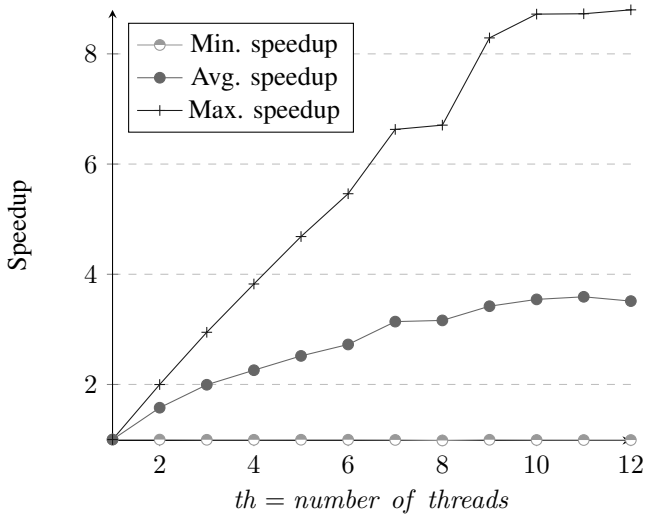

Fig. 4: Speedups for Morton-based algorithm with $c\_max = 16$.

algorithm is crucial for preprocessing of matrices into some advanced storage formats. We have also developed a parallel version of this algorithm. We performed experiments on the parallel system and their results showed that the proposed algorithm is both execution- and space-efficient.

1st Workshop on Constraint Programming and Operation Research Applications

THE aim of the CPORA-Workshop on Constraint Programming and Operation Research Applications is to bring together interested researchers from constraint programming/constraint logic programming (CP/CLP), operations research (OR) and artificial intelligence (AI) to present new techniques or new applications in decision support, combinatorial optimization, modeling and control processes arising in manufacturing, transportation, telecommunication, computer networks, logistic systems etc. and to provide an opportunity for researchers in one area to learn about techniques in the others. The aim of this workshop is share ideas, projects, researches results, models, experiences etc. associated with CP/CLP/OR/AI and to give researchers the opportunity to show how the integration of techniques from different fields can lead to interesting results on large and complex problems. Additionally, we would like to stimulate the communication between researchers working on different fields and practitioners who need reliable and efficient modelling and computational methods for industrial and business processes.

Contributions containing of both: the theoretical and practical results obtained in this area are welcome.

***Abstract*—**Various techniques of portfolio selection are applied to interpret the status of the market and predict the market's future trend, but they are not beneficial to small investors because these techniques should be administered by an expert. In addition, these techniques desire accumulation of data about the market and complicated calculations, which is too much effort for individual small investors. Therefore, portfolio selection with two significant financial ratios using the ELECTRE III method is proposed for these investors to make trading decisions. In order to demonstrate the effectiveness of this new method, it is compared to the situation where a fix percentage allocation existed and data was collected from the Stock Exchange of Thailand (SET).

I. Introduction

The Stock Exchange of Thailand (SET) is the national stock exchange of Thailand. Retail investors in Thailand have long been a majority of players. They account for approximately 41%, whereas foreigner and institution flows are 36% and 21% of daily trading value respectively [13]. Since many factors (such as political and economic factors) are likely to influence the trend of the market [3], forecasting the trend requires various market analysis techniques [2, 5, 10, 11, 19, 22]. In addition, there are a number of machine learning techniques proposed as a solution to the problem such as reinforcement learning [17, 18, 20], neural networks [9, 12], genetic algorithms [1, 15, 16], decision trees [24], support vector machines [4, 14, 23], and boosting and expert weighting [6, 7, 8]. Arthur Samuel in 1959 defined machine learning as the "field of study that gives computers the ability to learn without being explicitly programmed". Such techniques build a model from an example training set of input observations in order to make data-driven predictions or decisions expressed as outputs. Although machine learning techniques are applied to interpret the status of the market and predict the market's future trend, but they are not beneficial to small investors because these techniques desire both accumulation of training data set about the market and complicated calculations to make data-driven predictions, which is too much effort for an individual small investor. Therefore, portfolio selection with only two significant financial ratios using the ELECTRE III method is proposed for those investors to make trading decisions. The two significant financial ratios are net profit margin and dividend yield. The Net profit margin is a ratio of profitability calculated as after-tax net income (net profits) divided by sales (revenue) and displayed as a percentage; whereby consideration focuses on stocks with high net profit margin. Dividend yield is the amount that a company pays to its shareholders annually for their investments; whereby consideration focuses on stocks with high dividend yield. It is expressed as a percentage and indicates attractiveness of investing in a company's stocks. The ELECTRE III method [21] is the most popular one of the outranking methods in Multi Criteria Decision Making (MCDM). Its performance of alternatives on each criterion in outranking is compared in pairs. An alternative a is said to outrank an alternative b if it performs better on some criteria and at least as well as b on all others. The outranking relation in the ELECTRE III is a fuzzy binary relation. It uses three distinct thresholds (indifference, preference, and veto) to incorporate the uncertainties that are inherent in most influence valuations. In addition, the ELECTRE III method is less of a complex than the machine learning techniques because it follows strictly static program instructions.

This report proceeds as follow. In the next section, previous related literatures are reviewed. Then the research methodology and data used are discussed. Empirical results found in the study are then presented and analyzed. Lastly, conclusion, implications, and limitations together with suggestion for further study are presented.

II. Backgrounds

An ELECTRE is a family of multi-criteria decision analysis methods (Roy, B. (1978)). The ELECTRE is working on the concrete, multiple criteria, and real-world problem of how firms can decide on new activities and had encountered problems using a weighted sum technique. It uses several mathematical functions to indicate the dominant degree of one alternative over the remaining ones. Additionally, it also facilitates comparisons between alternative schemes by using a weighted sum technique. The outranking relationships between alternatives are constructed and exploited eventually.

In order to be consistent with the basic concept of similarity in case based reasoning, different terminologies from the classical ELECTRE is used.

Let the distance between case a_k and case a_l on the j feature be denoted by $|a_{kj} - a_{lj}|$ or d_{lkj}. Let w_j express the weight of the feature.

Definition 1: The indifferent threshold of criterion j q_j: a_k and a_l are indifferent if $|a_{kj} - a_{lj}| < q_j$.

Definition 2: The strict preference threshold of criterion j p_j: a_k is strictly preferred to a_l if $|a_{kj} - a_{lj}| < q_j$.

Definition 3: The weak preference threshold of criterion j p_j: a_k is weakly preferred to a_l if $|a_{kj} - a_{lj}| \leq p_j$.

Definition 4: The veto threshold of criterion j v_j: reject the hypothesis of outranking of a_k over a_l if $|a_{kj} - a_{lj}| > v_j$.

The Index of Concordance and Discordance

Definition 5: The degree of concordance with the judgmental statement that a_k outranks a_l under the j the criterion $cr_j(k,l)$ is defined as

$$cr_j(k,l) = \begin{cases} 1 & if\ q_j \geq a_{lj} - a_{kj}, \\ 0 & if\ p_j \leq a_{lj} - a_{kj}, \\ \frac{p_j - (a_{lj} - a_{kj})}{p_j - q_j} & otherwise \end{cases}$$

Definition 6: A concordance index of each ordered pair (a_k, a_l) of alternatives $cr(k,l)$ is defined as

$$cr(k,l) = \frac{\sum_{j=1}^{r} w_j cr_j(k,l)}{\sum_{j=1}^{r} w_j}$$

Where w_j is the weight determining the relative importance of j th criterion.

Definition 7: The degree of discordance with the judgmental statement that a_k outranks a_l under the j the criterion $d_j(k,l)$ is defined as

$$d_j(k,l) = \begin{cases} 0 & if\ a_{lj} - a_{kj} \leq p_j, \\ 1 & if\ a_{lj} - a_{kj} \geq v_j, \\ \frac{(a_{lj} - a_{kj}) - p_j}{v_j - p_j} & otherwise \end{cases}$$

The Degree of Outranking

Definition 8: The degree of credibility of outranking with the judgmental statement that a_k outranks a_l is defined as

$$s(k,l) = \begin{cases} cr(k,l) & if\ J(k,l) = \varnothing, \\ cr(k,l) \prod_{j \in J(k,l)} \frac{1 - d_j(k,l)}{1 - cr(k,l)} & otherwise \end{cases}$$

where $J(k,l)$ is defined as the set of criterion for which $d_j(k,l) > cr(k,l)$. If $J(k,l) = \varnothing$, we have $d_j(k,l) > cr(k,l)$ for any criterion, then $s(k,l)$ is the same as $cr(k,l)$.

Definition 9: The ranking of the alternatives is defined as

$$\delta_k = \sum_{l=1}^{n} s(k,l) - \sum_{l=1}^{n} s(l,k), k = 1,2,\ldots,n$$

III. THE ELECTRE III MODEL FOR SELECTING STOCKS

A. *The ELECTRE III Method*

Let A = {a_1, a_2, …a_n} be a set of stock alternatives, $P_{purchase}$ be prices of the purchased stocks in any year, P_{sell} be prices of the sold stocks in any year, and C = {c_1, c_2} be a set of criteria in this research which are net profit margin and dividend yield. W = {w_1, w_2} is a set of weights of influence on criteria net profit margin and dividend yield, a_{kj} is the performance values of criterion c_j of stock alternative a_k, and (a_k, a_j) is any ordered pair of stock alternatives. Net Profits of any stocks are the difference between the price of the purchased stocks and their sold stocks. Total profit is summation of Net Profits and their Dividend yields.

In this section, Combinatorial Portfolio selection with the ELECTRE III method is described. There are three steps as follows:

Table 1: The ELECTRE III method for Selecting Stocks

Input: a list A of stock alternatives, $P_{purchase}$ is prices of the purchased stocks in any year, P_{sell} is prices of the sold stocks in any year, C is a set of criteria: net profit margin and dividend yield, W is a set of weights of influence on criteria net profit margin and dividend yield, Percent of ranking allocation
Output: Total profit of each allocation
1. Ranking the stocks. The results are ranking based on the ELECTRE III method.
2. Allocating percentage of top ranking stocks.
3. Calculating total profit from each allocation.

B. Description of the Scenario

In this section, we present an application of the ELECTRE III method to select any stocks. Suppose that Somsri want to select stocks of any company. Table 2 shows all stocks that the she wants to purchase. Criteria that are considered in selecting each stock are their weights, their preference threshold, their indifference index, and their veto threshold are defined for this application, as in Table 3. The criteria net profit margin and dividend yield are to be maximized. The last price and dividend yield of stocks from 2011 to 2014 are shown in Table 4 and 5 respectively. Finally, the final ranking of the ELECTRE-III methods is shown in Table 6.

Table 2: Stock alternatives

Stock alternatives	Description
A1	BTS: BTS GROUP HOLDINGS PUBLIC COMPANY LIMITED
A2	PTT: PTT PUBLIC COMPANY LIMITED
A3	SPALI: SUPALAI PUBLIC COMPANY LIMITED
A4	SCB: THE SIAM COMMERCIAL BANK PUBLIC COMPANY LIMITED
A5	AHC: AIKCHOL HOSPITAL PUBLIC COMPANY LIMITED

Table 3: Indifference, preference, and veto thresholds values

Criteria	Description	Units	Indifference Threshold (q)	Preference Threshold (p)	Veto Threshold (q)	Weight
C1	Net Profit Margin (%)	%	5	10	20	0.6
C2	Dividend Yield (%)	%	0.5	3	5	0.3

Table 4: Price of stocks of any company in any years

Alternatives	Last Price(Baht)			
	30/12/2011	28/12/2012	27/12/2013	30/12/2014
A1: BTS	0.7	7.15	8.70	9.65
A2: PTT	318	332	286	324
A3: SPALI	14.30	17.70	14.6	24.10
A4: SCB	116.5	181.5	143.5	182.0
A5: AHC	77.50	21.40	19.40	28.50

Table 5: Dividend yields of stocks of the company in any years

Alternatives	Dividend Yield (%)			
	30/12/2011	28/12/2012	27/12/2013	30/12/2014
A1: BTS	5.03	3.55	4.21	6.2
A2: PTT	3.21	3.91	4.55	4.01
A3: SPALI	4.2	3.67	4.45	2.9
A4: SCB	2.57	1.93	3.14	2.88
A5: AHC	3.23	1.64	2.58	2.25

Table 6: Final rankings of the stock alternatives

Stock Alternative	ELECTRE III
A1: BTS	3
A2: PTT	5
A3: SPALI	2
A4: SCB	1
A5: AHC	4

Finally, we can rank stock alternatives. In ELECTRE III method, the best case is A4 and it is followed by A3, A1, A5, and A2 respectively.

IV. EMPIRICAL RESULTS AND ANALYSIS

The empirical experiment to measure the total profit of ELECTRE III algorithm is conducted in this research. Several parameters are needed to be defined when applying the ELECTRE III algorithm:

A. Experiment setting

To demonstrate the effectiveness of the proposed schema the total profits under the two scenarios (that is, the ELECTRE-III method allocation and fixed-percentage allocation) are compared.

Then, assume that a budget is equal to 100,000 Thai Bahts. The number of years that the stock is hold is 4 years. The result of combination of two, three, four highest ranking stocks in the the ELECTRE-III method are shown in Tables 7, 8, and 9 below. Here, a fixed-percentage allocation of 20 % has been assumed for all alternatives and are shown in Table 10.

Table 7: Results of the ELECTRE III method allocation with two highest ranking stocks (ELECTRE III (2))

Stocks	Ranking	Percentage	Budgets	$P_{purchased}$	Units	P_{sold}	Profits	Total
A3: SPALI	2	50	50000	14.3	3496.50	24.1	9.88	87,762.24
A4: SCB	1	50	50000	116.5	429.18	182	65.5	32,626.61
Total								120,388.8

Table 8: Results of the ELECTRE III method allocation with three highest ranking stocks (ELECTRE III (3))

Stocks	Ranking	Percentage	Budgets	$P_{purchased}$	Units	P_{sold}	Profits	Total
A1: BTS	3	33.33	33333	0.7	47619.05	9.65	8.95	1,330,476
A3: SPALI	2	33.33	33333	14.3	2331	24.18	9.88	58,508.16
A4: SCB	1	33.33	333333	116.5	286.12	182	65.5	21,751.07
Total								1,410,735

Table 9: Results of the ELECTRE III method allocation with four highest ranking stocks (ELECTRE III (4))

Stocks	Ranking	Percentage	Budgets	$P_{purchased}$	Units	P_{sold}	Profits	Total
A1: BTS	3	25	25000	0.7	35,714.29	9.65	8.95	997,857.1
A3: SPALI	2	25	25000	14.3	1,784.25	24.18	9.88	43,881.12
A4: SCB	1	25	25000	116.5	214.59	182	65.5	16,313.3
A5: AHC	4	25	25000	77.5	322.58	28.5	-4.9	-12,677.4
Total								1,045,374

Table 10: Results of the fixed-percentage allocation evaluation

Stocks	Ranking	Percentage	Budgets	$P_{purchased}$	Units	P_{sold}	Profits	Total
A1: BTS	3	20	20000	0.7	28571	9.65	8.95	798285.7
A2: PTT	5	20	20000	318	62.89	324	6	1363.52
A3: SPALI	2	20	20000	14.3	1398.6	24.18	9.88	35,104.9
A4: SCB	1	20	20000	116.5	171.67	182	65.5	13,050.64
A5: AHC	4	20	20000	77.5	258.06	28.5	-4.9	-10,141.9
Total								837,662.86

To evaluate the performance of the ELECTRE-III method allocation the above algorithms were run 100 times for various simulation parameters and the average values of the profits were calculated. Table 11 shows various parameters used in the experiment.

Table 11: Simulation parameters used in both scenarios

Parameters	Range of values used for simulation
Fixed percentages	20%
Budgets	100000 baths
Years	2 – 4 years
Alternatives	5

In Table 11, there are four parameters. Fixed percentage of a fixed-percentage allocation scheme is 20%. Budget means the budget for all stocks or alternatives. Years mean the number of years that the stocks are hold from 2011 to 2014. Alternatives mean the number of stocks.

B. Results

The above results (Table 7, 8, and 9) show the total profits under the proposed scheme with different top-n choices. Figure 1 compares these results with a fixed-percentage allocation scheme (Table 10). In Figure 1, the vertical axis represents mean of total profit.

In these simulations, the total profits of the alternative ELECTRE-III (3) is higher than of the fixed-percentage allocation. To determine whether a significant difference exists between the total profits of the two groups, an independent t-test and a Wilcoxon signed rank statistic used with a significance level of $\alpha = 0.05$ were applied to the results of these simulations. The test results reject the hypotheses: the total profit of the ELECTRE-III (3) is equal to of the fixed-percentage allocation. It implies that the total profit of the ELECTRE-III (3) is not equal to that of the fixed-percentage allocation comparisons. Additionally, the ELECTRE-III (4) method gives the same results as the ELECTRE-III (3) method. However, the ELECTRE-III (2) method gives the results opposite from the ELECTRE-III (3) because the number of stocks is not much to guarantee a risk from investment.

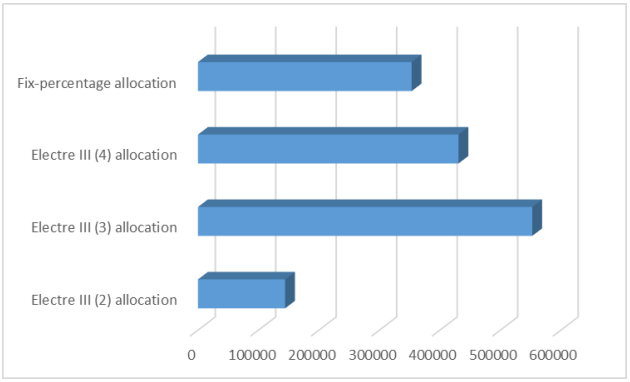

Figure 1: Results of satisfaction evaluation

V. CONCLUSION, LIMITATIONS, AND FUTURE WORKS

Portfolio selection with two significant financial ratios using the ELECTRE III method is proposed for small investors to make trading decisions. We have presented fundamental principles of the ELECTRE III method in detail. In this research, we use a veto indicator deriving from non-veto relations, weak veto relations, and strong veto relations to enhance the mechanism of similarity measure between two cases. 100 times is employed to assess ranking performance of various ELECTRE III methods. From the results of the experiment, we find that the new offer a viable approach for investment advisory ranking. Empirical results show that they offer significantly better ranking performance than the fix-

percentage allocation method. Our proposed prototype using the ELECTRE III method has been successfully validated. This was demonstrated in Figure 1. Such results illustrate that user can get not vague information from application of the ELECTRE III method allocation to help he/she in investment planning and then it could lead to a growing total profits of retail investors in Thailand. Limitations of our study is that it doesn't considered situations with vary alternatives and percentages of ranking stocks.

***Abstract*—In advanced logistic systems, there is a need for a comprehensive optimization of the transport of goods, which would reduce costs. During past decades, several theoretical and practical approaches to solve vehicle routing problems (VRP) were proposed. The problem of optimal fleet management is often transformed to discrete optimization problem that relies on determining the most economical transport routes for a number of vehicles in order to deliver (or pick up) certain amount of goods to geographically distributed set of customers. However, real life problems generally differ from the classical cases because they impose additional constraints to be satisfied. Therefore, research related to developing dedicated theoretical and technological solutions fitted to particular real life use case are very important. In the paper, the particular variant of the VRP problem which is an exemplification of the real-life business case is presented. Authors of the paper proposed an architecture of modular system and an algorithm designed to solve the real-world variant of the VRP which is important from the business perspective.**

I. Introduction

THE fleet management support systems are becoming important tools for various branches of logistics industry. Currently, dedicated software information systems provide tools for optimal resource utilization that in consequence allows for cost reduction related to goods transportation. Therefore, recently significant number of R&D projects related to the problem of optimization of fleet management is being held.

In theoretical terms, the problem of fleet management is often transformed to discrete optimization problem that can be included to the class of so called "NP-hard" problems, which are generally characterized by exponential complexity. Many theoretical approaches to solve vehicle routing problem (VRP) since its first formulation by Dantzig and Ramser 1959 [1] have been studied. Heuristic approaches like Clarke and Wright algorithm [2] based on greedy routes creations or two stages approaches like "route-first cluster-second" (or the opposite) were considered. While such heuristic approaches were mostly proposed for rather simple variants of VRP, recently, local search algorithms with metaheuristic control strategies involved like tabu search [3] or simulated annealing are often considered, especially for solving more complicated variants [4]. Some bio-inspired metaheuristics, including evolutionary approaches like memetic algorithms [5] or ant colony optimization techniques for VRP are also under investigation [6]. Many of the specific variants of VRP are nowadays classical. Some more prominent are Capacitated Vehicle Routing Problem (CVRP) or CVRP with time Windows (CVRPTW). However, real life transportation and logistics problems differ from such classical due to several reasons. The structure and size of real-world input datasets, like fleet heterogeneity, number of customers and many others makes them differ from classical benchmarks and therefore it forces developers to solve business scenarios independently. Also, adding additional constraints to the classical variants of VRP problems caused by business background and clients' requirements is needed. Usually, these conditions are very specific and matched to dedicated implementation. Although many approaches for VRP have been proposed so far, there is still a need to develop dedicated and fitted solutions. Therefore, research and development related VRP that arise from real-world problems is an interesting and important direction [7].

In this paper, the specific variant of VRP is considered. It includes additional constraints mostly related to time windows (TW) and truck/trailer (TT) specifics. Many variants of VRP with time windows were considered in the literature. Relatively simple variants assume only time window and capacity constraints [8]. More complex variants may add additional time dependency of travel time matrix [9] or even introduce classes of customers, e.g., pickup and delivery [10]. The truck and trailer routing problem (TTRP) were proposed and formalized by Chao [11], who also proposed 21 benchmark instances for the problem which are the classical and improved till now [12]. Even a combination of TW and TT were recently considered by Lin et al. [13] as TTRP with Time Windows (TTRPTW). However, even such complicated model is not sufficient for all the real-world demands included in business scenario considered in this article.

In the II section real-world case study was presented. It was performed on the basis of the data retrieved from the existing enterprise resource planning (ERP) system, that is actually used in leading dairy companies from northern Poland. The existing ERP system only partially supports the

This research was sponsored by the National Centre for Research and Development within Applied Research Programme under the project "Multi-criteria routing algorithms for fleet management supporting systems" (contract no. PBS3/B3/37/2015).

vehicle planning process for milk transport industry, so the III section presents the software architecture meant as an lightweight extension of the existing system with dedicated VRP capabilities. The proposed heuristic approach for to the specific variant of the problem and its implementation that uses constraint programming helper library (e.g., google's or-tools library) is presented in the IV section.

II. The problem formulation and analysis

The considered variant of VRP can be considered as a generalization of the classical Truck and Trailer Routing Problem with Time Windows (TTRPTW), therefore it will be called GTTRPTW. Some of the additional restrictions related to GTTRPTW are vehicle heterogeneity and their possible re-use, three types of customers (i.e., not every trailer customer have to provide parking space), maximal vehicle and driver working time and distance as well as additional complexity issues for service time and transshipment time evaluation.

The time interval when the customer is serviced must be within the time window of this customer, and the type of the vehicle to service this particular customer (with or without the trailer) must be acceptable by the customer. Additionally, a list of customers at which it is possible to leave the trailer is given. The vehicle fleet consists of truck units and truck and trailer units. Trailers can be uncoupled en-route at some of the customers where truck sub-tours are built. The truck driving with a trailer can be disconnected, then pick up a load from clients, and then go back to the trailer left and go further.

The vehicle can be assigned to an additional route (or routes) if the previous route is completed. The driver may be exchanged and the vehicle limits renewed. The algorithm should exclude solutions, for which the total time of the designated vehicle route is greater than the maximum total working time of this set or situations where total route distance exceeds specified vehicle maximum route length.

Nine test cases derived from the existing ERP system were converted into GTTRPTW instances. Currently, the system works for the region of northern Poland and allows for manual route planning, that relies on assigning points to route certain vehicles, as well as automatic planning. As specified in Tab. 1, number of clients (nodes in the graph) that goods have to be transported from in 8 of 9 cases exceeds 700, except for test case no. 5. Third row represents total amount of load to be transported in particular problem instance. In this case, it is the number of liters of the milk, since the problem is specific for the dairy transport problems. Some of the node clients allow for entrance of the vehicle with the trailers and, analogically, some of the clients allow for load transshipment at their location. This information is specified in 4th and 5th row of the table respectively. Clients of the system also specify 3 variants of time windows constraints of load pick-up, namely: 24 h windows (no TW restrictions), 6:00 AM -12:00 AM (morning windows) and all-day window (6:00.AM-18:00 PM). Statistical interpretation of the input data characteristics was presented in Tab. 2. In this case, only 30% of clients allow for entrance of the trailer to their localization, and about 25% of clients allow for transshipment. Moreover, if we take under consideration fleet of available vehicles, only 10%-20% of units is equipped with the trailer. The considered GTTRPTW is a combination of classical VRP approach with some particular constraints related to TT and TW. However, TT only applies to 15% of vehicles of the fleet. Moreover, the detail analysis of TW constraints also shows that, for most of the clients (over 80%) no time window is specified. For the rest of the clients, all day window (6AM-18PM) is the most often appearing.

III. SYSTEM ARCHITECTURE

The aim of the proposed system is to solve or validate different variants of VRP problem instances. The system may be used to find a new solution, as well as it allows to improve any previous solution when provided.

The architecture of the system, presented in Fig. 1, is modular in order to adjust to new formats and variants. The front-end layer module is handling different file formats and VRP variants for solutions and problem instances (e.g., handles proprietary JSON-based format dedicated to describe the GTTRPTW). There are also front-end modules dedicated to classical benchmarks' formats like CVRP, CVRPTW, TTRP and TTRPTW.

Data abstraction layer handles transparently different formats. It's common object-model is used by modules in the solvers' layer. The system uses different VRP solvers and the choose is up to the user. One of the solvers implemented is for GTTRPTW and is described in IV section.

The source code of the system and its modules is implemented in C/C++ language, in order to achieve high efficiency with a reasonable portability. The solvers are implemented separately and may differ from each other.

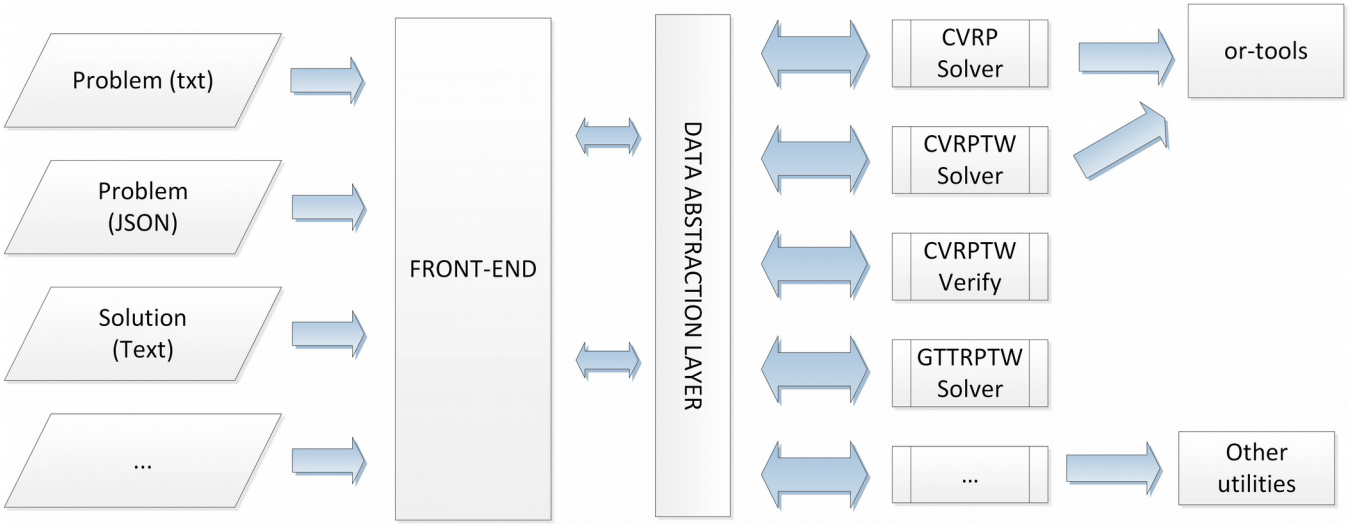

Fig. 1. The architecture of the proposed system

IV. PROPOSED APPROACH

Already implemented solvers including GTTRPTW use constraint programming approach and third party libraries (e.g., or-tools constraint programming library). The proposed approach is based on the observation related to features of input considered test cases. Time windows in the real-world cases is not as restricting. We can distinguish between the time window related to the customer and the time window of the vehicle unit. Typical vehicle unit is often used two times during a single day (different drivers). It means that a single unit will be available within two separate time windows. Most of the customers (as can be seen in the Tab. 1 and Tab. 2) do not specify constraint on the time windows. Although, there is a significant set of customers which specify the time window, most often the time window corresponds to the single shift of the drivers. Therefore we may observe, that if the customer is served on a route by a specific truck and driver it can be often reordered within the route without violating the time window constraint.

Therefore the outline of the strategy used in the GTTRPTW solver is as follows:

1. Find the solution *S* of the relaxed variant (i.e., CVRPTW) of the problem;
2. For each route *r* in the solution *S*;

if the route have truck-only customers and the vehicle is truck and trailer; we need to reorder the route and chose transhipment points;

- 2.1 For each transhipment customer *t* in the route *r* compute the route r_t;
  - 2.1.1 Assume *t* is the transhipment and compute the new route *r′* for all the customers from the original route *r*;
  - 2.1.2. Start the *r′* from depot to *t* and then traverse all customers with only the truck, the number of cycles needed may vary between 1 to 3. Finally, go back from *t* to the depot.
    - 2.1.2.1. The optimal cycles from *t* are computed with use of homogeneous CVRPTW solver with *t* considered to be the depot and the capacity of the fleet equal the capacity of the truck;
    - 2.1.2.2. Optimize the route *r′* greedy by moving some truck and trailer customers from the truck cycle to the segment which represent the starting or ending part of the new route *r′* (the part between original depot and the assumed transhipment *t*).
  - 2.1.3. Remember the route if it has smallest cost among all the previous assumptions for transhipment *t*;
- 2.2. Remember the best r_t as the new route in the solution S';

3. Optimize the solution greedy by moving and exchanging some customers between routes. Must not violate other constraints.

- 3.1. Find a feasible move giving biggest savings,
  - 3.1.1 If there is one go to 3.3;
- 3.2. Find a feasible exchange giving biggest savings
  - 3.2.1. If there is no feasible exchange available go to 4.
- 3.3. Apply the modification found
  - 3.3.1. If the time exceeds the available then go to 4.

makes it its generalization - GTTRPTW. The GTTRPTW was identified during demands analysis of real-life business scenarios from dairy mil companies. Authors proposed an architecture of a lightweight extension to existing ERP system designed to solve many variants of VRP including the one proposed in this paper. Dedicated modules responsible for solving simpler variants (e.g., CVRP, CVRPTW), which are also useful in simpler business scenarios, were already implemented into the system [14]. Beside the formulation, authors presented an algorithm that solves GTTRPTW. The algorithm in its first stage uses constraint programming approach, implemented with use of or-tools library, for solving relaxed variant of problem (e.g., without TT restriction). In the second stage the algorithm continue computation with TT and additional and performs

some local search improvements. Further research and development is planned to finally compare the results obtained by the proposed algorithm with other state of the art approaches. Since the problem variant may be considered as an extension of TTRPTW, the relaxation of the proposed algorithm and its comparison to best known results, for 36 benchmarks from [13], would be valuable. An adaptation of local search strategies like Attribute Based Hill Climbing (ABHC) into more complicated variant of TTRPTW, is also under consideration, especially that ABHC have revealed promising results [15] for classical TTRPTW.

Abstract—The following paper discusses the development of a risk-based cost estimation model for completing non-standard manufacturing orders. The model in question is a hybrid of Monte Carlo Simulation (MCS), which constitutes the main module of the applied model. Vector of order risk probability, which is the input data for the MCS module, is highly difficult to assess and is burdened to a considerable degree with subjectivity, therefore it was resolved that it should be generated with the application of artificial intelligence. Depending on the accessibility of historical data, the model incorporates fuzzy logic or artificial neural networks methods. The presented model could provide support to managers responsible for cost estimation, and moreover, after slight modification also in setting deadlines for non-standard manufacturing orders.

I. Introduction

Analysis of trends in the development and operation of modern manufacturing enterprises indicates that competitiveness of an enterprise can by improved mainly through innovation in the fields of: manufactured products, technology, management and marketing [1]. Introducing new products into the offer [2], improving manufacturing and support processes [3] is becoming increasingly hard owing to rising costs and strong market competition, particularly from big enterprises. An outstanding advantage of small and medium-sized enterprises (SME) consists in their flexibility, which enables them to compete successfully for non-standard and low-batch orders [4]. Realisation of such orders usually requires accepting a project approach, which demands scheduling times, resources and costs with every order [5]. Correct cost and order delivery estimation is imperative, as the contract with the customer must specify such arrangements as order delivery date and cost.

Non-standard manufacturing orders realised by medium-sized enterprises include, for instance:

- special tool orders for big enterprises, used in large-batch production,
- matrices and punches,
- custom machines and appliances (e.g. paper tube and core making machines, CNC nesting machines, storage systems etc).

The literature describes a range of various attempts at classification of risk, which proves it to be complex a and multidimensional phenomenon [6]. Risk modelling is a developing and ongoing process [7], which causes that risk is frequently among the major factors behind miscalculation of non-standard order costs [8]. There is a crucial necessity for cost estimation method that would cover all estimation factors. There are many proposals that lack scientific justification for the produced results, *i.e.* lack technical description of how the results were achieved [9].

In the case of non-standard orders, the risk of untimely delivery or exceeding the budget increases. Efficient cost estimation for diverse manufacturing orders becomes more complicated with the increasing number of factors that remain beyond the control of the manufacturer. These factors include uncertainty of any cooperative tasks, changing currency exchange rates, strict design or material requirements or industrial accidents [10]. Missing deadlines often results in enforcing contractual fines, losing customers and tarnishing the company's reputation, the last one being one of the key assets of any company and a critical success factor

Given the circumstances, it becomes a matter of high importance to develop an efficient method for risk minimisation concerning time and cost estimation of non-standard manufacturing orders [11].

II. Concept

There are three major indicators for the effectiveness of risk-based time-cost estimation of manufacturing orders: accuracy, time effectiveness and applicability. Clearly, solving these problems would not be possible without the application of IT solutions, which can meet the aforementioned criteria. Therefore, enterprises apply expert systems oriented towards aiding the decision-making process in the field of order cost estimation. The market offers numerous software solutions integrating business and production processes, nevertheless, the analysed case is more elaborate and therefore calls for a more versatile tool. Here, the input quality data must be correlated with results of quantitative character, *i.e.* time and cost.

The body of literature points at several methods for estimation of project risk. The most commonly used is the Monte Carlo Simulation (MCS), along with such methods as Artificial Neural Networks (ANN), Fuzzy Logic (FL), and Support Vector Machines (SVM) [12].

What contributes to the popularity of MCS is its uncomplicated applicability. MCS is a quantitative method that consists in building probability distribution for any risk involved. The consequences of unforeseen incidents could lead to unplanned change of costs or order delivery date, which in small-batch/non-standard orders as described here, is understood as a project.

A marked disadvantage of the method is the need for deterministic estimation of particular project risks probability. It is usually carried out by a single expert or a group of experts representing vast knowledge in a given discipline or branch. Eventually, this is still a subjective evaluation of probability, which is exactly one of the key drawbacks of MCS.

One of the most popular ANN methods is multilayer perceptron (MLP). In this variation of ANN it is required that a sufficiently large quantity of suitable historical data is available, which could be then used as input in train, test and validation sets. Another problem is to find cause-and-effect relationship between suitably selected input data sets and order delivery date.

SVM resembles to a certain extent ANN/MLP, inasmuch as it requires a set of historical data to conduct the training process. One advantage over ANN is that SVM training always finds a global minimum and that it mitigates the risk of overtraining, however, the estimation with this method is quite time inefficient.

Fuzzy logic (FL) can be put to use in time-cost risk assessment, particularly when no historical data is available [13]-[14]. The method employs several heuristics, which are developed with *e.g.* Delphi method [15] or Brainstorming. Heuristics are recorded as reasoning rules, which in the next stage provide the core for the fuzzy inference system [16]. Apart from the reasoning rules, this method requires selection of suitable inputs, membership functions and defuzzification.

The short descriptions of each method indicate clearly that each model is burdened with certain limitations of different magnitude, which makes it difficult to apply in estimation of costs and time of individual orders, which can be treated as separate projects.

In order to eliminate the negative impact of subjective estimation, present in the classical MCS, AI can be applied in probability estimation of particular project risks.

Enterprises that do not possess historical data that could be used for training neural network or SVM controller could employ the FL method.

The proposed hypothesis for the application of a hybrid system, incorporating AI for percentage estimation of project risks in Monte Carlo method, will increase the accuracy of the MCS.

The second hypothesis states that determining the probability of project risks with the application of artificial intelligence is more reliable than the deterministic method, based on the subjective opinion of experts.

III. PROPOSED METHODOLOGY

Table 1 shows an exemplary project risk calculation of non-standard manufacturing orders carried out with Monte Carlo simulation. Column 1 contains Risk Breakdown Structure. Column 2 specifies identified risks. Column 3 shows subjectively estimated particular risk probability. Column 4 contains costs of risk that would have to be covered if the risk occurred. An analogical approach could be accepted in determining the risk of untimely delivery dates, by substituting cost with time. In such a case, the set of risks in column 2 would be different as well.

Column 5 shows an expected number of risks, which is a product of columns 4 and 5. The sum of column 5 amounts to 71.50 EUR, which would not cover the potential expenses should the risks R-1, R-2 or R-6 take place. Columns 6 and 7 enable simulation of numerous risk-related variants. Column 6 shows a function randomly generating absolute numbers from the range <0,1). Column 7 contains logical conditional formulas:

$$\text{IF (col.3) >= (col.6) THEN (col.4)} \qquad (1)$$

The sum of column 7 contains the cost of risk in the simulated case. After 1000 simulations with the random number generator and formula (1) cumulative distribution function was obtained, whose part is shown in Fig. 1.

The x-axis shows costs of risk for particular scenarios, the y-axis the number of scenarios population, counted as a percentage share of probable situations. The best-case scenario estimates that the project risk amounts to 50 EUR.

Planning the budget for the realisation of order must account for two opposite goals: cost and risk minimisation. Increasing the budget by 600 EUR for the minimisation of project risk would result in a practically 100% guarantee that the project expenses will not exceed the budget. Nevertheless, excessive costs might not be covered by the customer, which is why, compromise solutions must be sought. It can be assumed that the acceptable compromise is setting the cost risk level at approx. 80%. Broken lines in Fig. 1 show the 84% level of probability, corresponding to 160 EUR of additional risk-related cost it can be observed that the majority of all analyzed scenarios are on the left of that amount.

To remove the element of subjectivity, artificial intelligence can be applied in probability selection of particular risks (Table 1, column 3)

The algorithm for the development of a hybrid system for estimation of project risks is shown in Fig. 2.

TABLE I.
QUANTITATIVE ANALYSIS OF PROJECT RISKS MONTE CARLO SIMULATION

RBS	**Risk description**	**Probability**	**Cost**	**Level**	**RAND()**	**Simulation**
1	*2*	*3*	*4*	*5*	*6*	*7*

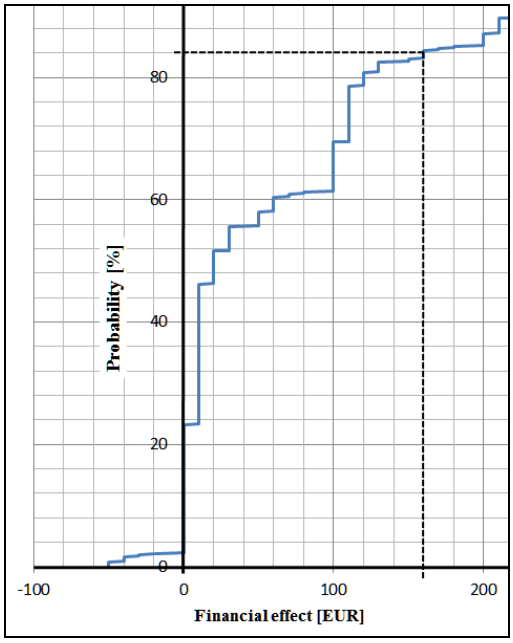

Fig. 1. Probability cumulative distribution function for project risk costs

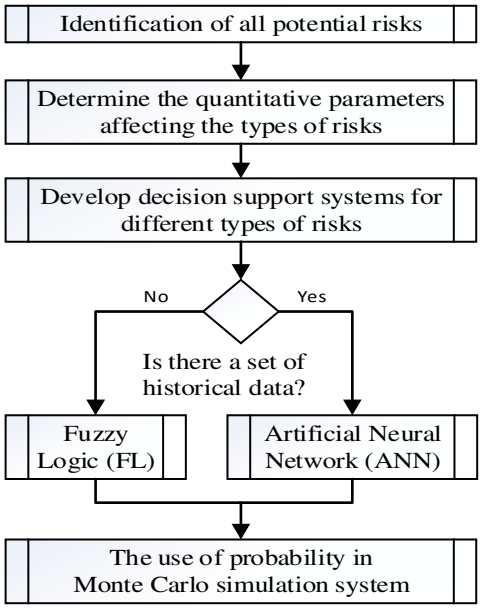

Fig. 2. Algorithm for the development of project risk estimation system for non-standard orders

The first stage of development consists in identification of all potential risks that could affect costs or delivery dates. Next step is to describe the identified risks in quantitative measures. These will provide input data for particular decision-making modules describing the probability of particular risks.

If a system can be fed with tabulated historical data, a decision-making subsystem based on ANN could be created. Otherwise, the application of FL is possible.

SVM was skipped in the present analysis due to extensive computational time, which means it does not meet one of the criterions - time efficiency, and as a result the criterion of applicability.

It ought to be noted that in selection of input vectors for particular modules for determining risk probability it is the historical data accessibility that plays a crucial role. It can be, for instance, assumed that risk R-1 (Subcontractor errors) is influenced by criteria shown in Table 2, corresponding to the intelligent subsystem for project risk estimation shown in the diagram in Fig. 3.

Column 3 Table 2 contains methods for R-1 module input features determination. While to determine feature I-1 is relatively simple, the situation becomes complicated in the case of I-2 and I-5 inputs.

TABLE II. INPUT FEATURES FOR MODULE R-1 (SUBCONTRACTORS ERRORS)

IBS	Input feature name	Measure
1	*2*	*3*
I-1	The number of tasks within the manufacturing order that require hiring subcontractors	[pcs]
I-2	The lowest rating of cooperation history for subcontractor among external service providers cooperating in realisation of order	[%]
I-5	The lowest score among external audits *in situ* at subcontractors'	[1..5]

For instance, determination of a percentage value of feature I-2 requires a prior analysis of timeliness of all subcontractors. This can be calculated from the relationship (2).

$$M_{1-2} = \left(1 - \frac{c}{s_o}\right) \times 100\% \qquad (2)$$

where:
M_{1-2} – feature value I-2
c – total number of claims from given subcontractor
S_o – number of all orders in the past from given subcontractor

Input I-5 can take the value from 1 to 5, where 1 denotes low assessment of quality model. Input feature I-5 requires obtaining the results of audits that would cover data from quality assurance systems of each of the subcontractor. Although I-5 feature values are specified by experts, they can be considered as fully reliable. This is because they were obtained in an analysis of appropriate parameters defined as a part of subcontractor's internal quality management system. If this is a certified system, such as ISO 9001, then evaluation based on the parameters is simple. Otherwise, the evaluation requires defining reliable methods of measurement.

Values of individual project risks probability based on the outputs of intelligent subsystems constitute input data for the system of risk cost calculation, based on Monte Carlo simulation.

Fig. 3. Shows the operation of an intelligent subsystem for project risk estimation. On the left side there is an N-element vector of identified input features, which could have an impact on *n-element set of project risks*; hence, $N \geq n$.

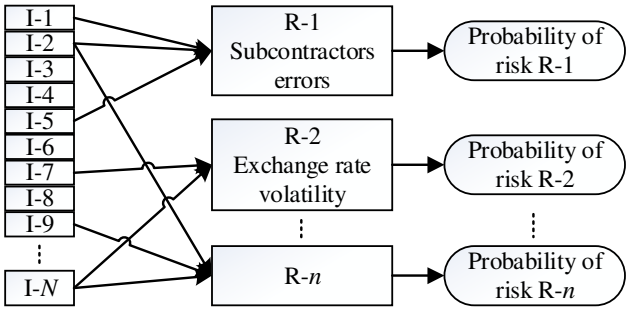

Fig.3. Diagram of an intelligent subsystem for estimation of project risk

Fig. 3 indicates that it is possible for a single output (*e.g.* I-2) to feed two or more module for R-I risk probability evaluation.

Fig. 4 shows a diagram of a complete hybrid system for the calculation of manufacturing order risk. It can be seen that the system is composed of two major subsystems: Artificial Intelligence (AI) and Monte Carlo Simulation (MCS).

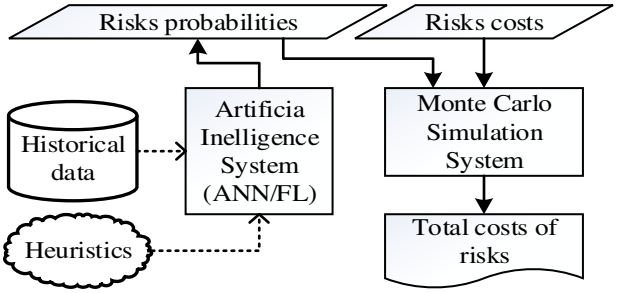

Fig. 4. Diagram of a hybrid system for the calculation of manufacturing order risk

The functioning of AI module is shown in Fig. 3. The process of risk estimation with MCS is shown in Table 1 and Fig. 1. Fig. 4 indicates that the risk probabilities vector, which constitutes the output of AI subsystem, is simultaneously the input of MCS subsystem.

IV. CONCLUSION

This paper presents solutions for the problem of risk calculation in non-standard manufacturing orders in small and medium-sized enterprises. Highly individual character of particular orders permits treating them as separate projects. The two initially formulated, mutually complementing hypotheses stated that employing hybrid systems based on artificial intelligence produces more accurate results of project risk calculations. The truthfulness of the hypotheses was initially confirmed by introduction of logical and coherent vision of reasoning rules, which could replace the subjective, hence imperfect decisions taken by human.

The algorithm for development of a system of risk estimation for non-standard manufacturing orders was created. We proposed an improved Monte Carlo simulation method with an additional subsystem variant, employing fuzzy logic or neural networks, depending on the availability of historical data.

It should be noted that by substituting cost with time, the presented solution could be easily adapted for risk estimation of order delivery delay in single orders.

***Abstract*—This paper deals with declarative decision support framework for scheduling groups of orders. All orders in a group should be delivered at the same time after processing. The authors present a novel declarative approach to modeling and solving scheduling problems as a declarative decision support framework. The proposed framework makes it possible to ask different types of questions (general, specific, logical, etc.). It also allows, scheduling emerging orders or groups of orders without changing the existing schedules. To implement was used CLP (Constraint Logic Programming) environment. To increase the efficiency of the framework, particularly in the area of optimization made its integration with MP (Mathematical Programming) environment. The paper also presents the implementation of illustrative model, using the proposed framework. In addition, an efficiency analysis of the presented solution in relation to the application of mathematical programming have been conducted.**

I. Introduction

THE proposed research problem (scheduling groups of orders) finds many applications in industrial and services companies, including but not limited to food, textile production industries, distributions, ceramic tile, supply chain, manufacturing of complex devices, fast-foods, restaurants, postal and courier services etc. Assume that each customer has different orders. Each order has a different process function and set of resources, but all items ordered by a customer or group of customers should be delivered at the same time in one package to reduce the transportation costs, subsequent processing steps time and costs, or/and assure proper quality of the product/service and customer satisfaction. In this type scheduling problems, in addition to standard constraints such as precedence or disjunction, new constraints appear related to the given group, concurrent delivery date, etc. In practice also logical constraints may occur, resulting from business, marketing or legal conditions. Therefore the modeling and solving of various constraints in scheduling groups of orders is a key issue. Managers/Decision-makers need to have schedules with defined parameters and/or the knowledge whether the schedule meets the requirements, which may be formulated as simple questions. Good environments for the modeling of constraints, questions and logical conditions include declarative environments, CLP (Constraint Logic Programming) in particular.

Our motivation was to develop an environment for the modeling and decision support of the problem for scheduling groups of orders. The use of this framework would help obtain quick answers to key questions (Is it possible…?, What If…?, What is the minimum/maximum..?) asked by managers/decision makers.

This paper proposes the concept of a declarative decision support framework for scheduling groups of orders and presents its implementation in the CLP environment. The illustrative example shows the potential of the framework.

The remainder of the article is organized as follows. Section 2 presents problem statement, research methodology, contribution etc. The concept and implementation aspects of a declarative decision support framework are provided in Section 3. Computational examples, tests of the implementation framework and discussion are presented in Section 4. Possible extensions of the proposed approach as well as the conclusions are included in Section 5.

II. Problem statement and methodology

Scheduling methods for optimal and simultaneous service to groups of orders are proposed most often in the flexible flow-shop system (FFS). In the FFS system, processing is divided into several stages with parallel resources/machines at least in one stage. All of the orders should pass through all stages in the same order [1,2]. The objectives of the problem [2] are minimizing the total amount of time required to complete a group of orders and minimizing the sum of differences between the completion time of a particular order in the group and the delivery time of this group containing that order (waiting period). In practical applications, flexible flow-shop system is insufficient since the sequence of operations/tasks in the orders from different users is rarely the same.

The majority of models for scheduling of group orders presented in the literature refer to a single problem and optimization according to single criterion. Fewer studies are devoted to multiple-criteria [2]. Most of them are modeled and solved by operations research (OR) methods. Declarative environments such as CLP facilitate problem

modeling and introduction of logical and symbolic constraints [3,4,5]. Unfortunately, high complexity and the multiple types of constraints of decision-making models as well as combinatorial nature contribute to poor efficiency of modeling in OR methods and inefficient optimization in CLP. Therefore, a new approach to modeling and solving such problems was developed [6,7,8]. A declarative environment was chosen as the best structure for this approach especially in modeling [3,5,9,10]. Mathematical programming environment was used for problem optimization [11]. This integrated approach is the basis for the creation of the implementation environment to support managers. In addition to optimizing particular decision making problems connected with groups of orders, such environment allows asking various questions while processing the orders.

A. Problem description –illustrative example

This problem can be stated as follows. Orders Z_i for different group of product p enter the system in groups at different periods v. Each order consists of a set of operations and should be processed with specific set of parallel resources. It is assumed that there are no gaps between the operations of the order. The orders in each group Z_i should be delivered at the same time. Special points a at which orders are submitted and then delivered are introduced. The problem does not cover the configuration of the points but relates to handling orders, as many orders may come from one customer. Each order may be processed by a different resource set in any order.

In this case, decision support is to respond to the questions asked, which in general can be: specific questions, general questions, logic questions etc.

Possible questions (Q) for such problem are (including but not limited to):

- What is the minimum makespan for groups of orders $Z_1,..,Z_n$ entering in period $v_1,..,v_n$ at the point $a_1,..,a_n$? (Q1)
- Is it possible to execute the new group of orders $Z_{n+1},..,Z_m$ from the period v_k with existing resources at specified period T? (No change orders that are in progress.) (Q2)
- Is it possible to execute group of orders $Z_1,..,Z_n$ in time T with use of the resource $k=N$? (Q3)
- What is the minimum use of resource k to execute orders $Z_1,..,Z_n$ in time T? (Q4)
- Is it possible to execute the new group of orders $Z_{n+1},..,Z_m$ from the period v_k with existing resources at specified period T and the use of resource $k=N$? (Q5)
- What is the minimum makespan for groups of orders/tasks $Z_1,..,Z_n$, entering in period $v_1,..,v_n$ at the point $a_1,..,a_n$? (with all the resources k reduced by C%) (Q6)
- Is it possible to execute the groups of orders $Z_1,..,Z_n$ in time T entering in period $v_1,..,v_n$ at the point $a_1,..,a_n$? with exclusively use resources k_i and k_j? (Q7)

Decision variables of this problem are shown in Table I.

TABLE I.
DECISION VARIABLES

Decision variables	
Calculated number of periods g delivery of all orders for point a.	Tkp_a
If at a given point a ordered product p then $Xzk_{a,p}=1$, otherwise $Xzk_{a,p}=0$	$Xzk_{a,p}$
Number of period g in which operation o can be started for product p ordered at point a	$B_{a,p,o}$
If the execution of operation o for product p ordered at point a uses resource k in period g then $X_{a,p,o,k,g}=1$, otherwise $X_{a,p,o,k,g}=0$	$X_{a,p,o,k,g}$
If the execution of operation o for product p ordered at point a uses resource k in period g then $Xo_{a,p,o,k,g}=zk_{a,p}$, otherwise $Xo_{a,p,o,k,g}=0$	$Xo_{a,p,o,k,g}$
If g is the last period in which resource k is used in the execution of operation o for product p at point a then $Y_{a,p,o,k,g}=1$, otherwise $Y_{a,p,o,k,g}$=0	$Y_{a,p,o,k,g}$
If g is the last period in which orders are executed for point a then $W_{a,g}=1$, otherwise $W_{a,g}=0$	$W_{a,g}$
Number of period g from resource k can be used for operation o of product p ordered at point a	$S_{a,p,o,k}$

The set of reference constraints for the problem was created and its mathematical/formal notation is included in Appendix A.

Constraint (1) determines whether in a given point a product p has been ordered (setting the value of variable $Xzk_{a,p}$). Constraints (2) ensures the order execution of operations for the product p (precedence constraint). Constraint (3) specifies the moment (period) from which resource k is needed to execute product p. Constraint (4) states no start is possible before orders appear. The term of delivery to the point a defines the constraint (5). Constraint (6) ensures that the number of available resources k in period g is not exceeded. Constraint (7) provides resource occupancy for the time of the order execution. Operations are not interrupted during their execution (8). Simultaneous completion of orders for product p from the given point a is ensured by constraints (9,10). Constraint (11) is responsible for the binarity of selected decision variables.

III. A DECLARATIVE DECISION SUPPORT FRAMEWORK FOR SCHEDULING GROUPS OF ORDERS-CONCEPT AND IMPLEMENTATION

The declarative decision support framework was proposed for scheduling groups of orders. The concept is based on the declarative programming paradigm, which allows high level programming with the use of predicates and facts. Due to the character of problems in the scheduling of groups of orders, CLP (Constraint Logic Programming) was selected from among many declarative options. The implementation of the framework was performed with the use of ECL^{i}PS^e [12].

The following general assumptions were applied:

- possibility of modeling constraints of any type;
- automatic generation of implementation models in the form of MILP models;
- data recorded as facts;

- problem dynamic taken into account (possibility of introducing new orders or groups of orders).

Figure 1 presents the general concept of the framework. The framework comprises several phases: modeling, presolving, generating and solving. It has two inputs and uses the set of facts. Inputs are the set of questions and the set of constraints to the reference model of a given problem. Based on them, the primary model of the problem is generated as a CLP model, which is then presolved. The built-in CLP method (constraint propagation [13]) and the method of problem transformation designed by the authors [6,9] (Section 3A) are used for this purpose. Presolving procedure results on the transformed model CLP^T. This model is the basis for the automatic generation of the MILP (Mixed Integer Linear Programming) model, which is solved in MP (with the use of an external Solver or CLP as a library). The general concept of the framework consists in modeling and presolving of a problem in the CLP environment with the final solution (including optimization) found in the MP environment. This approach is the result of experience as well as extensive research devoted to both environments [6,9,10] and their integration[6,14]. In all its phases, the framework uses the set of facts having the structure appropriate for the problem being modeled and solved (Fig. 2). The set of facts is the informational layer of the framework, which can be implemented as a relational database, XML database, etc.

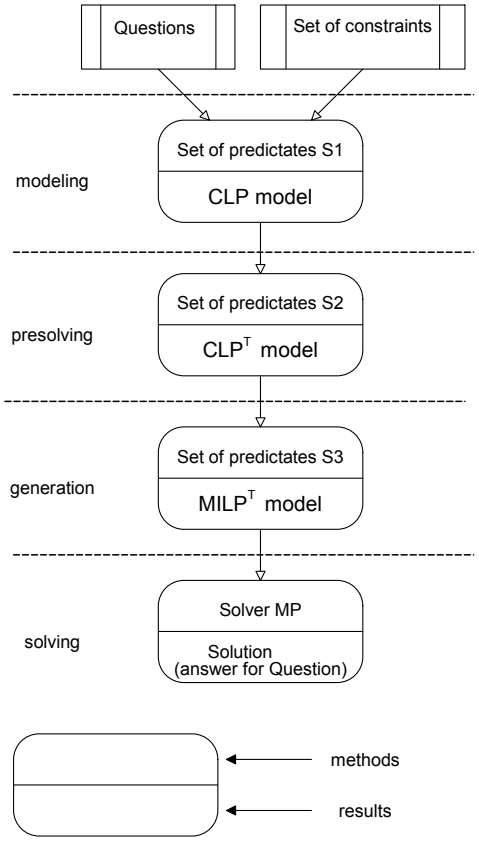

Fig. 1 A concept of a declarative decision support framework

In order to take into account the dynamics resulting, for example, from new orders, the $MILP^T$ model is solved iterative way with the use of the algorithm [15]. The main characteristic of this algorithm is iterative activation of MP solver and update of resource availability [15].

A. Presolving

The presolving phase is an important element of the framework as it makes it possible to simplify the model for the problem being solved and to reduce the combinatorial search space.

For the presolving phase to be effective, unfeasible combinations of model dimensions have to occur. In practice, unfeasible combinations of the index of decision variables and/or facts occur.

The proposed framework uses constraint propagation and transformation for the presolving procedure. Constraint propagation is a concept and method that appears in constrained-based environments. Constraint propagation embeds any reasoning which consists in explicity forbiding values from some varable domain of a problem, because all constraints can not be satisfied otherwise. Transformation transforms decision variables of the problem along with constraints and facts. The transformation method for the illustrative example is shown in Fig. 2, and the post-transformation variables are compiled in Table AII. For the problem presented, the transformation consisted in the change from the problem's operational representation into the resource representation. This resulted in the removal of all decision variables, parameters, etc. From the operation index, thereby reducing their numbers. The new set of decision variable, constraints and facts was the basis for creating the CLP^T model.

IV. COMPUTATION EXAMPLES FOR ILLUSTRATIVE MODEL

In order to verify and evaluate the proposed framework, many numerical experiments were performed for the illustrative example. In the first phase, all the experiments relate to the system with five points ($a=1..5$), eight order types (products) ($p=1..8$), eight resource types ($k=1..8$), thirty time periods ($g=1..30$) and eleven orders $zg_{v,p.}$ *(five groups of orders* Z_i in three periods*)*

All data instances for these experiments were recorded in the form of facts and included Appendix B.

Computational experiments consisted in asking questions Q1..Q7 to illustrative example. For each question was generated and solved suitable implementation model using declarative decision support framework. Orders are placed in groups for v_1=1, v_2=2 and v_3=5 (only for Q2 and Q5) periods. The answers to these questions are shown in Table II. Figure 3 shows the implementation schedule of all group of orders for question Q1 (minimizing makespan). A proper schedule utilization of resources corresponding to the schedule of Figure 3 is shown in Figure 4. By contrast, Figure 5 shows the implementation schedule of all group of orders for question Q6 (with all the resources k reduced by

50%). In analogy to the previous question, a proper schedule utilization of resources corresponding to the schedule of Figure 5 is shown in Figure 6.

The answer to the question Q4 determines the minimum resource requirements ($k_1..k_8$) necessary to complete all group of orders within T (Table II).

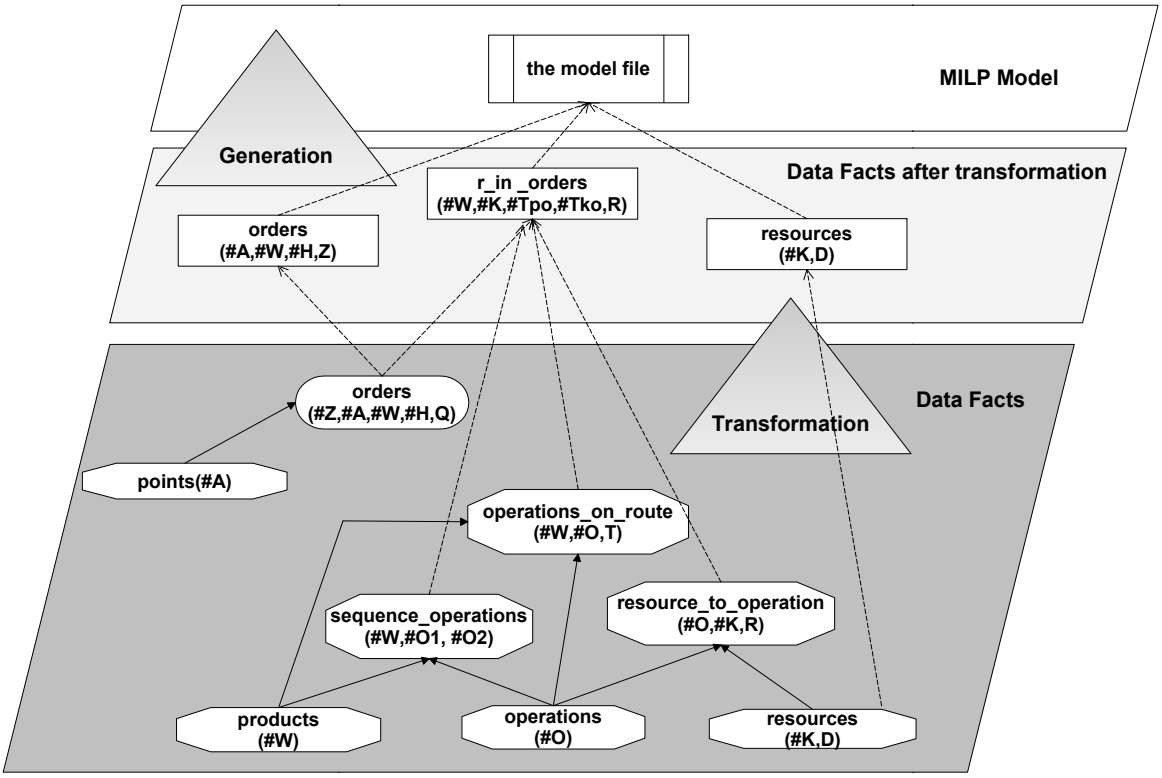

Fig. 2 Information layer of the framework (data fact before and after transformation, MILP model file)

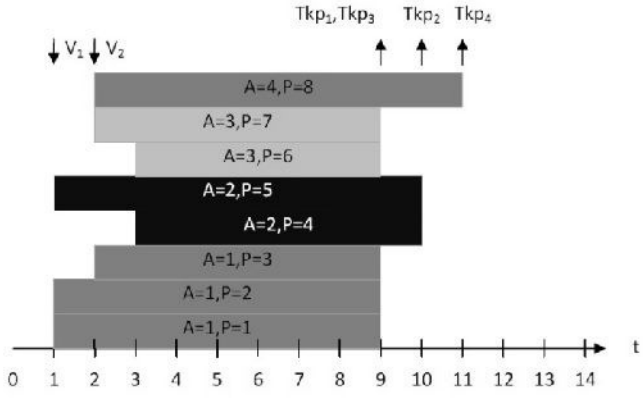

Fig. 3 Gantt chart for illustrative question Q1 (V_1=1, V_2=2, Tkp_1=Tpk_3=9, Tkp_2=10, Tkp_4=11, C_{max}=11)

The answers to the remaining questions confirm feasibility or unfeasibility of the schedule in the set conditions and at defined parameters (Table II). Information about the feasibility of the schedule and about available resources is especially useful when a new group of orders (Q2,Q5) appears. The last question from the set (Q7) is the question with a logical condition relating to disjoint use of resources.

In the second phase of the experiments, a comparative analysis was performed for questions Q1 and Q6 (most compute-intensive of all) in two environments (declarative decision support framework and MP) to evaluate the effectiveness and efficiency of the proposed framework relative to the classical MP environment.

Obtained more than 400-fold reduction of time searching for solutions (Table III). This is due to the fact that the application of the framework has allowed the reduction of decision variables from 134616 to 13873 (10-fold) and constraints from 252541 to 31239 (8-fold) (Table III).

TABLE II.
ANSWERS TO QUESTION FOR ILLUSTRATIVE EXAMPLE

Question	Parameters	Answer
Q1	---	C_{max}=11
$Q2_A$	T=12	NO
$Q2_B$	T=14	YES
$Q3_A$	T=12, k_1=k_2..= k_8=k=12	NO

TABLE IV.
STRUCTURE OF THE FACTS

Fact	Description
points (#A)	points of ordering and delivery A – point id
products (#W)	products, services, etc. W – product id
operations (#O).	technological operations, tasks, etc. O – operation id
resources (#K,D).	resources (machines, tools, peoples, etc.) K – resource id, D - the number of available resources
resource_to_operation (#O,#K,R)	the resources necessary to execute the operations O – operation id, K – resource id, R – the number of resource *k* needed for the operation
operations_on_route (#W,#O,T)	a set of operations for the product (route), W – product id, O – operation id, T – duration of the operation
sequence_operations (#W,#O,#O)	the order of operations for the product, W – product id, O – operation id
orders (#Z,#A,#W,V,Q)	orders, Z – orders id, A – point id, W – product id, V – order period, Q – order size
r_in _orders (#W,#K,#Tpo,#Tko,R)	the allocation of resources to products, W – product id, K – resource id, Tpo – the beginning of the use of the resource, Tko – the end of the use of the resource, R – the number of resource *k* needed for the operation

V. CONCLUSIONS

Two types of questions can be asked in the proposed declarative decision support framework.

General questions may require domain solution, which in practice determines the availability of resources to execute orders, timely execution etc. The specific wh-questions will in practice define the best, fastest, cheapest, or the most

expensive of the possible solutions. To obtain answers to these questions, optimization is necessary.

Both question types can contain logical conditions relating, for example, to the disjoint use of resources, etc.

The illustrative example shows only part of potential of the framework designed to increase both the speed and the size of the problems solved.

This is particularly evident if we compare the possibilities of the framework in relation to the classical approach based on mathematical programming (Table III).

Further work will consist in the implementation of more complex models, uncertainty, product demand interdependencies [16], fuzzy logic [17,18] etc., and as a cloud internet application [19]. New questions will be implemented to broaden the scope of decision support.

APPENDIX A

TABLE AI.
SUMMARY INDICES, PARAMETERS

Sets	
Set of points (tables)	LA
Set of resources	LK
Number of periods	LG
Number of periods in which orders can be entered	LV
The set of operations	LO
The set of products (orders)	LP
Indices	
Points (tables)	a=1..LA
Resources	k=1..LK
Period	g=1..LG
Period in which orders can be entered	v=1..LV
Operation	o=1..LO
Products	p=1..LP
Parameters	
Number used to convert periods to moments (for connecting index *g* with variable)	pp_g
The number of available resources *k* in the period *g*	$dkg_{k,g}$
Duration of operation *o* for product *p*	$t_{p,o}$
Time to complete all operations *o* for the product *p*	$t1_{p,o}$
If the operation o_1 precedes o_2 for product *p* than $kol_{p,o1,o2}$=1 otherwise $kol_{p,o1,o2}$=0	$kol_{p,o1,o2}$
If the operation *o* uses resource *k* than $zas_{o,k}$=1 otherwise $zas_{o,k}$=0	$zas_{o,k}$
Number of *k* resources needed for execution operation *o*	$r_{o,k}$
How much of the product *p* ordered at the point *a*.	$Zk_{a,p}$
The number of period in which new orders appeared.	ts
Inputs	
How much of the product *p* ordered at the point *a* in the period *v*.	$zgp_{v,a,p}$

3rd International Workshop on Cyber-Physical Systems

PROLIFERATION of computers in everyday life requires cautious investigation of approaches related to the specification, design, implementation, testing, and use of modern computer systems interfacing with real world and controlling their environment. Cyber-Physical Systems (CPS) are physical and engineering systems closely integrated with their typically networked environment. Modern airplanes, automobiles, or medical devices are practically networks of computers. Sensors, robots, and intelligent devices are abundant. Human life depends on them. Cyber-physical systems transform how people interact with the physical world just like the Internet transformed how people interact with one another.

The event is a continuation and extension of 2006-2010 Real-Time Software FedCSIS workshops as well as 2013 and 2015 IWCPS. The objective of the workshop is to assemble and develop a community with main interest in cyber-physical systems.

Due to an extensive scope of the topics, the workshop will accept papers in the following areas:

- Control Systems
  - embedded/networked/intelligent
  - wireless sensing/actuation
  - adaptive/predictive
- Scalability/Complexity
  - modularity
  - design methodology
  - legacy systems
  - tools
- Interoperability
  - concurrency
  - models of computation
  - networking
  - heterogeneity
- Validation and Verification
  - assurance
  - certification
  - simulation
- Cyber-security
  - intrusion detection
  - resilience
  - privacy
  - attack vectors
- Applications of CPS
  - robotics
  - transportation
  - military
  - medical
  - consumer
  - manufacturing
  - power systems
- CPS Education
  - curriculum development
  - web-based laboratories
  - academic courses
  - pedagogy issues

EVENT CHAIRS

***Abstract*—The contemporary electric power system is highly dependent on Information and Communication Technologies which results in its exposure to new types of threats, such as Advanced Persistent Threats (APT) or Distributed-Denial-of-Service (DDoS) attacks. The most exposed components are Industrial Control Systems in substations and Distributed Control Systems in power plants. Therefore, it is necessary to ensure the cyber security of this critical infrastructure and develop new cyber security technologies able to protect from advanced cyber threats. In this paper a pioneering Situation Awareness Network for the electric power system is presented together with a set of metrics for its testing.**

I. Introduction

MODERN energy infrastructures aim at reducing peak demand, shifting usage to off-peak hours, lowering total energy consumption and carbon dioxide footprint [1] or enabling consumers to control their power consumption based on local needs and real-time electricity price rates [2].

To meet these requirements it is necessary to ensure the continuous exchange of data between all points of the network. Although the communication infrastructure may partially exist, it is necessary to facilitate its vast expansion by increasing bandwidth (among the others due to the introduction of two-way communication as an inherent component of the new energy infrastructure and smart grid) and connecting consumers (residential, commercial, industrial, etc.). To reduce the costs which are incurred by this process, the Internet is often used as communication backbone for the energy management systems [1].

However, such an approach exposes the power system to a great security breach. Every network layer and technology used in the new energy infrastructure represents a potential target of a cyber-attack. This in particular refers to Industrial Control Systems (including SCADA) in substations and Distributed Control Systems (DCS) in power plants. Moreover in the recent years wireless networks have been widely employed as part of many industrial communication systems, which exposes the entire network to even greater risk [3].

Advanced Persistent Threats (APT) are dedicated attacks able to persistently target a specific entity and to cause an intended effect, such as an interruption to the power supply [4], [5]. DDoS attacks, on the other hand, attempt to delay, block or corrupt the communication in the grid [6].

Stuxnet [7] was the first wide manifestation of malware that was specifically designed to attack networked industrial control systems used in the power system. Detected for the first time in 2010, Stuxnet is a cyber worm able to infect process servers and Programmable Logic Controllers (PLCs) and alter physical processes. The ultimate goal of Stuxnet is to sabotage the attacked facility by reprogramming programmable logic controllers (PLCs) to render them operating out of their specified boundaries. Later studies revealed that Stuxnet was not the first threat of that type. In fact that it had its precursor called Flame that was undetected [8]. Flame is a large complex malware designed to aggressively gather information from its target systems. Apart of conventional information stealing methods it is able to capture Skype calls and record audio [9].

Since the manifestation of Stuxnet both information security experts and hackers have shown a much greater level of interest in this area. As a result, 64 ICS vulnerabilities were discovered in 2011 and 98 additional ones were announced in the first eight months of 2012 alone – more than the total number for the preceding seven years combined [10]. In parallel sophisticated attacks have been appearing – Duqu, Red October, Gauss and Black Energy – each of them more complex and advanced than its predecessor [9], [11]. Duqu was designed to steal information in preparation for a Stuxnet-like attack and it used new techniques never previously noted [9]. Red Dragon and Gauss utilise encryption in order to effectively penetrate the infiltrated information systems [11], [9]. Black Energy is the most recently discovered malware which aims at Industrial Control Systems used in critical infrastructures [12].

Taking into account all these threats and the attacks already carried out, it is necessary to take countermeasures. Standard cyber security technologies and best practices – such as access control, anti-malware, firewalls, intrusion detection and prevention systems, defence in depth, and system hardening

The study presented in this paper is based on work carried out in the DEnSeK (Distributed Energy Security Knowledge) project founded by the European Commission, Directorate-General for Home Affairs (Programme „Prevention, Preparedness and Consequence Management of Terrorism and other Security-related Risks" – CIPS, Project Reference: HOME/2012/CIPS/AG/ 4000003772) and partially supported from the project funds. It is also supported by the DS Programs of Faculty of Management and Economics and Faculty of Electronics, Telecommunications and Informatics of Gdańsk University of Technology.

– are indispensable in protecting the power system. However, they are only a partial solution [4], [13], [14], [15].

To counter the evolved, highly sophisticated threats, advanced cyber security technologies are required, such as Security Information and Event Management (SIEM) systems, application whitelisting, and Trusted Platform Modules (TPM) [4], [13], [16] together with an efficient and effective risk assessment and management [17]. Developing and deploying Situation Awareness Networks (SANs) with SIEM software will improve situational awareness and will allow for better control and faster response to threats [18].

Such a Situation Awareness Network (SAN) has been developed in the project DEnSeK (Distributed Energy Security Knowledge) [19]. The project aimed at improving the security and resilience of the new energy infrastructure against cyber-threats by providing a platform for the security knowledge exchange between companies of the European energy sector and establishing a European Energy ISAC (Information Sharing and Analysis Centre) which enables interactive and real-time knowledge and information sharing between all involved parties [19].

In this paper the SAN architecture is presented along with the set of metrics to be used for its evaluation. To the best of authors' knowledge such a dedicated set of metrics for Situation Awareness Networks (SANs) has not been proposed so far, most probably because the concept of SAN is relatively new. It must be underlined that evaluation of Situation Awareness Networks is an area distinct from the quantitative assessment of the level of situational awareness. For the latter several approaches exist [20].

II. Situational awareness network architecture

The Situational Awareness Network encompasses and combines a number of diverse network-based sensors, which facilitate network traffic and data monitoring and detection of various events. Collected and processed data sets are visualised to a SAN operator who responds to emerging threats.

The need for combining together multiple sensors stems from the observation that in the past half-decade monitoring tools have become more specialised and now they focus on specific threat vectors and/or analysis approaches. Hence, in order to offer a broad overview of network activities and potential issues, it is crucial to combine diverse monitoring engines.

The purpose of the visualization is two-fold. First, operators can spot anomalies that the automatic systems might not be able to detect or might not be configured to detect. In this case, a visualisation dashboard supports the analysis of a large amount of data as it reduces it significantly focusing on key parameters for detecting anomalies.

Secondly, once an event is reported by one of the automatic systems (for instance, a malware spread is detected), operators can leverage the visualisation dashboard to observe the way network traffic evolves and either confirm or reject the alert previously raised.

In the DEnSeK project a three-tier architecture of the Situational Awareness Network, presented in Fig. 1, was proposed. The lowest, data tier consists of sensors which collect network data. In the logic tier, Security Information and Event Management (SIEM) software processes data from sensors and transmits them to the top layer. Finally in the presentation tier, the dashboard visualises the data by a user-friendly operator interface.

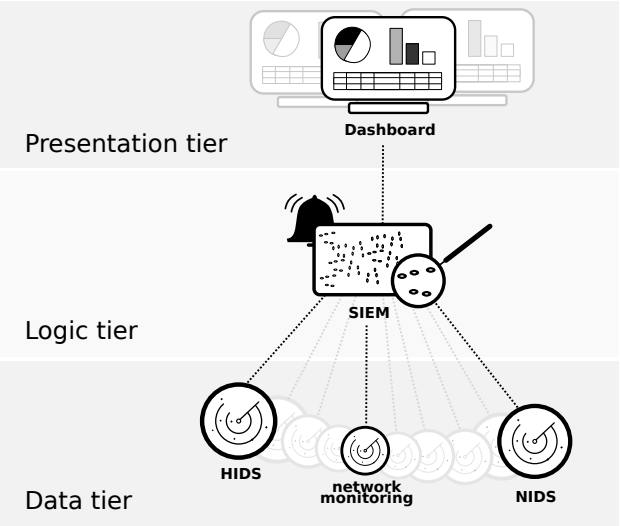

Fig. 1. SAN three-tier architecture

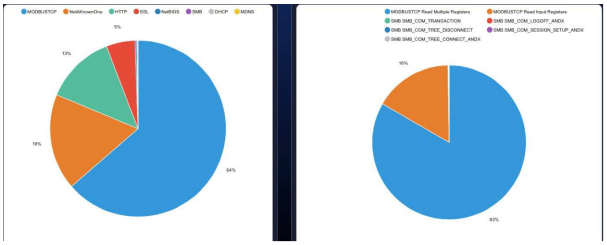
In the approach presented in this paper, SAN needs a signature-based NIDS (such as Snort [21], [22] and Suricata [23]), to detect well-known attack payloads, and several behavioural-based engines to analyse both payloads and flows for anomalies. As it relies on open-source/freely available tools, currently exist few alternatives for behavioural-based systems that can be used in production environments. One of them is Bro [24], [25], which can be used to code any type of algorithm on top of its protocol parsers.

On top of regular network monitoring tools and SIEMs that are available off-the-shelf, a visualisation dashboard is located. Its main role is to allow operators to observe the behaviour of the underlying industrial network. The dashboard provides several widgets, presented in Fig. 2 that can be instantiated to present various dimensions of network traffic (IP addresses, TCP ports, protocols, etc.) using different metrics (bytes, packets, protocol messages, etc.).

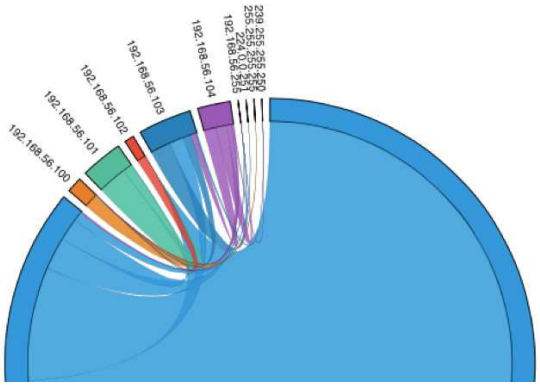
The central SIEM node is provided with Syslog (system logging) messages by various network-based sensors. This is a standard practice that enables required flexibility while providing all the necessary information. The visualisation dashboard leverages diverse software and components in order to deliver the extracted metadata to a central repository.

At the bottom of the architecture, a Linux-based computer equipped with Argos (a Linux-based SCADA alternative [26]) analyses network streams and extracts relevant metadata. Such data are sent via Apache Kafka [27] publish-subscribe messag-



(a) Network protocols and commands used in the communication

(b) Bandwidth by protocol and destination



(c) Connections between network hosts

Fig. 2. SAN Dashboard widgets

ing service to a central repository based on Druid [28]. This is a real-time data store that takes advantage of an in-memory architecture to facilitate data aggregation and fast querying. Data processed by Druid are queried via graphical web widgets based on the D3JS framework.

The visual analytics component does not fulfil only the task of depicting network data flows and interactions in real-time, but can be also applied to guiding the development of specific controls and checks. Every organisation in fact will exhibit a slightly different network layout and configuration, even those within the same industrial sector and/or running the same software package. This diversity requires a certain degree of customisation of controls, to tackle the specificity of a certain environment.

End users can perform an assessment of their network through the visual analytics component to baseline network behaviour, discover misconfigurations and assess issues. After this initial assessment, end users can select key indicators that can point at operational issues or cybersecurity breaches. To provide some examples, RTUs used in the field typically exchange data with the SCADA master via long-lasting connections that could be running for weeks or months. In case an RTU loses too often connectivity and re-establishes connectivity frequently, this could indicate an issue with the device itself (for instance, end of life) or with the network infrastructure (because of a wireless link). Key indicators can be enforced by writing a specific script in Bro, or a signature in Snort and/or Suricata.

III. Metrics in the Testing and Evaluation Process

Testing is an integral part of software development process. In the document „Standard Glossary of Software Engineering Terminology" IEEE defines *testing* as the „process of operating a system or a component under specified conditions, observing or recording the result and making an evaluation of some aspect of the system or component" [29].

The goal of testing is to detect the difference between existing and required conditions and to evaluate the features of the software items [30]. Currently, testing is a mature and well-defined area of software engineering. Good testing process design should ensure the repeatability, manageability and measurability [31].

As a part of the development of the Situational Awareness Network for the DEnSeK project, integration tests have been carried out. Their aim was to validate a selection of SAN components and check their operational capability in a complex test environment. During the tests appropriate interaction between the components was verified.

The tests were performed in the cyber security laboratory of one of the largest European electricity companies. They proved that the architecture and system components were properly selected and the system operates as intended [32].

Despite the positive results of the tests, the lack of quantitative indicators made it difficult to objectively assess the results. It was only possible to grade binary – it works or does not work. The extent to which the requirements are met, however, could not be determined in a measurable way. As far as only integration tests are concerned, this binary evaluation is sufficient. Nevertheless the majority of evaluations require higher precision.

Thus in order to enable objective evaluation of a software product and its development process *software metrics* were introduced. A *software metric* is a „quantitative measure of the degree to which a system, component or process has given attribute" [29]. The knowledge gathered on the basis of metrics should lead to an improved process and products [33]. The metrics can be divided into two groups: product metrics and metrics for testing process [34].

Metrics from the first group are used to provide information about the quality and maturity of the tested product. They

facilitate early detection of product flaws and related problems and enable their more accurate correction or elimination. In addition, metrics provide quantitative criteria which may be used in the process of acceptance of the final product.

The latter group contains metrics that allow for monitoring of the progress of the testing process and its results after the execution. They are used on one hand, to evaluate the effectiveness of the testing process. On the other hand, they provide test termination criteria.

The use of software metrics as objective evaluation criteria is extremely important in the management of the software development process [35].

Software metrics have been developed practically for all application domains. However, to the best of authors' knowledge the metrics for Situational Awareness Platforms have not been proposed so far. This is most probably due to the fact that the concept of Situation Awareness Network and the implementing it platforms are relatively recent.

In order to fill this gap the relevant research studies have been investigated to provide a comprehensive set of metrics for testing SANs. The metrics' proposals in several fields have been identified and analysed, including Intrusion Detection and Prevention Systems, Security Information and Event Management systems as well as general domains such as software engineering, testing or cyber security. The data collected allowed for selecting the relevant metrics.

When choosing the metrics, the Jaquith's [36] recommendations were taken into account. According to him, good metrics should be [36]:

- consistently measured,
- expressed as cardinal number or percentage,
- expressed using unit of measure,
- contextually specific,
- possible to obtain at reasonable cost.

In order to design the test procedure for the SAN system, a set of metrics was selected. Metrics described in Section IV regard the testing process. They facilitate the control and management of the testing process, as well as deciding when to end it.

Other metrics are related to the product. In the evaluation, the product is understood as a complete SAN system. Given the characteristics of the system the metrics are also divided into two groups. In Section V cyber security metrics are presented. They allow for evaluating the core SAN functionality answering the question of how the system copes with the detection of security threats. The last group of metrics, presented in Section VI, refer to system usability. As one of the functions of the SAN, provided by the Dashboard, is the visualisation of security threats to an operator, the quality of user interface is very important.

The main criterion taken into account when selecting the metrics was the possibility of their straightforward implementation to assess SAN platform at every stage of development. In addition, a set of metrics was chosen to cover as widely as possible all aspects of the testing process.

IV. Metrics for testing process

Testing metrics are widely used in the field of software testing. Their aim is to „provide information about the testing status of a software product" [34].

Quadri and Farooq [34] divided testing metrics into several groups. First of all they highlighted the metrics related to measuring time, such as time required to run a test, time interval between failures or number of failures in specific time interval. After that the metrics for evaluating test efficiency, source code coverage and quality were described. Finally metrics related to defect identification and fixing were presented.

Chen et al. [37] conducted an in-depth analysis of software metrics, examining the effectiveness of a set of complementary metrics for cost, time, and quality to measure the quality of test process. Based on the result they proposed four new testing metrics: two related to product improvements and two related to costs.

Kaur et al. [35] surveyed, classified and systematically analysed the metrics proposed in the previous decades. They discussed advantages or disadvantages for each product metric along with its need and purpose. The suitability, effect, data calibration and interpretation of metrics was also evaluated.

Based on the studies as well as the specificity of the DEnSeK project four testing metrics were selected.

A. Source code coverage

The source code coverage metric enables evaluating the confidence in the effectiveness of a test suite. The metric is defined as follows:

$$SC = \frac{St_t}{St} \tag{1}$$

where:

- SC – source code coverage,
- St_t – number of statements of a source code covered by test suite
- St – number of statements of a source code,

The metric shows what part of the source code has been covered with tests. If the value is too low, there should be written additional test cases for uncovered source code.

B. Test case defect density

Test case defect density metric indicates whether the test cases are effective and efficient in their ability to detect a larger number of defects. It is defined as:

$$DD = \frac{F}{TE} \times 100\% \tag{2}$$

where:

- DD – test case defect density,
- F – failures detected,
- TE – number of executed test cases.

C. Failures detection rate

Failures detection rate metric test indicates whether the prepared tests are time effective in terms of the number of detected defects per unit time. The metric is defined by the following formula:

$$FD = \frac{F_T}{T} \tag{3}$$

where:

- FD – failures detection rate
- F_T – failures detected in T time
- T – number of business days used for testing

D. Test improvement in product quality

Test improvement in product quality metric shows the relation between the number of weighted defects detected and the size of the product release. It is defined as:

$$TI = \frac{W_p}{KCSI} \tag{4}$$

where:

- TI – test improvement in product quality,
- W_p – number of weighted defects found in one specific test phase,
- $KCSI$ – number of new or changed source lines of code in thousands.

The higher this number, the higher is the improvement of the quality of the product contributed during this test phase.

V. Cyber security metrics

Cyber security metrics are strictly related to the functional operation of the Situational Awareness Network. The selection was made among the metrics defined for security systems such as Intrusion Detection Systems. One of the main problems that SAN operators would face is the reliability of the threats detection. There are two main aspects to be taken into consideration: false positives and true negatives. [38]

A *true positive* is when SAN informs about threat that really exists. This is the desired situation. A *false positive* takes place when SAN informs about threat that does not occur. A *true negative* refers to the situation when SAN does not inform about threat that really occurs.

Using these terms three metrics have been defined. Additionally two metrics based on the research conducted by Bayuk and Mostashari [39] were proposed.

A. Accuracy

Accuracy metric describes the proportion of true results (both true positives and true negatives) in the population of all network events. It is defined as:

$$A = \frac{TP + TN}{TP + TN + FP + FN} \tag{5}$$

where:

- A – detection accuracy
- TP – number of true positives
- TN – number of true negatives
- FP – number of false positives
- FN – number of false negatives

A higher value indicates a more reliable system operation.

B. Detection rate

Detection rate determines the effectiveness of threats' detection. When the metric value is closer to 1, the system is more effective. A value of 1 means that each threat has been detected.

$$DR = \frac{TP}{TP + FN} \tag{6}$$

where:

- DR – detection rate
- TP – number of true positives
- FN – number of false negatives

C. False positive rate

False positives are one of SAN biggest issues. Their frequent occurrence significantly undermines the effectiveness of the SAN. Efforts should be made to the lowest value of this indicator.

$$FPR = \frac{FP}{FP + TP} \tag{7}$$

where:

- FPR – detection accuracy
- FP – number of false positives
- TP – number of true positives

D. Mean Time Between Failures

Mean time between failures (MTBF) is a standard metric that describes reliability of the system. In the case of SAN failure is defined by the occurrence of either false positive or true negative. The metric is defined as:

$$MTFB = \frac{\sum_2^{NF}(B_n - E_{n-1})}{NF - 1} \tag{8}$$

where:

- $MTFB$ – Mean Time Between Failures
- B_n – beginning of *n*-th failure
- E_n – end of *n*-th failure
- NF – number of failures

E. Time To Protect

The metric is defined as the mean time between the detection of the threat and noticing it by the operator. In this way, both the effectiveness and efficiency of the system, as well as the legibility of the information about the threat on the dashboard, are evaluated.

$$TTP = \frac{\sum_1^{NT}(A_n - D_n)}{NT} \tag{9}$$

where:

- TTP – Time To Protect
- A_n – time of *n*-th threat notice
- D_n – time of *n*-th threat detection
- NT – number of threat detections

VI. User experience metrics

In addition to testing against the above criteria, software should be evaluated in terms of usability. This is particularly relevant to software interface, but not exclusively. As far as the DEnSeK SAN is concerned, the Dashboard requires special attention in regard to usability. Based on the metrics proposed by Tullis and Albert [40], the following metrics are proposed for evaluation of the SAN usability.

A. Task success

This metric enables measuring the extent to which a user is able to perform a given task. Task success can be measured binary (succeed/failed), or as a level of success. The tasks with a lower coefficient of success must be analysed to detect the elements of the user interface which cause problems.

B. Time-on-task

Time-on-task allows for measuring the time required to complete a specific task. The faster a user can complete a task, the experience is better. In the DEnSeK project the metric serves for evaluating the efficiency of the Dashboard.

C. Efficiency

In contrast to the previous metric, which concerned time, the efficiency metric enables measuring the amount of work required to complete a task. For instance such an effort can be expressed by means of the number of mouse clicks or keystrokes.

D. Errors

This metric allows for detecting improperly designed user interface elements that cause users' confusion. It is measured as the number of user errors when performing a task. Errors may be related to spelling, pressing a wrong key, etc.

E. Learnability

The learnability metric supports examining whether and how user productivity increases with the better knowledge of the system. Measuring learnability requires intense studies spanning a long period of time. For this reason it is often left out.

VII. Conclusion

The metrics described in the paper are used to evaluate Situational Awareness Network (SAN) system developed in the DEnSeK project. The SAN was designed as a three-tier architecture. The lowest tier encompasses a number of sensors for network monitoring. In the middle tier, the SIEM software collects and processes the data from the sensors. Finally, the dashboard on the top tier visualizes information about the threats.

In order to select the appropriate set of metrics a thorough literature analysis was conducted. To the best of authors' knowledge the metrics for SAN have not been proposed so far. Therefore software metrics developed for several related fields, including cyber security, Intrusion Detection and Prevention Systems, SIEM systems, software engineering and testing have been analysed. The study made it possible to derive a set of metrics for testing Situational Awareness Networks.

The selected metrics were divided into three groups. The first group contains metrics related to the evaluation of the testing process, the second – to the effectiveness of threat detection, and the last – to the usability of the dashboard. The metrics are used at each stage of the SAN development. In addition they will be applied during final product evaluation and acceptance process.

***Abstract*—A solar car is an electric vehicle that runs entirely on solar energy. Designing, building and racing solar cars has been a longstanding worldwide challenge for engineering and computer science students, with the overarching goal being to design devices that use sustainable energy sources. This article describes our experience and educational outcomes (*the modeling and design of computer-based systems in a way that demonstrates comprehension of the trade-offs involved in design choice*) attained while designing the network architecture for a solar car project.**

The computer science members of the University of Kentucky Solar Car Strategy Team are tasked to reliably collect and analyze car data in real-time, both to assist in the car development process, and then to provide important sensor readings to the driver during racing. The challenges in designing the architecture and protocols for the computer system that supports the solar car are to ensure that: (1) energy consumption is minimal, (2) data collection is reliable, (3) the network system is secure, and (4) the implementation of the system is not overly complex.

Our computer system supporting the telemetry tasks uses three micro-controllers to collect and send data over serial communications to a master micro-controller (the Raspberry Pi), that parses and stores data in an on-board database.

We compare three protocols: a simple USB-based protocol, and two protocols used in traditional non-solar cars: CAN and Ethernet. We analyze (1) their energy consumption over a period of time, (2) their reliability (by performing stress tests such as disconnecting devices and driving over bumpy terrain), (3) their security (by attempting to compromise the system by remotely sending data over communication lines), and (4) their complexity in terms of time and effort for implementation and development.

I. Introduction

SOLAR Car racing (see Figure 1), the competitive racing of fully electric vehicles using solar energy, has existed since 1985. Universities and businesses around the globe participate with different goals in mind. Universities typically participate in order to improve engineering and technical knowledge and skills of the students, while businesses typically participate to develop renewable energy technologies. Traditionally, a solar car requires a collaboration of electrical, mechanical, and computer engineers (see [6]). However, with data storage becoming cheaper, and micro-controllers becoming more abundant and inexpensive (such as the Arduino and Raspberry Pi) these make programming embedded systems just as easy as programming an application for a typical computer. In other words there is a growing need for computer science students to be a part of the team. Solar car teams can easily capture, store, and analyze data in order to improve the overall performance of the car.

In the context of power consumption, we analyzed a telemetry system for the solar car project. An automated communications process collected and transmitted car performance data to receiving equipment and personnel for monitoring, processing, testing and decision making. When choosing the network architecture to support telemetry to achieve the aforementioned capturing, storing, and analysis of data, we must determine trade-offs that are critical to the car's functionality. It is also important to carefully consider and design the underlying software architecture that is the driving force behind the network architecture.

Minimizing the power consumption, and comparing various solutions and their trade-offs, are some of the contemporary challenges, addressed in many projects, including the past workshops of this conference. See for example, [1], [2], [4], and [5].

This paper reports on experimental results of a student team, for whom the Solar Car project serves as an attractive way of learning engineering topics. Clearly, tools, instruments, and methods are unequal to sophisticated, advanced, and likely expensive telemetry systems developed for professional motor racing, such as in Formula One. However, the experience with a real-life project of designing the network architecture for a solar car project, contributes to the important computer science student outcome: *the modeling and design of computer-based systems in a way that demonstrates comprehension of the trade-offs involved in design choice*. See also [3] for a discussion on using real-life projects for "developing skills needed for the proper formulation of system visions and requirements specifications."

The subsequent sections describe and compare three different network solutions, the architecture of our telemetry system, and finally, provide our conclusions.

II. Network Comparison

We now discuss the trade-offs of using USB [7], CAN [8], and Ethernet while trying to meet these four challenges: low power-consumption, reliability, security, and simplicity.

A. Low Power-Consumption

Low power-consumption is by far one of the most critical requirements in the development of a solar car. Naturally, the

Fig. 1. Solar Car – team UK

architectural design of the network was not exempt. Since we are racing the car, keeping the power consumption down allows us to allocate more power towards other critical parts of the car. Saving this power for the motor has the potential to result in more mileage out of the total amount of power. We hypothesized that USB and CAN would require about the same amount of power and that Ethernet would require much more than the previous two. Consequently, we chose to compare USB and CAN first and then talk about Ethernet afterwards.

1) USB versus CAN: USB and CAN are known to be very low power networks as long as they are not being used to power a device. To accurately compare these two approaches, we chose to measure the amount of power required to power a CAN chip and a USB chip with no data being sent over them. From experiments, we found that the CAN chip required 11% less power than the USB chip. Although 11% may appear big, in practice the difference is negligible due to the measured values being low.

2) Ethernet: Compared to USB and CAN, Ethernet is known to use significantly more power. This is because of larger hardware requirements to allow for an Ethernet network. Not only would one need to put a router or switch on the car, one would also have to add more hardware on the actual micro-controllers to be able to communicate with Ethernet.

B. Reliability

The reliability of each of the protocols is important because it ultimately determines whether or not data are received. When discussing the reliability of the three network architectures, we focus on the hardware aspects.

1) USB: USB provides data integrity within the cables, meaning that there is a high degree of confidence that the data sent over the transmitting end will make it to the receiving end. Any unrecoverable errors will likely be noticed and reported to the appropriate end of the cable. Data integrity is provided through USB's self-recovery system. This approach guarantees that a message will be resent at least three times before reporting an error to the client software, and will throw time-outs for lost or invalid packets.

Unrelated to the actual data integrity within the cable, but still considered in our evaluation, is the observation that USB has a high likelihood of becoming mechanically disconnected from its transmitting or receiving end due to jostling that occurs while the car is in motion.

2) CAN: CAN is similar to USB in that it also provides data integrity. The CAN protocol defines no less than five different ways to detect error:

- Cyclic Redundancy Check (CRC) acts similar to a checksum by doing polynomial division on the bits and comparing the end result to the 15 bit CRC field located within the packet.
- Acknowledgment (ACK) Check - The node that transmitted a message has essentially sent a recessive level and would expect to receive a dominant ACK message. If it does not, then it acts as if the previously sent message was lost and responds accordingly.
- Form Error Check - If there is a dominant bit in the CRC field delimiter, ACK field delimiter, or EOF (end of frame) then the message is re-sent because, per protocol definitions, there must not be a dominant bit in these fields.
- Bit Stuffing - If six consecutive bits with the same polarity occur between the SOF (start of frame), then the CRC field throws an error. The EOF field should be the only field with six consecutive bits of the same polarity.
- Bit error occurs when the transmitter reads a signal that is opposite of what it sent except during arbitration and in the ACK field. Arbitration is a method that provides a bitwise losslessness if all of the nodes on the CAN network are synchronized to allow for every bit on the CAN network to be sampled at the same time.

In contrast to USB, the few devices on the car that utilize CAN have never had any issues with disconnectivity due to the jostling of wires.

3) Ethernet: Ethernet in itself is not reliable. It does not support retransmission, it does not provide acknowledgment of successful frame delivery, and if a frame were to become corrupt it simply drops it without letting the transmitting or receiving end know. Due to this characteristic, we consider the use of Ethernet with TCP, Transmission Control Protocol. TCP is a protocol that is often overlaid on top of Ethernet. TCP supports detection of duplicate data, retransmission, and sequencing. Because Ethernet is usually used to send packets over long distances, and because multiple Ethernet switches are used, packets can be duplicated. TCP detects duplicate packets and drops the unnecessary ones. In conjunction with this duplication, packets can get out of order. Therefore TCP

supports sequencing - placing packets in the order that they were sent. Additionally, if a packet gets lost or corrupted, TCP provides retransmission of the affected packet.

C. Security

The UK solar car was designed just for races, and not intended for mass production. Nevertheless, network security is becoming a general concern and should always be accounted for. Especially considering the recent cyber-security incidents related to private cars being hacked ([10]). Even though our specific network application represents a minimal security threat, security was not ignored.

1) USB: From a security standpoint USB is actually a very good option. It only allows for peer-to-peer communication, so there is essentially no network to abuse. However, due to the nature of peer-to-peer, there is no form of authentication. Simply, each computer does not have a way of being completely sure who it is talking to. Given this situation, the only realistic way to attack a USB-based system would be to plug in directly to the device you wanted to lie to.

2) CAN: A CAN network is riddled with security problems stemming from the underlying protocol. Much like the IP protocol, it relies on the sender to accurately choose a message ID. From this message ID you can tell what kind of data are being sent, as well as what device is sending it. This is done by a device choosing a range of IDs, and making sure that every message it sends is inside of this range. Given this type of protocol, it is trivial to impersonate another device on the network. A person could just send a message onto the network with an ID that is not their own, and the receiving device would not know the difference. As a proof of concept, we simulated this vulnaribility and were able to get the Raspberry Pi on our CAN network to tell the motor to accelerate even though the pedal was not being pressed. It is understandable why the developers of this network originally left this vulnearibility, because CAN was always intended to be an internal network. Getting on to the network to abuse its security faults is not easy. This vulnerability is also why there has been so much news about cars being hacked lately; see [10]. Since CAN is the industry standard, it is not too difficult for a hacker to use a laptop with a CAN cord and plug into the network manually to break in. In some cases, where the car has an Internet access, there may be ways to get from the Internet network to the CAN network and remotely hack a car.

3) Ethernet: Ethernet has almost the same set of vulnerabilities as CAN. However, it is substantially easier to abuse a CAN network than it is to abuse the security vulnerabilities in Ethernet. Numerous protocols built on top of Ethernet reduce its vulnerability. Clearly, it is still possible for hackers to abuse Ethernet network by misrepresenting the identity and impersonating devices on the network.

D. Simplicity

Simplicity, a universal value and software development practice, is commonly used by student teams. These teams operate on schedules dictated by the academic calendar. In addition, once they graduate, the code base is picked up by future Computer Science students to continue assisting the Solar Car project; see [11] for the repository with our code.

1) USB: On the software side, USB is relatively simple. The majority of languages that would be commonly used in these type of applications (Python, Java, C, C++, etc.) support serial communications. One must simply identify the port to communicate with and open a serial connection with said port.

On the hardware side, USB actually is not native to the majority of the solar car peripherals except for the micro-controllers themselves. As a result, USB use can cause problems for the developers with the devices on the car that communicate through CAN. To alleviate this difficulty, the team utilizes CAN-to-USB converters in order to receive data.

2) CAN: Even though, communicating with CAN through software is not as common, it can be done in a relatively standard way. In fact, communication support is implemented in `Python`, the main language used on the Raspberry Pi. However, CAN is more complex to use rather than USB or Ethernet. In fact, even the documentation about the implementation through `python-can` library suggests that working with `python-can` is much more complex than the implementation of USB through the `pyserial` library. Thus, in our solution, we actually use a CAN to USB converter between the CAN network and the Raspberry Pi, to keep the software implementation as simple as possible.

The hardware side for CAN is the upside, however, with CAN being the industry standard for regular cars due to its reliability, upgradeability, performance, and cost. As the benefit of standardization, one can expect that the majority of the car peripherals communicate over CAN. Among them is the Motor Controller that drives the rear third wheel of the solar car.

3) Ethernet: Ethernet is very similar to USB when it comes to software aspects. Almost all languages have some kind of built in library that handles communication over sockets, which are the Ethernet equivalent to ports in USB. This gives Ethernet a distinct advantage over CAN when it comes to software implementations.

For the hardware side, Ethernet is in the same category as USB. Ethernet is not common among any of the car peripherals besides the micro-controllers. In effect, Ethernet switches and CAN to Ethernet converters have to be used.

Table I summarizes the above evaluation.

TABLE I
SUMMARY OF THE COMPARISON FOR THE SOLAR CAR PROJECT

	Power usage	Reliability	Security	Simplicity
USB	low	good	good	poor hardware support
CAN	low	good	poor	nontrivial software support
Ethernet	high	good (with TCP)	poor	poor hardware support

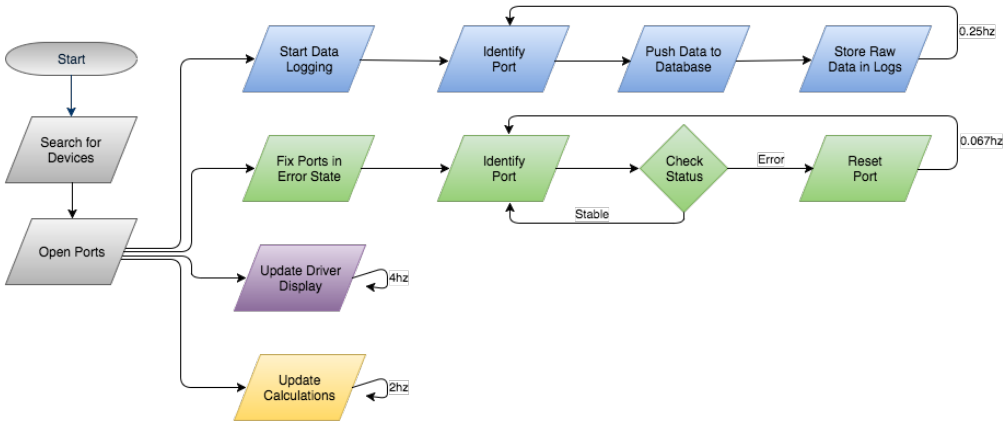

Fig. 2. High-level overview of the software architecture

III. Software Architecture

There are multiple choices for the network architecture and the final decision on whether or not CAN, USB, or Ethernet would be better choice for us is greatly influenced by the current software architecture.

Depicted in Figure 2 is a high-level overview of our software architecture. When the program is started on boot, it immediately opens the ports where data are expected, and then connects to the corresponding devices for those ports.

Rules in UDEV - a device manager for the Linux kernel - are used so that each device is assigned a unique identifier based off of the product id on the USB chip.

The flow of control is as follows. The program starts off by initially searching for any connected devices and opening up a connection to them. After this point four threads are started up and read from a global state containing of a list with each device. The threads run concurrently, and access the global state, but do not communicate directly with one another. The first thread, *the logging thread*, starts off by ensuring that the device has been identified. Then it logs the device buffer to the database on the car, and stores the raw data logs for the *post mortem* analysis.

The second thread, *error correcting thread*, iterates through all of the devices and identifies their kind. Then, this thread looks at the statistics of each device to determine whether the device is in an error state.

The third thread, *update drive display*, sends the vehicle speed and battery current measurements to the attached Arduino. The Arduino then takes these values and displays them on two seven segment displays.

The last thread, *update calculations*, does the calculations that would otherwise require too much bandwidth to send the sufficient amount of information for the other end of the telemetry system to calculate.

The responsibilities of the threads described above, and presented in Figure 2, are:

1) Thread Data Logging: This thread loops through every device (port), logs any data that have been saved up in the device buffer, pushes the data to the SQL database and writes the data to raw text files as a backup.
2) Thread - Port Fixing: This thread also loops through every device, but instead of logging data it checking to ensure that the device is still connected and that we are receiving data. If the device is in an error state then this thread will attempt to fix it until it attains a stable state again. This thread is also the only thread with the capabilities to significantly change the global state, so its actions are heavily synchronized with the other threads.
3) Thread - Updating Driver Display: This thread updates the driver display with the current car speed and voltage usage.
4) Thread - Update Calculations: This thread updates any calculations that are being sent over the radio telemetry system in the trail (chase) car. As an alternative solution, these calculations could be moved to the Java application on the receiving end to lessen the amount of work that the program on the Raspberry Pi has to do. The tradeoff would be in using more bandwidth to send the data.

The diagram in Figure 3 shows the general layout for the current USB based telemetry system for our solar car. There are multiple devices that are plugged into a powered hub: two battery boxes, the motor CAN network, an Arduino, and a telemetry box. Also you may note that the Arduino controls many devices: two seven-segment displays (used to show speed and current), gyro, accelerometer, and GPS. These extra devices data are eventually sent on to the Raspberry PI for processing. There is also a small CAN network between the drivers control box and motor controller that must be there regardless of the choice of architecture. Regarding the powered hub, on the other end there is a Raspberry PI micro-computer that uses this powered hub to create separate connections to each device and manage each of them individually. The micro-computer then reads and interprets data from each device, and then sends them to the telemetry box; a matching telemetry box in the chase car receives these data. During the interpretation of data on the Raspberry

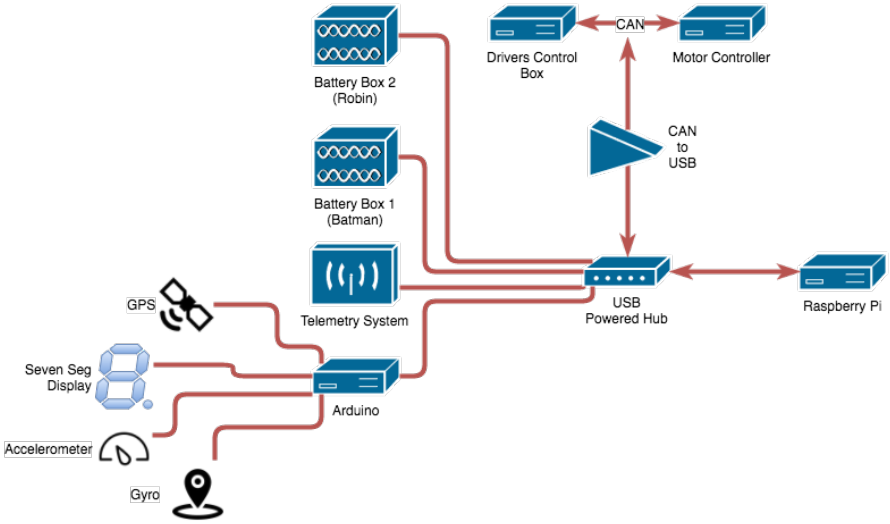

Fig. 3. Architecture of our telemetry system

Pi that data are permanently stored in an on-board MySQL database.

IV. Conclusion

By analyzing various network solutions, we have determined trade-offs in Solar Car network architectures that try to meet the four challenges: low power consumption, reliability, security, and simplicity. In comparing these solutions, we have found that USB and Ethernet are very respectable options. USB provides a quick starting point. For example, if a project involves a micro-controller then it is very likely that the micro-controller contains, at the least, a USB port. Furthermore, communications over a serial connection, which is what USB is, are very easy to implement. On the other hand, Ethernet, being a class D network, can handle very high data rates (up to 100 mb/s). If the Solar car needed to transfer this much data then Ethernet high energy usage could be countered by the trade-off for high data rates and easy implementation. Even with USB and Ethernet being respectable options, CAN still has been found to be the best overall option. The hardware is easy to implement, cheap, and upgradeable. It uses a low amount of energy, which is highly critical to our application, and although it is not as common to implement in software, there exists workarounds. Working on a solar car design, along with implementing and testing solutions, has provided us with incomparable learning outcomes in networking, security and teamwork, and have allowed all the participating students to clearly see design trade-offs, even when some of them are subtle.

***Abstract*—The main topics of the Cyber-Physical Systems (CPSs) cover the specification, modeling, control, design, verification and testing. The CPSs implementation consists of reactive programs conceived using models that are capable to sustain the mentioned activities. Component diagrams (introduced by Unified Modeling Language) are used here for the architecture design, with the goal to split the CPS complexity into smaller entities that are easier to tackle. All the components are modeled by Fuzzy Logic Enhanced Time Petri Nets (FLETPNs) that can simultaneously describe the discrete event and the time discrete features. This unique and compact approach facilitates the control synthesis, the software design, the verification and the testing.**

An example of application to the control of a system composed of a wind turbine generator, a photo-voltaic generator and loads is used to show the model utilization and its benefits.

I. Approaches of the Cyber-Physical Systems

CPSs integrate the dynamics of the physical processes with those of the software and communication. There are some surveys that present the main characteristics, the main domains where they are applied and the main topics of the CPSs [10], [11], [12]. The main topics of the CPSs cover the specification, the modeling, the control, the design, the verification and the testing. The CPSs implementation consists of reactive programs that are based on models that are capable to support the mentioned activities.

The main goal of the current research is to conceive a control system that concurrently reacts to discrete events and continuous modifications of plant state. The target is a set of interacting dynamic models capable to approach the following specification:

- the reaction to synchronous and asynchronous (plant) events that are signaled by continuous variables (instead of single level events)
- the continuous time reaction to modification of some (plant output) variables
- the reaction control signals that belong to continuous domains (the discrete domains, as the binary set, should be particular cases)

Some reactions require the execution of activities involving non-ignorable durations and could have real-time constraints that have to be fulfilled. This requirement leads to the conclusion that the target model has to be capable to describe concurrent behavior.

A relevant issue is to conceive a model that is capable to describe the controller behavior and its structure. A practical goal is to make possible the verification that the implemented model fulfills the specified requirements.

The implementation of controllers on digital computers supposes that the information of continuous variables can be represented with a limited and tolerated accuracy (due to the limited length of the number representation) and the calculus can add other losses of the precision. On the other hand, the continuous time reactions are not possible to be implemented on digital computers. For this reason, instead of continuous time models, the discrete time models are used. The loss of accuracy due to the conversion of the continuous time models into discrete time models is supposed to be tolerated too.

The OMG (Object Management Group) Unified Modeling Language could successfully fulfill the requirements using a set of state machines, but these dynamic models have to be endowed with many variables, equations and condition expressions to completely describe the desired behavior [1]. The verification that the obtained models fulfill the requirements needs the use of other complex methods (such as different kinds of Petri nets) or simulation tools.

Many authors emphasize that CPSs are hybrid systems [2], [10], [11]. A hybrid system is composed of a discrete event side and a continuous time side in an interaction that provides a complex behavior. The control of a hybrid system is a challenge due to the requirements of asynchronous reactions to the discrete events as well as to the continuous adjustment of some controlled outputs. The CPSs involve interdependencies between physical behavior and digital control [13]. The control system implementation should be based on asynchronous interrupts and synchronous discrete time reactions.

The controller asynchronous reaction involves the execution of rules of the form:

$$ON\ event\ IF\ condition\ THEN$$
$$action_1 \wedge action_2 \wedge \cdots \wedge action_k \quad (1)$$

The ordinary Petri nets can model the handling of events, the binary conditions, the concurrency and the controller structure. These models are not capable to model the cases when the

978-83-60810-90-3/$25.00

involved reactions require input of continuous variables and outputs that signal continuous variables. These models are not appropriate to model continuous type operations.

The fuzzy logic controller (FLC) based on fuzzy logic provides a means of converting a linguistic control strategy based on expert knowledge into automatic control strategies. This approach was chosen (in the current research) for its capability to conceive controllers that tackle, beside the synchronous reactions (i. e. the periodic discrete time feature), the asynchronous reactions for the cases that require variable output control signals.

An overview of the possibility of implementing the fuzzy control systems as fuzzy rule-base systems is contained in [6]. Here it is justified that the conventional methods are good for simpler problems, while the fuzzy systems are suitable for complex problems or control applications that involve human descriptions or intuitive thinking. Lee presents a survey of the general methodology for constructing an FLC and the assessing of its performance [7].

In [9] another model that links the Petri nets with FLC is introduced.

II. Fuzzy Logic Enhanced Time Petri Net Models

A. Low Level Petri Nets

As it is well known, a Petri Net (PN) is a directed graph with two kinds of nodes. An *ordinary PN* is a 5-tuple

$$PN = (P, T, pre, post, \mathbf{M}) \tag{2}$$

with:

- a finite place set $P = \{p_1, p_2, ..., p_m\}, (m \geq 0)$
- a finite transition set $T = \{t_1, t_2, ..., t_n\}, (n \geq 0)$
- $pre : P \times T \rightarrow \mathbf{N}$ (natural number set) is the backward incidence function:
- $post : P \times T \rightarrow \mathbf{N}$ is the forward incidence function

In the current approach

- $pre(p,t) = 0$, if there is not an arc from p to t and $pre(p,t) = 1$, if there is an arc from p to t,
- $post(p,t) = 0$, if there is not an arc from t to p and $post(p,t) = 1$, if there is an arc from t to p.

$N = (P, T, pre, post)$ describes the structure without marking. $PN = (N, \mathbf{M}_0)$ is the structure with a marking $\mathbf{M}$ where $M : P \rightarrow \mathbf{N}$ is the marking specifying the number of tokens of each place. The marking $\mathbf{M} = [M(p_1), M(p_2), ..., M(p_m)]^T$ describes the PN state.

The lack of the PN capability to handle the time is removed in the models *Time Petri Nets (TPNs)*. The TPNs are suited for modeling the time-dependent systems with timing constraints [3] A timed Petri net can be defined with delayed transitions, or delayed tokens [4],[5]. The current approach uses the timed transitions. A TPN is a PN with each transition t_i delayed by an assigned delay d_i from a set of non-negative integers $D = \{d_1, d_2, ..., d_n\}$. That means, each transition t_i is delayed with d_i time units from the moment of time when it becomes enabled.

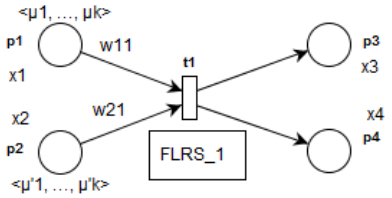

Fig. 1. Example of a FLETPN

The definition of TPN is:

$$TPN = (P, T, pre, post, D, \mathbf{M}) \tag{3}$$

where $P, T, pre, post$ and $\mathbf{M}$ have the previous meanings. $D : T \rightarrow \mathbf{N}$ is a mapping that assigns to each transition a delay.

An Enhanced Time Petri Net (ETPN) is a TPN endowed with an input place set *Inp* and an output place set *Out* [5]. In ETPN only the transitions with single input places can be delayed. The input places (Inp) are loaded with tokens by the plant. The ETPN injects tokens in the output places (Out) and these tokens are extracted immediately by the plant.

All these kinds of Petri nets have a single type of tokens.

B. High Level Petri Nets

Unlike the above defined Petri nets, the high level Petri nets have distinct tokens. The current approach is based on a particular case of high level Petri nets. There are some kinds of Petri Nets endowed with fuzzy features. A relevant review of fuzzy Petri nets and industrial applications can be found in [8].

A FLETPN is an ETPN extended with fuzzy logic rules that is capable of processing fuzzy information. Each place has a distinct token and its capacity is equal to one. Each place of the ETPN is assigned a variable and each transition has assigned a fuzzy logic rule set, but one fuzzy logic rule set could be assigned to more than one transition. A token injected into a place expresses the membership degrees of the (assigned) variable to the fuzzy sets. Figure 1 shows a FLETPN that has a transition with two input places and two output places. Each place p_i has assigned a variable x_i.

The definition of a FLETPN is:

$$FLETPN = (P, T, pre, post, D, W, X, EFS, \mathbf{FLRS}, \alpha, \beta, \mathbf{M}) \tag{4}$$

where $P, T, pre, post$ and D have the previous meanings. $X = \{x_1, x_2, \cdots, x_m\}$ is a set of variables with $x_i \in \mathbf{R}$ (with $\mathbf{R}$ a domain in the real number set). α is a bijective mapping $\alpha : P \rightarrow X$ that assigns to each place a variable from the set X. EFS is an extended fuzzy set of the fuzzy set $FS = \{A_1, A_2, \cdots, A_k\}$, $EFS = FS \bigcup \{\Phi\}$. The statement $x\, is\, \Phi$ means there is no information about the value of the variable x at the current moment of time.

The marking $M(p_i)$ of a place p_i is the vector of the membership degrees of the assigned variable to the fuzzy set

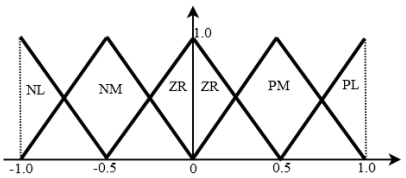

Fig. 2. Fuzzy logic membership functions.

TABLE I
Fuzzy logic rules $FLRSx, y$ in Fig. 4

NL	NM	ZR	PM	PL
Φ,ZR	Φ,ZR	PL, PL	ZR,Φ	ZR,Φ

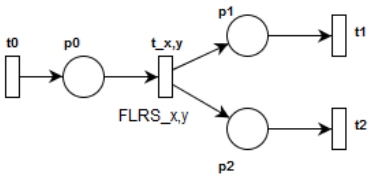

Fig. 4. Selection by FLRS.

FS. Any distinct token of the form

$$\mu =< \mu_1, \mu_2, \cdots, \mu_k > \tag{5}$$

inserted into a place p_i expresses the membership degree of the variable x_i to the fuzzy set FS. In the current case, a place corresponds to a set of statements and the information is available only when a token μ is contained.

Each input arc of a transition is endowed with a weighting coefficient: $W : P \times T \rightarrow \mathbf{R}$ (with **R** a domain in the real number set), $W(p_i, t_j) = w_{ij} \in \mathbf{R}$.

FLRS is a set of fuzzy rule sets. β is a mapping that assigns to each transition a fuzzy logic rule set $\beta : T \rightarrow$ **FLRS**. The fuzzy logic rules considered here have the form:

$$IF\ x_1 isA_1 \wedge x_2 isA_2 \wedge \cdots \wedge x_k isA_k\ THEN \\ x'_1 isA_1 \wedge x'_2 isA_2 \wedge \cdots \wedge x'_k isA_k \tag{6}$$

with $x'_1, x'_2, \cdots, x'_k$ belonging to the same set X and representing the consequences of the inference rules.

An example is $FS = \{NL, NM, ZR, PM, PL\}$ where the elements mean negative large, negative medium, zero, positive medium and positive large respectively. For simplicity reasons, the membership functions used for fuzzification and defuzzification are those presented in Figure 2. For practical reasons the values of the variables $x_i \in X$ were bounded to the real number set [-1,1].

An example of rule using FS is:

$$IF\ x_1 isZR \wedge x_2 isNM\ THEN\ x_3 isPM \wedge x_4 isPL \tag{7}$$

In an earlier release of FLETPN model (see [9]) the selection of alternatives was implemented based on logical expressions assigned to transitions. For example, the selection to continue the execution with transitions t_1 or t_2 included in the partial FLETPN model represented in Figure 3 was chosen using the expressions $expr_x$ and $expr_y$. In the current release the logical expressions were removed and the selection is performed by appropriately conceiving the $FLRS_{x,y}$, as shown in Figure 4 and in Table I.

Supposing that all the rules have the same two inputs and two outputs (i. e. consequences) the fuzzy logic rule set can be described in a table such as Table II. There are represented the following rules:

$$IF\ x_1 isNL \wedge x_2 isNL\ THEN\ x_3 isNL \tag{8}$$

$$IF\ x_1 isPL \wedge x_2 isPL\ THEN\ x_4 isPM \tag{9}$$

The consequence of rule (7) injects a token into the place p_3 and another one into the place p_4. The consequence of rule (8) means that if only this rule is activated, the execution of the transition leads to a token in the place p_3 and no token in the place p_4. Unlike rule (8), rule (9) leads to a token in the place p_4 and no token in the place p_3. This manner allows the selection to continue the execution from the place p_3, the place p_4 or from the both of them.

An input x_i can belong to the fuzzy set A_j with a membership degree $\mu_j(x_i)$. For the given example, if the variable x_i is assigned to a place p_i a token injected into this place can be $< \mu_{NL}, \mu_{NM}, \mu_{ZR}, \mu_{PM}, \mu_{PL} >$ and it describes the membership degree of the variable x_i to the fuzzy set FS. All the rules included into a fuzzy rule set have the same inputs and outputs. The dimension (cardinal) of a fuzzy rule set of a transition t_i is $|FS|^l$ where $|FS|$ is the cardinal of the fuzzy set and l the number of the input places of the current transition.

The fuzzy rule set provides an output vector of the dimension equal to the cardinal of the transition output place set. The elements of this output vector are fuzzy sets.

The *execution of an enabled transition* t_j involves:

- the extracting of the tokens from the transition input places (denoted by ${}^o t_i$);

TABLE II
Example of inference rules

$x_1 \backslash x_2$	**NL**	**NM**	**ZR**	**PM**	**PL**
NL	NL, ϕ	NL, Φ	NL,PL	ZR,PL	PL,PL
NM	NM, Φ	PL, Φ	PL,PL	PL,PL	NL,PL
ZR	PM,PL	PM,PL	ZR,PL	NL,PL	PM,PL
PM	ZR,PL	PL,PL	NL,PL	ϕ, NM	ϕ, PL
PL	NL,PL	ZR,PL	ZR,PL	ϕ, PM	ϕ, PM

- the defuzzification of all input variables x_i;
- the multiplication of the variables with the corresponding weighting coefficients $x'_{ij} = w_{ij}x_i$;
- the fuzzification of the variables x'_{ij};
- the use of the FLRS with x'_{ij} as inputs;
- the normalization operation that reduces the previous consequences to a single one and leads to injection of a single token into the output places;
- the injecting of the resulted tokens into the transition output places (denoted by t_i^o) when the delay elapses.

Due to the fact that a variable number of rules can be involved (activated) for a transition execution, this could inject a variable number of tokens into the output places. To avoid this, a *normalization* operation is required. Let $r_l, l = 1, \cdots$ be the rules that are activated. The *strength* s_l of a rule is calculated with $s_l = \mu_1 \cdots \mu_k$ where μ_i is the membership of the input variable. Let z_l be the crude value provided as a consequence by the rule r_l. The value of the transition output variable x' is:

$$x' = \frac{\sum\limits_{l} z_l \cdot s_l}{\sum\limits_{l} s_l} \tag{10}$$

The regular fuzzification of the variable x provides the token that is injected into the output place. As a consequence, the execution of every transition leads to a single token or no token in each output place. The result of the normalization operation leads to a token the fulfills the relation:

$$\sum_{i} \mu_i = 1 \tag{11}$$

A FLETPN can model the synchronous and asynchronous reaction to a signal belonging to a continuous domain. The handling of the discrete events can be implemented by constraining the membership degree. For example, if a variable x_i assigned to a place p_i is of the discrete event type, the variable belongs (by convention) to PL set. That means all the tokens injected into the place p_i have the form $< 0, 0, 0, 0, 1 >$.

A discrete event variable is a particular case of a continuous variable. All the discrete event variables belong to the same set (could be a fuzzy set) with a membership degree $\mu = 1$. A transition could have input places corresponding to discrete event variables and places corresponding to continuous variables. The assigned fuzzy rule set has to be constructed according to this structure.

In conclusion, a FLETPN model can mix the continuous type tokens with the discrete event type tokens, but every place can contain only one type tokens. Using Petri nets with tokens integrating higher complex information simplifies the program structure, while the program functionality is moved to the associated FLRSs. A program with a simpler structure is easier to be synthesized and to be tested for fulfilling the real-time features. The FLRSs have to be found such that the program fulfills the functional requirements.

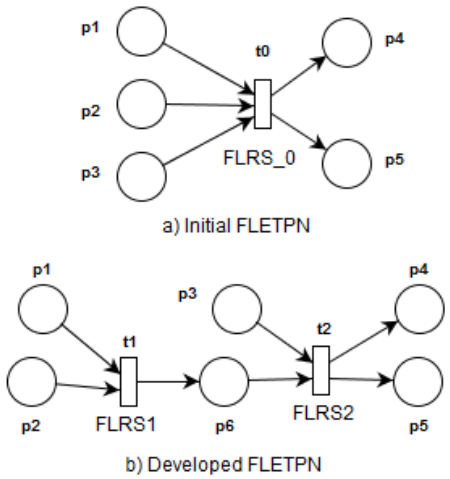

Fig. 5. Reducing the number of a transition's input places.

The FLETPN model should be free of conflicts. If conflicts exist in the ETPN model, the executor grants the execution to the transitions with shorter delays, and if multiple transitions with the same delays are simultaneously enabled, the transitions with lower indexes are chosen for fire. Even if an ETPN model has conflicts, these can be removed by the appropriate conceiving of the FLRSs using the method shown in Figure 4 and Table I.

According to [8] the reasoning process by using fuzzy PN can be implemented by algorithms involving reachability trees, algebra forms and high level PNs. The current approach concerns the modeling of dynamic control systems implemented by reactive programs. The TPNs describe the program structures, while the FLRSs implement their functionalities.

C. FLRS construction

For practical reasons it is convenient to have transitions with maximum two input places. In this case all the fuzzy logic rules have maximum two premises. If there are requirements to have transitions with more than two input places, each of them can be replaced by two transitions as shown in Figure 5. Consequently, all the FLRSs have maximum two premises, but the number of consequences of a rule is not limited.

Supposing that the control system synthesizer constructed the FLETPN, a remained relevant task for the current method consists of the construction of the fuzzy logic rule sets that are assigned to transitions. The proposed method uses the Genetic Algorithm (GA) to search a FLRS that is capable to control the given plant with a specified competence. The control system fulfills the competence requirements if the assessment of the system behavior exceeds a specified threshold. The control system synthesizer has to provide the set of relevant tests used for system evaluation.

The genome is composed of genes coding (by non-negative integers) the consequences of the all FLRSs and genes coding (by real numbers) the weighting coefficients. Table III shows

TABLE III
Example of a genotype.

$c_{1,1}$	$c_{1,2}$	...	$c_{4,5}$	$c_{5,5}$	w_{11}	w_{21}
000010	010100	...	100100	001100	$2,35$	$-3,28$

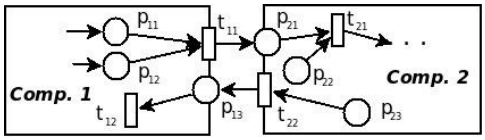

Fig. 6. Example of CPS component diagram.

an example of a genotype for the FLETPN presented in Figure 1. The notations $c_{i,j}(i = 1,\ldots,5; j = 1,\ldots,5)$ represent the pairs of consequences included in a table (e. g. Table II) considered as matrix.

Two kinds of mutation operators were used: one acting on the integer number part and another on the real number part. The synthesizer has to provide the domains of the parameters w_{ij}. The crossover operator splits the genotypes in one point. The selections are performed using the classical performance functions taking into account the plant set points and the constraints.

III. CPS Component Diagram

The design of a control system is based on a set of components that contain discrete event, discrete time or hybrid models. They are included into a component diagram. The models of the current approach are FLETPN.

Fig. 6 shows an example of a CPS component diagram. The two components Comp.1 and Comp.2 are connected through the ports represented on the frontiers. The component ports on the frontiers contain transitions and places. The transitions on the frontier describe outgoing actions (send tokens), and the places receive the tokens.

All the components have input and output ports implementing interfaces. In the given example the component Comp. 1 has the interfaces $Out = \{t_{11}\}$ and $Inp = \{p_{13}\}$. In a well designed component diagram the transitions of a set Out have input places only from the places included in the FLETPN model of the current component, and the places of a set Inp have output transitions only from the current component.

Each component has its own thread of execution. An interface Inp is implemented by an input port and an interface Out by an output port.When a transition of the set Out is executed, the component (output port) sends the corresponding tokens to the components that have in their input interfaces places of the current transition output set via linked component ports. This is denoted by $send(t_i^o, X_{i,out})$ where $X_{i,out}$ corresponds to the tokens (i.e. the variable values of the marking) that have to be sent and included in the transition output places. The destination component executes $receive(Inp, X_i)$ and updates its marking.

The component thread is executed cyclically or when an external event is signaled. The thread is awoke by the input port when a new token arrives or when the clock tic occurs. If the signaled event is tic, the delays of the activated transitions are decreased. If the signaled event is *new token*, the cycle of the thread starts with updating the information of its input place set. The FLETPN marking is updated with the newly received information.

Complex applications can be conceived including components in other components. The links between a component and its included components implement the same protocol outgoing port-ingoing port based on the transition-place connection.The proposed models partition the program structure and functionality at the component level in a compact manner.

IV. FLETPN executor

The executor algorithm of FLETPN is executed with the period of 1 time unit (t.u.) or when an external event is signaled loading an input place with a token. The algorithm updates the places of the input set and determines the transitions that are enabled taking into account the markings of the transition's input place set. If a transition is chosen to be executed, the tokens from its input place set are removed and injected into a temporal marking vector M_t. A time counter $Delay[t_i]$ is loaded with the transition assigned delay if it has any or zero. If the time counter is zero or it reaches the value 0 (after decreasing), the execution of the transition is finished. If a transition belongs to the output set *Out*, its execution is signaled to the linked output place and the corresponding token is loaded.

The counters of all the started transitions are decreased after each sample period.

FLETPN executor algorithm:
Input: ***Pre***, ***Post***, $X, M_0, P, T, D,$ ***FLRS***, Out, Inp;
Initialization: $M = M_0$, *execList* $= empty$;
* reorder the transition set T according to their delays;
repeat
  wait(event);
  if event is tic **then**
    * decrease the Delays of the transitions in *execList*;
  else
    $receive($*Inp*$, X_i)$;
    * update M;
  end if;
  repeat
    for all $t_i \in T$ **do**
      if all $p \in {}^o t_i$, $M(p) \neq \Phi$ **then**
        * move the tokens of ${}^o t_i$ from M to M_t;
        * add t_i to *execList*;
        $Delay[t_i] = d_i$;
      end if;
    end for;
    for all t_i in *execList* **do**
      if ($Delay[t_i]$ is 0) **then**
        * remove t_i from *execList*;
        * calculate and inject the tokens in M for all t_i^o;

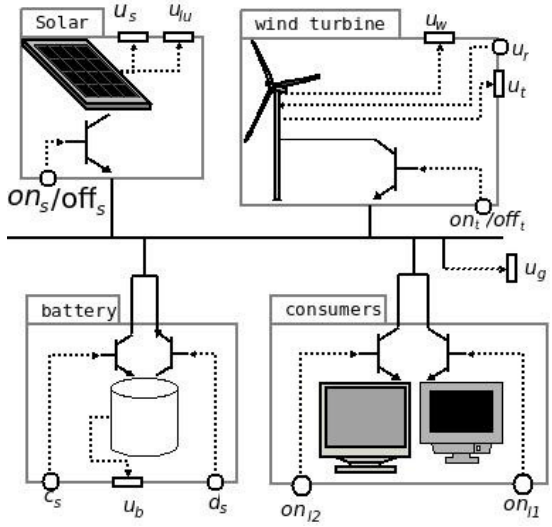

Fig. 7. Microgrid architecture.

* remove the tokens from M_t for all ${}^o t_i$;
end if
if $t_i \in Out$ **then**
$send(Out, X_{i,out})$;
end if
end for
until there is no transition that can be executed;
until the time horizon;
END algorithm;

V. Examples of Application

A. Energy microgrid specifications

The plant represented in Fig. 7 concerns an energy micro grid composed of a solar cell, a wind turbine, a battery and two loads. The plant has to be controlled according to the specification. The control system has to maintain the voltage (u_g) of the main bus between u_m and u_M. The turbine and solar generators asynchronously inject energy into the system. The consumers asynchronously demand the use of the energy as well. When the produced energy exceeds the demands, the surplus has to be discharged on the battery. If the level of the generated energy is lower than the demand, the battery should be used to increase the voltage to guaranty that the bus voltage level remains between the specified limits. The control system is composed of load controller (L-Controller), turbine controller (T-Controller), solar cell controller (S-Controller) and battery controller (B-Controller) as can be seen in Fig. 8.

The following notations are used:

- u_t the turbine output voltage
- u_w the wind force applied to the turbine
- u_n the main bus nominal voltage
- u_g the voltage of the grid main bus
- u_s the solar cell output voltage
- u_{lu} the luminosity on the solar cell
- on_s/off_s control signal to connect or disconnect the solar cell
- on_t/off_t control signal to connect or disconnect the turbine
- d_s control signal to connect the battery to increase the voltage
- c_s control signal to connect the battery to charge it
- u_b the battery level
- on_{l1} control signal to connect the first load
- on_{l2} control signal to connect the second load

The control system requirements are:

repeat
$u_g = read(u_{bus})$;
if $(u_g \geq u_M)$ **then**
* connect the battery to discharge energy;
end if;
if $(u_g \leq u_m)$ **then**
$u_b = read(u_{battery})$;
if $u_b > u_{minim}$ **then**
* connect the battery to increase the voltage;
end if;
end if;
if $(u_m \leq u_g \leq u_M)$ **then**
* disconnect the battery;
end if;
$u_t = read(u_w)$;
if $(u_t < u_n)$ **then**
* stop(turbine);
else
*start(turbine);
end if;
$u_s = read(u_{lu})$;
if $(u_s < u_n)$ **then**
* stop(solarCell);
else
* start(solarCell);
end if
wait(1 t.u.);
$u_g = read(u_{bus})$;
if $(u_g < u_m)$ **then**
* stop(load 2);
else
*allow(load 2);
end if;
wait(1 t.u.);
$u_g = read(u_{bus})$;
if $(u_g < u_m)$ **then**
* stop(load 1);
else
*allow(load 1);
end if;
wait(1 t.u.);
until (the time horizon);

B. Plant model

The loads are considered pure resistances. The photo voltaic solar cells produce energy proportionally with the environment luminosity. The most complex is the wind turbine model.

The discretization (by approximation) of the wind turbine model constructed of differential equations [14] leads to:

$$X_1(k+1) = A_1 \cdot X_1(k) + B_1 \cdot u_r(k) \tag{12}$$

$$Y_1(k+1) = C_1 \cdot X_1(k) \tag{13}$$

$$U(k) = u_w(k) \cdot \cos(Y_1(k)) \tag{14}$$

$$X_2(k+1) = A_2 \cdot X_2(k) + B_2 \cdot U(k) \tag{15}$$

$$u_t(k+1) = C_2 \cdot X_2(k) \tag{16}$$

The notations are:

- X_1 and X_2 are 3 dimensional state vectors,
- Y_1 is a mono dimensional output vector,
- u_r is the input control signal used for the positioning of the turbine,
- U is a combination of the output Y_1 and the wind force u_w.
- u_t is the turbine output voltage.

The corresponding matrix are:

$$A_1 = \begin{pmatrix} 0.050558 & 2.6979e-10 & 5.9355e-05 \\ 0.029825 & 1 & 0.77505 \\ 0.034992 & -4.1333e-06 & 0.58666 \end{pmatrix}$$

$$B_1 = \begin{pmatrix} 0.052746 \\ 0.0020924 \\ 0.0049453 \end{pmatrix}$$

$$C_1 = \begin{pmatrix} 0 & 1 & 0 \end{pmatrix}$$

$$A_2 = \begin{pmatrix} 0.0021802 & -5.8872e-08 & 0.0062 \\ 0.029825 & 1 & 0.77505 \\ 0.034992 & -4.1333e-06 & 0.58666 \end{pmatrix}$$

$$B_2 = \begin{pmatrix} 0.0019624 \\ 0.010389 \\ 0.18356 \end{pmatrix}$$

$$C_2 = \begin{pmatrix} 300 & 0 & 0 \end{pmatrix}$$

The discretization of the continuous model of the wind turbine was performed for the aim of reducing the calculus volume involved by the GA.

C. Control system architecture

The control system can be conceived as:

- independent controllers
- coordinated controllers or
- cooperative controllers.

Figure 8 shows the proposed component diagram for the control system. The component T-Controller solves the control problem related to the turbine, the component S-Controller concerns the solar cell and the component B-Controller connects or disconnects the battery. The L-Controller has the role to receive the user demands to connect *load 1* and *load 2*. The L-Controller decides to perform these actions taking into account the current energy produced and accumulated. The L-Controller can work independently, to coordinate the other controllers, or to cooperate with them according to the specifications.

D. Wind turbine control component

Figure 9 shows the FLETPN model synthesized for the turbine control. The zero delays of the transitions are not represented on the FLETPN for simplicity reason. The coefficients of the FLETPN are given in Table IV. Some transitions have associated FLRSs as they are mentioned in Tables V, VI, VII, VIII and IX. Other transitions perform simple transformations or store operations.

The T-Controller achieves a kind of fuzzy logic PID (Proportional Integrative Derivative) control function. The place p_0 is loaded with a token corresponding to u_n (nominal voltage, i.e. set point) and the place p_1 with a token corresponding to u_t (turbine output voltage; when it works, it is equally to the main bus voltage). The transition t_0 calculates (using the FLRS assigned to the current transition) the error $e(k) = u_n(k) - u_t(k)$. The resulted tokens are injected into the places

p_2 and p_3. The transition t_1 injects tokens corresponding to the variable e(k-1) into the places p_4 and p_8 after 1 t.u. (time unit) delay. Similar injection performs the transition t_2 for the value e(k-2) into the place p_5. The transition t_3 calculates if the wind turbine can work properly and inject into the output places p_7 the token on_t. The transition t_4 calculates a function of the type $f(w_1e(k), w_2e(k-1))$ using the $FLRS_4$ presented in the Table V. A similar function is performed by the transition t_5 using the $FLRS_5$ given in Table VI. The place p_{10} contains the current variation $\Delta u(k)$ of the control signal. The transition t_6 calculates the current control signal, using the values $w_5\Delta u(k)$ and $w_6u(k-1)$, and injects it into the places p_{13} and p_{14}. The transition t_7 sends the control signal u_r to the turbine. The transition t_8 reloads the place p_{12} with the previous value of the control signal and permits a new execution loading the place p_{11}.

The input place p_{19} is loaded with the wind force u_w (speed) value. If the u_w is lower than a specified value, the turbine is stopped by injecting a token off_t into the place p_{18}. This allows the execution of the transition t_9. If the turbine was stopped (p_{16} has a token) and the wind speed is according to specification, the transition t_{11} allows the turbine to start injecting a token into the place p_{15}. The $FLRS_{11}$ assigned to the transition t_{11} discerns if the wind turbine can work properly injecting a token into the place p_{15} or not and as a consequence it injects a token into the place p_{18}. Table IX contains the $FLRS_{11}$ assigned to transition t_{11}.

E. Load control component

Figure 10 presents the FLETPN model of an independent L-Controller component. This receives in place p_1 as a continuous variable the bus voltage u_g and transforms it into a fuzzy logic value. The L-Controller receives the user's demand d_1 to connect *load 1* as a discrete input $< 0, 0, 0, 0, 1 >$ or disconnect as the value $< 1, 0, 0, 0, 0 >$. The controller uses these two pieces of information to accept or not the demand using the $FLRS_1$ and signals this by the port (transition) t_4 with the values $< 0, 0, 0, 0, 1 >$ or $< 1, 0, 0, 0, 0 >$. The information is passed further to the place p_4. The transition t_2 takes the user demand d_2 to connect or not *load 2*, calculates the controller behavior using the $FLRS_2$ and signals this by the transition t_5.

Figure 11 presents a FLETPN that correspond to a cooperative L-Controller. It added the information on_t and on_s to determine the connection or disconnection of the *load 1* and *load 2*. The L-Controller also sets the reference point u_n for the T-Controller to a better adjustment of the bus voltage u_g. Unlike the previous L-controller, the cooperative controller uses the information $E(k)$ denoting the current power (energy)

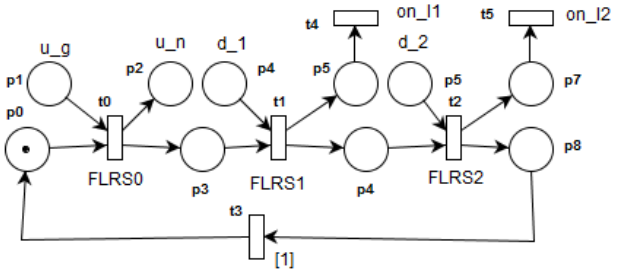

Fig. 10. FLETPN of the independent L-Controller.

introduced into the system. $E(k-1)$ stores the power available at the previous clock tic. The input place p_2 is injected with a token on/off_t signaling the event that the wind turbine is working or not working respectively. The transition t_1 is used to increase or decrease the information about the current power level. Similar function performs the transition t_2 for the solar cell using the token on/off_s for that purpose. The demand for connecting *load 1* or *load 2* is granted according to the current available power and the voltage u_g. The transitions t_5 and t_6 permit or not the connections and modify the power level. The transitions $t_1, t_2, ..., t_6$ have assigned the necessary FLRSs. Table X shows $FLRS_5$ and $FLRS_6$ assigned to transitions t_5 and t_6.

VI. Tests and Results

All the tests were performed by simulations using standard Java language. Figure 12 presents the test results for the turbine generator. The weighting coefficients $w_i, i = 1, 2, \cdots, 6$ and the FLRSs are calculated using a genetic algorithm. The genome contains the rows of the FLRSs and the weighting coefficients. The fitness function assesses the response to perturbations as shown in Figure 12. The searching process was stopped when a competent solution was obtained, that is the control performances exceed the specified values. The FLRSs obtained by GA are given in Table V, Table VI, ... and Table IX.

Adding the empty set Φ to the fuzzy logic set permits the deterministic selection of the execution on the different paths as can be seen in the FLETPN presented in Figure 9. The conflict between the transitions t_8 and t_9 was solved by the rule *execute the earliest possible transition*. The conflict between the transitions t_9 and t_{10} is solved by transition t_{11} injecting tokens into the places p_{15} or p_{18} according to the token introduced into the input place p_{19}.

In Figure 11 the conflict between the transitions t_3 and t_4 is solved by the rule *execute the transition with the lowest index*. The conflict between t_5 and t_6 is solved by the previous selection.

VII. Conclusions

The proposed method can be easily used to conceive the hybrid control system for different kinds of hybrid plants. It needs the use of knowledge from the same field combining the Petri nets capabilities to implement the discrete event systems

requirements with fuzzy logic models suitable for continuous systems.

There are some benefits of the proposed method: Constructing the tokens with the membership degrees of a variable to all the fuzzy set and assigning to any transition an entire fuzzy rule set leads to a smaller Petri net, and this increases the capability of the model to be used in more complex applications.

The FLETPN models are capable to include the discrete event part and discrete time part. The distinct tokens injected into the corresponding discrete event type places and continuous type places make possible to comprise in the same model the discrete event and discrete time behavior. The FLETPN models can describe the concurrent, synchronous and asynchronous behavior. The reactions to asynchronous events are taken into account when the event occur. These models can easily be implemented, and if a TPN executor is used, the need of a real-time operating system can be avoided.

The structure of the model can be verified using the TPN analyses methods. The proposed method can be used for the verification of the discrete event behavior.

The verification (i. e. the performance evaluation) of the continuous side behavior can be performed by simulation. The weighting coefficients added to input arcs increase the continuous control capabilities enhancing the fuzzy logic rules with the possibility to amplify the relative significance of some variables.

***Abstract*—Decentralized Critical infrastructure management systems will play a key role in reducing costs and improving the quality of service of industrial processes, such as electricity production. The recent malwares (e.g. Stuxnet) revealed several vulnerabilities in today's Distributed Control Systems (DCS), but most importantly they highlighted the lack of an efficient scientific approach to conduct experiments that measure the impact of cyber threats on both the physical and the cyber parts of Networked Critical Infrastructures (NCIs). The study of those complex systems, either physical or cyber, could be carried out by experimenting with real systems, software simulators or emulators. Experimentation with production systems suffers from the inability to control the experiment environment. On the other hand the development of a dedicated experimentation infrastructure with real components is often economically prohibitive and disruptive experiments on top of it could be a risk to safety. In this paper, we focus on the implementation of a Cyber-Physical (CP) testbed which includes physical equipment. We illustrate and the cyber security issues on the communication channel between the Critical Infrastructures(CIs), such as a power grid, a nuclear plant and the energy market. We simulate the power grid network (including nuclear plant), but we emulate the Information and Communications Technology (ICT) part which is the focus of our work. Within this context we assume that we are able to implement scenarios, which produce consequences on the normal operation of the power power grid and the financial area.**

I. Introduction

EUROPEAN security, both physical and economic, rests upon a foundation of highly interdependent critical infrastructures. A critical infrastructure [1] refers to an asset, system or part thereof located in Member States that is essential for the maintenance of vital societal functions, such as health, safety, security, economic or social well-being of people. The disruption or destruction of such infrastructures would have a significant impact on a Member State as a result of the failure to maintain these functions. The damage to a critical infrastructure, its destruction or disruption by natural disasters, terrorism, criminal activity or malicious behaviour, may have a significant negative impact on the security of the EU and the well-being of its citizens [2].

Given the lack of practical experience with massive infrastructure failures, modeling a multi-CI testbed is highly crucial. Interdependencies between CIs are similarly highlighted in numerous technical publications [3][4][19][20]. The underlying technical theme is that modeling and designing of critical infrastructures must take a holistic, systemic perspective and incorporate interdependencies. In this paper, we examine the complexity of the infrastructure interdependency and highlight the relevant cyber security impact.

In the past, CIs were isolated environments and used proprietary hardware and protocols, thus limiting the threats that could affect them. Nowadays, CIs or more accurately Distributed Control Systems (DCS) are exposed to significant cyber-threats; a fact that has been highlighted by many studies on the security of Supervisory Control And Data Acquisition (SCADA) systems [5], [6], [7].

In this paper, we explore the complexity of the infrastructure interdependency security issues and we design a testbed (Fig. 1), which combines:

- simulated physical infrastructures (e.g. power grid and nuclear plant),
- simulated power stock market,
- emulated ICT controlling infrastructure, and
- real physical equipments, i.e. Programmable Logical Controllers (PLCs).

Based on this implementation, the Network & Information Security Laboratory (NIS Lab) created a cyber-physical system/prototype in order to underline and motivate the need for modeling multiple interconnected critical infrastructures, since the behavior of an interconnected one can be propagated. We discuss the implementation of the testbed and illustrate a possible attack scenario, which shows that network anomalies can produce financial and power disturbances.

The paper is structured as follows. Our study is presented in the context of other related approaches in Section II. In section III we show in detail our experimentation infrastructure and its elements. The experimental scenarios and setup are presented in Section IV. Conclusions are presented in Section V.

II. Related Work

Recent events such as Stuxnet [8], Duqu [9] and Flame [10], caused the scientific community to address cyber security concerns regarding CP systems. In this section we provide a brief presentation of the most relevant approaches addressing

978-83-60810-90-3/$25.00

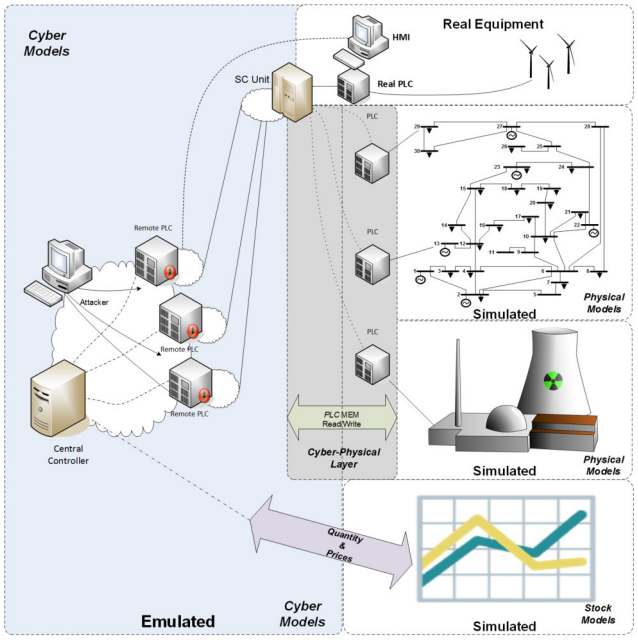

Fig. 1: Experimentation framework architectural overview

the resilience of cyber physical systems, which take into consideration both the communication infrastructure and the control of physical processes.

Nai Fovino *et al.* [18] proposed an experimental platform to study the effects of cyber attacks against NICS. In their paper the authors described several attack scenarios, including DoS attacks and worm infections that send Modbus packets to control hardware. Although the authors provided a wide range of countermeasures, they did not however identify communication parameters that affect the outcome of the attacks. They took into consideration the skills and efforts required by the attacker, as was the case of Stuxnet, where developers also had knowledge of the PLC code, OS and hardware details.

An approach where a cyber physical system is tested for cyber events, has been proposed by Hahn *et al.* [12]. They offer a high level overview of testbed functionality, including its control, communication, and physical components along with a mapping of components to research requirements. Additionally, Yardley *et al.* [13] propose that complex cyber-physical systems like the ones found in the smart grid require a combination of methodology, quantification, and testbed environments to drive tool creation to assist in the evaluation of the systems under test. They present an approach to security testing methodology and illustrate the use of testbeds in developing tools for cutting-edge systems. Both papers highlight the issue but they do not integrate additional infrastructures in order to show the interdependency issues.

Finally, a similar experiment has also been documented by Davis, *et al.* [14] that used the PowerWorld server to study the effects of communication delays between the physical process and human operators.

III. Experimentation Framework Overview

The experimentation framework developed in our previous work [16] follows a hybrid approach, where the Emulab-based testbed recreates the control and process network of NICS, including Programmable Logical Controllers (PLCs) and SCADA servers, and a software simulation reproduces the physical processes.. The main two elements of our laboratory are:

- an experimental platform for resilience, security and stability research, called Experimental Platform for Internet Contingencies (EPIC) [11], which supports the security assessment of cyber-physical systems. The EPIC test-bed can efficiently recreate realistic network topologies and conditions (e.g. delay and loss characteristics of Wide Area Network - WAN links) of the Internet infrastructure.
- a physical system simulator, called the Assessment platform for Multiple Interdependent Critical Infrastructures (AMICI)[16], which can simulate in real time critical physical infrastructures, e.g. a power grid, and can interact with the emulated network test-bed.

The architecture of EPIC suggests the use of an emulation testbed based on the Emulab software [11] in order to recreate the cyber part of NCIs, e.g., servers and corporate network, and the use of software simulation (AMICI) for the physical components, e.g., power grid and nuclear plant.

A. The controlling ICT network

The cyber layer is recreated by an emulation testbed that uses the Emulab architecture and software [17] to automatically and dynamically map physical components (e.g. servers, switches) to a virtual topology. In other words, the Emulab software configures the physical topology in a way that it emulates the virtual topology as transparently as possible. This way we gain significant advantages in terms of repeatability, scalability and controllability of our experiments.

Besides the process network, the cyber layer also includes the control logic code, that in the real world is implemented by PLCs. The control code can be run sequentially or in parallel to the physical model. In the sequential case, a *tightly coupled* code (TCC) is used, i.e. code that is running in the same memory space with the model, within the SC unit. In the parallel case, a *loosely coupled* code (LCC) is used, i.e. code that is running in another address space, possibly on another host, within the *R-PLC* unit (Remote PLC). The cyber-physical layer incorporates the PLC memory, seen as a set of registers typical to PLCs, and the communication interfaces that glue together the other two layers.

In Fig. 2, we illustrate the emulated cyber-part of our experimental setup. Each simulation of the physical processes runs at a different host. Moreover, in conjunction with Fig. 1 (i) the simulation of the main power grid is running on the lower right part of the network, (ii) the PLC is connected on the upper right, (iii) the power market on the upper left, and (iv) the nuclear plant on the left lower part. All these simulated infrastructures communicate though the ICT network .

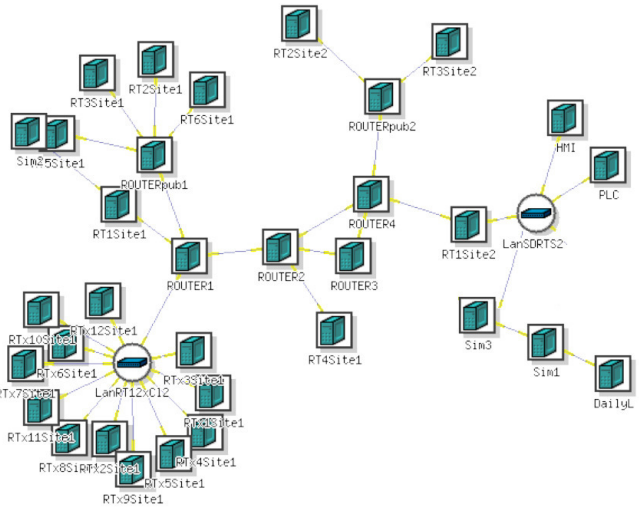

Fig. 2: The EPIC network topology for the specific implementation taken directly from Emulab's web interface.

B. Description of Nuclear Plant

In this section we present our simplified Pressurized Water Reactor (PWR). PWRs constitute the most established and diffuse types of operational Nuclear Power Plants (NPPs), so they have been included in this study to represent the nuclear typology of the generating capacity of the power grid [25].

The proposed reactor model serves as an example to illustrate the concept behind the framework of analysis of cyber-attacks on ICT communicating infrastructure of a power grid including nuclear power plants: it is admittedly simplified in its technical features and strong assumptions are made to keep the focus on the methodological framework.

In a PWR, the energy generated by the fission of atoms heats water, which is pumped under high pressure from the primary circuit to the reactor core. The heated water then flows through a heat exchanger, where it transfers its thermal energy to a secondary circuit, where steam is generated and flows to turbines, which in turn spin an electric generator [26]. The model presented here concentrates on the primary circuit. In the reactor, water, which acts as the moderator and the coolant, passes through the core with upward flow and removes the heat, which the fuel contained in the fuel bars has generated through fission (Fig. 3).

Water enters the bottom of the reactor core at about 275 °C (T_{IN}) is heated and flows upwards through the reactor core at a temperature of about 315 °C (T_{OUT}). Despite the high temperature, water remains liquid due to the high pressure in the primary coolant loop, usually around 155 bar.

Within the hypothesis of a thermal power P_{TH} uniformly distributed along the core, the dynamics of the reactor can be modeled considering the variation of the power generated by the fuel and the power absorbed by the moderator [26]:

$$M_F C_F \frac{dT_F}{dt} = P_{TH} - k\,(T_F - T_M) \tag{1}$$

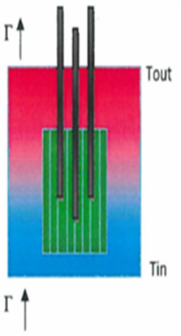

Fig. 3: Simplified model of the core of a PWR. The water flow Γ enters the bottom of the reactor at temperature T_{IN} and is heated to a temperature T_{OUT} while flowing upward through the core.

$$M_M C_M \frac{dT_M}{dt} = (T_F - T_M) - \Gamma C_M\,(T_{OUT} - T_{IN}) \tag{2}$$

$$T_{OUT} = 2T_M - T_{IN} \tag{3}$$

where

- M_F and M_M are respectively, the fuel and moderator masses,
- C_F and C_M are the fuel and moderator thermal coefficients,
- k is the global thermal coefficient, which accounts for the thermal exchange between fuel and water,
- Γ is the moderator flow and it can vary within the range of 104-105 tonn/h, and
- T_F and T_M are the fuel and the moderator temperatures. In particular, T_M is computed as the average between the inflow (T_{IN}) and the outflow (T_{OUT}) temperature of the water.

The equations (1), (2) present energetic balances on fuel and on moderator respectively. On the fuel side (first equation), the change in the produced energy is given by a source term P_{TH}, the produced thermal power, subtracted by the energy exchanged with the moderator. On the moderator side (second equation), the change in the absorbed energy is given by the difference between the energy exchanged and absorbed by the moderator. The equation (3) represents the assumed tie between the inflow and the outflow temperature of the water.

In the model, the demanded power P_{TH} and the inflow temperature T_{IN} of the moderator are the inputs. When an increase of 1kW of power and of 1 °C is given to the input variables, the step response of the system (Fig. 4) evidences that temperature rises by a factor of P/($M_F C_F$) ≈ 0.2. Since power acts mostly on the fuel temperature, the effects on the moderator temperature are negligible (Fig. 4). It is noteworthy that if the power is considered uniformly distributed inside the core, the thermal exchange between fuel and moderator is slow (Fig. 4).

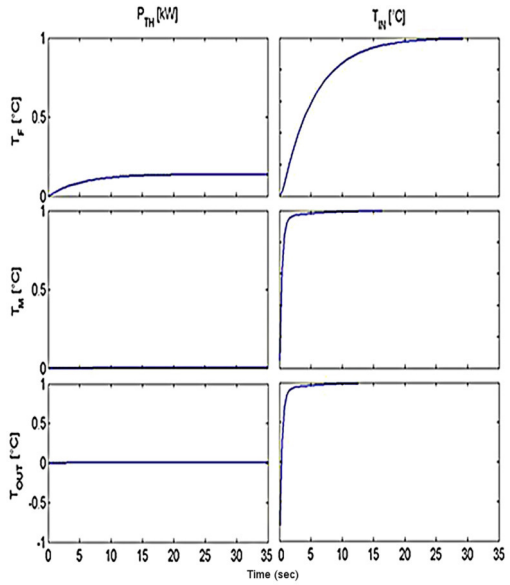

Fig. 4: Step response of the system. Thermal power P_{TH} and inflow temperature T_{IN} have been given respectively a raise of 1 kW and 1 °C.

C. Power market

Since more than one decade, a political change of mind has led to the liberalization of the power markets. Its goal: the creation of an internal European market that achieves security of supply and competitive prices and services for the customers. In this market, a growing variety of enterprises organizes the production, the trading, the marketing, the transmission and the supply of electricity, respecting appropriate regulation.

Producers compete to sell energy at the best possible price. The suppliers which deliver electricity to the final consumers buy the energy on the wholesale market from the producers or the trading companies. Power markets or spot markets offer trading platforms [21][22][23][24] to allow members to exchange information on values and prices and to submit bids for buying and selling power. Therefore a possible interruption between the communication of the power grid and the power market can lead to financial disturbances and even to market/prices manipulation.

In our testbed we have implemented a spot market, which provides automatically the prices on the requested quantity. If the requested energy quantity is not able to be provided by the lowest price energy producer, then the rest is obtained by the next one. For example, if the requested quantity is 100 KW and the lowest price producer is able to provide only 70 KW, the remaining 30 are going to be obtained by the second lowest one.

D. The power grid model

The IEEE electrical grid models [15] are extensively used by the scientific community since they are known to accurately encapsulate the basic characteristics of real infrastructures. As such, AMICI provides a broad range of grid models to experiment with, including the Western System Coordinating Council's (WSCC) 3-machine 9-bus system, and the 30-bus, 39-bus and 118-bus test cases, which represent a portion of the American Electric Power System as of early 1960. These constitute realistic models which are well-established within the power systems community and provide a wide range of power system configurations. An example graphical "bus-view" of the IEEE 30-bus power grid test system is given in Fig. 5. The IEEE 30 Bus Test Case represents a portion of the American Electric Power System (in the Midwestern US). Apart from the connecting buses, it consists of 6 generators and 20 load consuming buses. This is the main IEEE power grid we are going to use for our testbed.

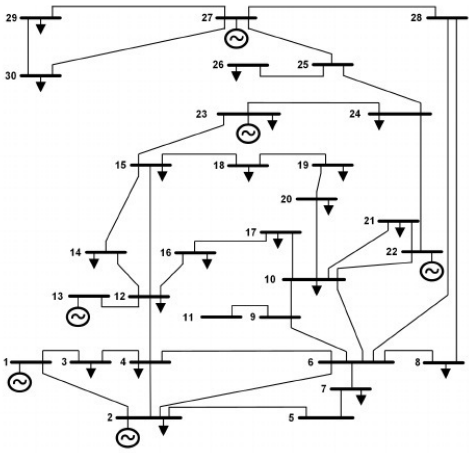

Fig. 5: The IEEE 30-bus test system.

E. Integration into AMICI

We have developed a generic approach to integrate a wide range of IEEE electrical grid models into Simulink and to prepare them for real-time simulation. This way AMICI [16] facilitates the timely integration of other models and eliminates manual, error-prone operations, which are mainly due to the large number of vectors and matrices that must be set-up.

The physical processes are implemented into AMICI by creating the Simulink models via the mathematical functions, but from a technical point of view real-time simulation of IEEE grid models in AMICI is enabled through a combination of two Matlab open-source libraries: MatPower [27] and MatDyn [28]. MatPower is an open-source Matlab package for solving power flow and optimal power flow problems. It is a simulation tool that includes several built-in IEEE test systems, which are already prepared for analysis. Since MatPower only provides static analysis of power systems, it needs to be coupled with MatDyn in order to benefit from its support for dynamic analysis, i.e., real-time simulation.

IV. Description of the Experimental Setup

A. Experimental Setup

The following experimental setup was implemented in the Joint Research Centre's (JRC) EPIC laboratory. The Emulab testbed included nodes with the following configuration: FreeBSD OS 8, Intel Xeon E5606 @2.1GHz and 2GB of RAM.

As shown in Fig. 2 the experimental setup consisted of 2 Routers (Cisco 6503), which have four Gigabit experimental interfaces and one control interface, and 22 hosts:

- one (1) host runs the power grid unit (AMICI model),
- one (1) host runs the nuclear plant (AMICI model),
- two (2) hosts for running the R-PLC units for the interconnection between power grid, nuclear plant and network,
- one (1) host for running the power market unit, and
- the (3) hosts to run the malicious software (attackers).
- the rest of the hosts to produce normal traffic.

The reason to use such a large testbed is to try replicate the attack from various hosts and verify the results. Within the Emulab testbed we emulated packet losses and background traffic (potentially DoS attack) in order to recreate a dynamic and unpredictable environment such as the Internet. For the background traffic we used UDP packets generated with both PathTest [1] and Iperf [2]. We have installed those tools in all the attacker nodes.

Additionally, we adjusted our networks in order to emulate the bandwidth limitations (10Mb/s) not only for the Internet but also for the communication to PLC. The communication between R-PLCs and the power grid model was implemented with a 100Mb/s to provide maximal performances for the interaction between R-PLC units. Finally, we should state that there is a synchronization algorithm between the models execution time and the system clocks ensuring reliable exchange of data.

B. Scenarios

The implemented scenarios are two, the first one affects the nuclear plant and the second one the real PLC, which is connected to the power grid.

1) Attack against a nuclear plant's PLC: In the implemented scenario the attacker interacts with PLCs by sending legitimate Modbus packets. This scenario assumes an attacker is able to access an internal network by bypassing the security of either the control center or substation networks. By doing so, it is possible to compromise the PLC, produce different values, and hide the fact that the plant produces approximately 30MW/h less without having any specific alarm. Since, the additional power is produced by the rest of the power grid, this means that the additional cost is around 793 euros/h, taking into account the average price for 30MW provided by the spot market (section III-C).

In Fig. 6 we see the minimal change of the temperature on the two different stages with normal and compromised PLC. It should be stated that the graph considers a timeframe of 10 hours: every hour the system registers a different level of energy demand and reacts accordingly. Since power acts mostly on the fuel temperature T_{fuel}, the effects on the moderator temperature T_m are negligible. When the system experiences a constant increase in the power demand, it reacts accordingly by varying the fuel temperature T_{fuel2} and the moderator temperature T_{m2}.

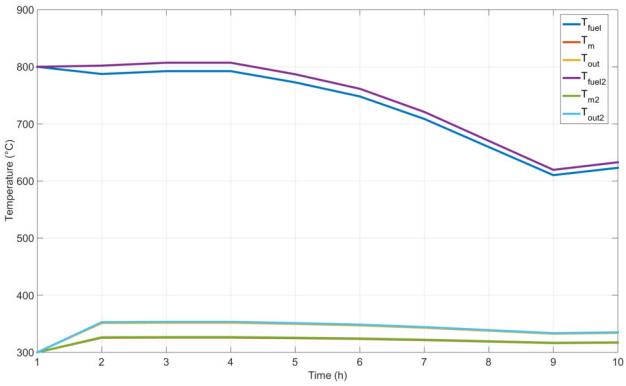

Fig. 6: Behavior of the system. The dynamics of the reactor is described by three quantities: the temperature of the fuel, T_{fuel}, the temperature of the moderator, T_m, and the temperature of the outflow water, T_{out}, and it is represented in two different load demand configurations (T_{fuel}, T_m, T_{out}) and (T_{fuel2}, T_{m2}, T_{out2}). Tm is computed as the average between the inflow (T_{in}) and the outflow temperature (T_{out}) of the moderator.

2) Attack against a generator's PLC: The DDoS attacks were implemented in different bandwidths up to 100Mbit/s, but we minimize our attacks till 20Mbit/s in order to be more realistic. We did not target the attack against a specific equipment because then the attack would be "extremely" successful. We aimed to minimize the network bandwidth between the physical equipment and the power market. Therefore there may be partial loss of communication between those entities.

In this scenario we have a dedicated router connecting the main elements. The router is not reachable through the Internet, but is used to pass communication for other services, such as web services, etc . This means that a DDoS attack cannot be aimed directly at the PLC, but by attacking a specific other service the network bandwidth is going to be limited. When the DDoS attack takes place, additional energy is needed by the consumers of the grid. So following the power market auction procedure, the producers place their bid and the power market decides on who has the best offer. During the scenario the needed load is constant 100MW split over various consumers. Moreover, the real PLC is connected to various simulated generators (each time to a different one) in order to identify any deviations based on the power grid topology.

The parameters we considered for the following experiments are packet losses and background traffic. For packet losses

[1]PathTest, Free Network Capacity Test tool, 2015
[2]Iperf: The TCP/UDP Bandwidth Measurement Tool, 2015

we used 3 rates: 0%, 10% and 20%. Finally, for the attack's background traffic we used: 5Mb/s, 10Mb/s and 20Mb/s. For each configuration setting, representing a combination of packet loss rate and background traffic we executed a separate experiment.

Within this context we measured a maximal success rate of 77% and a minimal success rate of 28%. The results show that even for 15% packet losses and 20 Mb/s the attack success rate is not 100%. More specifically, this means that from 100 attempts, an average of less than 50 will fail to produce some financial gain for the attacker or loss for the consumer. It should not come as a surprise that we measured a higher success rate for a larger loss rate. An explanation for this behavior is that the reduced number of packets does not assist the power market to verify that the offers need confirmation. These results are depicted in Tab. I. The cost is calculated by taking into account the success rate and the average price provided by the spot market for 100 MW.

TABLE I: Attack success rate and additional cost

DDoS success rate				
2.5Mb/s traffic	**5Mb/s traffic**	**10Mb/s traffic**	**Packet loss(%)**	**max Cost (euros/h)**
28%	32%	60%	0%	1586.58
29%	35%	68%	10%	1798.12
28%	37%	77%	20%	2036.11

V. Conclusions and further research

Cyber-physical systems are engineered systems that are built from, and depend upon, the seamless integration of computational algorithms and physical components. In this paper we present the implementation of a cyber-physical testbed including multiple Critical Infrastructures (CIs):

- two simulated interconnected infrastructures, power grid and nuclear plant,
- a simulated power market for providing the cost for the provided energy,
- a real PLC which is interconnected with a specific bus of the power network,
- an emulated cyber network which interconnects and controls all the aforementioned elements

To the best of our knowledge, this is the first time that those elements were presented/interconnected in a prototype and provides a step forward towards understanding the cyber security vulnerabilities of the current cyber-physical systems. In this paper we have analyzed the effects of network parameters on coordinated attacks and we show that they could be significants.

Based on this implementation, more advanced experiments will be created at the Network & Information Security Laboratory (NIS Lab) in order to show the effect of cyber-attacks against real infrastructure including the actions of real human actors (e.g. human operators) in the cyber-physical testing/simulation process. Moreover, we plan to propose and implement a set of countermeasures to tackle and mitigate the attacks, based on the exchanging signals and their statistical analysis for detecting anomalies [29][30].

9th International Symposium on Multimedia Applications and Processing

SOFTWARE Engineering Department, Faculty of Automation, Computers and Electronics, University of Craiova, Romania "Multimedia Applications Development" Research Centre

Background and Goals

Multimedia information has become ubiquitous on the web, creating new challenges for indexing, access, search and retrieval. Recent advances in pervasive computers, networks, telecommunications, and information technology, along with the proliferation of multimedia mobile devices—such as laptops, iPods, personal digital assistants (PDA), and cellular telephones—have stimulated the development of intelligent pervasive multimedia applications. These key technologies are creating a multimedia revolution that will have significant impact across a wide spectrum of consumer, business, healthcare, educational and governmental domains. Yet many challenges remain, especially when it comes to efficiently indexing, mining, querying, searching, retrieving, displaying and interacting with multimedia data.

The Multimedia—Processing and Applications 2016 (MMAP 2016) Symposium addresses several themes related to theory and practice within multimedia domain. The enormous interest in multimedia from many activity areas (medicine, entertainment, education) led researchers and industry to make a continuous effort to create new, innovative multimedia algorithms and applications.

As a result the conference goal is to bring together researchers, engineers, developers and practitioners in order to communicate their newest and original contributions. The key objective of the MMAP conference is to gather results from academia and industry partners working in all subfields of multimedia: content design, development, authoring and evaluation, systems/tools oriented research and development. We are also interested in looking at service architectures, protocols, and standards for multimedia communications—including middleware—along with the related security issues, such as secure multimedia information sharing. Finally, we encourage submissions describing work on novel applications that exploit the unique set of advantages offered by multimedia computing techniques, including home-networked entertainment and games. However, innovative contributions that don't exactly fit into these areas will also be considered because they might be of benefit to conference attendees.

Call for Papers

MMAP 2016 is a major forum for researchers and practitioners from academia, industry, and government to present, discuss, and exchange ideas that address real-world problems with real-world solutions.

The MMAP 2016 Symposium welcomes submissions of original papers concerning all aspects of multimedia domain ranging from concepts and theoretical developments to advanced technologies and innovative applications. MMAP 2016 invites original previously unpublished contributions that are not submitted concurrently to a journal or another conference. Papers acceptance and publication will be judged based on their relevance to the symposium theme, clarity of presentation, originality and accuracy of results and proposed solutions.

Topics

- Audio, Image and Video Processing
- Animation, Virtual Reality, 3D and Stereo Imaging
- Big Data Science and Multimedia Systems
- Cloud Computing and Multimedia Applications
- Machine Learning, Data Mining, Information Retrieval in Multimedia Applications
- Multimedia File Systems and Databases: Indexing, Recognition and Retrieval
- Multimedia in Internet and Web Based Systems
- E-Learning, E-Commerce and E-Society Applications
- Human Computer Interaction and Interfaces in Multimedia Applications
- Multimedia in Medical Applications
- Entertainment and games
- Security in Multimedia Applications: Authentication and Watermarking
- Distributed Multimedia Systems
- Network and Operating System Support for Multimedia
- Mobile Network Architecture
- Intelligent Multimedia Network Applications
- Future Trends in Computing System Technologies and Applications

Best Paper Award

A best paper award will be made for work of high quality presented at the MMAP Symposium. The technical committee in conjunction with the organizing/steering committee will decide on the qualifying papers. Award comprises a certificate for the authors and will be announced on time of conference.

STEERING COMMITTEE

- **Amy Neustein, Boston University,** USA, Editor of Speech Technology

***Abstract*—In this paper the problem of segmentation of volumetric medical images is considered. The fast and effective segmentation is obtained by applying the proposed approach which combines the idea of supervoxels and the Fuzzy C-Means algorithm. In particular, Fuzzy C-Means is used to cluster supervoxels produced by the fast 3D region growing. Additional acceleration of the method is achieved with the support of graphical processor (GPU). The detailed description of the proposed approach is given. The results of applying the method to volumetric CT and MRI brain images and CT images of various phantoms are presented, analysed and discussed. The issues related to accuracy of the method, memory workload and the running time are also considered.**

I. Introduction

ONE of the main challenges of recent medical image processing is the development of 3D image segmentation algorithms. These algorithms should be fast, efficient and accurate. Additionally, they should be easy to use and thus diminish the amount of user interaction required to extract the region of interest.

Although the problem of 3D image segmentation have been widely considered and numerous dedicated segmentation approaches have been proposed (e.g. [1], [2], [3]), it is still far from the satisfactory solution. This is caused mainly by the constant increase of the resolution of volumetric images acquired by computed tomography (CT) and magnetic resonance imaging (MRI) scanners. This manifests itself both, by the increase of the spatial resolution of single slices as well as the number of slices included into a scan. This in turn translates into the significant increase of the time and the memory workload required to perform segmentation of volumetric medical data.

Because of these reasons the existing approaches to image segmentation often cannot be directly used in everyday clinical routine. Therefore, recently a lot of effort have been put into the optimization and adaptation of popular segmentation approaches to fast and efficient processing of high resolution 3D medical images. This problem is also considered in this paper where Fuzzy C-Means (FCM) algorithm [4], [5] is adapted to segmentation of three dimensional images of brain. This is obtained by processing so called supervoxels (i.e. blocks of connected voxels of similar intensity) instead of single voxels. In particular, the input image is firstly divided into a number of supervoxels which are next clustered using FCM approach. This kind of processing significantly reduces the memory workload required to perform image segmentation.

It should be also mentioned, that supervoxels used in this paper extend the idea of superpixels, which has been known for few last years. However, the existing approaches to image division into blocks of pixels of similar intensity (e.g. watersheds [6], mean-shift [7], SLIC superpixels [8], Turbopixels [9] or FH superpixels [10]) are mainly dedicated to 2D images and their extension into the third dimension is not explicit or significantly increases time and memory workload and thus reduces benefit obtained due to processing blocks of pixels instead of single pixels. The method incorporated in this paper for creation of supervoxels is simple and straightforward. It is based on the fast and efficient region growing and thus can be directly adapted to three dimensional images [11].

Additionally, the graphical processor (GPU) support is also proposed to diminish the running time of both image division into supervoxels and FCM segmentation. What is more, the proposed approach reduces a user interaction to minimum, since only indication of one point is required to select the region of interest.

The following part of this paper is organised as follows. Firstly, in Section II the proposed approach is described in details. This is followed in Section III by the presentation and discussion of the results provided by the introduced method. These include both: the test performed on the CT and MRI brain scans, as well as the tests performed on various phantoms. Finally, Section IV concludes the paper.

II. The proposed approach

A. Building supervoxels in the image space

The main idea behind the introduced approach is to use Fuzzy C-Means algorithm to cluster supervoxels produced by the fast region growing [11], [12]. The supervoxels divide an image into blocks of similar intensity. Each of the supervoxels is built starting from a randomly selected seed voxel still not assigned to any region. The growing is performed with regard to the allowable difference in pixel intensities ΔI_{IMAX} and the maximum size V_{MAX} limiting the supervoxel size.

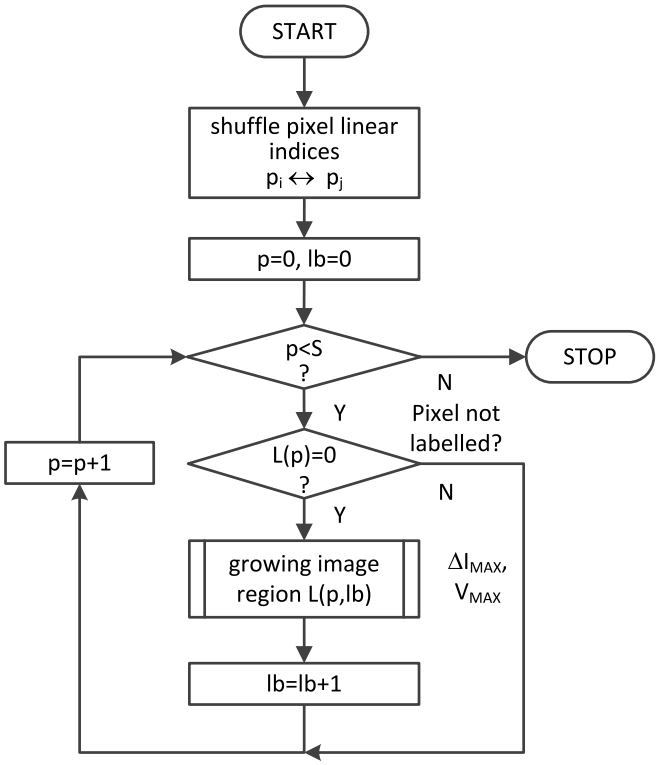

Fig. 1. Algorithm creating the label image L of three dimensional regions from the input intensity image I, L(p) - the label assigned to the voxel p ∈ [0,S), lb - the currently used label number.

The algorithm of image division into supervoxels shown in Figure 1 initially shuffles the voxel linear indices p of the input image I in the range $[0, S)$, where S is the number of voxels in the image. It speeds up the selection of unlabelled seeds. The indices randomly swapped in pairs can later be sequentially searched providing random selection of region seeds at the pixels which remain unlabelled. The procedure of growing image region around the seed p is shown in the Algorithm 1. It uses the queue Q_S of the next seed pixels and the queue of seed candidates Q_C. The queue Q_S is initially loaded with the primary seed pixel p, selected as shown in Figure 1.

For each pixel from Q_S the queue Q_C is created from its nearest 6 neighbours, assuming that their intensities fit in the range $I(p) \mp \Delta I$. Labelling the Q_C voxels increases the cumulated region volume V_R, explicitly limited to the value V_{MAX}. Exceeding volume limit V_{MAX} and empty voxel queue Q_S stops the region labelling process. Supervoxels are assigned label numbers as consecutive non negative integers. The supervoxel intensities are computed after the labelling process as the means of all original voxel intensities in the region.

    end if
  end foreach
  $Q_S \leftarrow Q_C$
end while

The results of image division into supervoxels are shown in Figure 2, where different colours represent different supervoxels. In particular, Figure 2a presents a sample CT brain slice, while the remaining subfigures show the corresponding slice after CT volume division into supervoxels of the increasing size V_{MAX}. All the results were obtained for the constant allowable difference in voxels intensity ΔI_{MAX} equal to 20. Due to the limited number of colours, they repeat for different supervoxels.

B. Fuzzy C-means specific solution

The segmentation of CT or MRI images with Fuzzy C-means (FCM) method [4] allows to assign any voxel with the intensity v_i, $i \in [1, N_V)]$ to a certain post-segmentation class (region) with the membership degree u_{ij}, $j \in [1, N_C)]$. The final deterministic assignment selects the class of the highest membership degree (probability) for each voxel v_i. FCM segmentation can be understood as an optimisation method minimizing the objective function G_m given in Equation (1).

$$G_m = \sum_{i=1}^{N_V} \sum_{j=1}^{N_C} u_{ij}^m \|v_i - c_j\|^2, \tag{1}$$

where $m > 1$, N_V is the image vector size, N_C is the given number of clusters (regions) of different intensities, u_{ij} is the membership degree of the voxel v_i to the region j, c_j denotes the intensity of j-th cluster centre and $\|\cdot\|$ represents the distance between the voxel v_i and the cluster centre c_j.

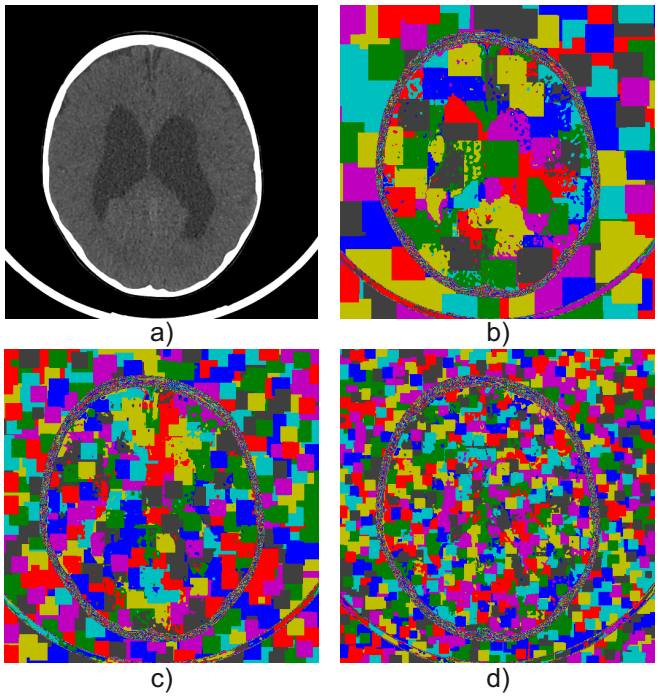

Fig. 2. The result of image division into supervoxels shown on a sample CT brain slice; a) original slice; b) ΔI_{MAX} = 20, V_{MAX} = 5000; c) ΔI_{MAX} = 20, V_{MAX} = 10000; d) ΔI_{MAX} = 20, V_{MAX} = 100000.

The execution of the FCM algorithm relays on the interactive correction of the class centres c_j based on the memberships u_{ij}. Next iteration class centres imply further modifications of u_{ij} until stopping u_{ij} changes or achieving the limit of iterations. Assuming the array of class centres $C = [c_j]$, $U = [u_{ij}]$ - the array of membership degrees and $m = 2$ the following computations are applied iteratively:

$$c_j^{(k)} = \frac{\sum_{i=1}^{N_V} u_{ij}^2 v_i}{\sum_{i=1}^{N_V} u_{ij}^2}, \tag{2}$$

$$u_{ij}^{(k)} = \left(\sum_{k=1}^{N_C} \frac{\|v_i - c_j\|^2}{\|v_i - c_k\|^2} \right)^{-1}, \tag{3}$$

The iteration stops when $\|U^{(k)} - U^{(k-1)}\|_\infty < e_{MAX}$. The number of intensity classes N_C must be defined a priori.

In the case of 3D CT or MRI images including tens of millions of voxels the FCM clustering process may be unacceptable slow. Therefore the authors proposed its acceleration in two ways:

- by using smaller number of supervoxels,
- by applying parallel computations with GPU.

The pseudocede of FCM algorithm with CUDA GPU computing [13], [14] is presented in Algorithm 2. The command *par foreach* built inside means a *for* loop executed in parallel by GPU processors. Capital letter symbols in the code refer to host data buffers, bold font of capital letters denotes arrays

Algorithm 2 FCM segmentation algorithm using GPU parallel computing. N_V –the number of supervoxels, N_B –the number of GPU memory blocks, N_t –the number of GPU threads per block, N_C –the number of classes, b –the current block number, t –the thread number in a block, sync() –the thread synchronization.

allocated in the GPU memory, double stroked font symbols represent GPU shared memory arrays.

The algorithm input data are: the supervoxel vector image $V[N_V]$, the assumed number of intensity classes N_C, the norm e_{MAX} of maximum acceptable error and k_{MAX} – the maximum number of iterations for Equation (2) and Equation (3). The output data consists of the host vector $C[N_C]$ of output class centres and the host array of each supervoxel membership degree $U[N_V \times N_C]$. The $\mathbf{U}$ array is at first allocated in the graphic card memory and randomly initialized in the probability range of $[0, 1]$. The GPU memory also includes local temporal arrays $\mathbf{P}$ and $\mathbf{Q}$ to store component parts of the numerator and denominator in Equation (2) corresponding to N_B blocks, each of the size $N_t = 256$ GPU threads.

The kernel function #1 for each thread computes the monomials in the numerator of Equation (2) and copies them to the GPU shared memory $\mathbb{S}$ to later evaluate partial sums $\mathbf{P}$ and $\mathbf{Q}$ by the process of reduction.

The kernel function #2 adds the partial sums and computes for each thread the values c_j given in Equation (2).

The kernel function #3 completely fulfils the formula in Equation (3), because it sums the relatively small number N_C of intensity classes.

The segmentation error e in a current computing cycle is evaluated as the maximum distance norm of supervoxel membership degrees in two successive iterations. The error value is copied to the host memory to make the decision of stopping iterations.

The array of membership degrees is allocated in the GPU memory in two copies $\mathbf{U}$ and $\mathbf{U\_}$, which addresses are swapped instead of copying data between $\mathbf{U}$ and $\mathbf{U\_}$ in every iteration cycle (Algorithm 2, line 8).

The FCM output array U includes N_C column images of the degrees of membership to a particular class. The class of the highest membership in each row of U is assigned to the output vector of intensity supervoxel classes as in Equation (4).

$$V(i) = \max_j(U(i,j)),\ i \in [0, N_V),\ j \in [0, N_C). \quad (4)$$

This output vector image $V[N_V]$ is then reshaped to the original matrix form $I[Y \times X \times Z]$ after its reverse mapping from supervoxels to voxels. In the image I of N_C intensity classes (labels) only a single region is identified, which belongs to a certain class determined by the voxel marker that was selected interactively. The identification can be fulfilled by the flood fill spatial expansion covering the whole region around the marked voxel.

The complete algorithm sequence of brain image segmentation starts with GPU averaging lowpass filter to reduce data noise coming from the CT or MRI acquisition systems. The noise is gained in particular when setting low doses of radiation during brain examinations in children. The filter fulfils the formula given in Equation (5).

$$J(x,y,z) = \frac{1}{UVW} \sum_{u=-\frac{U}{2}}^{\frac{U}{2}} \sum_{v=-\frac{V}{2}}^{\frac{V}{2}} \sum_{w=-\frac{W}{2}}^{\frac{W}{2}} I(x+u, y+v, z+w), \quad (5)$$

where $[V \times U \times W]$ – the cube of image data averaging with the odd numbers U, V, W. The segmentation is finalized with the operation of morphological opening (Equation (6)).

$$J_B = (I_B \ominus S(R_X, R_Y, R_Z)) \oplus S(R_X, R_Y, R_Z), \quad (6)$$

where $S(R_X, R_Y, R_Z)$ denotes an ellipsoidal structuring element with the radii R_X, R_Y, R_Z in the particular space directions, I_B and J_B are the input and output binary images of a selected region in the original brain image. The ellipsoidal structuring element S represents an ellipsoid mask mapped into the discrete space of image voxels with the radii R_X, R_Y, R_Z respectively in X, Y, Z space directions. Using the ellipsoid instead of the ball shape enables mapping different image resolutions in space directions into the voxel space (in particular, the spacing between slices). Post processing morphological operations allow controlled smoothing of the borders in the extracted brain region.

III. Results

A. Tests on brain images

The results of applying the proposed segmentation approach to sample volumetric CT and MRI brain images are shown in Figures 3 and 4 respectively. In both figures the top panel shows the original brain slices with the region of interest indicated by the green square marker. In the middle panel the corresponding segmentation results overlaid on the input slice are presented. Finally, the segmentation results are visualised in 3D in the bottom panel. In both figures, cases are numbered from the left to the right. In the case of CT images the image division into supervoxels was performed for the maximal volume of supervoxel equal $V_{MAX} = 7500$ and maximal intensity difference $\Delta I_{MAX} = 40$. For FCM segmentation the number of classes was set to $N_C = 6$, while maximal number of iterations k_{MAX} was set to 400 (with $e_{MAX} = 0.001$). In the case of MRI images image division into supervoxels was performed for $V_{MAX} = 5000$ and $\Delta I_{MAX} = 40$. The number of classes N_C ranged from 8 (for case 1) to 6 (for the remaining cases). As previously, the maximal number of iterations k_{MAX} was set to 400 (with $e_{MAX} = 0.001$). In both cases the parameters were tuned manually, to obtain the subjectively best results. Prior to segmentation all images were subjected to preprocessing (Gaussian filtration).

The time and memory workload required to perform image segmentation in the considered CT and MRI datasets is summarised in Table I and Table II respectively. In both tables the first column indicates the case ID. This is followed by image resolution given in the second column. The third

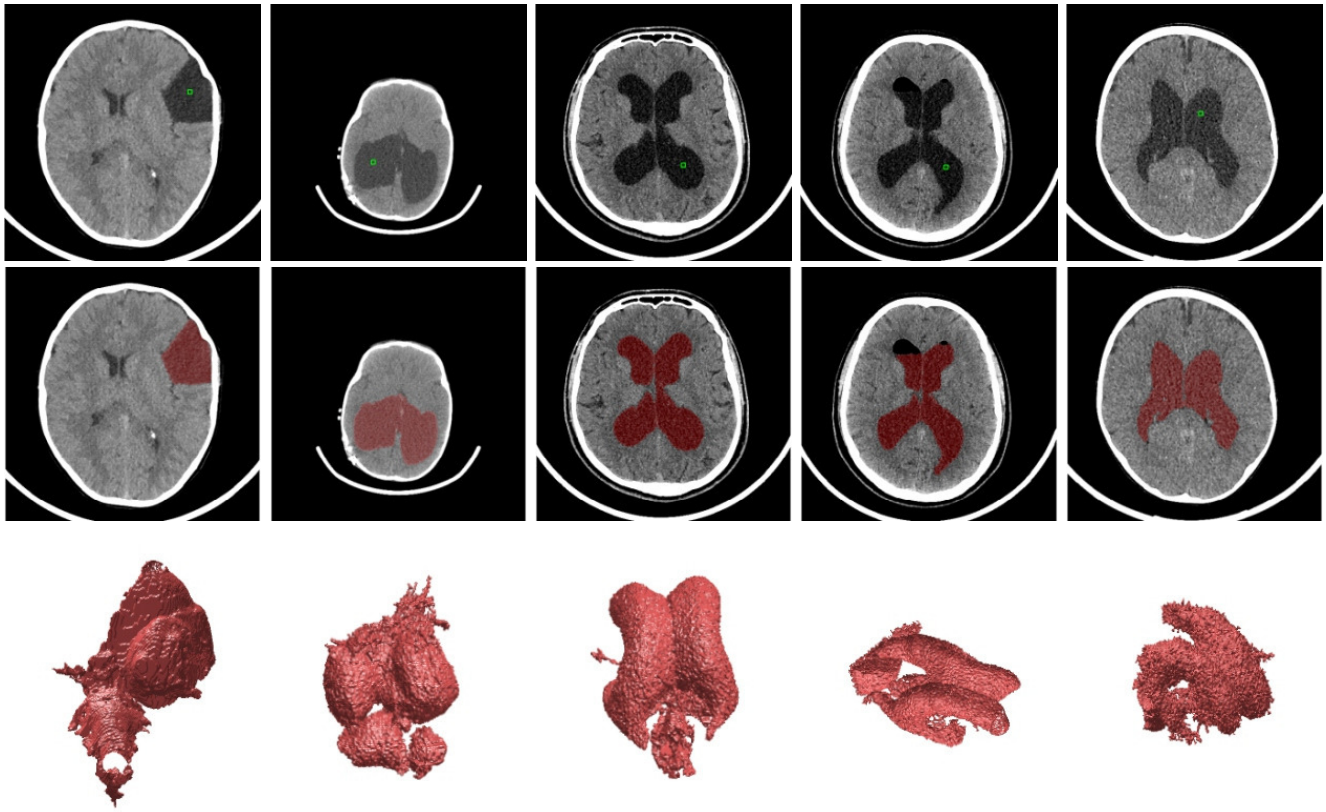

Fig. 3. The results of applying the proposed approach to sample CT brain images; top row - original images with a region of interest indicated by green square marker; middle row - the results overlaid on a sample slices; bottom row - the results shown in 3D. Cases are numbered from left to right.

column shows the level of data reduction r due to image division into supervoxels. In particular, it means that the number of supervoxels was $r\%$ lower than the number of voxels. The fourth column shows the GPU memory workload given in MB, while columns five, six and seven present time T_0 of preprocessing (filtration), time T_1 of image division into supervoxels and time T_2 of FCM execution respectively. All times are given in miliseconds. The tests were performed on a computer with Intel Core i7 3.6 GHz processor, 32 GB RAM memory and graphical card Nvidia GeForce Titan (6 GB).

TABLE I
THE TIME AND MEMORY WORKLOAD OF THE PROPOSED METHOD - THE RESULTS FOR CT DATASETS.

ID	Image size [px.]	r [%]	GPU [MB]	T0 [ms]	T1 [ms]	T2 [ms]
1	512×512×115	95.02	140.9	426.2	5410.2	560.5
2	512×512×112	96.59	80.4	435.3	9313.5	288.8
3	512×512×216	97.03	314.0	548.9	15366.1	818.9
4	512×512×220	97.24	293.9	538.8	18518.3	1087.7
5	512×512×202	97.34	344.4	544.6	17022.1	1103.9

From the Figures 3 and 4 it can be seen that the proposed approach was successful in segmenting indicated regions of interest both CT and MRI images. Based on visual assessment it can be concluded that the borders of ventricular fluid and cysts were properly determined and details of its shape were captured by the image segmentation algorithm. The accuracy of object shape determination is sufficient for further quantitative analysis.

TABLE II
THE TIME AND MEMORY WORKLOAD OF THE PROPOSED METHOD - THE RESULTS FOR MRI DATASETS.

ID	Image size [px.]	r [%]	GPU [MB]	T0 [ms]	T1 [ms]	T2 [ms]
1	512×448×25	88.15	88.6	0	1750.5	446.5
2	512×512×22	88.97	83.3	311.3	1326	406.4
3	512×512×21	86.23	75.5	323.8	1405.4	403.5
4	256×256×23	88.54	19.0	306.7	340.2	101.9
5	256×256×20	87.10	18.5	0	360.7	89.1

In the case of CT images it was possible to run the algorithm with a uniform setting of parameters, especially the number of classes N_C considered during FCM segmentation. In the case of MRI images, to obtain better quality results it was necessary

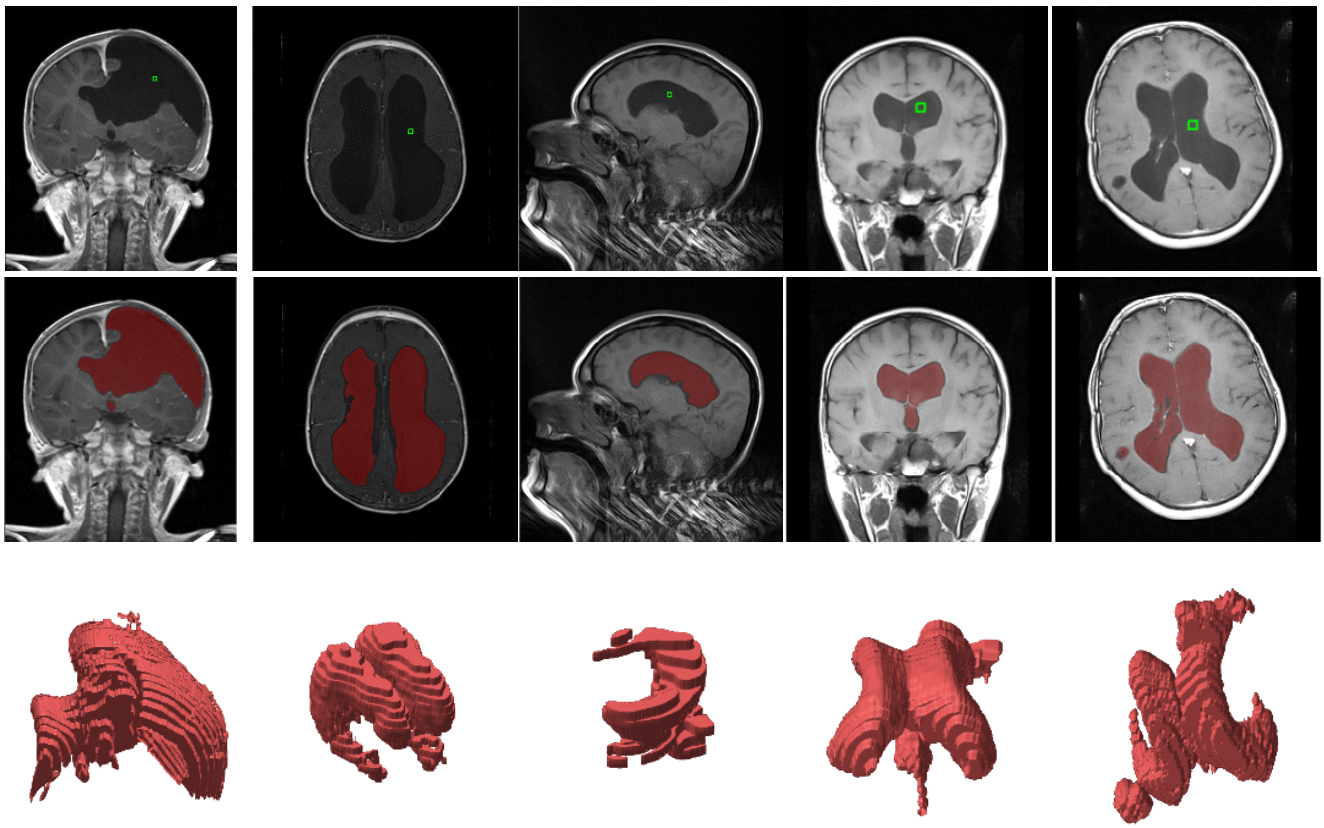

Fig. 4. The results of applying the proposed approach to sample MRI brain images; top row - original images with a region of interest indicated by green square; middle row - the results overlaid on a sample slices; bottom row - the results shown in 3D. Cases are numbered from left to right.

to tune the number of classes in the case of one considered dataset. Additionally, in cases 1 and 5 preprocessing was not applied since it deteriorated segmentation results.

From the Tables I and II it can be seen, that the proposed approach is fast and efficient. For all the considered cases the running time of the method wasn't longer than 20 seconds including preprocessing, image division into supervoxels and FCM segmentation. This is a very good result, regarding that the considered datasets consisted of up to 220 slices of resolution 512×512 pixels each. The corresponding time of FCM segmentation performed with respect to single voxels last hours. This acceleration is obtained due to significant reduction of clustered data. In the considered cases, processing of supervoxels instead of voxels diminished the number of data points clustered by FCM by on average 96.6% for CT images and 88.7% in the case of MRI images.

The memory workload of the proposed approach was also significantly reduced due to application of supervoxels. When run on the original datasets the FCM required several gigabytes of RAM memory to cluster all the voxels. As it can be seen from Tables I and II the improved method in the worst case used less than 350 MB of GPU RAM memory. In the case of volumetric images this is a very good results which makes the method available for a common use on a standard PC computer.

TABLE III
THE INFLUENCE OF SUPERVOXELS AND GPU COMPUTING ON THE FCM SEGMENTATION TIME IN CT DATASETS. T2 - THE EXECUTION TIME WITH SUPERVOXELS AND GPU, T2' - NO SUPERVOXELS, T2" - NO SUPERVOXELS OR GPU.

ID	Image size [px.]	T2 [ms]	T2' [ms]	T2" [ms]
1	512×512×115	560.5	9594	186873
2	512×512×112	288.8	7301	147686
3	512×512×216	818.9	21934	540873
4	512×512×220	1087.7	19562	595971
5	512×512×202	1103.9	24196	552163

In tables III and IV different variants of FCM segmentation times are compared for CT and MRI images respectively. The column $T2$ refers to the proposed method applying both supervoxels and parallel GPU computing. Two next columns describe the same cases omitting supervoxel creation ($T2'$) and also GPU computing ($T2''$). The exclusion of supervoxels increases CT segmentation time $17 \div 27$ times (on average

TABLE IV
THE INFLUENCE OF SUPERVOXELS AND GPU COMPUTING ON THE FCM SEGMENTATION TIME IN MRI DATASETS. T2 - THE EXECUTION TIME WITH SUPERVOXELS AND GPU, T2' - NO SUPERVOXELS, T2" - NO SUPERVOXELS OR GPU.

ID	Image size [px.]	T2 [ms]	T2' [ms]	T2" [ms]
1	512×448×25	446.5	9813	84817
2	512×512×22	406.4	11576	90933
3	512×512×21	403.5	9126	119840
4	256×256×23	101.9	2652	26286
5	256×256×20	89.1	3198	28595

$\approx$ 22 times) and additional removing of GPU computing extends it up to $330 \div 660$ times (on average ≈ 510 times). For the MRI images the FCM execution is slowed down on average 27 and 258 times in the two algorithm variants with $T2'$ and $T2''$. The acceleration with supervoxels is achieved at the expense of their preparation time. Therefore real speed-up of the algorithm in this approach is only 1.2 and 28 times for the tested CT images or respectively 6 and 56 times for MRI cases. The example CT images of larger size than the example MRI require more effort to prepare supervoxels. Hence, their use only gives less profit on time, which can be still enhanced during subsequent parallel computations.

B. Tests on phantoms

The accuracy of the introduced supervoxels based FCM segmentation approach was assessed using three different physical phantoms including: phantom of head, phantom CIRS 045 of prostate [15] and phantom CIRS 062 [16] used for calibration of computed tomography scanners. All these phantoms were scanned using a CT scanner. The resulting images were next subjected to segmentation using the proposed approach. The aim of the segmentation was to extract characteristic objects contained within phantoms. Finally, the volumes of these objects were determined based on segmentation results and compared with the volumes given in phantom specification.

The phantom of head was prepared using the 3D printing technique. The phantom consists of two main parts: the skull made from a material of the density 2.1-2.3 g/cm^3 and the brain made from a material of the density 1.02-1.04 g/cm^3. In the brain there is a hole of a shape similar to ventricular system and volume equal to 41.69 cm^3. The hole was filled with water imitating the cerberospinal fluid. The head phantom is presented in Figure 5. In particular, Figure 5a shows the general view of the phantom, while Figure 5b presents a sample CT slice. Additionally, in Figure 6 the shape of the ventricular system of the phantom is presented.

The phantom CIRS 045 is dedicated to prostate brachytherapy. Inside it contains three cysts of the increasing volumes (namely: 4 cm^3, 9 cm^3 and 20 cm^3). The general view of the phantom is shown in Figure 7a, while a sample CT scan is presented in Figure 7b.

Finally, the phantom CIRS 062 is shown in Figure 8. The phantom consists of two rings with inclusions of equal size.

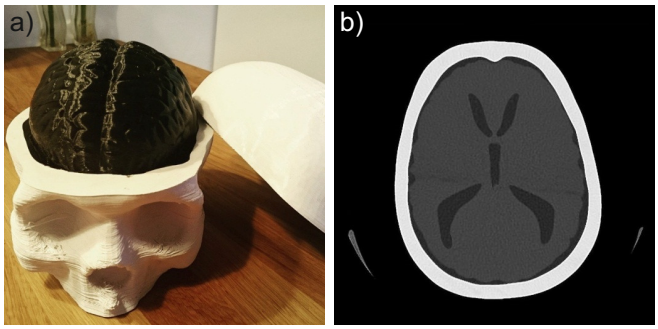

Fig. 5. The brain phantom; a) the general view; b) a CT scan.

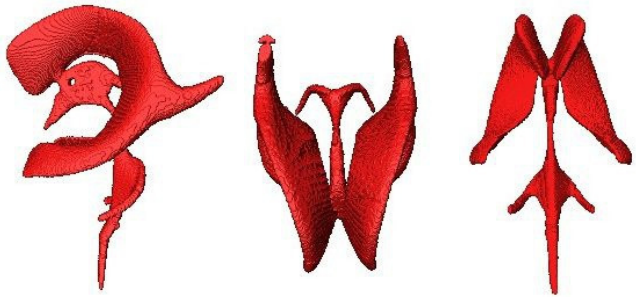

Fig. 6. The shape of the ventricular system within the brain phantom.

Each inclusion corresponds with different tissue and thus exhibit different attenuation of X-rays (see Fig. 8b).

The results of applying the introduced segmentation approach to images of phantoms are shown in Figure 9. In the case of head phantom, the proposed approach was used to extract the ventricular system (see Fig. 9a). From prostate phantom CIRS 045 the largest cyst was extracted (see Fig. 9b). Finally, from the phantom CIRS 062 a randomly selected inclusion was extracted using the proposed approach (see Fig. 9c). For each case, the segmentation result is both: shown in 3D and overlaid on a sample slice.

The results of comparison between the real and the determined volumes of the considered regions are summarised in Table V. In particular, the considered phantom is indicated in the first column. The real region volume V_0 is given in the fifth column, and followed by the determined volume V in the sixth column. The corresponding relative error of volume

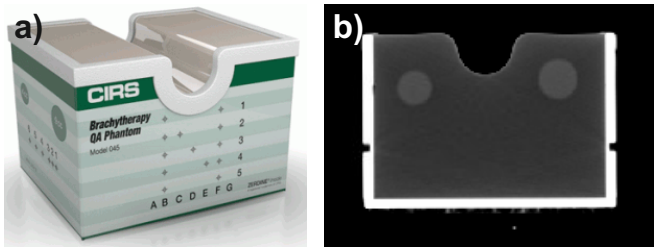

Fig. 7. Phantom CIRS 045; a) the general view (©CIRS Tissue Simulation & Phantom Technology); b) a sample slice from a CT scan.

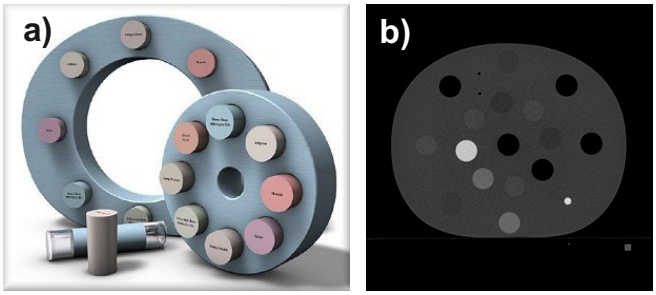

Fig. 8. Phantom CIRS 062; a) the general view (©CIRS Tissue Simulation & Phantom Technology); b) a sample slice from CT scan.

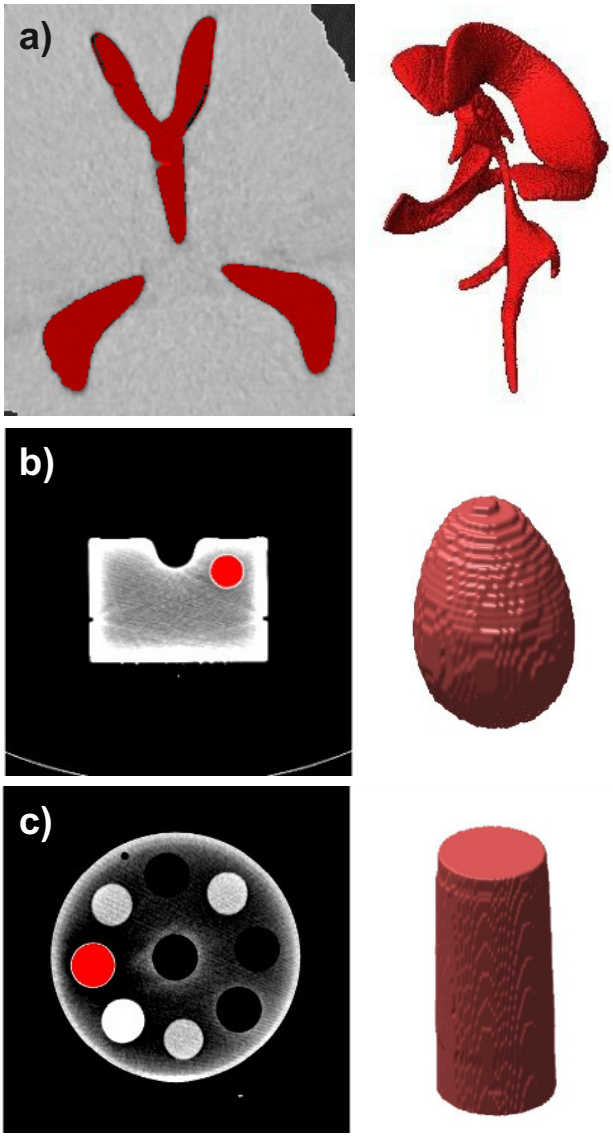

Fig. 9. The results of supervoxel based FCM segmentation applied to the considered phantoms; a) brain phantom; b) CIRS 045; c) CIRS 062.

determination is shown in the last column. Additionally, for each phantom image resolution, time of image division into supervoxels T_0 and time of FCM segmentation T are given in columns two, three and four respectively.

TABLE V
THE ASSESSMENT OF SEGMENTATION ERROR.

phantom	Image size [px.]	T0 [s]	T [s]	V0 [cm^3]	V [cm^3]	dV [%]
head	512×512×515	36.88	1.66	41.69	40.77	-2.20
CIRS 045	512×512×61	3.85	0.42	20.00	17.44	-12.80
CIRS 062	512×512×55	3.46	0.41	42.44	53.75	1.41

From Figure 9 it can be easily seen that the proposed segmentation approach successfully extracted objects of interest from the considered phantoms. The shape of the segmented objects correspond with the real one. This is especially visible in the case of the ventricular system segmented from the phantom of head (see Fig. 9a). In this case all important anatomical details are clearly visible in object after segmentation. The shape of objects extracted from the CIRS phantoms also correspond with the description given in phantoms specification.

The relative error of volume determination equals on average 5.5% (see Tab. V). It is worth highlighting, that in the case of the ventricular system extracted from the phantom of head the error is only -2.2%. This is a very good result, especially having in mind the complex shape of the ventricular object.

IV. CONCLUSIONS

In this paper the fuzzy C-means method FCM) was specifically adapted to the segmentation of volumetric brain images. In particular CT images include from tens to hundreds of millions of voxels to analyse within a reasonable time. Although the FCM method has the advantage of the same functionality in two and three dimensions, the algorithm execution time is proportional to the number of image voxels and can exceed large values for hundreds of CT slices. The proposed reduction of input data size based on supervoxels varies from 85% to 95% in the tested examples at the expense of several seconds for creating supervoxel regions. For the assumed parameters the segmentation accuracy of about 2% tested for the head phantom still remains acceptable. The above data compression and GPU parallel computing limit processing time to single seconds, practically without any extra cost for hardware equipment. Standard CUDA compatible NVIDIA graphic card of computing capabiility $3 \div 3.5\%$ will be sufficient in this case, because the GPU memory workload falls below $0.5\,GB$ for 200 CT slices. The bottle neck of such graphic computing is the maximum acceptable size of shared memory per block (up to $8\,kB$) implying the limited class number to preserve the parallel computation efficiency. Additionally in some medical cases establishing a priori the number of segmentation classes to extract desired objects is a very intuitive task. Nevertheless the proposed approach make the modified FCM method very promising for its very fast processing of bulk data and dimensionality independence.

ACKNOWLEDGEMENTS

The authors would like to thank Mikołaj Kopernik's Hospital in Lodz (Poland) for providing CT images of Electron Density Phantom CIRS 045 and Brachytherapy Phantom CIRS 062.

***Abstract*—In this paper research on a compact deep convolutional neural network (DCNN) architecture for age and gender estimation from facial images has been presented. The proposed solution was tested on the FERET and the Adience Benchmark databases. In the first case a 98.6% accuracy for gender and 86.4% for age estimation was obtained. For the Adience database, which contains images recorded in unconstrained conditions and is much more demanding, a 62.0% for gender and 42.0% for age accuracy was obtained. When compared to the reference results on a much larger network, the performance should be considered as satisfactory. The research shows that a compact DCNN with small input images can provide quite good classification results.**

I. Introduction

A VISION system which allows the estimation of age and gender of a person using a face image can have a number of important practical applications in biometric and statistics systems, as well as advanced human-computer interfaces (HCI) and so-called smart advertising (with personalized content). It typically consists of a face detection [1] and the actual estimation module. The designed vision system must be resistant to changes in face appearance (facial expressions, hairstyle, presence of beard or moustache, glasses and to some extent also make-up), different lightening conditions, inaccurate face localization in the image, face orientation (frontal, from profile and also rotated), size of the input image and it's quality (presence of noise, blur caused by movement of the person, underexposure, overexposure, shadows, etc.).

Deep convolutional neural networks (DCNN) are one of the most interesting tool available for the image processing and machine learning community in recent years. It is worth noting that the approach in not new – the first concepts were already proposed in the 70's of the last century [2]. However, due to limited performance of the available computing platforms, these solution were not used. The breakthrough came with the emergence of programmable graphic processing units (GPU). They proved to be an almost perfect platform for neural networks implementation, mainly because of the massive parallelization possibility and floating point support. At the same time learning methods for such complex structures were developed and refined. In addition, the dynamic growth of social networks services like Facebook, Flickr or Instagram allowed to obtain quite easy access to huge image databases. Currently DCNNs are used for almost all machine learning tasks – from speech recognition through image recognition to information about social networks users categorization. Only in computer vision the following applications should be mentioned: face detection, pedestrian detection, road sign detection and recognition and object tracking. What is more, the DCNN based approaches usually significantly outperform the "classic" (i.e. feature extraction and classification – e.g. HOG + SVM) ones.

In this paper, a compact DCNN for age and gender estimation from facial images is presented. The obtained results indicate, that it is possible to use a quite small, energy and resource efficient architecture, without much loss on classification performance. Moreover, all experiments were performed on a typical PC computer, without a powerful GPU accelerator.

The reminder of this paper is organized as follows. In Section II a brief review of age and gender estimation algorithms is presented. The proposed solution is described in Section III. Then, in Section IV the evaluation results are presented and discussed. The paper ends with a summary and indication of future research directions.

II. Age and gender estimation systems

Age and gender estimation is a quite popular topic in the computer vision community. An in-depth review is far beyond the scope of this article and therefore only selected works directly related to DCNNs are presented.

A. DCNN based solutions

One of the earlier works on gender recognition using CNNs was presented in paper [3]. The solution consisted of a face detection and gender recognition module – both using neural networks. The architecture involved three layers (two hidden and output). Input images had a 32×32 pixels resolution. The reported accuracy on the FERET dataset was 97.2%.

Most of the work related to the DCNNs appeared in 2015 and later. In the article [4] two approaches were compared: "classic" and DCNN based. In the first case the following

978-83-60810-90-3/$25.00

features were considered: HOG (Histogram of Oriented Gradients), LBP (Local Binary Patterns) and SURF (Speeded Up Robust Features). As regression the CCA (Canonical Correlation Analysis) was applied. In the second, many different variants of network architectures were examined (the Caffe library was used). The best result were obtained for two convolutional and one fully connected layer. Input images had 50×50 pixels size. The authors noted a significant disproportion between the time required for learning and actual operation in both cases. Finally, for the MORPH database, the "classic" solution obtained 4.25 and DCNN 3.88 mean absolute error (MAE) value.

In the work [5] a DCNN for age and gender estimation was proposed. The network had three convolutinal and two fully connected layers. Input images of size 256×256 were cropped to 227×227. The authors did not use a pre-trained network model – in contrast to many other approaches. On the Adience dataset this solution achieved 86.8% $\pm$ 1.4 accuracy for gender and 50.5% $\pm$ 5.1 for age estimation. In the latter case 8 age categories were used. If an "off by one" error is allowed, the performance increases to 84.7 $\pm$ 2.2. In this study the Caffe library and GPU with 1,536 CUDA cores and 4 GB of RAM were used.

In 2015, at the IEEE International Conference on Computer Vision Workshop (ICCVW) a competition on age estimation (ChaLearn) was conducted. The Looking at People 2015 (LAP) dataset with 4,961 images was used [6]. The DEX system from ETH Zurich, Switzerland obtained the best results [7]. In the first step the face was detected. Then, it was rescaled to 256×256 pixel size. The authors used a pre-trained DCNN on the ImageNet dataset. In addition, it was fine-trained on the IMDB-WIKI database (260,282 images) and finally on the LAP set. In total 20 separate networks were used. This allowed to achieve 3.21 MAE value. The Caffe framework and NVIDIA Tesla K40C GPU were used. Learning a single network lasted 5 days, fine-learning 3 hours and processing a single image about 200 ms.

This short (compared to the available material) overview can be concluded with the following statement: "age and gender estimation with DCNNs is very accurate (sometimes even better than human), however the used network architectures are very complex". Therefore, their training and usage requires a lot of computing resources – most authors used specialized and expensive GPU accelerators like NVIDIA K40.

B. Our previous solution

During our earlier work [8], a "classical" age, gender and race estimation system was created. In the pre-processing stage the face was detected (Viola-Jones method), eyes and mouth were detected (also by the Viola-Jones approach) and image alignment was performed – an affine transform was used to assure that eyes and mouth are at predefined locations for every considered image. The local binary patterns (LBP) were used as features. After their computation, the image was divided into non-overlapping blocks in which histograms were computed – their concatenation formed the feature vector. The support vector machine (SVM) with radial basis functions (RBF) was used as classifier. In case of non-binary problems (race, age) multiple SVMs were used – one for each class.

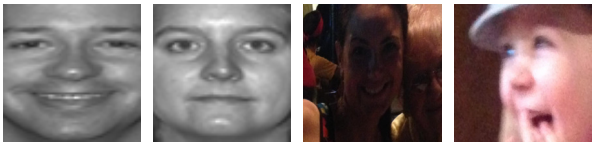

Figure 1: Samples from the FERET (a) and Adience (b) databases

In the experiments on the FERET database quite good performance (94.0% for gender, 86,7% for race and 69.5 % for age in 10 years interval) was obtained. Unfortunately, real-life tests in unconstrained conditions on images acquired with a standard USB webcam revealed the weakness of this solution. Actually, even for gender determination it was quit difficult to get a proper result. This was a direct motivation to improve the vision system and use the DCNN approach.

III. The proposed solution

In this work the impact of simplifying the network structure, especially the size of the input image, on the overall accuracy of age and gender recognition was evaluated. Also the computing resources and single image processing time were considered. The ultimate goal of the ongoing research is to implement DCNN solutions in embedded devices and support real-time video stream processing.

A. The used datasets

In the experiments two databases were used: FERET [9] and Adience [10]. The first was chosen to compare the obtained results with our previous work [8]. It includes 2,413 images of 856 individuals. Examples are shown in Figure 1a. The biggest drawback is that these pictures were taken under controlled conditions. This results in poor generalization of the trained classifier, especially for cases registered under real-life conditions. In addition modern methods obtain almost 100% accuracy for this set, which indicates that it is not longer an appropriate challenge.

The Adience set was used because it is considered as challenging and the images were registered in unconstrained environment. It contains 26,580 annotated images of 2,284 people. Samples are shown in Figure 1b.

B. The used hardware and software

All experiments were performed on mid-range laptop – Intel Core i5-2410M (2.3 GHz up to 2.9 GHz), 4 GB DDR3 RAM, NVIDIA GeForce GT 540M with 2 GB DDR3 RAM, 96 CUDA cores and 672 MHz core frequency. There are several computing libraries for DCNNs – eg. Caffe, Torch and Google Tensor Flow. After a preliminary analysis, Torch (`http://torch.ch/`) was selected, mainly due to easier installation and configuration (in comparison to Caffe), as

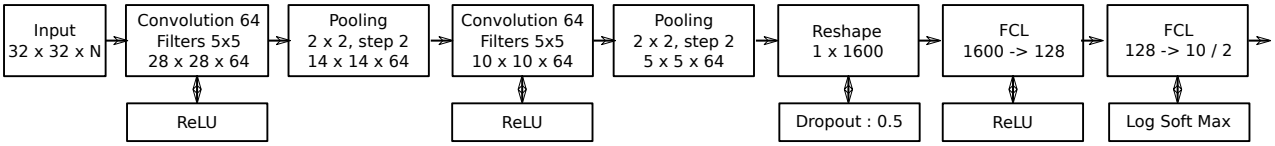

Figure 2: The used DCNN architecture

Table I: Results for the FERET (F) and Adience (A) dataset

	Conv. 1	Conv. 2	# Training	# Test	# Epoch	Acc. gender	Acc. age	Computing time
F1	5×5	5×5	100	100	100	81.3%	41.2%	48s
F2	5×5	5×5	250	100	200	96.0%	70.1%	181s
F3	5×5	5×5	500	200	300	88.5%	74.5%	534s
F4	5×5	5×5	1000	500	500	93.7%	58.9%	1795s
F5	5×5	5×5	2000	500	500	**98.6%**	85.4%	3324s
F6	3×3	5×5	2000	500	200	97.6%	**86.4%**	1572s
F7	7×7	5×5	2000	500	200	97.6%	85.6%	1683s
F8	3×3	3×3	2000	500	200	98.0%	**86.4%**	1354s
F9	7×7	7×7	2000	500	200	97.6%	85.8%	1709s
A1	5×5	5×5	2000	500	300	50.2%	42%	2317 s
A2	5×5	5×5	12000	500	200	51.4%	32.1%	3h
A3	5×5	5×5	12000	500	200	59.5%	33.1%	3h
A4	5×5	5×5	12000	500	200	**62.0%**	**42.0%**	3h

well as a more convenient to manage network model and the whole project (LUA language). Additionally, in our opinion the available documentation is very extensive and there are many resources on the Internet (ready scripts and educational materials). It is also possible to import models from the Caffe library.

C. Image preprocessing

In the first stage, the images from the FERET and Adience databases were rescaled to 32×32 pixels. Unfortunately, on the used hardware, experiments for higher resolution lasted too long (several hours) and for larger models were even impossible. Then, the original RGB colour space was transformed to YUV, which allowed to separate luminance and chrominance information and slightly improve the performance.

In the next step the input data was normalized using the well known scheme with mean and standard deviation. First, this two values were computed for each colour component separately. Then, from all pixel in the input image the mean value was subtracted and the result was divided by the standard deviation.

D. Network architecture

As stated earlier, the main assumption of the presented work was to design a simple and computationally efficient network architecture. Therefore, it was decided to use 32×32 pixels input images. It should be emphasized that usually larger images are considered (cf. Section II-A).

The used network architecture was essentially based on the one described in [5]. However, many simplifications were introduced. The scheme is presented in Figure 2. It consists of the following components: two convolutional layers (Convolution 64), three ReLU transfer layers (in-place operation – $f(x) = max(0, x)$), two subsampling layers with a *max* operator (Pooling), data reshape, two fully connected layers (FCL), in-place dropout with 0.5 probability and LogSoftMax operation ($f_i(x) = log(\frac{1}{\sum_j e^{x_j}} \cdot e^{x_i})$).

E. Network training

In the experiments the following labels were used. For gender: 1 – man, 2 – woman. For age: 0 – 9, as the range $[0, 100]$ was divided into 10 intervals (we used the value 10 due to compatibility with our previous research). Some solutions allow to determine the age with one year accuracy – for example [7]. However, this increases the complexity of the network structure and for a lot of applications this precision is not required.

After creation of the network model, the weights were initialized (in this work random values were used). Then, during an iterative learning process (using stochastic gradient descent (SDG) method) the weights were modified to reduce the classification error.

IV. Evaluation

For the FERET database 9 experiments were carried out. Their main aim was to examine how the size of used convolutional filters and sizes of the training and test sets, as well as the number of iterations (epochs) affected the classification performance. The obtained results are summarized in Table I (upper part). As the training times for both networks (age, gender) were similar, only the mean value is presented.

Like expected, increasing the number of training samples had a positive effect on the recognition efficiency – using 2,000 images allowed to obtain a 98.6% gender recognition accuracy. It is worth noting, that this is 4% better than the "classic" solution descried in Section II-B and work [8].

Age estimation is a more complex issue. In addition, it was not easy to provide enough training and test samples for each of the 10 classes. Again, the best results were obtained for

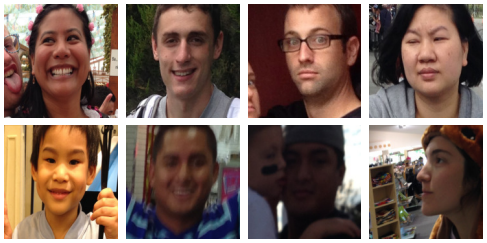

Figure 3: Sample positive (top row) and negative (bottom row) gender classification results from the Adience dataset

the largest network – 86.4%. It is over 15% better than the "classical" solution and slightly better than reported in [3].

Using different filter sizes (3×3, 5×5 and 7×7) had only a minor impact on the final classification performance (not more than 1% difference). A small 3×3 filter allowed to achieve best age estimation – 86.4%.

For the Adience dataset 4 test were conducted. Their results are summarized in Table I (bottom part). Images of size 32×32 were used. In the first test 50% for gender and 42% for age accuracy was obtained. This is much worse than on the FERET base, but the reference DCNN from [5] on this demanding set allowed for approx. 87% for gender and 50.7% for age accuracy. Because the size of the input image could not be increased, two optimizations proposed in the work [5] were evaluated on the compact DCNN. In the third test, the input image was restricted only to the centre part of the original image. In the fourth test, 5 images were passed to network – one centre and 4 from corners. This allowed to compensate the incorrect alignment of faces in the input images. Especially the second modification had a positive impact on the final solution – 62% for gender and 42% for age accuracy. Some sample gender classification results are presented in Figure 3. It should be noted that the unsuccessful cases (bottom row) are quite difficult.

V. Conclusion

In this paper the use of a compact DCNN architecture for age and gender estimation was proposed. The input image size was defined as 32×32 pixels. This allowed to obtain 98.6% accuracy for gender and 85.34% for age in 10 years intervals on the FERET database. When compared to our previous solution based on LBP and SVM, respectively a 4% and 15% improvement was obtained.

For a much more demanding Adience database 62% gender and 42% age accuracy was measured. These are results respectively 25% and 8% worse than for the large DCNN with input image size 227×227. It is worth to emphasize that the measured classification time was 16 ms (vs 200 ms) and this despite of the used computing platform (mid-range notebook).

The obtained results are interesting due to at least three reasons. Firstly, the access to powerful GPU platforms or even clusters in not common. Especially nowadays, where most personal computers are notebooks which are being slowly replaced by advanced smartphones. Secondly, the "didactic" aspect should not be missed. It seems that deep learning and convolutional neural networks should be introduced for graduate students of electrical engineering and computer science faculties. For an effective teaching process, students should be able to carry out simple experiments on their own hardware. In addition, the network training should not take too long (e.g. not several hours) and the classification result should be "decent" (reasonable when compared to large DCNNs). Thirdly, the use of a compact DCNN in an embedded vision system allows to reduce costs (less computing resources required), minimize the energy consumption and perform real-time video stream processing.

In the near future our research will concentrate on analysing the use of reprogrammable FPGA devices, heterogeneous Zynq SoC (which both are proven platforms for embedded real-time vision systems), as well as the recently proposed solutions like NVIDIA Jetson FX-1 for implementing compact, energy efficient but also accurate DCNN based classifiers and vision systems.

***Abstract*—Shadow rendering is one of the most important aspects of rendering 3D environments, yet, the problem is far from trivial. A number of shadow rendering algorithms exist, with various degrees of rendering quality, fidelity and performance. Additionally, many of such algorithms offer high degrees of flexibility when it comes to fine tuning. This paper proposes a new method of measurement of quality of shadows produced by rendering algorithms, which method can be used for automation of algorithm choice and fine-tuning of such algorithms to specific data sets and use cases.**

I. Introduction

ONE of the most important aspects of rendering virtual objects and environments is rendering of shadows [1]. While a great number of shadow rendering algorithms was developed, all of them require some degree of compromise between image quality, fidelity and rendering performance. With ray-tracing allowing very high shadow fidelity at the cost of rendering performance, and shadow map techniques offering [2] real-time performance even on low-end devices at the cost of image quality, the choice of shadow rendering algorithms is often one of key decision taken during development of rendering applications. Many of such algorithms offer further parametrization, which allows fine-tuning to given purpose. To simplify the task of such choices and enable some degree of automation in this matter an automated shadow rendering quality measurement algorithm is required. This paper presents a proposal of such an algorithm.

II. Related Work

While a lot of research has already been done in the area of image quality assessment, it is surprising that we couldn't find any proposal of a complete metric fit to measure and compare quality of rendered shadows. The proposed NoRM No-Reference Image Quality Metric [3] was capable of detecting certain type of shadow rendering artifacts (shadow map aliasing), but because the method was heavily based on machine learning, it was impossible to be easily reproduced in our environment. Another study [4] evaluates existing full-reference image quality metrics in the context of detection and measurement of two certain types of shadow artifacts (acne and peter panning) showing that SSIM [5] and MSSIM [6] metrics outperform other evaluated methods. Still, in our research of existing works we were unable to find a quality metric that would focus on all aspects of evaluating quality of shadow rendering algorithms.

III. Proposed Model

The proposed quality metric is capable of quality assessment of shadow rendered for a single light source (for any type of such light source) as seen from a single view point. The model is based on weighted average of several submetrics, each focusing on a key aspect of rendered shadow quality:

- shadow fidelity
- aesthetics
- detail
- rendering performance

The weighted average of the above aspects allows tuning the metric itself to given purpose and expectations. For example, while rendering performance will be much more important in the real-time applications than absolute shadow fidelity, the exact opposite will be true for offline rendering in cinematography.

Because the proposed metric was developed mostly for use in comparing shadow rendering algorithms, the metric computation itself does not need to be real-time. Therefore, we allowed ourselves to use full-reference, white-box methods for simplicity. The reference images were generated using ray-tracing algorithm with accurate soft-shadow simulation and high sample count (1024 samples per pixel). White-box approach allows easy separation of the shadow information from the rest of the scene by use of shadow masks. The shadow mask is an additional output from a renderer, which represents only the geometry term (the visibility factor) for a given light. The example of shadow mask image generated for our test scene can be seen on Figure 1.

IV. Shadow Fidelity Measurement

The purpose of the shadow fidelity metric component is measurement of how closely the shadow under evaluation matches the expected physical shadow. This component includes assessment of correct shadow placement and topology, as well as correct representation of fully shadowed and fully unshadowed area, but does not include noise errors, which will be included in the shadow aesthetics component of the metric. Such separation was implemented in order to enable fine-tuning the final metric by specifying the weights for each submetric separately to adjust the importance factors to specific needs.

The shadow fidelity submetric is, just like the main metric, a weighted average of several components:

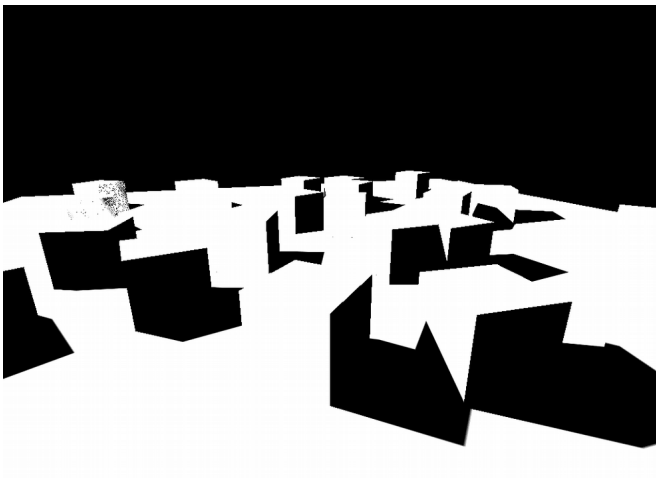

Fig 1.An example of shadow mask image for our test scene

- 10% shadow contour match
- 50% shadow contour match
- 90% shadow contour match
- dark area coverage
- lit area coverage

The first three components assure that the soft shadow boundary in test image is located where it ought to be, while the last two components assure that there are no extra features present in regions, which are empty in the reference image.

A. 10%, 50% and 90% Shadow Contour Matching

The shadow contour line is defined as isoline, for which the shadow factor (the geometry factor from the lighting equation) is equal to specified percentage value. Three contour lines are used in our method: the 10% line, 50% line and 90% line. These factors were chosen experimentally to provide 10% margin from fully lit and fully shadowed areas. Such margin is needed, as the submetric should minimize impact of noise errors, which are to be detected with different submetric. Additional line, the 50% contour line, was introduced to test the fidelity of shadow cross-section – the distribution of shadow mask values across the penumbra region.

The method for extracting shadow contour lines is identical for all contour line values. First, the shadow mask image is blurred to reduce impact of noise on the shadow line. In our tests we used 11x11 blur kernel for images with 1024x768 pixel resolution. Then, the isoline is extracted by comparing each pixel of the blurred mask with its right, lower and lower-right neighbors. The pixel is marked if and only if a region consisting of the pixel and the neighbors contains shadow mask value transition across the contour value. As a corner case, if the region has all pixel values equal to the contour line threshold, the pixel is still marked in order to guarantee continuity of the contour line. The above operation (blurring and contour line extraction) is carried on both the test and the reference images. In the final step, for each contour pixel in reference image a contour pixel in test image is found, and quadratic mean of distances to such pixels is computed. The final score of the given contour line match submetric is computed as:

$$CM = 1 - \frac{D_{RMS}}{D_{MAX}} \tag{1}$$

where:

CM – is the contour line submetric score,

D_{RMS} – is the quadratic mean of contour distances,

D_{MAX} – is the worst-case maximum contour distance

Ideally, the mean would equal zero, which means perfect match, yielding a perfect score of 1. A worst-case scenario, yielding a score of 0, is assumed to be a scenario in which the quadratic mean of contour distance is equal to D_{MAX} – an arbitrarily chosen maximum contour distance. In our implementation, that distance was set as a 20% of image size (a geometric mean of image width and height in pixels). The choice of that parameter can be arbitrary, because the metric is intended to be a comparative one, and any fine-tuning is meant to be done by choosing the weights of the submetrics.

B. Dark and Light Area Coverage

The dark and light area coverage submetrics are computed in a manner similar to each other. First, the shadow mask image is blurred to reduce the impact of noise and shadow acne on the submetric score. In our implementation, we use the same blurred image as in shadow contour matching submetrics. Then, depending on whether we compute the dark or the light area coverage submetric, we mark all pixels which contain blurred mask values below 10%, or above 90%, for dark and light areas correspondingly. This process is carried on both the test image as well as on reference image. In the final step, both images are compared. Only the region of pixels marked on the reference image is considered. Within that region all unmarked pixels on test image are counted, giving final score of the submetric as:

$$AM = 1 - \frac{N_{unmarked}}{N_{region}} \tag{2}$$

where:

AM – is the area coverage submetric score,

$N_{unmarked}$ – is the count of unmarked pixels in the test image (within considered region),

N_{region} – is the count of all pixels of the considered region

In the event of a perfect match, all pixels marked on the reference image will also be marked on the test image, resulting in ideal score of 1. In worst case, none of the considered pixels will be marked on the test image, giving the score of 0.

V. Shadow Aesthetics Measurement

With the aesthetic submetric score we aim to detect two types of shadow rendering artifacts: the shadow acne and shadow noise in the shadowed region. While the aesthetic quality of shadow can be hard to measure, we decided to focus on shadow noise in this metric, as image noise is one of the most frequent and typical image rendering errors. The shadow aesthetics sumbetric is, again just like the main met-

ric, a weighted average of several (in this case: two) components:

- shadow ACNE value
- shadow noise value

With both components scaled to yield a value of 1 in case of perfect shadow image and a worst-case value of 0.

A. Shadow Acne Detection

The shadow acne rendering artifacts are typical to shadow map rendering algorithms and are characterized by appearance of high frequency noise within the fully lit regions of the shadow mask. Therefore, to detect such errors we need to measure the noise level within the lit portion of the shadow mask. To compute that level, we first process the shadow mask image using the Roberts cross operator to isolate high-frequency image noise [7]. Then we compute the quadratic mean of computed noise values within the lit region of the shadow mask. The lit region is considered to be the light region computed during measurement of the light area coverage in one of the earlier submetrics. Both the test shadow mask and the reference shadow mask images are processed in the above manner and the final acne detection score is computed as:

$$AV = min\left(\frac{1-T_{RMS}}{1-R_{RMS}}, 1\right) \quad (3)$$

where:

AV – is the score of acne detection,

T_{RMS} – is the quadratic mean of noise detected within the lit region on the test image,

T_{RMS} – is the quadratic mean of noise detected within the lit region on the reference image

The above equation normalizes the acne score of the test image to the acne score of the reference image because some features of the reference image (such as penumbra edges) can be falsely detected as acne, therefore making ideal score of 1 impossible to reach. The final value is limited to 1 to prevent the score from going above that value if test image lacks features, present on the reference image, that would otherwise be falsely detected as acne.

B. Shadow Noise Detection

The shadow noise is detected in a manner identical to the acne detection method outlined above, with the exception that now only the dark region is considered. The dark region is the region detected as a dark portion of the shadow mask during dark region coverage measurement. The rest of the noise detection algorithm remains the same as in acne detection algorithm.

VI. Shadow Detail Measurement

The insufficient shadow detail comes in most cases from the low shadow map resolution, as compared to its projection on the screen. To measure the quality of shadow detail as a shadow resolution compared to image resolution, we have to utilize white-box testing method and produce yet another image output from our shadow rendering algorithms: the shadow map texels projection on the scene. Such texel projection image is prepared first by assigning each shadow map texel an unique color index, then projecting such shadow map directly on the scene. To limit further computations to region of interest where shadow map detail can possibly affect rendering, in such projection we ignore any geometry that is not facing the light for which shadow quality is measured, as well as any regions that don't contain any geometry (e.g. sky). The example of texel projection image generated for low resolution shadow map (for the purpose of readability) can be seen on Figure 2.

To compute the shadow detail submetric score the following method is used. For each pixel of interest within the shadow map texel projection image we count the number of pixels, that share the same texel index. Then this count is averaged using quadratic mean. Then the final score of shadow detail submetric is computed as:

$$SD = \frac{1}{S_{ratio}} \quad (4)$$

where:

SD – is shadow detail submetric score,

S_{ratio} – is share ratio computed using the quadratic mean

Because we consider only pixels that have any shadow texels projected on them, the share ratio can never drop below 1. Therefore, the perfect score, when each pixel has its own shadow map texel assigned, is 1. Note that the shadow map resolution exceeding the pixel resolution across any portion of the scene does not further increase the score.

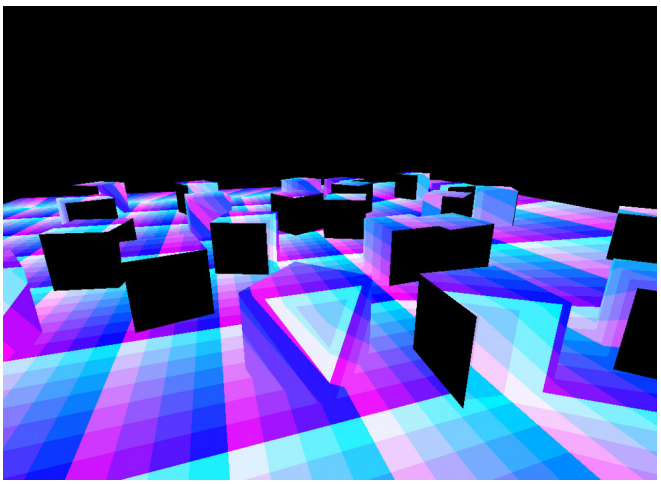

Fig 2.An example of a shadow texel projection image

In the event the given shadow rendering technique does not rely on intermediate projected texture maps and has infinite detail resolution (like raytracing or shadow volume techniques), the shadow detail metric is skipped entirely assuming perfect score of 1.

VII. Rendering Performance Score

The rendering performance submetric score is computed basing on shadow rendering time and is computed as:

$$RP = \frac{1}{1 + \frac{T_{shadowed} - T_{unshadowed}}{T_{ref}}} \quad (5)$$

where:

RP – is the rendering performance score,

$T_{shadowed}$ – is the rendering time of the scene with the shadow rendering algorithm enabled,

$T_{unshadowed}$ – is the rendering time of the scene with the shadow rendering algorithm disabled,

T_{ref} – is the reference time value, scaling the score distribution

We suggest using value of T_{ref} equal to the inverse of the minimum final target frame rate (maximum time of rendering allowed for a complete single frame). With rendering performance score specified this way, the score assumes value of 1 in ideal case of shadow rendering not taking any time. When shadow rendering time rises to maximum time allowed for rendering the whole frame (making the shadow algorithm impossible to use), the performance score drops to value of 0.5. Further increase in shadow rendering time causes the score to drop further towards 0 as the rendering time rises towards infinity.

During our tests we did not use performance measurement submetric, as our implementations of shadowing algorithms were not fully optimized. Therefore, any performance comparisons would not produce any meaningful results.

VIII. Example Results

To test our quality metric on real data sets we have implemented four different shadowing techniques, in addition to raytracing, which was used as reference. All of the implemented test techniques were based on the shadow mapping technique for point light shadows. The most widely used for such cases Cube Shadow Map technique (CSM) was implemented, as well as slightly modified Tetrahedral Shadow Map technique introduced by [8]. Additionally, both Cube Shadow Map and Tetrahedral Shadow Map techniques were implemented with Variance Shadow Map variants (CVSM and TVSM, respectively). The four techniques were tested with various shadow map texture resolutions using a simple synthetic test scene with a single point light. The test cases are named after the technique being tested and shadow map resolution being used (e.g. CSM 1024). For cube shadow maps, the resolution is specified as edge length of the shadow map cube, in texels. For tetrahedral shadow maps the resolution is specified as edge length of a cube map, which would have a number of map texels closest to the number of texels in the tetrahedral map, thus making the resolution specification comparable to the cube shadow maps.

The reference shadow mask image for our data set can be seen on Figure 3.The shadow mask images used for each test variant are presented on Figure 4. The quality measurement results are presented in Table I, separately for each submetric component. As expected, the lower resolution shadow map variants achieve lower scores, with score changes most noticeable for really low resolution shadow maps. The tetrahedral shadow mapping techniques score on average worse than cube shadow map techniques, as the map shape distortions are more prominent in the tetrahedral maps, resulting in uneven distribution of shadow map texels over the lit scene. The Variance Shadow Mapping variants perform comparably to the non-VSM variants, with noticeable improvement within the lit region at the cost of degradation of shadow region coverage, resulting from softening the shadow edge across the region transitions. It can be seen, that this also slightly influences acne and noise measurements, as this influence was limited, but not completely removed from the metric.

IX. Conclusion

In this article we presented a quality metric proposal for quality measurements of shadow rendering algorithms. We presented several components of such metric, which were designed to measure quality of various characteristics of the shadow mask images. While there is still room for improvements when it comes to the methods and algorithms used, the quality measurement metric presented can already be useful in comparison of shadow rendering algorithms, detecting common rendering artifacts and yielding stable and comparable results.

Abstract—**The paper considers increasing the precision of detection of words in unsupervised keyword spotting method. The method is based on examining signal similarity of two analyzed media description: registered voice and a word (textual query) synthesized by using Text-to-Speech tools. The descriptions of media were given by a sequence of Mel-Frequency Cepstral Coefficients or Human-Factor Cepstral Coefficients. Dynamic Time Warping algorithm has been applied to provide time alignment of the given media descriptions. The detection involved classification method based on cost function, calculated upon signal similarity and alignment path. Potential false matches were eliminated in the algorithm by applying two-staged verification, using the Longest Common Subsequence algorithm and analyzing formant frequencies of eleven English monophthons. The use of formant frequencies at the stage of verification increased overall detection precision by about 10% as compared to original algorithm.**

***Index Terms*—keyword spotting, formant frequency analysis, pattern matching, audio information retrieval**

I. Introduction

INCREASING use of digital sound processing methods to simple daily tasks is currently very popular due to widespread availability of mobile devices having implemented this type of methods. Regarding this trend [1] considers an approach that could be used to detect words in recorded speech of unknown language without training, by using publicly available, free of charge online translation services with Text-To-Speech support e.g.: Google Translate, Bing Translator, Yandex Translate[1].

The problem of word detection consists in searching for given words in a speech medium, which is either solid container or a stream. The detection is usually given by the two coupled values [2]: time code of the beginning of the word and a quality ratio. This problem in contemporary literature is usually called "keyword spotting[2]" (shorten as KWS) [3], [4].

This work was supported by Cybernetics Faculty (Military University of Technology, Warsaw, Poland) under the grant no. RMN/765/2015

[1] Names of the products have been presented in this paper only in relation to the contemporary, publicly available technology, not for marketing purposes.

[2] Also „spoken term detection" (shorten STD).

Classical solutions to this problem address supervised approach where models such as hidden Markov model (HMM) or support-vector machine (SVM) are trained like in a typical automatic speech recognition (ASR) system, using Large Vocabulary Continuous Speech Recognition (LVCSR) methods [5]. In consequence the speech signal is divided into segments of equal-size, from which speech features are extracted. Next, an appropriate algorithm is employed to determine the type of signal in each segment. As a result, recognized words, together with the corresponding indexes are stored in a database. Then, a text query is performed within the indexed data [6].

Based on the fact that for some applications it is not possible to have model trained, either due to lack of relevant training data or due to time-specific limitations, different unsupervised approaches to the problem have been developed [2], [7].

Under the concept of unsupervised matching lay suitable speech features and a classification strategy. The approach presented in [1] employs cepstrum-based features: Mel-Frequency Cepstral Coefficients (MFCC) and Human-Factor Cepstral Coefficients (HFCC). As for classification strategy that approach points Dynamic Time Warping (DTW) algorithm.

However results of applying the method shows relatively high overall rate of false positives: 13,51% for MFCC and 14,86% for HFCC.

In this paper, the author propose an approach to minimize this insufficiency, by adding additional verification stage, based on the analysis of formant frequencies. The motivation for this came from [12]. Using formant frequencies analysis, as shown below, has a positive influence on the results, but limits the versatility of the KWS method to specific language only. Different improvement techniques used for KWS could involve combining of multiple features, like described by Mitra et al. in [5].

II. Problem statement

A. Method background

This paper considers the same use case as in [1]. In this approach the KWS method supports human operator in searching for specific words in a given speech medium. For

this scenario, the sound queries are synthesized directly from text. The method gives coarse detection, prior to involving precise detecting methods or just hearing by the operator.

B. Speech features model

The approach assumes at this point the choice of appropriate speech signal features. In the research two types of feature vectors have been used: Mel-Frequency Cepstral Coefficients (MFCC) and Human-Factor Cepstral Coefficients (HFCC). MFCCs have been computed according to the following algorithm:

1) given signal S has been windowed by Hamming window resulting in N segments, $s_1 \ldots s_N$;

2) each segment has been processed by short-time Fourier transform (STFT) with length of 51 ms and step size of 10 ms;

3) then the triangular filter bank has been developed with 40 equally spaced mel-scale center frequencies f_i, $i = 1,\ldots,40$ and with uniform bands controlled by the neighbor center frequencies $f_{i\pm1}$;

4) next, the actual filtering has been done, by multiplication of each STFT segment (representing magnitude spectrum) with magnitude spectrum of bands for MFCC;

5) finally, the result has been decorrelated using Discrete Cosinus Transform (DCT), keeping only 15 the most decorrelated vectors (MFCC coefficients).

The same model has been applied to Human-Factor Cepstral Coefficients, with a change in point 3). In HFCC, center frequencies are still equally spaced in mel frequency scale, but unlike MFCC filter bandwidth is treated as a parameter, which determines filter bands' cut-off frequencies, using measure called Equivalent Rectangular Bandwidth (ERB) [8]:

$$ERB(f) = 6.23f^2 + 93.39f + 28.52 \text{ Hz} \quad (1)$$

where f states for filter center frequency, expressed in kHz.

C. Textual query

In the presented method Text-to-Speech (TTS) system is exploited to generate synthetic voice from a text query. Next, the query (pattern) is transformed to chosen speech feature space. Then a chunk of speech signal from a given source is read. This chunk is transform to the same speech feature space. Then a classification strategy is applied. In case of the pattern matched, time code of the corresponding sound segment is registered.

Using textual query and TTS make it easy to extend the approach to reflect language variations assumed in the scenario, to search for the same word translated to several languages [1].

D. Similarity and time alignment

DTW is used in the method to compare two feature vectors of different length (analyzed voice and the reference pattern) and to find an optimal alignment path P of both. P is usually calculated upon the local distance matrix (similarity matrix) from the minimal indexes (usually lower left corner) to maximal indexes (usually upper right corner) of the matrix. Optimal means here the lowest cost path P for passing from one point of matrix to another, within given constraints. For details of applying DTW to exemplary speech features vectors, see [1].

Building similarity matrix $D_{A,R}$ where A stands for analyzed voice feature vector and R stands for reference pattern feature vector, is the first step considered in speech classification. Feature vector consists of either MFCC or HFCC coefficients computed for segments $s_1 \ldots s_N$. Individual element $d(a,r)$ of similarity matrix, where a,r stands for specific element of vector A and vector R respectively, is given by inner product:

$$d(a,r) = \frac{\langle A_a, R_r \rangle}{\|A_a\| \|R_r\|} \quad (2)$$

Next, the two-staged cost path algorithm is executed. The first stage stands for the calculation of an accumulator $C_{A,R}$ (where C is of size D). The resulting structure contains at each of its element $c(a,r)$ the value of accumulated lowest transition cost to this element from its neighbors, including the cost of lowest transition to the neighbors from theirs consequent neighbors until the starting element $c(1,1)$. The computation retains directional constraints, according to the recursion:

$$c(a+1,r+1) = d(a+1,r+1) + \min \begin{cases} c(a-1,r) \\ c(a,r) \\ c(a,r-1) \end{cases} \quad (3)$$

where: $a,r \geq 1$ and $c(1,1) = d(1,1)$.

The second stage stands for an optimal aligning of analyzed voice and the reference pattern. In this stage the path P is created. Its creation is based on the accumulator traceback, starting from its last point $c(N_A, N_R)$ and ending in point $c(1,1)$ recursively by searching across all allowable predecessors to each point. Because each point holds the value of the lowest transition cost to itself, the actual calculation of the path is based on choosing the next point upon the minimal value.

E. Classification and verification

After applying DTW, to proper classification an additional matching procedure is proposed in the method, see Fig. 1.

This procedure assigns weight values v based on referring points of matrix $D_{A,R}$ and a path threshold T_P to the path P, satisfying inequality (4).

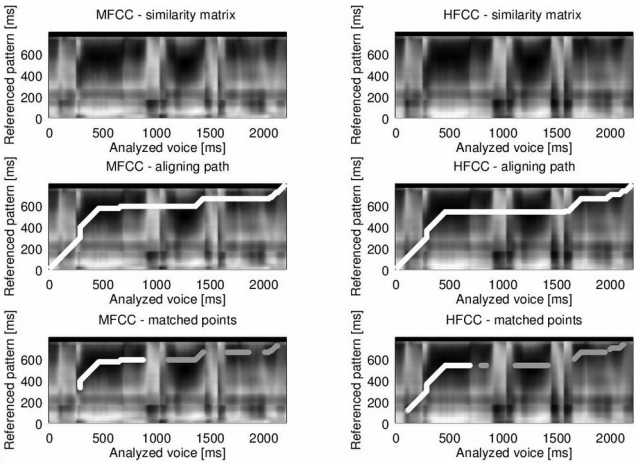

Fig. 1. Pattern matching procedure. Upper images present computed similarity between the pattern (the word "school" - synthesized woman's voice) and analyzed voice (recorded man's voice "school is closed today"). Images in the middle present global alignment path. Bottom images present resultant match: white strip is for the best match, gray strips are for remaining matches.

$$T_P \le v := 1 - d \le 1 \tag{4}$$

where T_P controls the number of points suspected to indicate detected words.

Assuming, that several possible word could occurre, which is indicated by subsequences: $p_{k_1}^{(l)} \dots p_{k_{N_p}}^{(l)}$, $l = 1,2\dots$, the verification step is executed.

Originally this step consisted of applying Longest Common Subsequence (LCS) with maximization criterion of cumulative weights of subsequences, i.e. the longest subsequence with the highest sum of weights wins.

The number of possible word reoccurrence was controlled by sequence threshold value, which restricted the minimal cumulative cost for a subsequence.

As a result of matching procedure, assuming only one occurrence of the searched word, the best match is projected to the analyzed voice time domain (e.g. white strips in the bottom images of Fig. 1).

F. Format frequencies analysis

Conclusions from experiments described in [1] indicate that relatively high level of false positive results could be minimized after applying less speaker-dependent speech features. By following that suggestion and motivated by [12], in this paper the author propose to extend verification step with formant frequencies analysis. Formant frequencies are defined either as an acoustic resonance of the human vocal tract or more technically as local maxima of the envelope of the signal spectrum. As stated in [12] they are important in determining phonetic content of speech sounds, but they are not quite good speech features. This is because of, on one hand: their little speaker dependency (assuming the same speakers gender) and existence of cataloged form for specific language (usually including frequency range for a specific phonetic unit). On the other hand: their strict connection with high signal energy of phonetic units, like vowels, and unreliable measure of purely defined signals (silence, weak fricatives, etc).

Nevertheless in this paper it was hypothesized that knowledge of at least a part of speech segment will positively influence the quality of detection.

III. KWS SUPPORTED BY FORMANT FREQUENCIES ANALYSIS

A. Formants estimation

In the described research formant frequencies have been estimated only for English vowels, as for all other phones such frequencies either do not exist or are difficult to be identified. The following phonetic convention of the vowels has been adopted (see table 1) in the presented research.

TABLE 1. PHONETIC CONVENTION OF ENGLISH VOWELS SELECTED FOR THE RESEARCH[3]

Classi-ficatio n	***IPA[4] notation***	***Own[5] notation***	***Example***	***Choice***
short vowels	/ʌ/	a	c<u>u</u>p	Yes
	/æ/	ae	c<u>a</u>t	Yes
	/e/	e	b<u>e</u>d	Yes
	/ə/	e_	<u>a</u>bout	No
	/ɪ/	y	h<u>i</u>t	Yes
	/i/	i	happ<u>y</u>	No
	/ɒ/	o	h<u>o</u>t	Yes
	/ʊ/	u	g<u>oo</u>d	Yes
long vowels	/ɑ:/	aa	<u>ar</u>m	Yes
	/ɜ:/	ee	b<u>ir</u>d	Yes
	/i:/	ii	s<u>ee</u>	Yes
	/ɔ:/	oo	c<u>a</u>ll	Yes
	/u:/	uu	f<u>oo</u>d	Yes

In English language, there are 5 vowels: <a, e, i, o, u>, but their pronunciation depends on a variety of factors, resulting in several distinguishable monophthongs[6]. Usually for phonetic analysis from 8 to 13 monophthongs are chosen [9]. According to [10] for further analysis 11 monophthongs have been chosen, the choice is marked in table 1, in the far right column[7].

TABLE 2. AVERAGE VALUES OF F_1, F_2 AND F_3 IN HZ [10].

	Male			Female		
	F_1	F_2	F_3	F_1	F_2	F_3
/i:/	280	2249	2765	303	2654	3203

/ɔ:/	415	828	2619	389	888	2790
/ʊ/	379	1173	2445	410	1340	2697
/u:/	316	1191	2408	328	1437	2674
/ɜ:/	478	1436	2488	606	1695	2839

[3] Own work based on [9] as well as other materials available at official IPA website: https://www.internationalphoneticassociation.org/

[4] International Phonetic Alphabet

[5] Own notation was used because of programming and results presentation reasons.

[6] Single and the smallest phonetic unit; pure vowel sound.

[7] The choice was caused by the most recent research found in this area, which published a comprehensive list of results.

B. Algorithm

In general overview the KWS algorithm discussed in this paper is presented in Fig. 2. Description of presented processing blocks can be found in [1], but the verification stage is described in details below. The input to the verification stage is given from the LCS algorithm, resulting in a few best matches (e.g. in the bottom images of Fig. 1 there is one best match colored white, the other stripes, colored gray, present remaining matches).

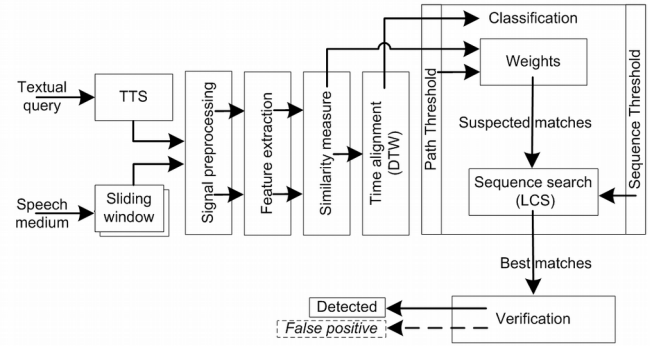

Fig. 2. Unsupervised key detection algorithm.

Let's assume there is only one best match and the verification stage is to decide if this match is a true detection or a false positive detection. Then the resultant match is subjected to verification, which is based on the analysis of formant frequencies: the reference pattern vector of formant frequencies and the analyzed voice vector of formant frequencies. It is worth noting that these two signals are after the whole procedure time-aligned, thus could be extracted and analyzed separately. Then for these excerpts the algorithm described in [11] is carried out to estimate formant frequencies.

As for the reference pattern excerpt the resultant formant sequences (exactly two formant frequencies F_1, F_2 have been chosen) are averaged and compared with the values described in table 2 to estimate appropriate monophthong.

The estimation of monophthong is performed by comparison of averaged estimated frequency F_1 from the excerpt, to all F_1 values from the table 2. The difference between the values (its absolute value), measured in the sense of Euclidean, is treated as the quality of the detection (monophthong cost). The smaller the difference the better the detection. The same estimation is done for F_2. As a result of this procedure monophthongs are detected (if any) for the reference pattern. From the collection of all detected monophthongs only the one with the smallest cost is chosen. The example of detection of /u:/ monophthong for the reference pattern is presented in the Fig. 4. on the vertical axis[8].

This estimation is carried out in an analogous manner to the analyzed voice excerpt. Finally, if the estimated monophthong for reference pattern matches analyzed voice monophthong, then according to the scenario assumed in the research, the excerpt with analyzed voice is played back to the human operator.

[8] It should be noted that the time position indicated by white lines has only illustrative value and not necessarily reflect the detection of a monophthong. This is due to successive averages made in the algorithm.

C. Experiments

A series of preliminary experiments have been conducted with regard to the presented algorithm. The target was to determine the influence of the proposed verification stage based on formant frequencies analysis to the quality of detection.

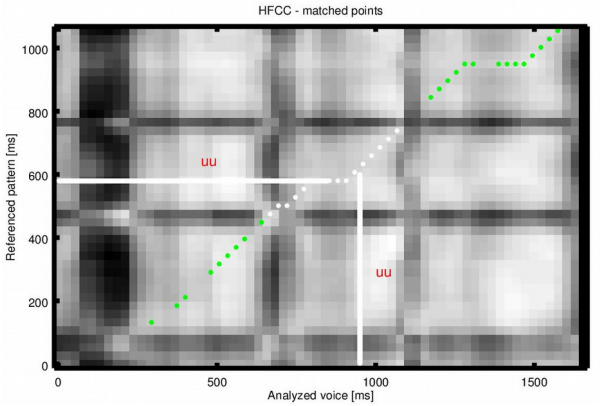

Fig. 3. An example of detecting monophthong /u:/ in the word "school". The dots represent optimal alignment path (as a result of DTW). White dots represent best matched sequence (as a result of LCS). While the white lines with the description "uu" represent the (averaged) position of the detected monophthong in the matched sequence.

The experiments have been conducted on the same research material as the original method [1], but only male voices have been chosen. Therefore the material consisted of five short (from 1 – 5 seconds) sentences in English language: spoken by one man (natural speech) and synthesized by six TTS systems with fourteen men voices. This material has been stored on a hard drive in the WAV containers.

The queries have been produced online by one chosen TTS system, different from these used in prepared research material. The TTS was accessed through the World Wide Web via HTTP protocol.

During examination all used sounds were resampled to 8000 Hz. The model (Fig. 2) was configured according to the same guidelines as in the original examinations.

Experiments have been conducted according to the following strategy: selected word to find (textual query) has been sent to the TTS system to obtain speech signal, the signal then has been read by program and compared with the entire research material according to the algorithm (Fig. 2).

D. Results

A series of preliminary results were obtained. They were compared to the results of the original method [1]. This allowed to determine the influence of the new verification approach on the quality of word detection. These results are shown in Table 3.

As it was hypothesized the percentage of false positives decreased. The decrease is about 40%. Surprisingly this had also positive effect to the percentage of detected words and had no negative effect on misses ("No detection").

The results showed that the unsupervised detection of word in a given set is possible with relatively high detection rate. Moreover, new verification method has given satisfactory results, approaching the method to industry

standards. Comparing the actual results with the original results of the method (MFCC: 82.43%, HFCC: 85.14%), it can be concluded, that MFCC recorded an increase of 8.32 percentage points, and HFCC recorded an increase of 8.66 percentage points. This gives an overall increase in precision of about 10% for both MFCC and HFCC features.

However taking into account small research material involved in the examination, these results do not allow for general statements.

TABLE 3. **Overall results by speech features**

	Detected words	**No detection**	**False positive (new method)**	**False positive (original method)**	**Overall increase in the elimination of false positives**
MFCC	90,75%	4,05%	5,19%	13,51%	38,41%
HFCC	93,8%	0,00%	6,2%	14,86%	41,72%

IV. CONCLUSIONS AND LESSON LEARNED

Results of the work shows that the inclusion in the KWS formant frequencies analysis, increases its quality. This partly proves the hypothesis that knowledge of a part of speech segment has a positive influence on the quality of detection. The main advantage of this approach is the elimination of false positives. However the presented approach limits the application of the method only to one language, due to the requirement of having a catalogue of formant frequencies. The requirement of possessing 3 formant frequency models (for male, female and children) for each language is also a strong one.

During the examination the author also encountered the problem of covering (overlapping) formant frequencies that lie in close proximity to each other (in the spectrum), also well known from the literature (see [12]). For example, for F_1 and F_2 in the spectrum only one peak is perceptible. In the described research it was noticed that generally F_2 overlaps F_1, therefore F_2 becomes F_1 and F_3 becomes F_2 in consequence.

One solution to this problem was to properly assign these frequencies as F_2 and F_3, leaving F_1 undetected (or arbitrary setting its value to 0).

Leaving the problem unresolved significantly deteriorates estimation of vowels, to the extent, that the result becomes random.

The problem in the presented approach (especially while applying DTW and LCS) that cannot be fully circumvent is the determination of the threshold values. According to literature search, the most popular technique for solving this problem in KWS, is to parallel true positive rate with false positive rate for several chosen threshold values, to create Receiver Operating Characteristic (ROC) and to find optimal threshold value by using graphical method.

An Improvement of Just Noticeable Color Difference Estimation

Kuo-Cheng Liu

***Abstract*—In this paper, the estimation of just noticeable color difference in color images is improved by using a new spatial masking. The internal generative mechanism of human of brain theory implies that the human visual system (HVS) is sensitive to the orderly stimulus possessing structural regularity which is easily to be predicted and is insensitive to the disorderly stimulus containing structural irregularity. It is obviously that the spatial masking in color images may be overestimated in the region with orderly structures and underestimated in the region with disorderly structures. By using a simple prediction model imitating the brain works of the HVS, the structural irregularity is computed to build a new masking function that can be used to improve the estimation of just noticeable color difference for color images. The masking function is further extended to build a color visual model of estimating the visibility thresholds of color images for performance comparison. Simulation results demonstrate that the proposed method is able to obtain better performance of estimating just noticeable color difference.**

I. Introduction

THE well known properties that the human visual system (HVS) has a limited sensitivity in perceiving visual information are always utilized to represent images more efficiently. Through assessing the human visual sensitivity inherent in images, the performance of many techniques has been improved in the perceptual research community and can be found in [1]-[5].

By using different levels of just noticeable color difference (JNCD), a simplified visual model introduced in [4] for estimating the perceptual redundancy for each color pixel as the visibility threshold of color difference was proposed to modify the coding efficiency of two existing image coders. In [6], Zhu *et al*. proposed a perceptual based no-reference objective image quality metric by integrating perceptually weighted local noise into a probability summation model. Unlike existing objective metrics, the proposed no-reference metric is able to predict the relative amount of noise perceived in images with different content, without a reference. Hsieh *et al*. [7] presented a copyright identification scheme for color images that takes advantage of the complementary nature of watermarking and fingerprinting was proposed to embed the watermark into the less sensitive R and B channels of the host image in the RGB color space. To gain high performance in color image processing, the properties of the human visual perception of color stimuli must be well utilized.

In this paper, the concept indicating that the brain works actively predict the input scenes and avoid the residual uncertainty/disorder is utilized to improve spatial masking for color images. Based on a simple prediction model, the luminance dominated structural irregularity is taken into account to explore a more strict spatial masking function in color images, while only background non-uniformity and texture content are used in the prior works. To avoid underestimating or overestimating the spatial masking effect in the region with structural uncertainty, the nonlinear additivity model is adopted to build a new masking function. By using this function, the visibility thresholds of color images are estimated for performance comparison under a fair viewing test.

II. Structure-based Adjustment for Spatial Masking

In [4], the spatial masking effect considering the local color image context is exploited to calculate variable just noticeable color difference (JNCD) or variable JNCD (VJNCD) of each color pixel in the uniform CIELAB color space. That is,

$$VJNCD_p = JNCD_{Lab} \cdot s_c(a_p, b_p) \cdot s_L\big(E(L_p), \Delta L_p\big) \qquad (1)$$

where $s_c(a_p, b_p)$ is a weighting function used by the CIE94 color difference equation for adjusting the dimension of the ellipsoid along the chroma a, b axis, $s_L(E(L_p), \Delta L_p)$ is texture masking adjustment primarily induced by average

background luminance $E(L_p)$ and luminance gradient ΔL_p for pixel p of the color image, and $JNCD_{Lab}$ is the basic visibility threshold of color difference in the CIELAB space. The basic threshold has been found around 2.3[10]. By using the colors on the surface of the VJNCD sphere, the perceptual redundancy inherent in each color pixel in color images can be estimated. According to the principle recently introduced in [8], the input scene information received by human eyes is not fully processed by the HVS and some information with structural irregularities is avoided and hard to be predicted. Herein, the structure-based adjustment, $s_U(LR_p)$, caused by considering the amount of luminance residual, LR_p, is proposed and incorporated to improve the estimation of variable just noticeable color difference. In this paper, both the structure-based adjustment and the texture masking adjustment are adequately combined to design a new spatial masking function $\Lambda(p)$ for modifying Eq. (1). For simplicity, only the luminance dominated structural irregularity inherent in the color image is investigated, while considering the fact that the human eye is more sensitive to luminance than to chrominance.

Based on the concept of internal generative mechanism of human of brain theory, the structural irregularity of an image is from the uncertain information which is hard to be predicted for the HVS. We reasonably regard the uncertain information of the image as the residual part between the image and its prediction part [9]. An computational prediction autoregressive (AR) model for the luminance component of the color image is therefore exploited and given by

$$L'_p = \sum_{p_i \in \Re} k_i L_{p_i} + \nu_p \tag{2}$$

where L'_p is the predicted luminance value of pixel p, p_i the i-th neighboring pixel in the surrounding region $\Re = \{p_1, p_2, \ldots, p_N\}$ and $\{k_i\}$ the model coefficients which are determined by minimizing the variance of the white noise $\{\nu_p\}$. The residual part is then computed as the uncertain information to construct the relation between structure-based adjustment and structural irregularity.

III. Verification of the Improved Variable Just Noticeable Color Difference

The performance of estimating the improved variable just noticeable color difference is verified by incorporating Eq. (1) into Chou's model [4] to compare the accuracy of estimating the visibility thresholds of color images. For a particular color pixel, the perceptual redundancy is quantitatively measured by analyzing the loci of colors which are perceptually indistinguishable from this color. In [9], the loci form a sphere centralized at this color's coordinate with the radius of VJNCD in the uniform CIELAB color space and used to compute the visibility thresholds of color pixels in color images. The improved VJNCD of the color pixel p within a complex image is then redefined as

$$VJNCD'_p = JNCD_{Lab} \cdot s_c(a_p, b_p) \cdot \Lambda(p) \tag{3}$$

The procedure for estimating the perceptual redundancy of a pixel in an arbitrary color space is firstly to transform the color pixel to the CIELAB space. By using Eq. (1) that utilizes the improved spatial masking function in this paper, the corresponding improved VJNCD threshold is obtained. Under the perceptually conservative restriction controlled by the luminance, some critical colors on the surface of the improved *VJNCD* sphere are selected to transform back to the target color space. Finally, an approximate rectangular subspace is obtained to quantify the perceptual redundancy and the visibility thresholds of the color pixel for each color channel are calculated.

The verification of the improved variable just noticeable color difference for color images is inspected by comparing the accuracy of estimating the visibility thresholds of color images in each color component. Herein, a subjective test is conducted to inspect if the estimated visibility thresholds is consistent with the HVS. Suppose a test image is represented in the YCbCr color space, the visibility threshold for each color pixel in each color component of the color image is randomly added to or subtracted from the corresponding color pixel. The accuracy of estimating the visibility thresholds is better if the PSNR of the contaminated image is lower, while the visual quality of the contaminated image has nearly the same as the original image under the specified viewing condition.

IV. Simulation Results

In the viewing test, the original color image and its noise contaminated image are randomly placed side by side on the monitor. The test is carried out in the dark room when the subject observes the image pair on the monitor at a viewing distance of six times the image's height. In the simulation, a variety of standard test color images are used. The color pixels are represented in YCbCr format. 16 subjects who have normal eyesight or had been corrected to be normal take part in test.

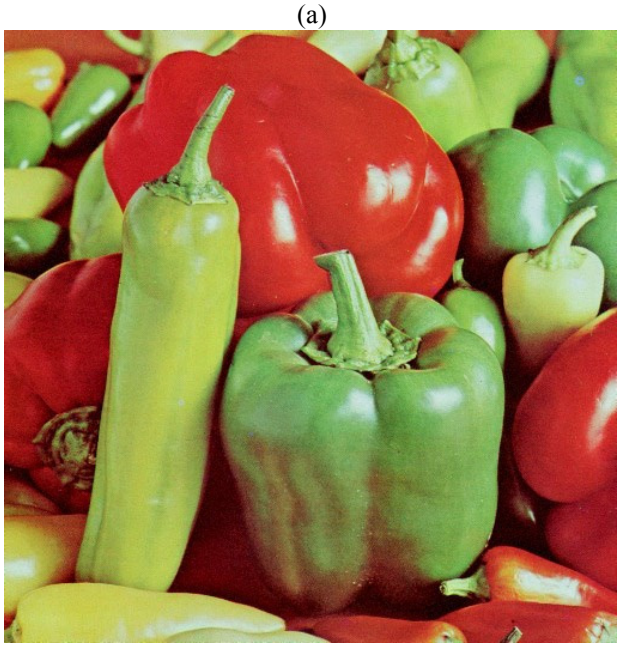
Fig. 1. (a) Original color image of "Zuerst" and (b) its noise contaminated image (PSNR=34.95B)

(a)



(b)

Fig. 2. (a) Original color image of "Pepper" and (b) its noise contaminated image (PSNR=33.20dB)

In Fig. 1, the original color image of "Zuerst" (Fig. 1a) and its noise contaminated version (Fig. 1b)of PSNR=34.95dB by the associated visibility thresholds in three color components are shown, while the two images are perceptually indistinguishable from each other under the viewing condition mentioned above. To achieve a fair comparison for verifying the improvement of the existing variable just noticeable color difference, the simulation results are compared with the color visual model proposed in [4]. The PSNR of the noise contaminated color "Zuerst" image by the method presented in [4] is 36.87dB at nearly the same visual quality. Fig. 2 shows the experimental results for "Pepper" color image. It is shown that the improved spatial masking estimation based on the uncertain information indeed achieve larger noise concealment in the regions with structural irregularity, while the visual quality of the noise contaminated image has nearly the same as the original image under the specified viewing condition. Under the same perceptually indistinguishable visual quality for 12 standard test color images, the average PSNR of the noise contaminated color images by the proposed method is 1.4dB lower than that by the Chou's method. The

proposed spatial masking adjustment successfully shows better performance.

V. Conclusions

In this paper, the estimation of just noticeable color difference in color images is improved by using a new spatial masking. By using the brain works of the human visual perception which is sensitive to the orderly stimulus that is easily predicted and is insensitive to the disorderly stimulus, the estimation is incorporated with a simple prediction model to effectively obtain a new spatial masking function. We use the function to improve the just noticeable color difference for computing the visibility thresholds of color images for performance comparison. With the new spatial masking function, the proposed spatial masking adjustment successfully shows better performance than the existing masking method.

***Abstract*—In this paper we present a new method for content-based image retrieval. The method is based on querying database by approximate shape representing given object. In this way all images containing the object may be found. Shapes are specified as a set of geometric primitives and attributes. Relations between primitives are represented by a graph. Our graph matching algorithm is used for computing the level of similarity between shapes. The method may be also used for searching transformed as well as partially covered objects. Experimental results showed the efficiency of our approach.**

I. Introduction

SEARCHING for specific images or any graphical objects is one of the most challenging problem in image analysis, called image retrieval. The large image data sets are stored in databases, file systems, Internet resources, and other repositories. Moreover, the size of each individual image is increasing due to the development of new high-resolution sensors. Methods which are used in order to retrieve images may be grouped into the following three categories: Keyword Based Image Retrieval (KBIR), Semantic Based Image Retrieval (SBIR) and Content Based Image Retrieval (CBIR) [1].

The KBIR methods are based on metadata which describes images stored in the database. During the query, the set of keywords is compared with the metadata- textual description for each image, which most often contains also a set of keywords. KBIR methods provide good results and are fast, but their quality depends on the image annotations. In many cases image descriptions are not available, annotations are incomplete or not ambiguous. For example the person who is preparing keywords for images may not have enough knowledge or identify some objects wrongly. There are also some algorithms which tries to prepare keywords automatically without human interaction, but they suffer for the same problems. Moreover the number and precision of descriptions is also very important. In order to overcome problems with proper keywords, the CBIR algorithms were proposed [2]. In this group, a query has a form of a sample image, which is used to retrieve similar images. In SBIR methods queries concern semantic meaning of the image. They are based on textual annotations or automatic image recognition.

In this paper, a new Content Based Image Retrieval method is proposed. The idea is based on image decomposition into primitives with attributes. The detected primitives are transformed into a graph which is used for object matching. The main advantage of our method is that it is not based on strict comparison of objects, but it compares approximate shapes, therefore it may be applied for transformed (e.g. scaled, rotated, tilted) as well as partially covered objects.

The paper is organized as follows: next section describes the review of existing content-based image retrieval methods and the motivation to this work. Our algorithm is presented in the section 3. Finally, experimental results, conclusion and further directions of our research are given.

II. Content-Based Image Retrieval

Two types of CBIR algorithms may be distinguished: low-level approach and high-level one. The low-level algorithms, during image processing, use the whole frame, e.g. computing normalized color histogram [3], a difference moment and entropy [5], spatial domain [4] or MPEG-7 shape and texture descriptors [6]. The results of low-level algorithms are most often precise when searching for the whole image (e.g. a painting), but when querying for a specific object they are insufficient. In this case, the high-level algorithms provides much better results. Most of them are based on regions which are groups of similar pixels. After region extraction, they are transformed into graphs and compared with graphs from the database. During the region extraction different techniques are used, e.g. color-based or fuzzy patterns recognition [7]. This group of algorithms provides very precise results but are problematic for users when they does not have full knowledge about searched objects or does not have sample query image.

Our work focuses on CBIR method based on query by shape. Such methods are useful when a user looks for images containing given class of objects, and the query is specified as an approximate sketch drawn manually or using graphical editor. There are some methods which deal with this problem. In [8] the human drawn image sketches are compared, but their algorithm relied on low-level image sketch and was not oriented on objects. There are a lot of methods for shape extraction from images for image retrieving. They are based of FFT [10] or on extracting some features of the shape [9]. Others are using stroke points with gradient fields which are combined with Poisson HOG [15] or edge based shape vectors [16]. There were also some attempts to use both raster and vectorized image, e.g. using color moment and topogeo

978-83-60810-90-3/$25.00

descriptors [17]. It was shown that shape-based image retrieval methods are very efficient. But existing methods are based on strict shape matching, therefore transformed or partially covered shapes may not be recognized. In [11] a method where query image may be a hand-drawn sketch was proposed. The method compares the query with the whole image using wavelet decompositions.

In our previous work [12], [13], [14] we proposed some high-level methods which are based on predefined shapes, easy to drawn by a human but also to extract from the query image. Our preliminary works showed that our graph-based representation of shapes is very suitable for object matching, even when object are deformed. Hence, we decided to continue our research. The goal of this research was to propose a new CBIR algorithm which will be suitable not only for queries specified by image objects but also for human drawn queries. The queries decompose object shape into smaller parts which are then compared with shapes extracted automatically from images stored in the database. Moreover, because objects are represented by approximate shapes, the matching is defined by the level of similarity.

Our previous researches were focused only on two primitive types - lines and ellipses. During the tests, we found that this set provide good results for human-based, angular objects, but for the other types, the results may be insufficient. In order to improve the precision of results for such objects, the primitive set had to be extended with rounded ones. Moreover, during experiments we also noticed that in some parts of objects there is very important to store the relations between primitives of the same type. For example, some of the lines in the bicycle object are connected with each others and when combined, they create a chassis. In our previous researches that situation was covered by connections between primitives in the graph, but we decided to strengthen the validity of that fact.

III. Query by Approximate Shape

The method is based on two ideas: an object representation and a matching algorithm. Objects are specified using shapes decomposed into primitives which are extracted from the image or are drawn by an user. Shapes are represented with graphs, where nodes correspond to primitives and edges are between nodes associated with adjoining primitives. After building a graph, the matching algorithm, which compares the queried object with an object from the database, is applied. The system overview is shown in the Fig. 1.

A. Object representation

The main idea of our approach is based on approximation of any shape with limited set of simple primitives. Each primitive shape may have attribute defining size, color, orientation etc. The two most basic types of primitives are line segment and arc. Usually lines and arcs compose more complex shapes, therefore we also consider polylines and poly arcs as primitives. When polyline (or poly-arc) creates closed loop, it creates a plane. Since the plane has additional attributes like texture or color of the surface, we also consider polygons and arc-sided polygons as primitives. Hence, 6 different primitives are distinguished (Fig. 2). All shapes are approximated using the above primitives with attributes. It is very important that approximation should be deterministic, i.e. similar objects should be approximated with similar shapes. Query images as well as images from the database are approximated in the same way.

The predefined set of primitives allows approximation of different shapes, even composed of curved segments. For each primitive we also define the following basic attributes, which describes orientation of the primitive:

- for line segment: the size and the angle defining the slope,
- for polyline and polygon: the number of line segments, attributes of the following line segments,
- for arc: the size and the angle,
- for poly-arc and arc-side polygon: the number of segments, attributes of the following arcs.

In order to allow comparisons of shapes with different sizes, all sizes are normalized and have values between 0 and 1.

The approximation of any object is done using the following procedure: first edge detection is performed. Then all segments are approximated with lines and arches, next all polygons and arc-sided polygons are extracted, finally connected lines and arches are converted into polylines and poly-arcs. Since after line segments detection in real life images very often lines are divided into smaller parts, a line merging should be applied. If the distance between endings of two line segments is below the line merging threshold (Fig. 3 a)), their angles should be tested. If for both segments angles are the same, the merging could be performed. Moreover there may be also a situation when an arc was detected as a set of lines (Fig. 3 c)). In order to detect and convert set of segments into an arc, firstly it should contain at least 3 connected segments with endings in very close distance. Next, the angles between lines should be measured. If their values are the same—the set of segments could be converted to an arc (Fig. 3 d)).

The predefined set of primitives covers most geometric shapes, the Fig. 4 shows the example car (b), bicycle (c) and flower (d) objects. There may be noticed that all circles are detected as arches (with 360° angle). Next, all primitives based on arches and line segments have to be detected. Firstly all polygons and polygon arches are extracted, next polylines and poly-arches. When a primitive is detected, all its line segments or arches must not be used as part of other primitives.

After detection of primitives, the graph representation is being built. During this process, the following relations between primitives are stored:

- which primitives are close to each other or which primitives are connected,
- positions of the above primitives (using 8 directions: N, E, W, S, NW, NE, SW, SE - see Fig. 5).

When some primitives are connected to each other, they create a more complex shape (e.g. adjoined triangles, quadrangles and arches). Because information about which primitives belong to which complex shape and how complex shapes are

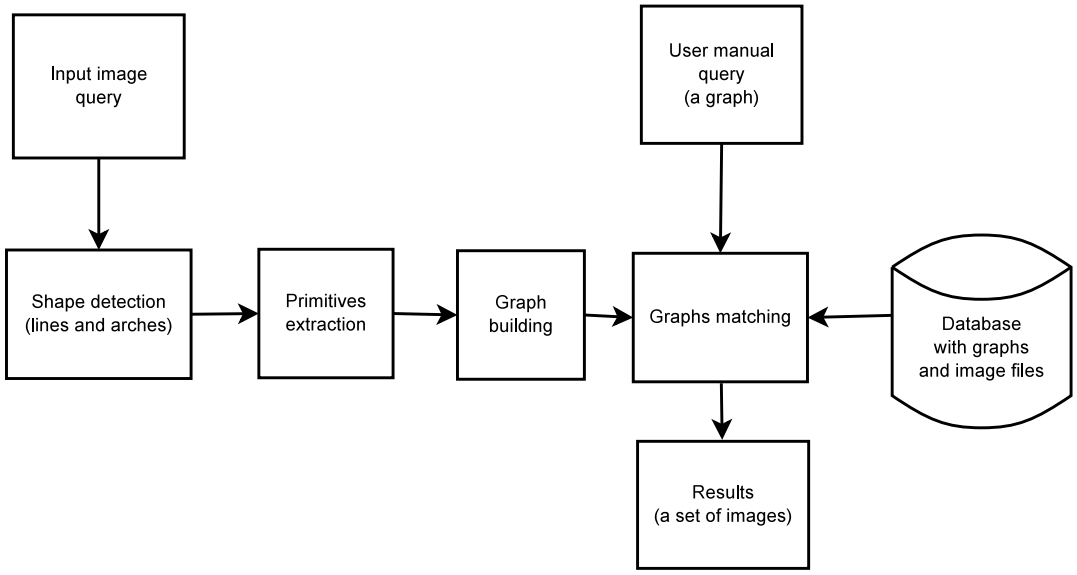

Fig. 1. The system overview.

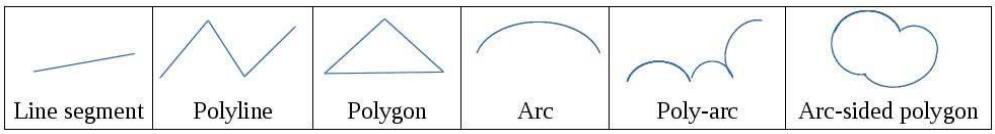

Fig. 2. Predefined primitives

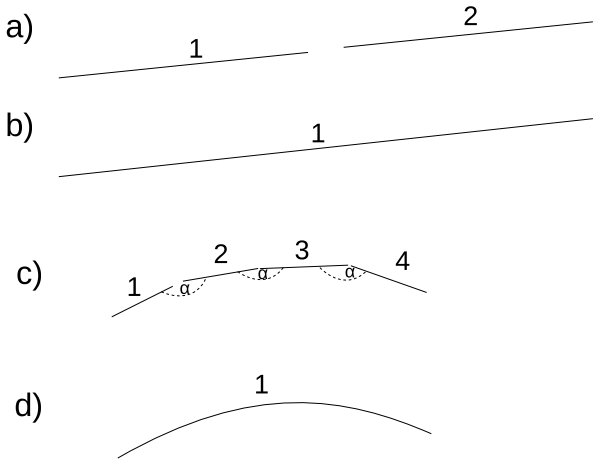

Fig. 3. Lines preprocessing. a) a splitted line into two segments with the same angles and very close distance between endings, b) line after merging, c) lines which may construct an arc d) an arc after lines conversion.

situated to each other may be useful during object matching, it is also stored. Moreover, in real life images, sometimes primitives which should be connected are not connected but are placed in a very close distance, for example because of inaccuracies of line segment detection algorithm. To overcome this problem, the maximal distance between primitives is used when creating connections.

The Fig. 4 shows the conversion of a sample car, bicycle and flower objects into graphs. Firstly, the algorithm detected all base primitives - arches and lines. For the car and bicycle objects, wheels and gear were detected as arches with $360°$, while their chassis as a set of lines. Some parts of car's body were recognized both as arches and lines. For the flower object, stalk and all petals were detected as arches. The second algorithm step, construct more complex primitives on the basis of the previous detection. Firstly, polygon arches and polylines are extracted as a result of the process of line and arches endings examination. For example, if the distance between two lines endings is lower than maximal distance threshold, they are combined as a polyline. The maximal distance threshold was introduced as a result of our previous tests with real life images. Very often we noticed the situation when the lines had to be connected, but as a result of some failures of line detection algorithm there was some space between the endings. In this step, all petals were combined as a one polygon arc, and car's windows and bicycle chassis as polylines. After polylines detection, the algorithm checks if they could construct a polygon (as a result, one of the windows and part of chassis were transformed). The last algorithm step constructs complex shapes and graphs. All detected primitives which are close to each others are combined using maximal distance threshold. All their position relations are stored, as was stated previously (e.g. the stalk arc is slightly on the left and below the petals polygon arc - the SW direction). For

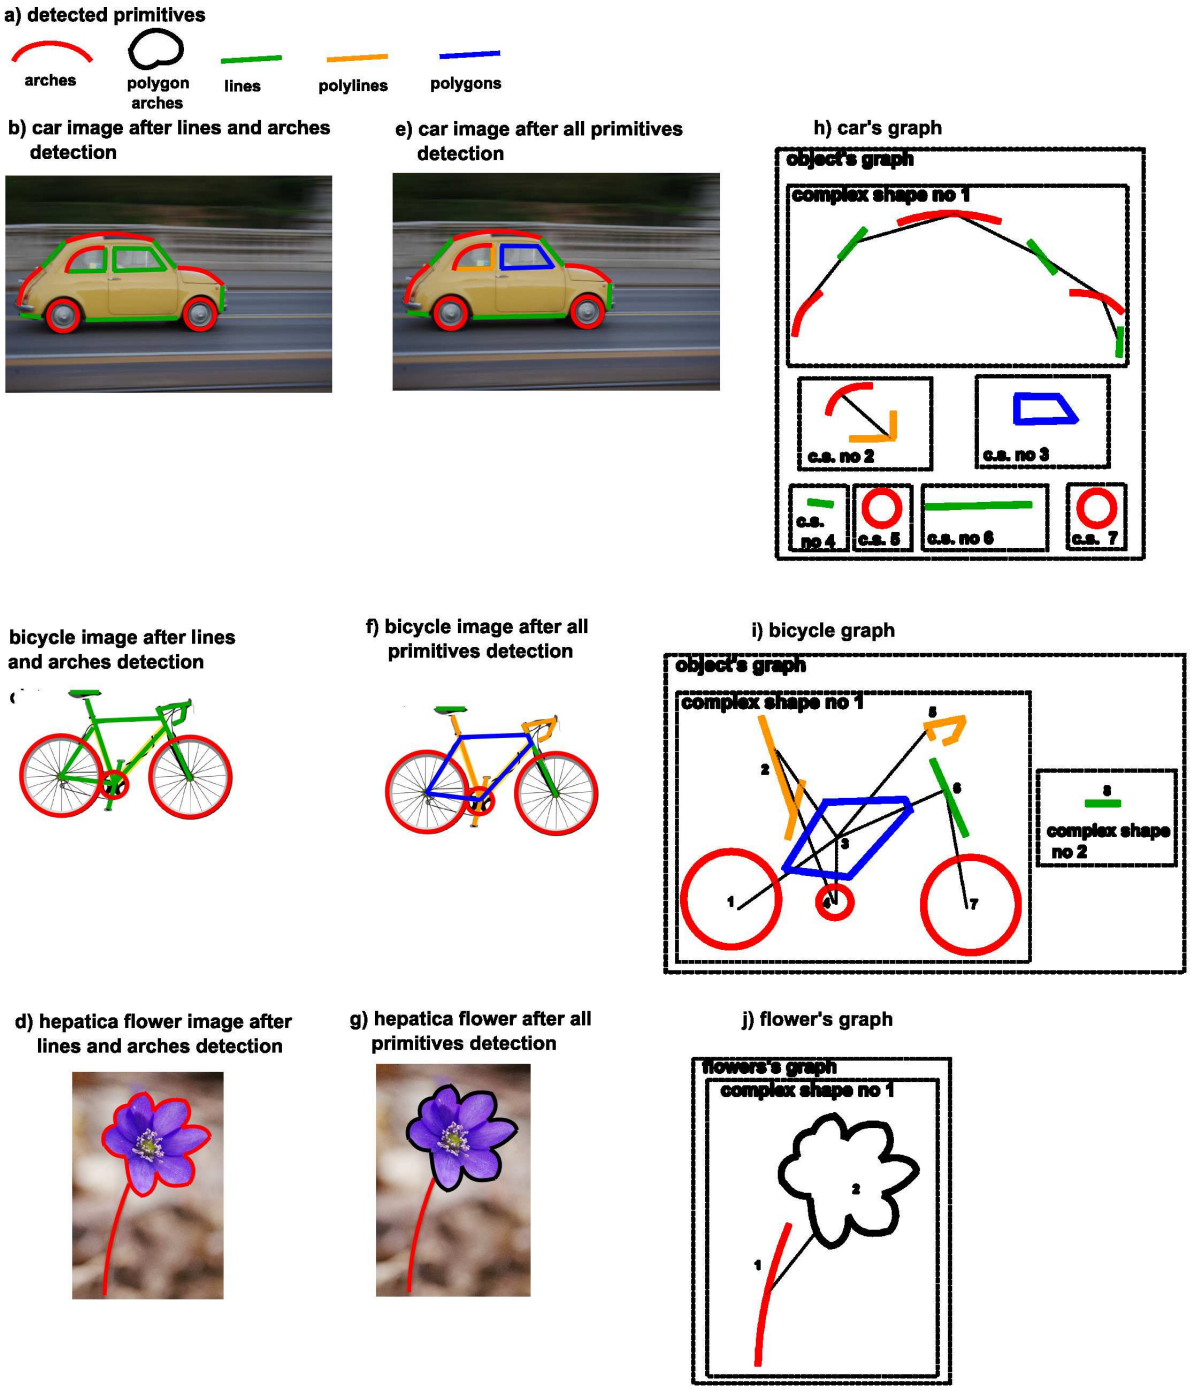

Fig. 4. The examples of primitives detection and graphs used for comparisons.

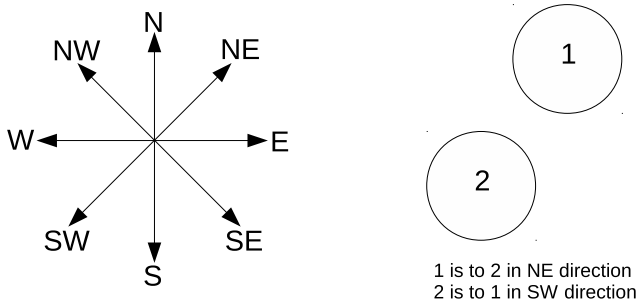

Fig. 5. The directions used in the algorithm and example of usage.

the car, 7 complex shapes were created, because there were unconnected groups of primitives. But in case of the flower, all primitives were connected and created only one complex shape.

B. Matching algorithm

The matching algorithm is partially based on our previous research [12]. All comparisons between objects are performed hierarchically in order to improve the performance, but also to reject objects which are not similar in the first steps. The algorithm is as follows:

Assumptions:

- O - searched object
- M - object from the database with which O is compared
- T_{CS} - threshold which defines the minimal number of complex shapes from O matched with M - values: $< 0, 1 >$, 0 - none, 1 - all
- T_P - threshold which defines the maximal difference between parameters, values: $< 0, 1 >$, 0 means the values are the same
- T_N - threshold which defines the minimal number of connections to other primitives with the same type and mutual position between primitives - values: $< 0, 1 >$, 0 - none, 1 - all
- T_{sim} - threshold which defines the minimal similarity of two objects graphs, values: $< 0, 1 >$, 0 - objects are completely different, 1 - the same objects
- thresholds: T_{CS}, T_P and T_N are used only to improve the performance and to reject not similar complex shapes or primitives in the earliest algorithm stages.

1) Try to match all complex shapes of O to all complex shapes of M, comparing the number and types of primitives and mutual positions.
   a) N_{CSP} = the number of primitives in O's complex shape with the same type as in M's complex shape
   N_{CSO} = the number of primitives in the O's complex shape
   N_{CSM} = the number of primitives in the M's complex shape
   $sim_{CS} = \frac{N_{CSP}}{max(N_{CSM}, N_{CSM})}$
   b) If $sim_{CS} < T_{CS}$ then go to a) and compare O's complex shape with the next M's complex shape.
   c) Add the pair of complex shapes to the list, storing theirs sim_{CS}.
2) For each pair of complex shapes CS_O (O's complex shape) and CS_M (M's complex shape) from the list:
   a) Try to match primitives - compare each primitive P_{CSO} of CS_O with each primitive P_{CSM} of CS_M:
      i) If P_{CSO} and P_{CSM} types are different, check another CS_M's primitive and go to a)
      ii) Compare primitives attributes and compute sim_P coefficient:
      $$c = \sum_{i=1}^{n} |(i^{th}\ attribute\ of\ P_{CSO}) - (i^{th}\ attribute\ of\ P_{CSM})|$$
      $$sim_P = \frac{c}{n}$$
      iii) If $sim_P > T_P$ then check another CS_M's primitive and go to a)
      iv) Compare connections of P_{CSO} and P_{CSM}:
      N_{PCSO} = the number of P_{CSO}'s connection to other primitives with the same type and mutual position as in P_{CSM}
      $$sim_N = \frac{N_{PCSO}}{the\ number\ of\ connections\ in\ P_{CSM}}$$
      v) If $sim_N < T_N$ then check another CS_M's primitive and go to a)
      vi) If $(1 - sim_P) * sim_N$ is greater than previously stored values, store them as a new P_{CSO}'s matching:
      $$P_{sim_{CS}} = (1 - sim_P) * sim_N$$
   b) Modify sim_{cs} value for complex shapes pair CS_O and CS_M:
   $$sim_{CS} = \frac{sum\ of\ P_{sim_{CS}}\ for\ each\ primitive}{number\ of\ primitives\ in\ CS_M}$$
3) For each CS_O choose the CS_M matching using the highest sim_{CS} values. If there are more than one maximum value, use the mutual positions of complex shapes.
4) Compute the graphs similarity coefficient:
   $$sim = \frac{sum\ of\ each\ complex\ shape\ sim_{CS}\ of\ O}{the\ number\ of\ complex\ shapes\ in\ M}$$
5) If $sim < T_{sim}$ then objects are not similar.

IV. Experimental results

The algorithm was firstly evaluated using cars, bicycles and flowers objects. The Fig. 6 and Fig. 7 shows sample images, their graphs and normalized attributes. In the tables, the 'Complex shape' column contains the sequence number (which may be used e.g. as a reference to a specific complex shape). The 'Primitive' column was divided into two sub-columns: 'No' and its 'type'. The 'No' contains the sequence number of a primitive which is unique in the whole image. The

'Attributes' column consists of the 'count' which informs how many sub-primitives constructs the primitive and the 'Values' which is a list of attribute values for each sub-primitive. As mentioned earlier, the attribute is computed as a normalized sub-primitive angle which stores values between 0 and 1. For lines the direction angle is used, for arches the central angle is used.

When comparing the same classes of objects, the sim values should be high. In our tests, for comparison of car 1 with car 2 from Fig. 6 the sim value was equal to 0.75 which means that objects are similar in 75%. Because in both graphs there are two complex shapes containing only one circle (arc with 360°= 1 after normalization), after algorithm execution, there were two candidates of matching for complex shapes no 5 and 7 (in car's 1 graph). In order to choose the best matching, the algorithm checked the mutual positions with other complex shapes. Comparisons with different classes should result with lower sim values. For example when car 1 was compared with a bicycle from Fig. 7 a) and b), the sim value was equal 0.14. For completely different classes, like hepatica flower (Fig. 7 c) and d)), the sim reached 0 value. The hierarchical comparisons enabled faster rejections of not similar complex shapes, which resulted in much lower number of detailed comparisons.

In order to evaluate the algorithm with greater number of images, the prototype application was developed using C++ and OpenCV image processing library. For line detection the Line Segment Detector (LSD) algorithm was used, which is known for providing precise line segment detection results [19]. All detected segments were tested if they can construct one bigger segment and an arc. Moreover, Circular Hough Transform was used to detect circles and improve number of correctly extracted primitives. The images were preprocessed using i.e. morphological operations. After primitives detection, all of them were grouped into complex shapes using minimal distance criterion. During our future research, the primitives extraction algorithm will be refined. As a database, 105 real life images of cars, motorbikes, bicycles and scooters were used. Some images contained background with other objects. In order to evaluate the performance of our algorithm the *precision* and *recall* coefficients were used, defined as following:

$$precision = \frac{number\ of\ relevant\ results\ images}{total\ number\ of\ results\ images} \quad (1)$$

$$recall = \frac{number\ of\ relevant\ results\ images}{total\ number\ of\ relevant\ images\ in\ the\ database} \quad (2)$$

Moreover, the algorithm was also compared with simple region-based method. The precision and recall results for example car, bicycle, scooter and motorbike query images (Fig. 8) are presented in the Table I. It can be seen that our algorithm provided much higher $precision$ values in comparison to the region-based method. For the region-based algorithm, bicycle objects are problematic due to the small uniform color areas which leads to smaller precision values. Contrary, car objects very often contain many big uniform areas and the results are much more precise. Our algorithm is not sensitive to such problems and for both object classes provided high number of correct results. The Query by Shape algorithm provided the best results for the bicycle sketch image, because it contained only the most important primitives for each bicycle. The worst results were obtained for the scooter object because for some bicycle and motorbike objects it obtained enough sim value to qualify them as a correct results.

One of our aim is to provide the algorithm which is able to perform both types of queries: manual (a sketch manually drawn by an user which is then converted into a graph) and automated (graphs automatically detected from input query images) using the same database without any modifications. Because of that fact, we performed also experiments using manually drawn objects and the same database (with the same automatically generated graphs) as in previous tests. For example the bicycle object (Fig. 9) provided results with 0.77 precision.

Since nowadays more and more people are using web searching engines to find specific images, we performed also another tests in order to compare our algorithm with Google Images Search engine. Due to the fact that our Query by Shape system was run on an average performance laptop and Google Images is using huge data centers to process queries, the results cannot be compared directly, but they show differences between approaches. As the query images, we used the same files as for our algorithm (Fig. 8). The results for almost all images were very precise, because the Google Images Search algorithm tries to firstly find the same images and then if none are available it tries to find similar ones. The Google algorithm during query processing uses not only the image data, but also some textual annotations which were chosen to best describe the image. The most precise results were obtained for Mercedes Benz (Fig. 12) and motorbike queries, which was caused by very precise recognized textual descriptions - "mercedes benz s class 1998" and "yamaha 125". However, Google Image Search did not provide the best results for all queries, e.g. the sketch of a bicycle and the scooter. The bicycle sketch was recognized as a "cyclist", but also as a simple, black and white sketch which resulted in only schematic images in the result set (e.g. our Query by Shape provided all types of bicycle images). For the scooter image, the results were much worse. The keywords assigned to the query were "dk raven" and as a result none scooter images were returned but only one type of a specific kind of a bicycle. The tests showed that Google Images Search engine provides very good results for images which are known for it, e.g. previously indexed with proper keywords. For objects which are new, the results may be moderate or even completely incorrect like for the scooter image. Moreover, the Google Image Search engine tries to find the exact object images (for example the same model, color and year of a car). Our algorithm, Query by Shape, tries to find images of objects with the same class (e.g. a car or a bicycle), allowing different

V. CONCLUSION AND FUTURE WORKS

In this paper the new CBIR algorithm, using query by approximate shape, was presented. The idea of the method is based on decomposition of shapes into smaller segments - primitives, which are described by theirs attributes. Based on detected primitives, a graph representation of the shape is built, then it is compared with graphs stored in the database. The algorithm is suitable for queries using input image as well as for human-drawn queries. In comparison with our previous research a complete set of primitives was defined, a new graph constructing procedure was used, the matching

algorithm was improved and adopted to complex primitives. The experimental results, especially in conjunction with our previous works, are very promising. The main advantage of our approach is that it may be applied to transformed or partially covered objects.

In the future research we will evaluate our approach using greater number of object classes from available image databases, and we also compare the efficiency of our method with more existing state of the art CBIR approaches. Moreover, some modification should be added in order to add ability to achieve better matching e.g. to detect mirrored objects. More advanced graph matching should be also performed, e.g.

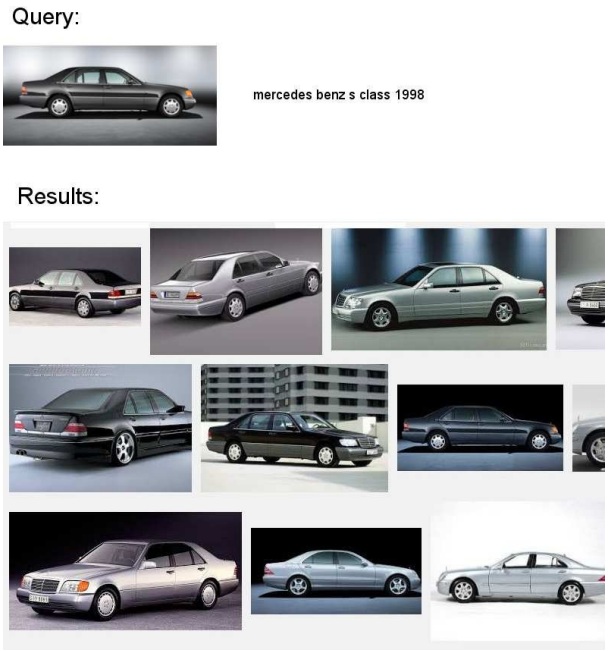

Fig. 12. Mercedes search example using google images.

solving an optimization problem with constraints [18]. Another direction of future research is an efficient storing of objects graphs in the database. Some initial works were performed in [14], but more advanced research should be done.

***Abstract*—The article presents new results achieved during researching the distance measuring method that is a part of Depth From Defocus techniques. The method has been developed to determine the shape of the flaccid diaphragm used in the Ventricular Assist Device (VAD). The shape is determined on the basis of distance measured between the CCD sensor plate of the camera and objects (markers) located on the flaccid diaphragm. Experiments were carried out using a stationary camera and circular markers with a diameter from 3 mm to 9 mm.**

The goal of this paper is to present the influence of the object (marker) size on the distance range measured between the camera and diaphragm used in the external pneumatic prosthetic heart.

I. Introduction

THE ARTICLE presents the impact of the size of the observed object (marker) on the result of the distance measurement method presented in [1], [2]. This method is part of the group of techniques defined by the formulated Depth From Defocus (DFD). It was developed specifically for the video sensor determining the momentary volume of ejected blood (*SV*) from the blood chamber of the pneumatic artificial heart. In [1], [2], the image is produced by a stationary camera equipped with a lens with a fixed focus. The camera is placed above the diaphragm so as to allow the observation of its entire surface. The proposed solution is characterized by the fact that during distance measurement the position of the camera and all lens and camera settings (focus, aperture, focal length) remain unchanged. Only the position of the observed markers located on the flaccid diaphragm is subject to change, Fig. 1a, which is located between the blood chamber and the air chamber, Fig. 1b. Method [1], [2] simultaneously determines the position of all of the markers in 3D space based on an analysis of only one image frame. In this respect, it has no equivalent in the literature. The vision systems, mentioned in the literature, used for measuring the distance consist of a light source and a camera, which usually form a stereoscopic system [3]. The distance in such systems is calculated by knowing the optical parameters of the cameras and their mutual position. Measuring systems equipped with one camera are also not rare [4]. The camera then performs two to eight photos of the object [4], and the distance is determined on the basis of the inverse perspective transformation [5]. There is also a measuring system variant with a camera equipped with autofocus. Such a system is calibrated with the help of a standard with known parameters. Measuring the distance to the object then depends on taking a picture at a specific focus setting and calculating the distance using the lens equation [6]. Other methods used to measure the distance is photogrammetry [7], [8] and the fringe projection technique [9] –[11]. Areas of application are, however, limited by the scope of the distances, the speed of the autofocus settings, image processing time, the resolution of the camera image sensor, the number of processed frames per second, as well as the dimensions and weight of the sensor.

In the application, considered in the article, real-time operation is particularly important with the simultaneous determination of the location of 49 markers located on the flaccid diaphragm in 3D space, Fig. 1a, which shape can change with the frequency of up to 3 Hz.

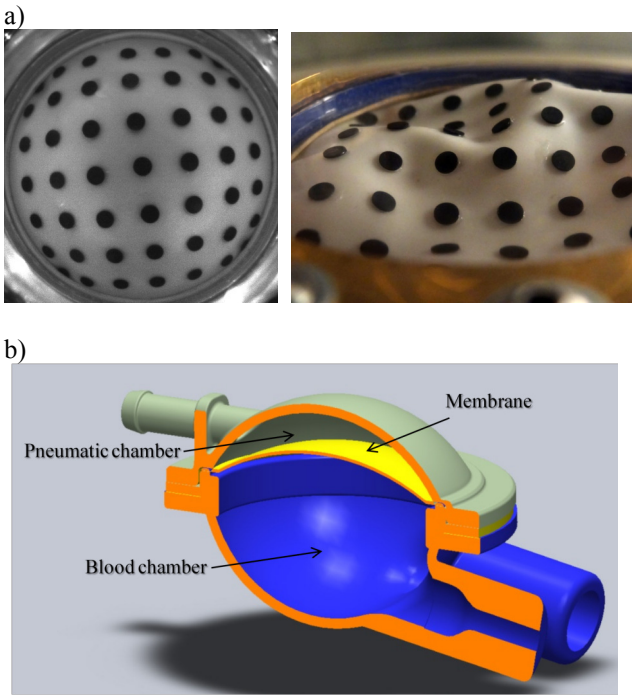

Fig. 1 View of flaccid diaphragm (a), location of the observed diaphragm in the artificial heart prosthetic (b)

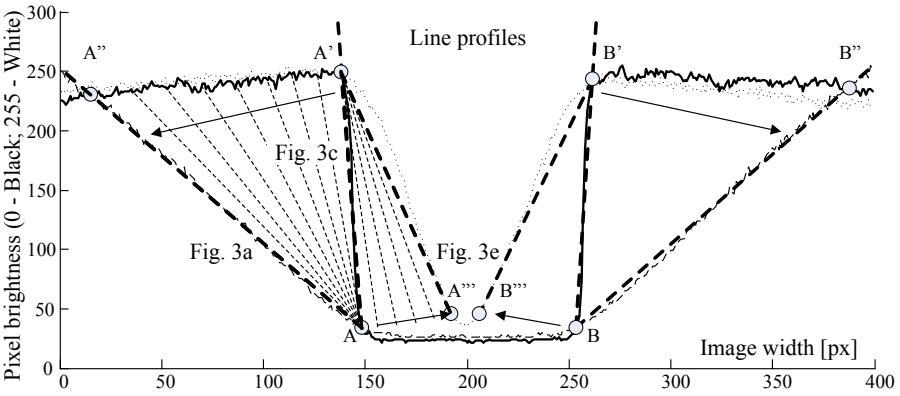

Fig. 2 Profile images of horizontal lines designated by the center of gravity of the object (the view on the standardization of brightness) [1]

II. New Depth From Defocus Method [1], [2]

The essence of the presented measurement solution is based on the analysis of the image produced by the marker moving away from its location for which its focus was set. Figure 2 shows the profiles of horizontal lines of images indicated by the center of gravity of the marker as well as their behavior during changes in the distance of the marker from the camera. For sharp views of marker lengths AA’ and BB’ in Fig. 2 are almost vertical, which indicates a sharp cut-off of the view of the marker from the background. When the marker approaches the camera image blurs. As a result, points A’ and B’ move respectively in direction A” and B”. At the same time the distance between points A and B remains practically unchanged. When the marker moves away from the camera points A” and B” return to their original position (A” $\rightarrow$ A’, B” $\rightarrow$ B’), and the marker image becomes sharp. The marker further distancing from the camera results in a decrease in the view of the marker and the image blurs. In the case under consideration a displacement of points A $\rightarrow$ A”’ i B $\rightarrow$ B”’is observed. The position of points A’ and B’ remains unchanged. The sequence of changes in the position of points A, A’, B, B’ determined when approaching and moving away from the marker with the camera at a step ΔL = 0.01m is presented in Fig. 3. Changes in positions of points A, A’, B, B’ shown in Fig. 2 and Fig. 3 are the basis for determining the distance marker. For this purpose, the image from the camera is subjected to defuzzification. Defuzzification was performed using image binarization with a threshold T_H equal to 70. The selection of the binarization threshold consists of determining such a T_H value, so that a uniform distribution of intersecting points of horizontal image line profiles is obtained (indicated by the marker center of gravity) with a line showing the T_H test value, Fig. 3. The location of the determined points univocally associated with distance d of the marker to the plane of camera image, Fig. 3. The points distribution is described by the equation during the calibration process. The result is a relation describing the distance of the marker to the image plane of the camera.

III. Motivation

The motivation to work on video sensor hardware and software (soft-sensors) to measure the *SV* pneumatic pulsating heart supporting pump were the test results obtained in the framework of the "Polish Artificial Heart"

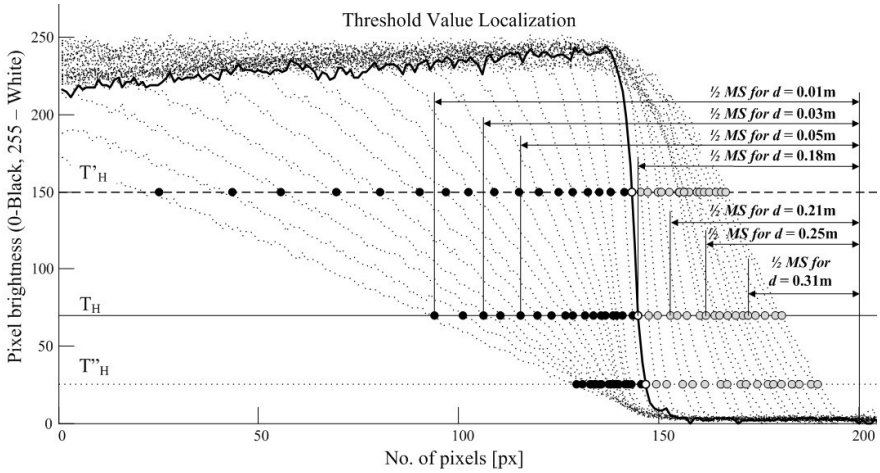

Fig. 3 The distribution of points relevant due to determining the distance to the marker for the established threshold T_H at L_{MIN} = 0.07m, L_{MAX} = 0.42m and ΔL = 0.01m [1].

project [12]. Both [13], [14] have demonstrated that the instantaneous stroke volume can be determined by an acoustic technique using the Helmholtz resonator theory. Knowing the limitations of the developed method the project also examined the possibility of using other techniques and measuring devices [15], including the video camera [16]. [16] shows that the measurement of momentary stroke blood volume of the ReligaHeart® EXT heart prosthesis using a video camera and a marker is ambiguous and burdened with error. The experiment described in [16] was verified by conducting a test using a model of the heart supporting pneumatic pump. In the test, just like in [16], occurrences of stroke volume measurements were noticed for which different shapes of the flaccid diaphragm were characterized with identical positions and marker areas, Fig. 4. This behavior of the marker prevents unambiguous determination of blood stroke volume only on the basis of analyzing changes in its position and the size of the surface area.

Using flaccid diaphragms in the heart prosthesis, even though raises many problems, is necessary and justified from a medical point of view. Such a diaphragm limits the formation of coagulation and eliminates the problem of sedimentation of blood (dividing into fractions). This does not change the fact that the problem of determining the momentary stroke volume of blood from the blood chamber of the pneumatic pump heart assist device (artificial heart) remains unresolved, and the safety of its use is based solely on its visual inspection: *"One of the main advantages of the extracorporeal, polyurethane blood pump is its transparency that allows running continuous visual inspection of the pump status and its quality of work."* [17] As an alternative to the present status it is proposed to use virtual reality technology in the sensor system of the chamber. In the method presented in [18], the camera captures a two-dimensional image of the diaphragm equipped with passive markers, Fig. 5. Markers are used to determine characteristic points of the flaccid diaphragm in 3D space. Knowing the position of these characteristic points in [18] the method of reconstructing the view of the diaphragm was stated.

This method initialized on an IBM PC type computer allows calculating the coordinates of nodal points of the diaphragm and to generate the visualization in 3D space with a frequency of 7 Hz. Exemplary results of the reconstruction

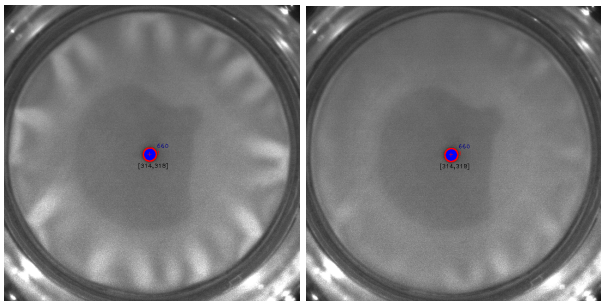

Fig. 4 Unambiguous measurement of SV resulting from the usage of one marker: marker position [314px,318px], surface equalling 660px

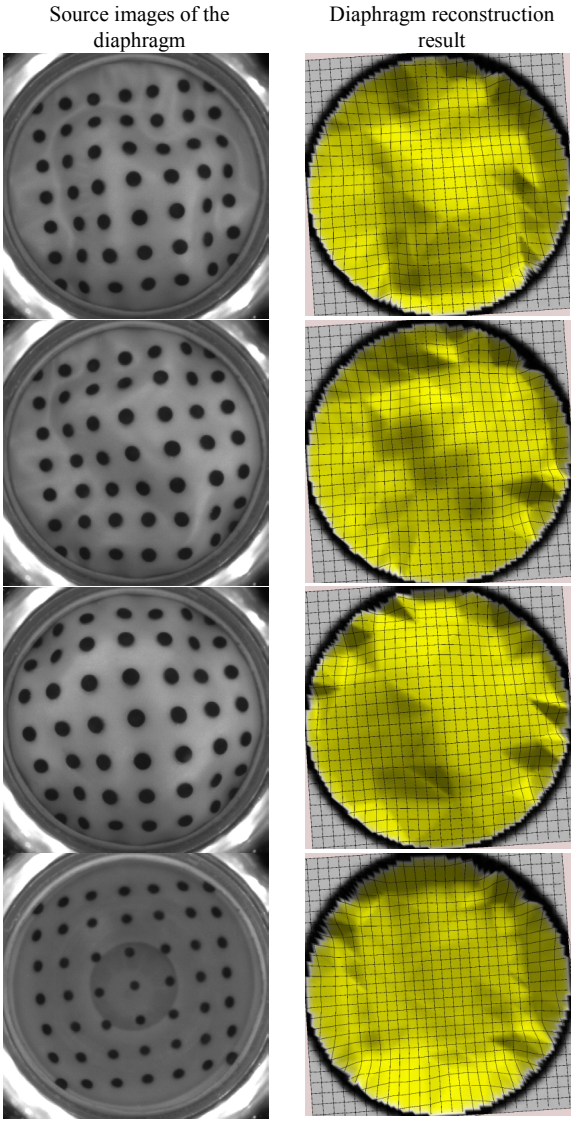

Fig. 5 Reconstructing the view of the flaccid diaphragm based on one photo using the technique provided in [18]

of the view of the diaphragm is shown in Fig. 5. The accuracy in the reconstruction, and thus determining the *SV* depends on [1],[2] by the number and arrangement of the markers as well as the precision of the determined distances. For this reason, the article placed great emphasis on the examination of the influence of the marker size on the value of the determined distance. The acquired dependencies and recommendations to use method [1],[2] was included in part V and VI of this study.

IV. Measurement System Configuration

The influence of the size of the marker on the value of the determined distance was studied using the Optitrack v100: Slim camera. The camera was equipped with a tripod, a lens with a brightness of $F = 2.0$ with a fixed focus of $f = 16$ mm, visible light filter (high-pass filter, $\lambda \geq 850$nm), infrared illuminator with the wavelength $\lambda = 850$ nm and a illuminator driver. The operation of the controller and the IR

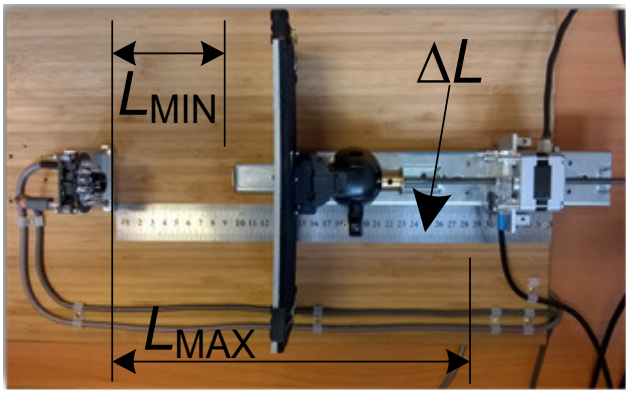

Fig. 6 View of the measuring system

lamp together are discussed in [19] – [21]. The experiment was performed in the configuration shown in Fig. 6. The distance marked in Fig. 6 equaled $L_{MIN} = 0.105$m, $L_{MAX} = 0.175$m, $\Delta L = 0.001$m. In the study, the focus of the lens was set to a distance of $L = 0.14$m, measuring from the image sensor plane of the camera. This position was taken as a reference point d_0 (zero position). All distance measurements were performed from this point. Measurements were performed for the range that included the permissible displacement of the front flaccid diaphragm occurring in the extracorporeal pneumatic heart prosthesis: $d_0 \pm 0.035$m. Studying the influence of the size of the marker area on the scope of measured distances was divided into two stages. The first stage consisted of acquiring images of marker views. Images were acquired in grayscale with a resolution of 640px × 480px. In the tests the distances were determined to the white plane, Fig. 6, bearing the marker. The marker was a black circle with a diameter from 0.003m to 0.009m. Exemplary views of the marker along with the result of its processing are shown in Fig. 7. The position of the plane with the marker was determined by setting it relative to d_0 with an accuracy of ±0.00001m. For this purpose a 39BYGL215A stepper motor was used. The engine with the pusher was placed on a crane. The tip of the

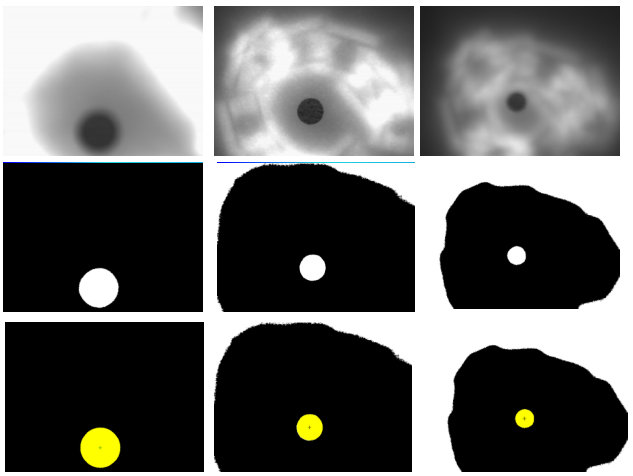

Fig. 7 Marker views (by rows): source image, image after segmentation, image result with the indicated center and analyzed marker surface

pusher was attached to a movable plane, Fig. 6. The straight edge was mounted parallel to the crane, which was used for visually checking the accomplishments of each push given.

The second stage consisted of carrying out activities related to the processing of raster images according to the method provided in [1],[2]. The analysis was then carried out with the aim of searching the connection existing between the initial value of the marker, the range of change observed on the surface of the marker and the obtained measurement range.

V. Results of Research

Studying the effect of the marker area size for distance measurement was performed for markers with a diameter of 0.003m, 0.004m, 0.005m, 0.006m, 0.007m, 0.008m, 0.009m. The experiment was performed in the configuration shown in Fig. 6. All distance measurements were carried out with the same lighting conditions. For each *i*-th marker the marker area was first defined in neutral position d_0. Then the screen was moved towards the camera with a step of 0.001m. This was repeated until achieving a displacement of 0.035m. The displacement was realized by a stepper motor controlled by a microcomputer system. For each of the predefined positions the marker made 100 measurements of its surface area. The test results were accepted as the arithmetic average determined from a series of measurements. After the completion of this experiment the screen with the marker would come back to the zero position. In the next step, measurements were carried out, in which the screen with the marker would move away from the camera image sensor plane. As before, the change in the area of the tested marker was recorded with a step of 0.001m. The last measurement was performed with removing the marker relative to the position for which the sharpness was fixed at 0.035m. These actions were implemented for all seven markers tested. The results are presented in Table I. The surface areas of the markers presented in Table I were determined through operations on the image. For this purpose, for each measurement the following was carried out:

- image defuzzification;
- identifying the location of the spot on the image that matches the location of the marker;
- identifying the location of the center of the marker;
- determining the area of the marker in pixels.

The range of measured distances, in the studied DFD technique, is due to the nature of changes in the surface area of the marker view visible in the image after defuzzification. The resulting variability of the surface areas of the markers in the measuring range of $d0 \pm 0.035$m is shown in Fig. 8. It shows that the least variability of 2383px (reference value), was obtained for the marker with a diameter of 0.003m. The marker with the given diameter, although most promising due to the possibility of a high density of markers on the diaphragm surface does not give the basis (only based on the

A displacement equal to zero was registered for markers: 2070, 3707, 5632, 7962, 10894, 14156, 22122.

knowledge of the measured surface area) to perform an accurate distance measurement. The change in the surface marker with a diameter of 0.003m is determined as a function of distance dependence $f(x) = 6.82x^2 - 279.42x + 3906.4$. A similar result was observed for the marker with a diameter of 0.004m and 0.005m. The variability of these markers equaled 4571px (increase of approx. 2 times) and 6773px (increase of approx. 3 times) accordingly, and the nature of changes are defined by dependencies $f(x) = 16.39x^2 - 579.83x + 7326.20$ for the 0.004m diameter marker and $f(x) = 26.81x^2 - 898.10x + 11{,}148$ for the 0.005m diameter marker. Better quality results were obtained for markers with a diameter of 0.006m, 0.007m, 0.008m and 0.009m. The nature of the changes in their surface areas are defined by third degree polynomials: $f(x) = -1.54x^3 + 70.44x^2 - 1{,}445.7x + 15{,}841$ for 0.006m; $f(x) = -1.93x^3 + 93.99x^2 - 1{,}966.5x + 21{,}631$ for 0.007m; $f(x) = -2.57x^3 + 120.74x^2 - 2{,}541x + 28{,}071$ for 0.008m and $f(x) = -3.56x^3 + 179.39x^2 - 3{,}887x + 43{,}535$ for 0.009m. For the given markers change ranges were determined: 9,646px (increase approx. 4 times), 12,984px (increase approx. 5.5 times) 17,193px (increase of approx. 7 times) and 26,298px (increase of approx. 11 times). The obtained results show that the best of the tested markers to measure distance was the marker with a diameter of 0.009m. The marker with such a diameter, however, is not suitable for use in the task of determining the shape of the diaphragm (flaccid diaphragm) of a pulsatile pneumatic heart assist pump. Due to its size it does not provide the assurance of performing a high density of markers on the surface of the diaphragm, in order to precisely reproduce its shape in a computerized measurement system. Accurate projection of

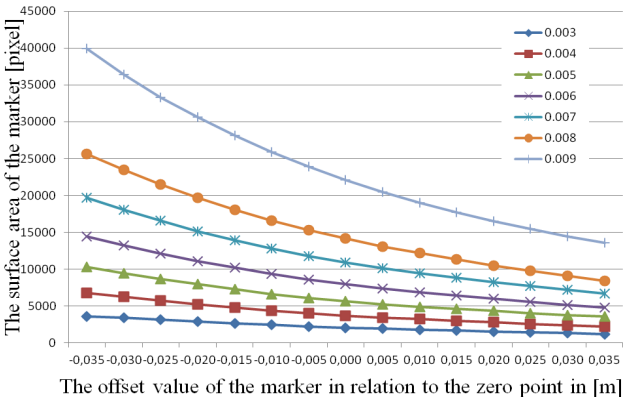

Fig. 8 Measurement results on the variability of surface areas of the markers

the diaphragm shape requires displaying the greatest possible number of markers on its surface, Fig. 5. Hence the simple conclusion that the markers should be as small as possible. Therefore, the analysis of the test results were repeated. At the time it was noticed that the implementation of the standardization of the results with respect to the surface area of the marker captured at point d_0 introduces a significant change in the acquired variable ranges of the marker surface areas, Table II. The graphic visualization of the results are shown in Fig. 9. As a result of carrying out the standardization of the results it turned out that the diameter of the marker had no significant impact on the accuracy of the distance measurement being performed. The shape of the "Mean Value" curve presented in Fig. 10 was described by the polynomial $f(x) = -0.025x^3 + 0.124x^2 - 0.238x + 0.140$, where x is the normalized surface area of the marker.

For a displacements equaling zero all sizes of determined surface markers took on the value of 1.

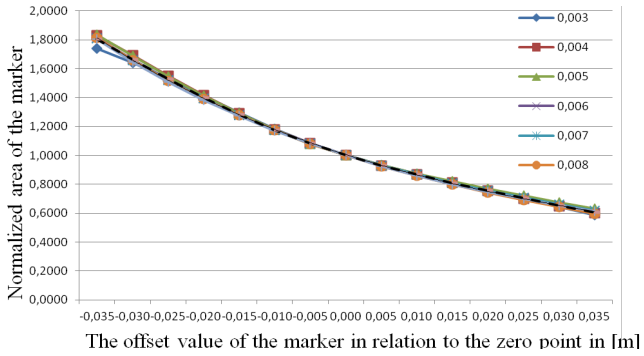

Fig. 9 The measurement results after normalization

For the given equation the average distance measurement error did not exceed ±0.00035m.

VI. Conclusion

The article includes the course and results of the new DFD technique [1],[2]. The purpose of the experiments was to determine the influence of the marker on the result and the scope of the measured distance. Tests were carried out for seven markers with a diameter of 0.003m to 0.009m.

The method of measuring the distance presented in [1],[2] have been developed to determine, in real time, the shape of the flaccid diaphragm [18] of the pulsating pneumatic heart assist pump (artificial heart), Fig. 5. Therefore, it was particularly important to evaluate the effect of the measurement method in the range of movements that the diaphragm is subject to in the prosthetic heart model.

The achieved results show that in the range of d0 ±0.035m the tested technique allows to obtain high accuracy measurements. The measurement error during the test did not exceed ± 0.00035m [1].

Based on achieved results the following recommendations were formulated:

1) where the standardization is not used it is recommended to use markers with a diameter no less than 0.006m;
2) the normalization of the determined surface area of the marker enables the use of markers having a diameter of no less than 0.006m.
3) in order for the distance measurement results to be independent from the diameter of the marker it is recommended to use the standardization of the marker surface area and determine the distance to the object from the polynomial $f(x) = -0.025x^3 + 0.124x^2 - 0.238x + 0.140$, where x is the standardized surface area of the marker.

***Abstract*—The method of key sharing between a mobile unit and a base station through a wireless MIMO-based fading channel is investigated. The description of a key distribution protocol is given. The expression to estimate the correct key bit agreement based on the use of guard interval is proved. Statistical properties of the key string are tested using the NIST criteria. Impossibility of key string eavesdropping by illegal users is guaranteed due to small values of correlation between legal and eavesdropper carrier phases. Numerical examples show that the MIMO system with 8 antennas is able to agree 256 bits with a reliability value 0.99 for SNR equal to 35 dB. This experiment confirms that the MIMO scenario is especially effective for secret key distribution.**

***Index Terms*—MIMO fading channel, key distribution, multi-phase detection, correlation, NIST tests.**

I. Introduction

SECURE transmission is still a concern for wireless mobile devices due to broadcast nature of signals. Although traditional secure systems employ private or public-key cryptography independently of physical transmission, there is a growing interest in *physical layer security* methods that exploit noisy telecommunication channels and channels with multi-path wave propagation.

In a pioneered paper [1], Wyner introduced the *wire-tap channel concept* with two types of channels: the main channel (less noisy) and the wire-tap channel (more noisy). Wyner's theorem states that under some (not very strong conditions) there exist such encoding and decoding procedures that reliable transmission on the main channel and zero information leakage on the wire-tap channel can be provided with an increasing of the block lengths if the transmission rate is less than the so called *secrecy capacity Cs.* In the post-Wyner's period there appear a lot of paper devoted to a generalization of wire-tap channel models [2], [3], [4], [5], [6] and to a specification of the amount of information leaking to eavesdropper [7]. But unfortunately it is still unknown constructive encoding and decoding procedures providing a transmission rate close to secrecy capacity. Next advance in the physical security area occurs due to Maurer's paper [8] at the cost of public discussion between legitimate users. Such approach allows to share secret keys between legitimate users even in the case when the wire tapper observes a "better" channel than one used by the legitimate user but only if the wire tapper is passive (that is in another words if legal channel is authenticated). After a common key sharing the legitimate correspondents can use ideal Shannon's one-time pad cipher [9].

The idea of a common key sharing and the execution of an ideal cipher is very positive especially in the so called *post-quantum* period when it is assumed that many cryptographic algorithms can be broken by a quantum computer [10]. But such approach requires to share a very long secret key string before ideal encryption. Moreover, in order to provide a secure key sharing that means to get a negligible amount of Shannon information leaking to an eavesdropper about this key, it is necessary to be sure that signal-to-noise ratio at the input of wire tapper receiver is fixed and known for legitimate users. In order to avoid such strong requirement it has been proposed to execute (for mobile users) a multipath wave propagation in some wireless channels [11], [12]. Unfortunately if mobile unit stops it may result in a very slow and small channel fluctuation. In order to take for granted some given randomness level it would be better to create this randomness artificially by means of legitimate users. In [13] it has been proposed a method using smart antenna excited randomly by electronic means. More detail investigation of such approach was undertaken in [14]. But such approach requires a special construction of a *Variable Directional Antenna.*

The explosion of interest to multiple-input multiple-output (MIMO) systems soon led to a realisation that exploiting the available spatial dimensions can also enhance the secrecy capabilities of wireless channels [15].

One of advantage of MIMO system for key sharing is its property that a presence of many antennas results in a better randomisation even for very small transfer of mobile units. It is worth to note that in contrast to communication system where a presence of MIMO devices results in interference of signals at the receiving antennas, key sharing occurs avoidable of such interference because in that case it is necessary to form any but only coinciding key bits. The last property is provided thanks to the *Reciprocity Theorem of radio wave propagation* between

978-83-60810-90-3/$25.00

transmitting and receiving sides of MIMO-based link. Further investigation of MIMO-based *key distribution protocols (KDP)* was undertaken by authors of the papers [16], [17]. But a final solution of this problem is very far from a termination. First of all it is requested to increase the key generation rate providing simultaneously high secrecy and good statistical properties of the shared keys that should be close to truly random data. Namely these questions form the main subject of our investigations undertaken in the current paper.

The reminder of the article is organised as follows. Section II describes the model of MIMO channel with point of view key sharing protocol. In Section III algorithm of key distribution is presented jointly with estimation of key bits reliability and key rate generation. Section IV discusses system parameters optimisation. Section V concludes the paper and formulates open problems for further investigations. The appendix presents the proof of the relation for the error probability given in Section III.

II. Mathematical model of MIMO-based channel

We assume that a key distribution protocol (KDP) is performed between a mobile unit A and a base station B that have the same number of antennas N_A and that the signal power radiated of each antenna is equal to P_S/N_A.

For a *frequency-flat fading MIMO channel*, the commonly used discrete-time input-output relation for test-signal is given by

$$y = Hs + z \tag{1}$$

where H is a square $(N_A \times N_A)$-matrix, s is a transmitted test-signal $(N_A \times 1)$-vector, y is a received signal $(N_A \times 1)$-vector, and z is an additive noise $(N_A \times 1)$-vector of the MIMO channel output.

Due to the Reciprocity Theorem the relation for back channel is

$$y' = H^T s + z'.$$

However the elements of the matrix H can change during the test signal transmission, generally speaking, and therefore in order to provide approximated equally channel matrices in direct and back channels it is necessary that the following inequalities hold [18]:

$$\Delta t << T_c \quad , \quad \Delta f << B_c$$

where Δt is the delay in transmission between direct and back test signals, Δf is the frequency (Doppler) shift, T_c is the coherent time and B_c is the coherent band width for the MIMO channel.

In order to specify the values of the matrix H, it is necessary to describe the channel model in detail.

Let us consider the multi-path MIMO channel model with Raleigh fading according to [19] and presented in Fig. 1.

We denote the number of rays as L and denote by β_l the attenuation in the l-th ray, by ϕ_l, ψ_l the transmitted and received angles, respectively, by Φ, Ψ the antenna diagram angles, and by ω_l the frequency shift due to mobile units transfer (Doppler effect).

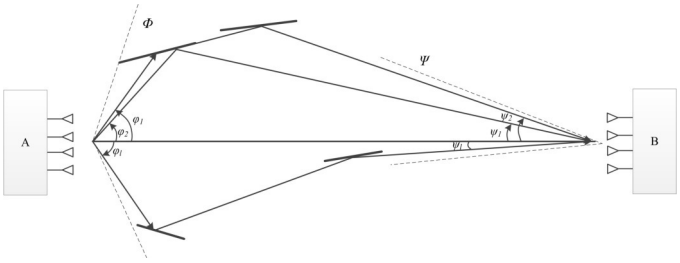

Fig. 1. General model of MIMO channel between mobile unit and base station.

Then the matrix $H(t)$ of the test signal at time t can be presented as

$$H(t) = \sum_{l=1}^{L} \beta_l \left(\mathbf{a}_{Rl}\mathbf{a}_{Tl}^T\right) e^{-j\omega_l t}$$

being

- $\beta_l = a_l e^{j\theta_l}$: signal attenuation resulting by reflection,
- $\mathbf{a}_{Rl}, \mathbf{a}_{Tl}$: response vectors at the receiver and at the transmitter respectively.

$$\begin{aligned} \mathbf{a}_{Rl} &= \left[1 \;\; e^{-j\Omega_{Rl}} \;\; \dots \;\; e^{-j(N_A-1)\Omega_{Rl}}\right]^T, \\ \mathbf{a}_{Tl} &= \left[1 \;\; e^{-j\Omega_{Tl}} \;\; \dots \;\; e^{-j(N_A-1)\Omega_{Tl}}\right]^T, \end{aligned}$$

- $\Omega_{Rl} = \frac{2\pi}{\lambda} d_R \sin\phi_l$: angular receiver frequency,
- $\Omega_{Tl} = \frac{2\pi}{\lambda} d_T \sin\psi_l$: angular transmission frequency,
- λ: wave length corresponding to carrier frequency,
- d_R: diversity interval for receiving antennas, and
- d_T: diversity interval for transmission antennas.

A typical example of the above channel model is the octal-rays model of the railway telecommunication system having 8 antennas with distances $\frac{\lambda}{2}$, between them, mobile object speed 100 km/h, $\Phi = 28°$, $\Psi = 180°$, and carrier frequency 2.6 GHz.

Investigation of such model has been undertaken in many papers (e.g. [20], [21] and others) and results of our investigations show that the entries of matrix H can be correctly approximated by zero mean Gaussian distribution with equal variances.

The space correlation is determined only by mutual antenna locations. Then space-time correlation can be presented following to the results of [22], [18] as

$$R_H(t) = R_H \cdot \rho(t),$$

where R_H is the matrix of space correlation between antennas, and ρ is the time correlation function of antenna location. For Jakes fading model [20], the function ρ can be determined as

$$\forall t: \;\; \rho(t) = J_0(2\pi f_D(t)),$$

where f_D is the Doppler spread and J_0 is the Bessel function of zero order.

III. KDP BASED ON MIMO CHANNEL MODEL

The KPD is described in the following steps:

1) User B (base station) sends the test signal to the mobile unit A executing all antennas.
2) A calculates some parameter of the received signals.
3) Just after step 2, A sends the same test signal to B.
4) B calculates the same (selected in advance by both users) parameters of the received signals.
5) Both users A and B form the key bits from the found parameters using a quantisation procedure.

It is worth to note that the knowledge of MIMO-based channel model parameters can be ignored in KDP design if during the time of its execution these parameters are approximately constant. But this knowledge it is necessary to estimate a reliability of KDP (the probability of key bits coincidence for both correspondents), the statistical properties of key strings and its security (in terms of information leakage about this key to eavesdropper who can be located in some vicinity of users A and B).

We can see from relation (1) that each coordinate y_i of the vector $\mathbf{y}$ is a complex Gaussian random value with amplitude $\mu_i = \sqrt{\Re(y_i)^2 + \Im(y_i)^2}$ (here $\Re$ and $\Im$ are the maps that take the real and the imaginary parts of a complex number) and phase $\theta_i = \tan^{-1}\left(\frac{\Im(y_i)}{\Re(y_i)}\right)$, and these variables have Rayleigh distribution and uniform distribution, respectively. It has been proved in [23] that phases are less correlated versus distance between legal users and eavesdroppers than amplitude. Therefore our selection as parameter for the key bit generation, namely the phase quantisation procedure into q integers, is determined as:

$$\begin{array}{rl} \text{if} & \theta_i \in \left[\frac{2\pi(q-1)}{Q}, \frac{2\pi q}{Q}\right) \text{ with } 1 \le q \le Q \\ \text{then} & f_Q(\theta_i) = q, \end{array} \tag{2}$$

where Q is the number of quantisation levels. Then the probability of an integer q equals $\frac{1}{Q}$. Since the channel noise results in a transition of q to $q' \neq q$ and it is more likely closer to the bounds of the decision areas in (2), we propose to introduce guard intervals between decision areas as key symbols may be erased. Then the decision function (2) can be modified as:

$$\begin{array}{rl} \text{if} & \theta_i \in \left((q-1)\Omega - \frac{\gamma}{2}, (q-1)\Omega + \frac{\gamma}{2}\right) \cup \\ & \left(q\Omega - \frac{\gamma}{2}, q\Omega + \frac{\gamma}{2}\right) \\ \text{then} & f_{QG}(\theta_i) = \textit{erasure}; \end{array}$$

$$\begin{array}{rl} \text{if} & \theta_i \in \left[(q-1)\Omega + \frac{\gamma}{2}, q\Omega - \frac{\gamma}{2}\right) \\ \text{then} & f_{QG}(\theta_i) = q; \end{array}$$

with $1 \le q \le Q$, $\Omega = \frac{2\pi}{Q}$ and γ a threshold, $\gamma \in \left[0, \frac{1}{2}\Omega\right)$.

Let us consider one of the decision areas (or *sector*) in Fig. 2, determined by $\mathbf{y}_i = (\mu_i, \theta_i)$, $\mathbf{x}_i = Hs = (a_i, \phi_i)$, $\mathbf{z}_i = (b_i, \psi_i)$. Under the decision taken about the phase ϕ_i when $\mathbf{y}_i$ is received, the following events may occur:

- $\mathbf{y}_i$ is in the same area that the vector $\mathbf{x}_i$ (correct decision area with angle $\Omega - \gamma$),

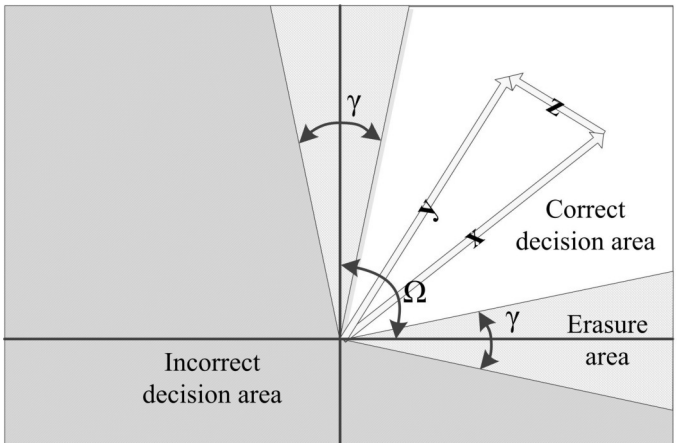

Fig. 2. Sectors of decision area.

- $\mathbf{y}_i$ belongs to the guard interval (erasure area with angle γ),
- $\mathbf{y}_i$ appears outside of both previous areas (incorrect decision).

Let us denote the probabilities of previous events by P_{cor}, P_{er}, P_{error}, respectively.

It is proved in the Appendix that

$$\begin{aligned} P_{error} &= \frac{1}{2\pi\Omega}\int_0^{\Omega} F(\phi)\, d\phi \\ F(\phi) &= \int_{\phi+\frac{\gamma}{2}}^{2\pi-(\phi+\frac{\gamma}{2})} \left[1 + \left[\frac{h\tan\left(\phi+\frac{\gamma}{2}\right)}{\sin\psi}\right]^2\right]^{-1} d\psi \\ P_{er} &= 1 - P_{cor} - P_{error} \end{aligned} \tag{3}$$

where P_{cor} is given by eq. (16) in the Appendix after combining (11)–(15).

In Fig. 3 there are plotted the dependences of P_{cor}, P_{er}, P_{error} with respect to signal to noise ratio for $Q = 8$ and different *guard intervals* (GI) that were calculated after numerical computations of corresponding integrals. We observe that it is possible to trade off P_{error} to the value of the guard interval but it affects also on P_{er}. Hence there appears the problem of KDP parameters optimisation, given some final requirements, as key generation rate maximisation for given SNR and the number of antennas N_A in MIMO system. (We remark that it is not obtained a precise expression for the corresponding probabilities but some bounds, namely an upper bound for P_{error}, a lower bound for P_{er} and lower bound for P_{cor} because it was not taken into account that correct key bits can be obtained sometimes even if both legal users got incorrect phase. But such incorrectness is acceptable).

From Fig. 3, it can be seen that a guard interval (GI) allows to decrease the error probability but simultaneously the probability of erasure increases. In reality a final decision about key bit has to be taken no by the single user B but by

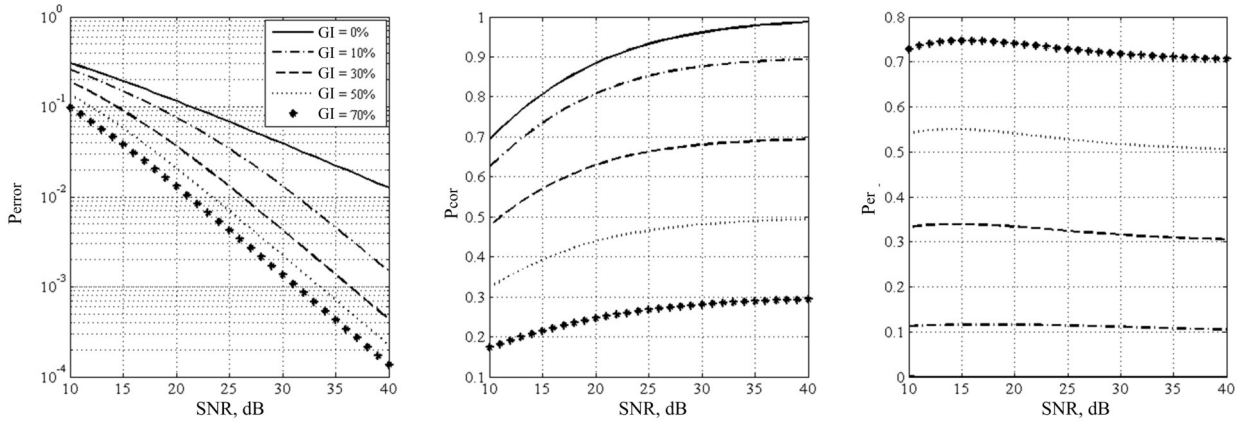

Fig. 3. Curves of P_{error}, P_{cor}, P_{er} against the values of SNR for $Q = 8$.

both users A and B. Thus the final probabilities P_{cor}, P_{er}, P_{error} should be changed as follows:

$$\begin{aligned} P^*_{cor} &= P_{cor}(A) \cdot P_{cor}(B) \\ P^*_{error} &= P_{error}(A) \cdot P_{cor}(B) + \\ &\quad P_{error}(B) \cdot P_{cor}(A) + \\ &\quad P_{error}(A) \cdot P_{error}(B) \\ P^*_{er} &= 1 - P^*_{cor} - P^*_{error} \end{aligned}$$

The KDP should be also slightly corrected under the condition of symbol erasures. Namely the numbers of the erased symbols have to be transmitted from both users to opposite ones in addition and next it is transmitted extra signal if it is necessary.

A relation for the probability $P_{n_0}(k)$ of the key bit string sharing of length n_0 is:

$$P_{n_0}(k) = \left(\frac{P^*_{cor}}{1 - P^*_{er}} \right)^{\frac{n_0}{\log Q}} \tag{4}$$

where Q is the number of quantisation levels. The key bit stream rate for the use of all N_A antennas is

$$R = N_A \log_2 Q (1 - P^*_{er}) \frac{bit}{sample}. \tag{5}$$

Then the following optimisation problem arises:

$$(\gamma^*, Q^*, N^*_A, (h^2)^*) = \underset{\gamma, Q, N_A, h^2}{\arg\max}\ R \tag{6}$$

subject to the restrictions

$$\begin{gathered} P_{n_0}(k) \geq P_{n_0}(k)_{\text{requested}}; \\ \gamma \in \left[0, \frac{\pi}{Q}\right); \\ Q \in [2, Q_{\max}]; \\ N_A \in [1, (N_A)_{\max}]; \\ h^2 \in [1, (h^2)_{\max}]; \end{gathered}$$

where the values $P_{n_0}(k)_{\text{requested}}$, $Q_{\max}$, $(N_A)_{\max}$, $(h^2)_{\max}$ have to be conditioned by the general requirements of the MIMO system design.

The solution of problem (6) has been found by the *branch and bound algorithm* [24].

In Fig. 4 there are presented the dependences R from SNR under the conditions $n_0 = 256$, $P_{n_0}(k)_{\text{requested}} = 0.9$ and 0.99, and $N_A = 1, 2, 4, 8, 16$.

In Table I the optimal values for $a = \frac{\gamma}{\Omega}$ and Q are displayed maximising the rate R for a given SNR.

An analysis of the curves in Fig. 4 shows that the key generation rate R increases with an increasing of the number of antennas in MIMO massive. Key generation rate increases obviously as SNR increases. For every SNR value there exist optimal number of phase quantisation levels and value of guard interval providing the requested probability of correct key sharing for both legal users.

IV. Investigation of Key Stream Statistic and Information Leaking to Eavesdropper

The statistics of the key stream distributed due to KDP is very important because if it is very far from uniform distribution it may result in effective attacks for cipher breaking. In order to investigate the key stream statistic after phase quantisation from different antennas they will be combined in a serial sequence containing bits from all antennas and this sequence investigated by statistical tests. In Fig. 5 there are presented the empirical density distributions for the length of binary strings equal to 1 and 16.

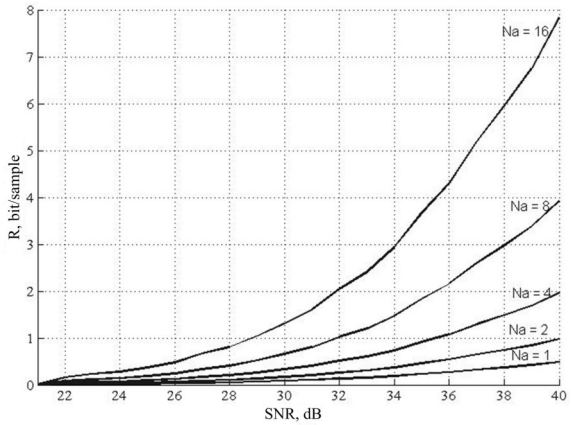
We see there that also a balance of zeros and ones (as follows from Fig. 5 a) is good, but the multi-variate distribution (Fig. 5 b) has anomalous peaks. In order to improve the statistics of the key string it was undertaken some deterministic transforms of two types recommended in [25]. The first type is so called *transposition of symbols* and the second transform is *adjacent bit XOR-ing*. The results of testing after such transforms are presented in Table II in which were used some NIST STS tests [26].

We see that after both transforms the key bit sequence passes the most of NIST tests.

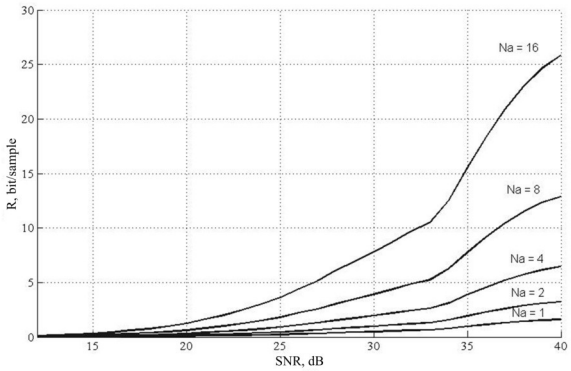
Now let us face with eavesdropping problem and assume that the following parameters hold [21]:

TABLE I
OPTIMAL PARAMETERS γ AND Q PROVIDING THE MAXIMUM RATE R FOR A GIVEN SNR.

$P_{n_0}(k)_{\text{requested}}$		SNR (dB)															
		10	12	14	16	18	20	22	24	26	28	30	32	34	36	38	40
0.9	Q^*	–	2	2	2	2	2	2	2	2	2	2	2	4	4	4	4
	a^*	–	0.89	0.86	0.82	0.77	0.71	0.64	0.56	0.47	0.38	0.30	0.22	0.37	0.24	0.15	0.10
0.99	Q^*	–	–	–	–	–	–	2	2	2	2	2	2	2	2	2	2
	a^*	–	–	–	–	–	–	0.89	0.86	0.82	0.77	0.71	0.64	0.57	0.48	0.39	0.30

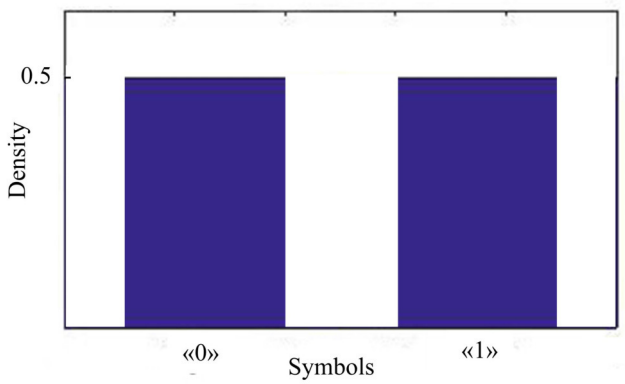


a) $P_{n_0}(k)_{\text{requested}} = 0.9$

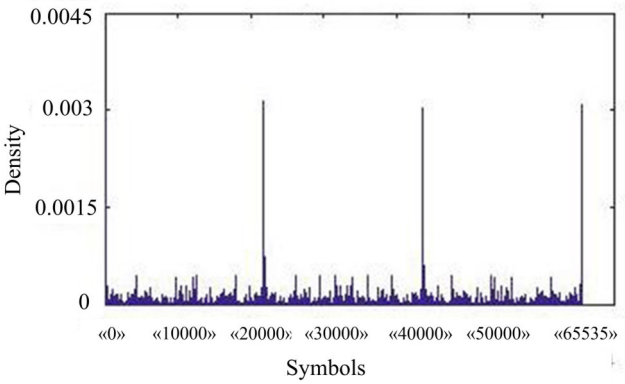


b) $P_{n_0}(k)_{\text{requested}} = 0.99$

Fig. 4. The key sharing bit rate of the length 256 bits with $P_{n_0}(k)_{\text{requested}} \in \{0.9, 0.99\}$ for optimisation of the system parameters.



a) String length 1



b) String length 16

Fig. 5. Empirical probability density distributions for two string lengths.

- frequency carrier: 2600 MHz;
- MIMO massive: 8×8;
- distance between MIMO antennas at the departure unit: 0.5λ
- distance between MIMO antennas at the arrival unit: 0.5λ
- number of rays: 8;
- departure ray angle: 28°;
- arrive ray angle: 180°;
- speed of mobile unit motion: 50 km/h;
- number of simulated channel matrices: 1000.

The mutual correlation between the phases of legal user B and an eavesdropper located at a distance d from B (in terms of wave length factors) is presented in Fig. 6.

We see from this figure that in line with similar results presented in [14] the correlation has not a monotonically decreasing dependence from d but it has a randomly-looking dependence. But in contrast to [14] it has significantly less values from all distances between $(0.1\lambda, \ldots, 20\lambda)$. This is a consequence of the multi-phase functional used for key bit generation and another channel model. Thus, we can believe that it can be neglected an opportunity of key eavesdropping

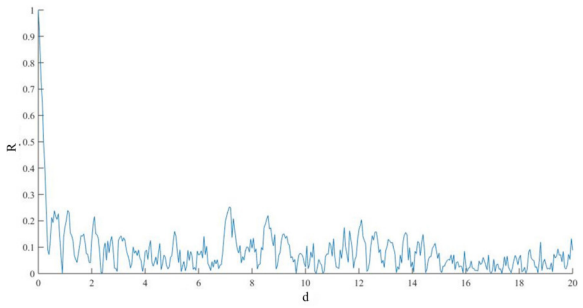


Fig. 6. Mutual correlation between phases of legal user and eavesdropper against distance between them in terms of wave length factors.

TABLE II
EXPERIMENTAL TESTING BASED ON NIST STS OF THE KEY SEQUENCES AFTER TWO TYPES OF TRANSFORMS.

Nr.	Name of test	Transposition	TXOR
1	The Frequency (Monobit) Test	10/10	10/10
2	Frequency Test within a Block	10/10	10/10
3	The Runs Test	9/10	10/10
4	Tests for the Longest-Run-of-Ones in a Block,	0/10	10/10

TXOR: Transposition plus XOR of adjacent bits.
The numerators of fractions are number of "passed" tests and the denominators are the total number of tests.

in large area of eavesdropper locations.

(It is worth to note that if phase had Gaussian distribution and even for binary quantisation values it would be results in the error probability for eavesdropper about one key bit near 0.47 [14] that it is very close to "break of eavesdropper channel".)

V. CONCLUSION

We considered a method of key sharing for wireless secret communication based on MIMO concept with the use of multi-phase functionals that seems to be especial effective for mobile unit and multi-path fading channels.

It has been proved that following to the proposed key distribution protocol it can be provided a key sharing of size 256 bits and with probability of its reliable performance about 0.99 for SNR equal to 35 dB, and 16 antennas after execution of about 74 test signals on average. It was also shown that the key sequence after simple transforms is very close to i.i.d. practically satisfying all NIST tests. Interception of key stream by eavesdropper is prevented by a very small correlation between phases at legal users and eavesdropper if distance between them is not lesser than 0.1λ.

We believe that a future work that can be undertaken is in the use of error correcting codes in order to maximise the key distribution rate and to short a delay in key delivering.

APPENDIX

Proof of the formula (3)

Let us consider one of the decision areas, namely $\angle\text{TOL} = \Omega$ (see Fig. 7). Assume that the vector $\mathbf{y}$ is in the sector $\angle\text{SOX}$ (area D_1') and that it is a sum of the vectors $\mathbf{x}$ and $\mathbf{z}$. Then the error for taking a decision on the phase of $\mathbf{y}$ occurs if $\mathbf{y}$ lays on the axis OS or at left to it. This event will occur if and only if:

$$\angle\text{BOA} \geq \angle\text{SOA} = \Omega - \phi + \frac{\gamma}{2}. \tag{7}$$

Let us draw the perpendicular from the point B on the axis OX. Then $\text{BC} = b\sin(\pi - \psi) = b\sin\psi$, $\text{AC} = -b\cos\psi$. We have

$$\angle\text{BOA} = \tan^{-1}\left(\frac{\text{BC}}{a - \text{AC}}\right) = \tan^{-1}\left(\frac{b\sin\psi}{a + b\cos\psi}\right). \tag{8}$$

where a is the amplitude of vector $\mathbf{x}$, and b is the amplitude of vector $\mathbf{z}$. By substituting (8) into (7) we get

$$\frac{b\sin\psi}{a + b\cos\psi} \geq \tan\left(\Omega - \phi + \frac{\gamma}{2}\right).$$

If $a >> b$ (which is very likely) then the term $b\cos\psi$ can be neglected and it results in the following condition to produce error:

$$u := \frac{b}{a} \geq \frac{\tan\left(\Omega - \phi + \frac{\gamma}{2}\right)}{\sin\psi} =: \ell_{\Omega-\phi,\psi}.$$

Let us denote by $P(u)$ the probability density of the random variable u. Then the error probability (P_{error}), provided that the received vector $\mathbf{y}$ lies at the left of OS, can be expressed by the following formula, on the assumption that phases ϕ and ψ are distributed uniformly:

$$P^{I}_{error} = \frac{1}{\Omega}\int_0^{\Omega} d\phi\,\frac{1}{2\pi}\int_{\Omega-\phi+\frac{\gamma}{2}}^{\pi} d\psi \int_{\ell_{\Omega-\phi,\psi}}^{+\infty} f(u)\,du \tag{9}$$

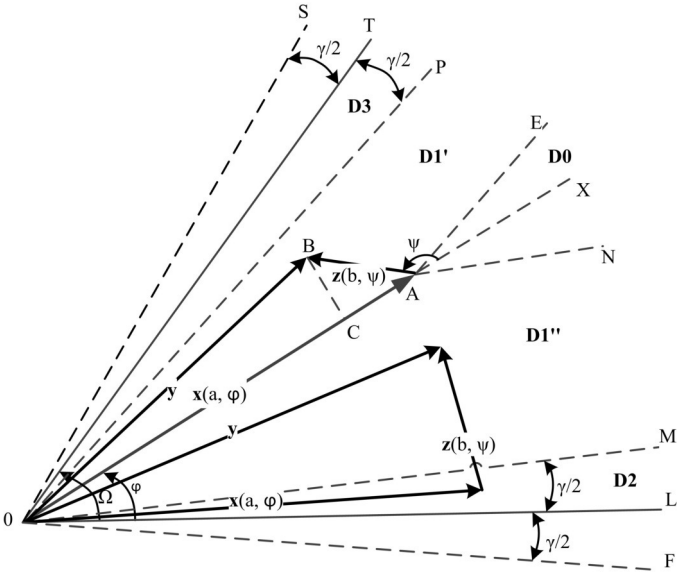

Fig. 7. Areas for taken of decision after quantisation.

(the superindex I emphasises that it is true whenever the received vector occurs to the left of line OS).

For the area $\text{D1}'' = \angle\text{LOX}$, we can repeat the derivation of (9) in order to get

$$P^{II}_{error} = \frac{1}{\Omega}\int_0^{\Omega} d\phi\,\frac{1}{2\pi}\int_{\pi}^{2\pi-\phi-\frac{\gamma}{2}} d\psi \int_{\ell_{\phi,\psi}}^{+\infty} f(u)\,du \tag{10}$$

Let us specify the formula for the probability of correct decision after quantisation and introducing of guard interval. We can see such areas at Fig. 7. Having received the vector $\mathbf{y}$ we get the following cases:

1) $\mathbf{x} \in \text{D1}, \mathbf{y} \in \text{D1}$, with $\text{D1} = \text{D1}' \cup \text{D1}''$. After repeating the procedure to obtain (9) and (10), we get

$$P_{cor\,\text{D1}} = \frac{1}{\Omega}\int_{\frac{\gamma}{2}}^{\Omega-\frac{\gamma}{2}} d\phi\,\frac{1}{2\pi}\int_{\phi-\frac{\gamma}{2}}^{2\pi-\phi+\frac{\gamma}{2}} d\psi \cdot \int_0^{\ell_{\phi,-\psi}} f(u)\,du \tag{11}$$

2) $\mathbf{x} \in \text{D2} \cup \text{D3}, \mathbf{y} \in \text{D1}$, with $\text{D1} = \text{D1}' \cup \text{D1}''$. After repeating the procedure to obtain (9) and (10), we get

$$P_{cor\,\text{D2}\cup\text{D3}} = \frac{1}{\Omega}\int_{\Omega-\frac{\gamma}{2}}^{\frac{\gamma}{2}} d\phi\,\frac{1}{2\pi}\int_{\phi-\frac{\gamma}{2}}^{2\pi-\phi+\frac{\gamma}{2}} d\psi \cdot \int_{\ell_{-(\Omega-\phi),\psi}}^{\ell_{\phi,-\psi}} f(u)\,du \tag{12}$$

3) $\mathbf{x} \in \text{D1}, \mathbf{y} \in \text{D0}$. In such situation the vector $\mathbf{x}$ transfers to the area of correct decision from the area of erasure due to noise.

$$P_{cor\,\text{D0}} = \frac{1}{\Omega}\int_{\frac{\gamma}{2}}^{\Omega-\frac{\gamma}{2}} d\phi\,\frac{1}{2\pi}\int_0^{\Omega-\gamma} d\psi \int_0^{+\infty} f(u)\,du = \frac{(\Omega-\gamma)^2}{2\pi\Omega} \tag{13}$$

4) $\mathbf{x} \in$ D2, $\mathbf{y} \in$ D0 (in this case, D2 and D0 are intersected)

$$P_{cor\,\mathrm{D2}\to\mathrm{D0}} = \frac{1}{\Omega}\int_0^{\frac{\gamma}{2}} d\phi\,\frac{1}{2\pi}\int_{\frac{\gamma}{2}}^{\Omega-\frac{\gamma}{2}} d\psi\,\cdot \int_{\ell_{-\phi,\psi}}^{+\infty} f(u)\,du \tag{14}$$

5) $\mathbf{x} \in$ D3, $\mathbf{y} \in$ D0. It is easy to see that

$$P_{cor\,\mathrm{D3}\to\mathrm{D0}} = P_{cor\,\mathrm{D2}\to\mathrm{D0}} \tag{15}$$

Combining (11)–(15) we get:

$$P_{cor} = P_{cor\,\mathrm{D1}} + P_{cor\,\mathrm{D2}\cup\mathrm{D3}} + P_{cor\,\mathrm{D0}} + 2\,P_{cor\,\mathrm{D2}\to\mathrm{D0}} \tag{16}$$

It is very easy to see that

$$P_{erasure} = 1 - P_{cor} - P_{error}.$$

In order to prove the relations (9)–(14) in a closed form it is necessary to derive the probability density function of the random variable $u = \frac{b}{a}$, where a and b have the Rayleigh distribution and they are mutually independent. This means that

$$f(a) = \begin{cases} \frac{a}{\sigma_a^2} e^{-\frac{a^2}{2\sigma_a^2}} & \text{if } a \geq 0 \\ 0 & \text{if } a < 0 \end{cases}$$

$$f(b) = \begin{cases} \frac{b}{\sigma_b^2} e^{-\frac{b^2}{2\sigma_b^2}} & \text{if } b \geq 0 \\ 0 & \text{if } b < 0 \end{cases}$$

After a simple transform, we get the following relation

$$f(u) = \frac{u}{\sigma_a^2\sigma_b^2}\int_0^{+\infty} a^3 e^{-ra^2}\,da, \tag{17}$$

where $r = \frac{1}{2\sigma_a^2} + \frac{u^2}{2\sigma_b^2}$.

The integral (17) can be expressed in a closed form [27]. Then for the definite integral (17) we get

$$f(u) = \frac{2\sigma_a^2\sigma_b^2\,u}{(u\sigma_a^2 + \sigma_b^2)^2}. \tag{18}$$

By denoting $\delta^2 = \frac{\sigma_b^2}{\sigma_a^2}$ then we get from (18)

$$f(u) = \frac{2\delta^2\,u}{(\delta^2 + u^2)^2}. \tag{19}$$

Substituting (19) into (9) and (10) we obtain

$$P_{error} = \frac{1}{2\pi\Omega}\int_0^{\Omega} d\phi\int_{\phi+\frac{\gamma}{2}}^{2\pi-\phi-\frac{\gamma}{2}} d\psi\,\cdot \int_{\ell_{\phi,\psi}}^{+\infty} \frac{2\delta^2\,u}{(\delta^2+u^2)^2}\,du \tag{20}$$

Last integral in (20) can be expressed in a closed form:

$$\int \frac{2\delta^2\,u}{(\delta^2+u^2)^2}\,du = -\frac{\delta^2\,u}{\delta^2+u^2}.$$

Then we get for the definite integral

$$\int_V^W \frac{2\delta^2\,u}{(\delta^2+u^2)^2}\,du = \left[\frac{1}{1+(hV)^2} - \frac{1}{1+(hW)^2}\right] \tag{21}$$

where $h = \frac{1}{\delta}$ is the signal-to-noise ratio.

Substituting (21) into (20) we get finally

$$P_{error} = \frac{1}{2\pi\Omega}\int_0^{\Omega} d\phi\,\cdot \int_{\phi+\frac{\gamma}{2}}^{2\pi-\phi-\frac{\gamma}{2}} \left[1 + \left[\frac{h\tan\left(\phi+\frac{\gamma}{2}\right)}{\sin\psi}\right]^2\right]^{-1} d\psi$$

***Abstract*—In a previous paper [1] we introduced an optimized version of the K-Means Algorithm. Unlike the standard version of the K-Means algorithm that iteratively traverses the entire data set in order to decide to which cluster the data items belong, the proposed optimization relies on the observation that after performing only a few iterations the centroids get very close to their final position causing only a few of the data items to switch their cluster. Therefore, after a small number of iterations, most of the processing time is wasted on checking items that have reached their final cluster. At each iteration, the data items that might switch the cluster due to centroids' deviation will be re-checked. The prototype implementation has been evaluated using data generated based on an uniform distribution random numbers generator. The evaluation showed up to 70% reduction of the running time. This paper will evaluate the optimized K-Means against real data sets from different domains.**

I. Introduction

THE MORE data continues to grow in both quantity (volume) and diversity, the more challenging clustering algorithms become. Clustering refers to identifying data items' common characteristics (features or attributes) and grouping the data items according to a quantitative estimation of these characteristics. The resulted groups are usually called clusters and they have to be strongly differentiated by their underlying characteristics.

A wide range of domains have successfully employed clustering. Paper [2] made use of clustering for analysing markets as well as recommendations. Papers [3] [4] apply clustering in medicine. Paper [5] uses clustering to analyse news articles and their comments for e-business related purposes. Paper [6] employs clustering for predicting students academic results, while paper [7] applies clustering to human activity recognition.

Unless a mathematical model is available, choosing the most suitable clustering algorithm might prove a hard decision. Arguments that might lead the decision can range from complex experimental results to our own intuition.

Among other challenging open clustering-related issues like: heterogeneity, volume or scalability, that are worth putting research efforts into, raised by clustering, the execution time plays a very important role.

Our proposed optimization focuses on improving the execution time of the K-Means algorithm while keeping the same output.

In use for more than four decades, the K-Means algorithm has been applied in a wide area of fields, ranging from artificial intelligence to image processing or from neural networks to machine vision, or more specifically in unsupervised learning, pattern recognition, classification analysis a.o.

The K-Means algorithm uses a set of cluster centers (cluster centroids) and distributes the data items to the cluster with the closest centroid in terms of Euclidean distance. Picking up the best initial centroids is still an open issue. Different centroids lead to different output and has an important influence on the performance of the algorithm. Choosing the right centroids is beyond the scope of this paper.

The standard K-Means algorithm implies successive exploration of the entire data space with the goal of distributing data items to clusters. At the end of every iteration, the centroids are re-computed by averaging the data items inside the cluster. The next iteration will make use of the newly computed centroids and re-distribute the data items. The loop continues until the centroids no longer change or until a maximum number of iterations has been reached.

The optimization introduced in [1] and presented also in this paper is based on an easily noticeable fact: after a small number of iterations, most of the data items no longer change their cluster, and at the same time, the centroids' deviation reduces significantly. So, why exploring the entire data space if only a small number of data items are subjects to changing the cluster?

Our solution aims of drawing a line between the data items that will certainly not change their cluster, avoiding their exploration in the next iteration(s), and the data items that might switch their cluster which obviously are to be checked.

Exploring the data space only partially on every iteration will not affect the centroid computation. The influence of the data items that are not subject to changing the cluster, on the future centroids, will be preserved in the next iteration(s).

That being said, it becomes obvious that the optimization does not affect the output in any way.

The paper's structure is as follows: section II presents previous attempts for reducing the execution time of the K-Means algorithm, section III describes our proposed optimization for the K-Means algorithm, section IV experimentally evaluates the algorithm against real data sets, (unlike paper [1] where the evaluation is performed against a randomly generated data

978-83-60810-90-3/$25.00

set with uniform distribution), while section V concludes the paper.

II. Related Work

The K-Means algorithm was subject to many research studies covering a wide range of optimization approaches, from computational complexity reduction to parallel and distributed implementations.

In paper [8] the authors propose an optimization that relies on the assumption that if a data item got closer to the centroid on the previous iteration, it will not change the cluster. The assumption allowed the implementation to reduce the amount of computations necessary for computing new centroids.

Parallel and distributed solutions have been discussed in [9][10][11] by treating important topics specific to this kind of environments: synchronization, communication overhead, data availability, architecture (peer-to-peer, client-server, a. o.). The parallel and distributed implementations showed considerable improvement when dealing with very big data sets.

GPUs proved to be a good host for highly-parallel implementations of the K-Means algorithm. Such platforms are addressed in papers [12][13]

III. Optimizing K-Means

In this section we will introduce both the standard K-Means algorithm and the optimized version of it, as proposed in paper [1]. The same optimization strategy will be discussed here, for a better understanding and reading experience.

Algorithm 1 presents the main phases of the standard K-Means algorithm.

Algorithm 1 Standard K-Means

1. Load initial centroids
2. Visit all data items and distribute them to the cluster with the closest centroid
3. For each cluster compute the average of all data items and set the result as the cluster's centroid
4. If the exit criteria (no centroid changes or the maximum number of iteration is reached) are not met, go to step 2
5. Exit.

At a closer look, we can immediately identify step number 2 as the one requiring the most execution time. The time spent on step 2 increases proportionally with the size of the data set, as the entire data set is explored at every iteration.

Figure 1 illustrates an example of centroids evolution of a standard K-Means algorithm. Data items are represented as 2D points. Centroids A, B and C start from their initial positions A_1, B_1, C_1, and successively traverse positions A_i, B_i, C_i, where $i = 1..6$. A_6, B_6 and C_6 are the final positions of the centroids. One can easily notice that after only few iterations, the centroids get very close to their final position, which means that after a few iterations, the number of data items that are subject to changing the cluster reduces considerably.

This observation plays a key role in improving step 2 of algorithm 1; it states that after a small number of iterations,

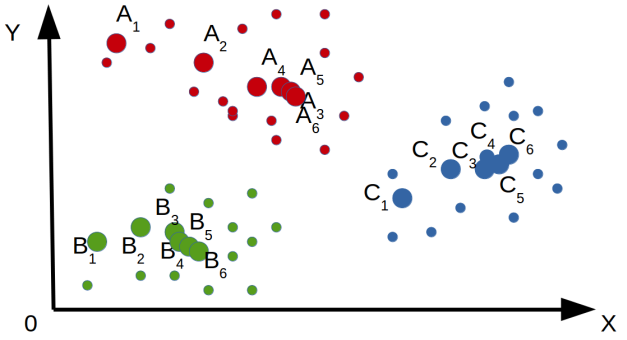

Fig. 1. Centroids Deviation

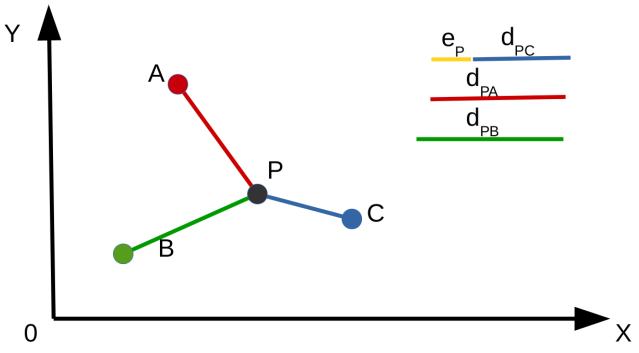

Fig. 2. Point P in an Arbitrary Iteration

the number of points that must be visited (that might change the cluster) is reduced considerably. This lead us to defining specific criteria for splitting the data set in two collections: the former would be made of all data items that are subject to changing the cluster (let's call that the border collection) and the latter would be made of all other points (not changing the cluster). Before providing the mathematical criteria behind the two data item collections, let's examine figure 2.

Figure 2 is a snapshot of an arbitrary iteration around an arbitrary point P. Point P is part of cluster C as a consequence of the fact that the distance from P to C (d_{PC}) is less than the distance to A (d_{PA}) and the distance to B (d_{PB}). We are interested in evaluating the "safety distance" of point P, that is, the distance that P is missing from jumping to the next closest cluster (the cluster represented by centroid A). Let's call this distance e_P (distance to the cluster's edge). We can state that P is e_P-away from the next closest cluster.

$$e_P = min(d_{PA} - d_{PC}, d_{PB} - d_{PC}) \quad (1)$$

At the end of the iteration, centroids A, B and C would be re-computed causing them to jump to new positions A', B', C'. The worst scenario for P is the following: A moves closer to P by $|AA'|$, B also moves closer by $|BB'|$ while C moves away from P by $|CC'|$. The conditions that e_P must fulfil in order for P to remain in cluster C is:

$$e_P > |CC| + |AA| \quad (2)$$

and

$$e_P > |CC| + |BB| \quad (3)$$

For the sake of computation reduction, we can merge conditions 2 and 3 into the following condition:

$$e_P > 2 * max(|AA|, |BB|, |CC|) \quad (4)$$

Inequality 4 help us determining whether a certain point might change the cluster or not, but doesn't save us from visiting the entire data set. The solution is to group the data items by the value of e_P. We can split the range of values that e can take into intervals. Each group would be associated an interval. As long as e_P is greater than the interval's lower bound and lower or equal to the interval's upper bound, P would become part of the group associated with that interval. This allows us to change step 2 of algorithm 1 so that instead of visiting all points, we could visit the groups and check inequality 4. If inequality 4 returns false, it means the points inside that group have to be re-visited. Otherwise, all points inside the group will hold the cluster.

At the end of each iteration, new centroids are to be computed, which might cause centroids to deviate from their current position. To keep the groups synchronized, we will need to also update the lower and upper bounds of the associated intervals. That is, we will assume the worst case scenario presented above, which means the interval bounds would shift towards 0 by at most twice the maximum centroid deviation. More precisely, the bounds of the intervals would be reduced by $2 * max(|AA|, |BB|, |CC|)$.

Algorithm 2 resumes the solution above.

Choosing the $WIDTH$ constant has a big impact on the performance of the algorithm. The number of groups could explode if the value of $WIDTH$ is to small. The other way around, if the value of $WIDTH$ is to big, the intervals for e_P would be very wide causing them to be marked for re-visiting very often. Both extreme scenarios might reduce considerably the improvement brought by algorithm 2.

It is very hard to accurately define a general approach for choosing the right value of $WIDTH$. It depends a lot on the data distribution. However, in our research, we defined $WIDTH$'s value as the average distance between adjacent data elements. Such a value for $WIDTH$, would increase the chances of balancing the groups. Algorithm 3 explains the procedure for defining the value of $WIDTH$, as it was used in our researches:

Therefore, the data set must be analysed prior to defining $WIDTH$, but if the data set is to big, this might require more time than we gain through the proposed optimization. A good compromise would be to analyse only a sample of the data set.

It can be easily noticed that the optimized K-Means has the same output as the standard K-Means. The quality of the clusters is preserved.

Algorithm 2 Optimized K-Means

1. Define constant $WIDTH$
2. Define group intervals
$I_i = (i * WIDTH, (i+1) * WIDTH]$
3. Mark the entire data set to be visited
4. For each point to be visited
5. $e = min(d_{PC_l} - d_{PC_w})$ where C_w is the center of the closest (winner) cluster and $C_l, l = 1..k, l <> w$ stands for all other centroids
6. Map all points with $i * WIDTH < e \leq (i+1) * WIDTH$ to interval $(i * WIDTH, (i+1) * WIDTH]$ where i is a positive integer
7. Compute new centroids C_j, where $j = 1..k$ and their maximum deviation $D = max(|C_j C_j|)$
8. If $D = 0$ or the maximum number of iterations was reached, move to 11
9. Update I_i s boundaries by subtracting $2 * D$ (points owned by this interval got closer to the edge by $2 * D$)
10. Pick up all points that are mapped to an interval whose lower bound became less than or equal to 0, mark them for re-visiting, then go to 4
11. Exit

Algorithm 3 Defining the WIDTH

1. Extract a 5-10% sample of the dataset
2. Traverse each data element in the dataset and compute the distance to it's neighbours.
3. While traversing, average the distances to neighbours that do not differ by more than 50% than the current average value.
4. Assign $WIDTH$ the result of 3.

IV. Experimental evaluation

Experiments were carried out for three publicly available real data sets posted on UC Irvine Machine Learning Repository [14]. The execution environment was made of a Intel(R) Core(TM) i5-3320M CPU @ 2.60GHz, with 8GB of RAM memory, Ubuntu 14.04 operating system. We have selected three data sets that will be described below. A number of 2, 4, 8 and 12 centroids were randomly selected. Multiple runs were carried out for each scenario. The execution times shown below represent the average of all measured execution times for each scenario.

A. US Census (1990) Data Set

The US Census 1990 [15] is a raw 1% sample data set (2458285 records) of the official US Census 1990, obtained of from the (U.S. Department of Commerce) Census Bureau website. For our experiments we've clustered the records by the age information. The $WIDTH$ used for experiments, computed according to algorithm 3, was 1.

Data distribution is shown in figure 3

Results are shown in table I

One could expect such results considering that the data distribution on a wide segment (ages 0-70) is almost uniform. The improvement raises to 61.39% for two centroids, but it

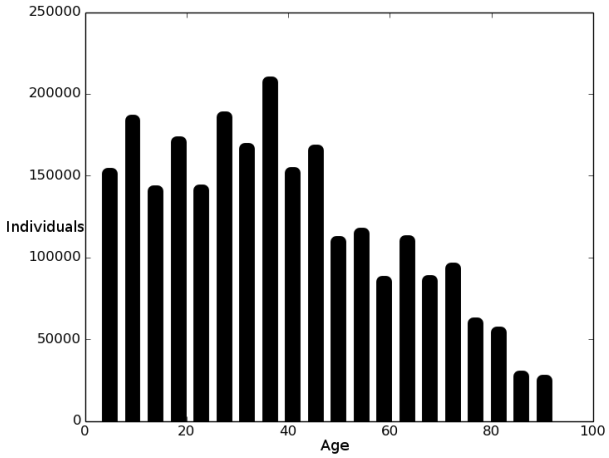

Fig. 3. US Census 1990 Data Distribution

TABLE I
RESULTS FOR US CENSUS DATA (1990) DATA SET

	Number of Centroids			
	2	4	8	12
Time(s) - Standard K-Means	1611	3016	6079	7846
Time(s) - Optimized K-Means	622	1843	4998	6539
Improvement (%)	61.39	38.89	17.78	16.66

TABLE II
RESULTS FOR 3D ROAD NETWORK DATA SET

	Number of Centroids			
	2	4	8	12
Time(s) - Standard K-Means	469	2543	9274	17894
Time(s) - Optimized K-Means	196	833	3438	8104
Improvement (%)	58.16	67.24	62.92	54.70

drops as the number of centroids grow, to as low as 16.66% in case of 12 centroids.

B. 3D Road Network Data Set

The 3D Road Network data set [16] gives the elevation information for a 2D road network in North Jutland, Denmark. There are 434874 road segments. The road segments were clustered using both standard and optimized K-Means algorithms by their elevation. After applying the algorithm 3, the resulted value for $WIDTH$ was 0.07.

Data distribution is shown in figure 4. It is not a uniform distribution, but the differences between adjacent data intervals are smooth.

Results are shown in table II

Results for the 3D Road Network Data set are very encouraging. Improvement was between 54% and 67% for a range of 2 to 12 centroids.

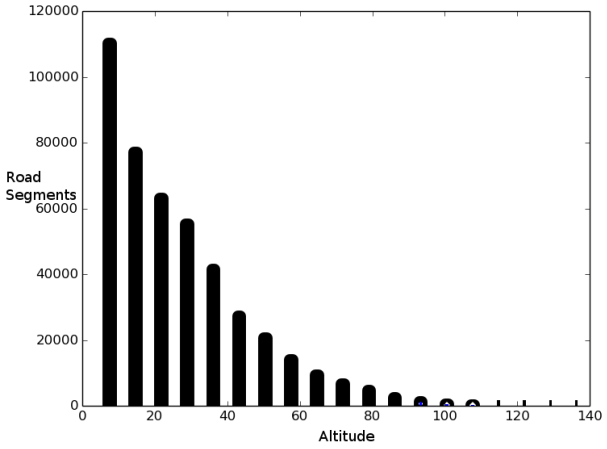

Fig. 4. 3D Road Network Data Distribution

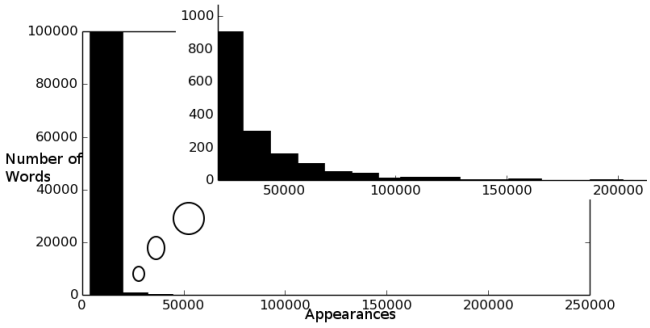

Fig. 5. Bag of Words Data Distribution

C. Bag of words Data Set

Bag of words [17] is a text collection obtained from five different sources. We've run our experiments against the New York Times collections which is made of words extracted from New York Times articles. The vocabulary is made of unique words resulted after removing stop-words and truncating the collection by only keeping words that occurred more than ten times. For each word, the number of occurrences was extracted, resulting a collection of 102660 words. The words were clustered using both standard and optimized K-Means algorithms by their number of appearances. Algorithm 3 indicated a value of 33.65 for the $WIDTH$ constant.

Data distribution is shown in figure 5

The distribution shows a concentration of words by their appearance in the interval [0 - 12000] where approximately 100000 words fit, so more than 97% of the data set.

Results are shown in table III

For the Bag of Words Data Set, the Optimized K-Means, together with algorithm 3 for determining the value of the $WIDTH$ constant, proved to be totally inefficient. They brought an increase of the execution time between 17.7% and 67.4%. The main reason for this increase seems to be the data distribution, which causes algorithm 3 to determine

TABLE III
RESULTS FOR BAG OF WORDS DATA SET

	Number of Centroids			
	2	4	8	12
Time(s) - Standard K-Means	125	339	1274	2697
Time(s) - Optimized K-Means	148	399	1768	4515
Improvement (%)	-18.6	-17.7	-38.7	-67.4

an inappropriate value for the $WIDTH$. The bigger the distance between adjacent words (in terms of the number of appearances), the greater the value of $WIDTH$ would be. A greater value for $WIDTH$ would result into wider word groups, which once invalidated, result into re-visiting a bigger number of words. Also, the wider the group, the greater the chances are for that group to be invalidated and re-visited, even on small deviations.

V. CONCLUSIONS

In this paper we evaluated an optimization for the K-Means algorithm proposed in a previous paper [1], by using real publicly available data sets. Two of the data sets (US Census (1990) and 3D Road Network) shown important improvements, very close the performance resulted by running the algorithm on the randomly generated uniform data set used in [1]. The common feature of the two data sets is that there is no sharp trend on their distribution chart. This is a very important feature when trying to calibrate the Optimized K-Means algorithm (computing the $WIDTH$ constant). The third data set used (Bag of Words), as opposed to the ones mentioned above, showed an unacceptable loss of performance. The main reason for this loss is related to the data distribution, namely, more than 97% of the data elements are concentrated into less than 5% of their distance range (number of word appearances range). Calibrating the algorithm under these circumstances requires a more intensive analysis of the data set. Our future research efforts will focus on improving algorithm 3 to cover a wider range of data distributions.

***Abstract*—The paper presents a framework that implements our original algorithm of automatic mapping a MySQL relational database to a MongoDB NoSQL database. The algorithm uses the metadata stored in the MySQL system tables. It takes into consideration the concepts from Entity-Relationship (ER) model: entity type represented by a relation in the Relational Model (RM), 1:1 and 1:M relationship type represented with Foreign Keys (FK) in the RM and N:M relationship type represented in RM with a join table that contains the Primary Keys (PK) from the original tables, each representing a FK and two 1:M relationships between the original tables and the join table. The initial results of our algorithm that was tested on small size databases (10-15 tables with many relationships and 100 records/ table) are presented in this paper.**

I. Introduction

RELATIONAL Database Management Systems (RDBMS) have became the first choice for the storage of information in databases mostly used for financial records, manufacturing information, staff and salary data, and so on starting with 1980. RDBMSs are based on the relational model defined by a schema. This model uses two concepts: table and relationship. A relational table represents a well defined collection of rows and columns and the relationship is established between the rows of the tables. Relational data can be queried and manipulated using SQL query language [8].

In practice, there are situations in which storing data in the form of a table is inconvenient, or there are other kinds of relationships between records, or there is the necessity to quickly access the data. In order to solve such problems a new type of NoSQL has been created. A NoSQL or Not Only SQL database provides a mechanism for storage and retrieval of data that is different from the typical relational model.

Another issue that NoSQL solves is the mismatch between relational databases and object-oriented programming. It is known that SQL queries are not well suited for the object oriented data structures that are used in most applications now [8].

Another closely related issue is storing or retrieving an object along with all relevant data. Some operations require multiple and complex queries. In this case, data mapping and query generation complexity rise too much and becomes difficult to be maintained on the application side [8].

Some of these problems have found their answer both in Object-relational mapping (ORM) frameworks, even though it still requires a lot of development effort and also in Object-Oriented Database Management Systems (OODBMS). The down side in this last alternative is the fact that it did not gain much popularity in replacing relational databases. However, most object oriented databases may be considered NoSQL solutions as well [8].

Another problem that relational databases cannot handle is related to an exponentially increasing amount of data. The direct consequence is the so-called big data problem. This problem arises when standard SQL query operations do not have acceptable performances, especially when transactions are involved [8].

As a result, the subject of developing an automatic mapping instrument has been brought up. This instrument will be able to represent the existing relational databases, already populated with a large number of records, as NoSQL databases. A significant amount of time and human effort is spared this way, which would have otherwise been needed to create and populate the NoSQL database from scratch.

This paper proposes a framework which implements an algorithm for automatic mapping of MySQL relational databases to MongoDB.

The paper is organized in the following way: Section II presents the main concepts used by MongoDB, one of the most used NoSQL database, Section III presents general principles of mapping relational databases to MongoDB considering the main concepts from ER model and RM. Section IV presents in detail our proposed algorithm for automatic mapping of a MySQL database to MongoDB and also an example of application of this algorithm. Conclusions and future work are shown in Section V.

II. MongoDB

MongoDB is a cross-platform, document oriented database that provides high performance, high availability and easy scalability. The main concepts in MongoDB are collection and document. Database is a physical container for collections. Each database receives its own set of files on

the file system. A single MongoDB server typically manages multiple databases [2], [3], [4], [5].

The collection is a group of MongoDB documents. It has as correspondent a RDBMS table. A collection exists only within a single database.

A MongoDB document is a set of key-value pairs. The documents do not have to necessarily respect a schema. Typically, all documents in a collection are of similar or have a related purpose. Dynamic schema means that documents in the same collection do not need to have the same set of fields or structure, and common fields in a collection's documents may hold different types of data.

Table 1 shows the relationship of RDBMS terminology with MongoDB [3], [4], [5].

TABLE I.
THE RELATIONSHIP OF RDBMS TERMINOLOGY WITH MONGODB

RDBMS	MongoDB
Database	Database
Table	Collection
Tuple/Row	Document
Column	Field
Table Join	Embedded Documents
Primary Key	Primary Key (Default key _id provided by MongoDB itself)

Any relational database has a certain design schema that shows the tables and the relationships between them. In MongoDB there is no concept of relationship.

The advantages of MongoDB over RDBMS are [2], [3], [4], [5]: schema-less (MongoDB is a document database in which one collection holds different documents whose number of fields, content and size can be different from one document to another), structure of a single object is clear, no complex joins, deep query-ability (MongoDB supports dynamic queries on documents using a document-based query language that is almost as powerful as SQL), tuning, ease to scale-out, conversion / mapping of application objects to database objects is not needed, uses internal memory for storing the working set, enabling faster access to data.

III. THE GENERAL PRINCIPLES OF MAPPING RELATIONAL DATABASES TO MONGODB

In MongoDB the relational database remains a database. A relational table is mapping to a MongoDB collection. The tuples or rows become documents inside MongoDB collections [3], [4], [5].

The 1:1 relationship describes a relationship between two entities. For example a Student has a single Address relationship. A Student lives at a single Address and an Address only contains a single Student. The 1:1 relationship can be modeled in two ways using MongoDB. The first is to embed the relationship as a document and the second is as a link to a document in a separate collection [4], [5].

In the one to one relationship embedding is the preferred way to model the relationship as it's more efficient to retrieve the document.

The 1:M relationship describes a relationship where one side can have more than one relationship while the reverse relationship can only be single sided.

The 1:M relationship can be modeled in several different ways using MongoDB. The first model is embedding, the second is linking and the third is a bucketing strategy that is useful for cases like time series [4], [5].

A N:M relationship in the ER model is an example of a relationship between two entity types where they both might have many relationships between entities. An example might be a Book that was written by many Authors. At the same time an Author might have written many Books.

N:M relationships are modeled in the relational database by using a join table that contains the primary keys from the original ones, each representing a foreign key, and two 1:M relationships.

In MongoDB we can represent this situation in many ways. The first way is called Two Way Embedding [4], [5].

In Two Way Embedding we will include the Book foreign keys under the book field in the author document. Mirroring the Author document, for each Book we include the Author foreign keys under the Author field in the book document.

Another way of modeling N:M relationships is called One Way Embedding [4], [5].

The One Way Embedding strategy chooses to optimize the read performance of a N:M relationship by embedding the references in one side of the relationship. An example might be a N:M relationship between books and categories. The case is that several books belong to a few categories but a couple categories can have many books. Let's look at an example with the categories represented into a separate document.

An example of Category documents:

{id=1,
Cname="Multimedia"}
{id=2,
Cname="Databases"}

An example of a Book document with foreign keys for Categories:

{id:1,
title"Multimedia Databases",
categories:[1, 2],
authors:[1]}
id:2,
title"Multimedia",
categories:[1],
authors:[1,2]}

IV. FRAMEWORK DESCRIPTION

The framework implements an algorithm of automatic mapping of MySQL relational databases to MongoDB.

The algorithm uses the MySQL INFORMATION_SCHEMA that provides access to database metadata. Metadata is data about the data, such as the name of a database or table, the data type of a column, or access privileges. INFORMATION_SCHEMA is the information database, the place that stores information about

all the other databases that the MySQL server maintains. Inside INFORMATION_SCHEMA there are several read-only tables. They are actually views, not base tables [6], [7]. For examples we use a database db1 that contains 5 tables: Employee, Department, Project, Child and Works_on. The relationships are 1:M between Department and Employee, Employee and Child, Department and Project (figure 1). In the ER model there is a N:M relationship, implemented in the relational model by the join table Works_on and two 1:M relationship between Employee and Works_on and Project and Works_on.

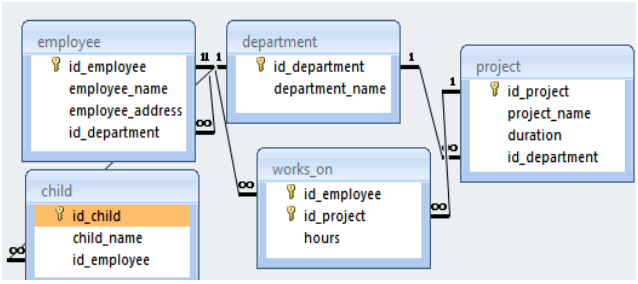

Fig. 1 A relational database

The steps of the algorithm implemented in our framework are presented next.

1. Creating the MongoDB database

The user must specify the MySQL database that will be represented in MongoDB. The database is created with the following MongoDB command: use DATABASE_NAME [5].

>use db1
switched to db db1

2. Creating tables in the new MongoDB database

The algorithm verifies for each table in what relationships is involved, if it has foreign keys and/or is referred by other tables.

2.1 If the table is not referred by other tables, it will be represented by a new MongoDB collection.

2.2 If the table has not foreign keys, but is referred by another table, it will be represented by a new MongoDB collection.

2.3 If the table has one foreign key and is referred by another table, it will be represented by a new MongoDB collection. In our framework, for this type of tables we use linking method, using the same concept of foreign key.

2.4 If the table has one foreign key but is not referred by another table, the proposed algorithm uses one way embedding model. So, the table is embedded in the collection that represents the table from the part 1 of the relationship.

2.5 If the table has two foreign keys and is not referred by another table, it will be represented using the two way embedding model, described in section IV.

2.6 If the table has 3 or more foreign keys, so it is the result of a N:M ternary, quaternary relationships, the algorithm uses the linking model, with foreign keys that refer all the tables initially implied in that relationship and already represented as MongoDB collections. The solution is good even the table is referred or not by other tables.

In order to find the name of the tables stored in MySQL database the next Select command is used:

Select table_name From information_schema.tables
Where table_schema='db1' Order By table_name;

The INFORMATION_SCHEMA.TABLES provides information about tables in databases [6], [7].

The table TABLES_CONSTRAINTS from INFORMATION_SCHEMA database describes which tables have constraints [6], [7]. It must be executed a Select command on each table in database, as in the next example:

Select constraint_type
From information_schema.tables_constraints
Where table_schema='db1'
And table_name='department';

The CONSTRAINT_TYPE value can be unique, primary key or foreign key. We are interested by primary key and foreign key constraints [6], [7].

The table REFERENTIAL_CONSTRAINTS from the same MySQL system database provides information about foreign keys. The attributes constraint_schema and constraint_name identify the foreign key. The attributes: unique_constraint_schema, unique_constraint_name and referenced_table_name identify the referenced key [6], [7].

With the data from these system tables: tables, tables_constraints and referential_constraints the framework can establish what step of the algorithm (2.1-2.6) must be applied.

Relational tables become collections in MongoDB. The collections are created using createCollection() method.

Basic syntax of **createCollection()** command is as follows [5]:

Db.createCollection(name, options)

Where name represents the collection name and options specify options about memory size and indexing.

For the relational database from figure the mapping according to the presented algorithm is presented next. The table Department has no foreign keys but is referred by other two tables, so it becomes a MongoDB collection (step 2.2).

The table Employee has one foreign key and is referred by the table Works_on, so it becomes a collection (step 2.3).

The table Project has one foreign key and is referred by Works_on, so it becomes also a collection (step 2.3).

The table Works_on has two foreign keys and is not referred by other tables, so it will be implemented using two way embedding model (step 2.5). The projects will be assigned to each employee and also, to each project will be assigned the employees that work on that project.

The table Child has foreign key but is not referred by another table, so it will be represented using one way embedding model (step 2.4). So it will be embedded in Employee collection.

The five relational tables will be represented by three MongoDB collections. Next, there are some samples of the MongoDB collections generated by the presented algorithm.

Department collection is presented in figure 2.

Fig. 2 MongoDB collection that represents the Department table

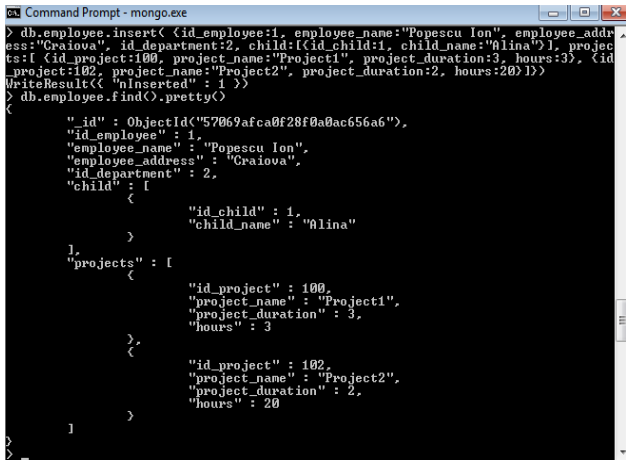

Fig. 3 MongoDB Employee collection

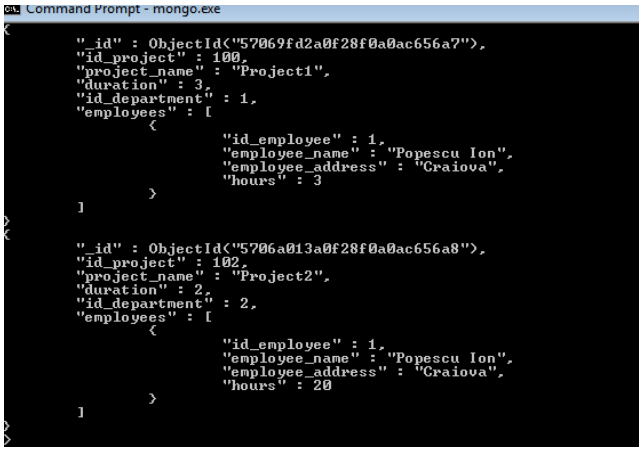

Fig. 4 MongoDB Project collection

Employee Collection that contains the document Child and Projects is presented in figure 3.

Project collection that embeds the documents employees that work on these projects is shown in figure 4.

V. Conclusion and Future Work

The paper presents a framework that implements our original algorithm of automatic mapping a MySQL relational database to a MongoDB NoSQL database. The algorithm uses the metadata stored in the MySQL system tables. It takes into consideration the concepts from Entity-Relationship (ER) model: entity type represented by a relation in the Relational Model (RM), 1:1 and 1:M relationship type represented with Foreign Keys (FK) in the RM and N:M relationship type represented in RM with a join table that contains the Primary Keys (PK) from the original tables, each representing a FK and two 1:M relationships between the original tables and the join table.

The algorithm was presented in detail, on steps. Also, the paper contains an example of automatic mapping of a MySQL database to MongoDB using our algorithm.

The paper also presents the initial results of our algorithm that was tested on small size databases (10-15 tables with many relationships and 100 records/table), the results being encouraging.

The future work will include the next steps:

- Experiments on complex databases (many tables and a large number of records/table)
- Taking into consideration the number of records in the tables and the operations on the database (insert, update, delete query) in order to implement the more appropriate model of mapping to MongoDB
- Modeling tree structures with parent references
- Extending the framework to execute mapping to MongoDB of other relational databases (Oracle, MS SQL Server and so on)

***Abstract*—The central idea of this paper is the modeling and implementation of a real-time dc servomotor angular speed control system with an unknown bounded uncertainty using a sliding mode observer (SMO) control strategy. We prefer to use a SMO in our approach due to its great potential in fault detection and isolation (FDI) of the actuators and sensor faults subjected frequently to several failures due to an abnormal change in their operating conditions or parameters. We use for this purpose the most suitable real time implementation tool MATLAB/SIMULINK software package. It provides special features for real time implementation by its extensions Real-Time Workshop (RTW) and the Real-Time Windows Target (RTWT). The novelty of our paper is to prove in an extensive simulation MATLAB/SIMULINK frame the real time implementation potential of a most recently sliding mode observer (SMO) control strategy applied to a particular case study, namely for a dc servomotor angular speed control system. The proposed real-time Sliding Mode Observer (SMO) consists of an embedded nonlinear Sliding Mode Observer (SMO) with the dc servomotor actuator in an integrated control system structure to estimate its angular speed and armature current and to implement the sliding mode control law.**

I. Introduction

THE most important common actuator integrated in a forward path of the control systems structure is the dc servomotor. It directly provides rotary motion and, coupled with wheels or drums and cables, can also provide transitional motion. The cause roots of the majority faults in control systems are the result of unexpected failures, interferences as well as the age of their crucial components. In our research defective measurement and control loops equipment, in particular a sensor and an actuator are under investigation. More precisely, we assume that the dc servomotor control system is subjected to an unknown but bounded uncertainty, and its speed is controlled in closed-loop feedback by using a state feedback control law with an embedded sliding mode observer (SMO) that is integrated in the closed-loop control structure. The dc servomotors are preferred in control area applications because they possess a high start torque characteristics, high response performance, and easier to be linearly controlled etc. Also the dc servomotor speed can be adjusted by varying its input voltage. Therefore, the dc motor control is better compared to all ac induction motors that need expensive frequency drivers. The real-time dc servomotor speed control can be easily understood and interfaced with MATLAB/SIMULINK or AnyLogic multi-paradigms hybrid simulator in the case of UML-RT implementations [8] with a fast response. Furthermore, the preliminary results of this research will be useful for us for future exploration of using a sliding mode observer to develop more attractive control strategies, for example the detection and isolation of the faults (FDI) [1], [5], [6], [7] that occur in the actuators and sensors, and also for trust modeling in Multi-agent Systems [3], will be an interesting future directions of our research. Whenever these critical situations come out the control systems could lose the control, require much more energy, and could operate harmfully. Therefore to operate in real-time at high energy efficiency and to guarantee the equipment safety and reliability it is important to develop suitable FDI strategies capable to detect and diagnose any time every faulty control system components and consequently corrective and reconfiguration actions should be initiated promptly [7]. Effectively the existing methods to identify and to adjust the equipment failures are mostly labor-intensive task, and consequently sustained, rhythmic and error-prone [7]. In the majority of these situations the windings currents are recorded to determine the health of the dc servomotors currents compared to statistical evaluation that necessitates considerable human knowledge, hence error-prone that could generate severely equipment operation. In these conditions the problem of control systems monitoring and fault diagnosis becomes a critical issue, of high complexity that need to be

978-83-60810-90-3/$25.00

implemented in mainframe environment by using more sophisticated control systems and artificial intelligence strategies. This research work is based on our previous results in implementation of different control systems strategies and now we are interested to prove the effectiveness of real-time implementation of our proposed SMO control strategy. Closing, the main objective of our research is to develop a more suitable, accurate and consistent real-time nonlinear SMO control strategy to be used in our future real-time FDI control strategies implementation development.

II. THE DC SERVOMOTOR DYNAMICS

The electric circuit of the dc servomotor armature and the free body diagram of the rotor are shown in figure 1. For simulation purpose we will assume the following experimental values for the physical parameters [9]:

- moment of inertia of the rotor: $J = 0.001\ [\frac{kgm^2}{s^2}]$
- damping ratio of the mechanical system: $b = 0.01[Nms]$
- counter electromotive force coefficient (*cemf*): $k_e = k_t = k = 0.0517\ [Nm/A]$
- motor electric resistance: R = 1 [Ω]
- motor electric inductance: $L = 0.5[H]$
- motor initial angular speed: $\omega = 1[\frac{\text{rad}}{\text{s}}]$,
- input dc power supply: $V = 12[V]$
- load torque: $T_L = 0.1\sin(t)\ [Nm]$

The dynamics of the dc servomotor actuator is described by the following input-state-output equations [8]-[9] :

$$J\frac{d^2\theta}{dt^2} + b\frac{d\theta}{dt} = k_t I_a - T_L$$
$$L\frac{dI_a}{dt} + RI_a = V - k_e\frac{d\theta}{dt}. \quad (1)$$

where $T_e = T = k_t I_a$ is the dc servomotor torque developed to the shaft, T_L is the load torque, and $e = k_e\frac{d\theta}{dt} = k_e\omega$ is the counter electromotive force (*cemf*) of the dc servomotor.

In a state-space representation the dc servomotor actuator dynamics is described by following equations:

(i) State Equation:

$$\begin{bmatrix}\frac{dx_1}{dt}\\ \frac{dx_2}{dt}\end{bmatrix} = \begin{bmatrix}-\frac{b}{J} & \frac{k_t}{J}\\ -\frac{k_e}{L} & -\frac{R}{L}\end{bmatrix}\begin{bmatrix}x_1\\ x_2\end{bmatrix} + \begin{bmatrix}-\frac{T_L}{J}\\ \frac{u}{L}\end{bmatrix} \quad (2)$$

$$x_1 = \omega, x_2 = I_a, u = V, x_1(0) = 1\left[\frac{rad}{s}\right], x_2(0) = 0[A]$$

(ii) Output equation:

$$y = [1 \quad 0]\begin{bmatrix}x_1\\ x_2\end{bmatrix} \quad (3)$$

where we assume that the only the state x_1 is measurable, and the input command $u = V$ is a function defined by the armature voltage (dc power supply) and is designed in closed-loop as a state feedback control law. Also the load torque T_L is considered unknown which is bounded and has a bounded derivative.

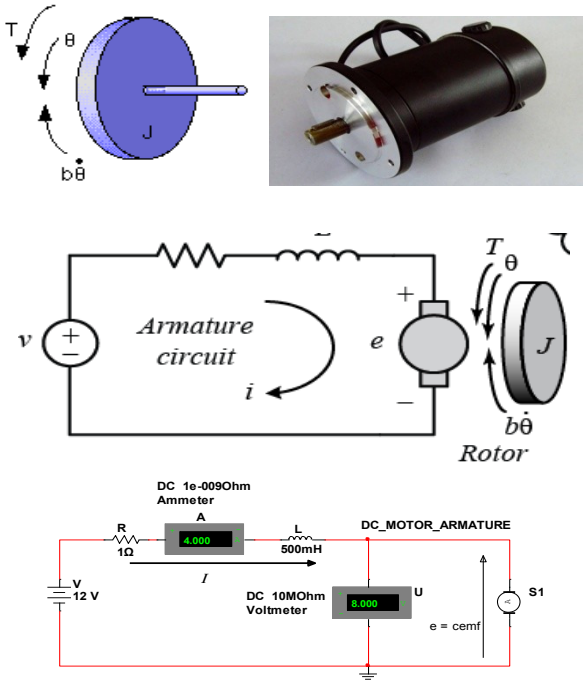

Fig. 1 The simplified equivalent electrical circuit of the dc servomotor (Reproduced from [8]-[9])

III. SLIDING MODE CONTROLLERS VERSUS SLIDING MODE OBSERVERS

To formulate any practical control application is not a straightforward task due to a more or less mismatch between the actual plant and its mathematical model used for the controller design. This mismatch could arise from unknown external disturbances, plant parameters, or modeling errors. To design a suitable control law in order to provide the desired performance to the negative feedback closed-loop control system in the presence of these disturbances or uncertainties is a very difficult task for any control engineer. This has led to an intensive research to develop some kind of robust control methods that are supposed to solve this problem. The sliding mode control (SMC) is one of particular attractive approach to design a robust controller due to its potential as a robust control method. A sliding mode control (SMC) is characterized by a suite of feedback control laws and a decision rule [1]. The decision rule is a sort of switching function that has as its input some measure of the current system behavior in order to generate as an output a particular feedback robust controller which should be used at that time instant [1]-[2]. The sliding mode control (SMC) strategy is designed such that the variable structure control systems have to be capable to drive the system states on the convergent phase trajectories and then to constrain these to lie within a neighborhood of the switching function

that can be represented by a switching line or switching surface, such is shown in figure 2 [8]. In this approach the dynamic behavior of the control system may be adapted to a particular choice of switching function, and also the feedback closed-loop response becomes totally insensitive to a particular class of uncertainty in the system, more precisely proving a high robustness feature to all kind of system uncertainties. The main drawback of using the sliding mode control (SMC) techniques to design a large variety of control industrial applications is the necessity to implement a basically discontinuous control signal which hypothetically must switch with infinite frequency to provide total rejection of the uncertainties [1]-[2].

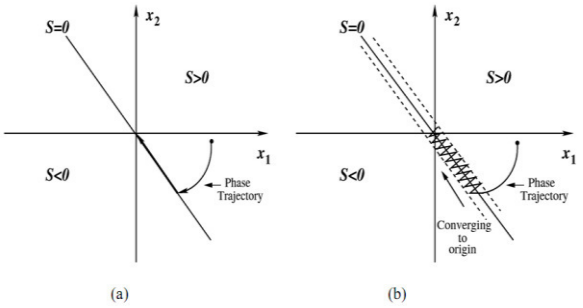

Fig. 2 Switching dynamics represented in phase plane for: (a) ideal sliding mode control and (b) practical sliding control mode (Reproduced from [8])

In contrast, the application of sliding mode methods in combination with observer control problems provide the ability to generate a sliding motion on the error between the measured plant output and the output of the observer such that to ensure that a sliding mode observer (SMO) produces a set of state estimates precisely matching with the actual output of the plant. Also the analysis of the average value of the applied observer injection signal, the so-called equivalent injection signal, contains useful information about the mismatch between the model used to define the observer and the actual plant. Furthermore, the discontinuous injection signals in this case don't remain anymore a drawback for software based observer frameworks in control applications [1], [2], [4], [5].

The development of SMO control strategy design in this research paper follows the same design guidelines suggested in [1],[2] and [4], [5] related to the design of sliding mode observer (SMO) control strategies for fault detection and isolation based on the equivalent injection signal principle.

IV. Sliding Mode Observer for Linear DC Servomotor Without Model or Disturbances Uncertainties

For simulation purpose we assume in this section that the experimental values for the physical parameters of the dc servomotor are the same with those introduced in section II. With these values, the dynamics of the dc servomotor is described in state-space representation by the following first order differential equation:

$$\frac{dx}{dt} = A_{n\times n}x + B_{n\times m}u + D_{n\times q}\Psi(x,u,t)$$
$$y = C_{p\times n}x = [1 \quad 0]x \tag{2}$$

$$A = \begin{bmatrix} -10 & 51.7 \\ -0.1034 & -2 \end{bmatrix}, B = \begin{bmatrix} 0 \\ 2 \end{bmatrix}, D = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$$
$$\Psi(x,u,t) = (-1000T_{Load}) = -10\sin(t).$$

where $x \in R^n$ is a n - dimensional state vector $(n = 2)$, $y \in R^p$ is a p-dimensional output vector $(p = 1)$, and $u \in R^m$ is a m-dimensional input vector $(m = 1)$. For this development phase the load torque disturbance uncertainty is considered $T_{Load} = 0$, (dc Servomotor no-load speed) and so $\Psi(x,u,t) = 0$, in order to investigate in the first phase of our development only the linear case. By some manipulations of the matrices A, B, C we can easily find that B, C have a full rank and the pair (A, C) is observable, as main requirements assumed in [1].

To design a sliding mode observer (SMO) for this control system we follow the same procedure as in [1]. Firstly we attach to the original system an *Utkin observer* [1], [2] in a canonical form. For this task we need to find a nonsingular state transform $T_c \in R^{n\times n}$ that changes the state vector x in a state vector

$$z = T_c x = \begin{bmatrix} z_1 \\ z_2 \end{bmatrix}, z_1 \in R^{n-p}, z_2 \in R^p, T_c = \begin{bmatrix} N_c^T \\ C \end{bmatrix},$$
$$N_c \in R^{n\times(n-p)} \tag{3}$$

where the column of the matrix N_C spans the null space of $C, \exists z_1 \neq 0_{(n-p)\times 1} \xrightarrow{yields} N_c \times z_1 = 0_{(n-p)\times 1}$.

This nonsingular state transform T_c converts the nominal system (2) in the following canonical form:

$$\frac{dz_1}{dt} = A_{11}z_1(t) + A_{12}z_2(t) + B_1u(t)$$
$$\frac{dz_2}{dt} = A_{21}z_1(t) + A_{22}z_2(t) + B_2u(t) \tag{4}$$

Now the dynamics of the observer is described by the following similar equations:

$$\frac{d\hat{z}_1}{dt} = A_{11}\hat{z}_1(t) + A_{12}\hat{z}_2(t) + B_1u(t) + L\vartheta$$
$$\frac{d\hat{z}_2}{dt} = A_{21}\hat{z}_1(t) + A_{22}\hat{z}_2(t) + B_2u(t) - \vartheta \tag{5}$$

where the pair $(\hat{z}_1, \hat{z}_2)$ represent the estimated values of the transformed components state vector z, and $L \in R^{(n-p)\times p}$ is the observer gain matrix, given by

$$\vartheta_i = Msgn(\hat{z}_{2,i} - z_{2,i}), M \in R_+, i = 1, \dots, p \tag{6}$$

The dynamics of the system errors is described by the following first order differential equations:

$$\frac{de_1}{dt} = A_{11}e_1(t) + A_{12}e_2(t) + L\vartheta$$
$$\frac{de_2}{dt} = A_{21}e_1(t) + A_{22}e_2(t) - \vartheta \tag{7}$$
$$e_1(t) = \hat{z}_1(t) - z_1(t),\ e_2(t) = \hat{z}_2(t) - z_2(t)$$

The observer gain matrix $L \in R^{(n-p)\times p}$ is chosen in order to make the spectrum of the matrix ($A_{11} + LA_{21}$) to lie in $\mathbb{C}_-$, where the pair matrices (A_{11}, A_{21}) is observable due to the fact that the pair (A, C) is also observable.

Without to lose the generality we can choose the coordinates transform matrix such as:

$$T_c = \begin{bmatrix} N_c^T \\ C \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} \quad (8)$$

that converts the triple (A, B, C) into $(\tilde{A}, \tilde{B}, \tilde{C})$, where the lines of the matrix N_c^T span the null space of the vector C, and also:

$$\tilde{A} = T_c A T_c^{-1} = \begin{bmatrix} -2 & -0.1034 \\ 51.70 & -10 \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}$$
$$\tilde{B} = T_c B = \begin{bmatrix} 2 \\ 0 \end{bmatrix} = \begin{bmatrix} B_1 \\ B_2 \end{bmatrix}, \tilde{C} = C T_c^{-1} = [0 \quad 1] = [C_1 \quad C_2] \quad (9)$$

From the matrix structure $\tilde{A}$ we get $A_{11} = -2$ (stable), and $A_{12} = -0.1034$, $A_{21} = 51.70, A_{22} = -10$. Also, $B_1 = 2, B_2 = 0, C_1 = 0, C_2 = 1$.

The value of the observer matrix gain L can be choose such as $A_{11} + LA_{21} < 0$, let take this $L = -1 < -\frac{A_{11}}{A_{21}} = 0.0387$. Setting the observer matrix gain L to 0.01 the dynamics of the linear observer and of its error are described by the following first order differential equations:

$$\begin{aligned} \frac{d\hat{z}_1}{dt} &= -2\hat{z}_1(t) - 0.1034\hat{z}_2(t) + 2u(t) - \vartheta \\ \frac{d\hat{z}_2}{dt} &= 51.70\hat{z}_1(t) - 10\,\hat{z}_2(t) - \vartheta \\ \frac{de_1}{dt} &= -2e_1(t) - 0.1034e_2(t) + 0.01\vartheta \\ \frac{de_2}{dt} &= 51.70e_1(t) - 10e_2(t) - \vartheta \\ \vartheta &= sgn(\hat{z}_2 - z_2) = sgn(e_2(t)), M = 1 \end{aligned} \quad (10)$$

4.1 SIMULATION RESULTS

In all the above equations we set $u(t) = 12\,[V]$ in order to solve the problem of designing a sliding mode observer (SMO) by using MATLAB/SIMULINK software package. The model of the original system in SIMULINK is shown in figure 3, and the evolution of the states, i.e. angular speed(x_1) and armature current (x_2) are shown in figures 4 and 5. The state-space representation model of the dc servomotor in canonical form and the *Utkin classical observer* dynamics model embedded in the same integrated control structure are represented in MATLAB/SIMULINK, as are shown in figure 6 and the evolution of the both model and estimated states, namely the angular speed (z_2) and the armature current (z_1) are shown in figures 7 and 8. The dc servomotor angular speed (e_2) and armature currents (e_1) SMO residuals are shown in figures 9 and 10. In figure 11 are shown the SMO errors dynamics modeled in SIMULINK.

An ideal sliding motion will take place on the sliding surface [1], [2], [4], [5]:

$$S_w = \{(e_1, e_2) | e_2 = 0)\} \quad (11)$$

After some finite time t_s, for all subsequent time, $e_2 = 0$, and $\frac{de_2}{dt} = 0$.

The corresponding sliding mode dynamics are given in [1]-[2]:

$$\frac{d\tilde{e}_1(t)}{dt} = \tilde{A}_{11}\tilde{e}_1(t) \quad (12)$$

where

$$\tilde{e}_1(t) = e_1(t) + Le_2(t) = e_1(t) - e_2(t)$$
$$\tilde{A}_{11} = A_{11} + LA_{21} = -2 - 51.70 = -53.70 < 0.$$

Since $\tilde{A}_{11} < 0$, the linear homogenous equation (12) has a stable solution, $\tilde{e}_1(t) = C_0 e^{-53.70t}$, where C_0 is a integration constant determined from the initial condition $\tilde{e}_1(0) = \tilde{e}_{10}$. By a suitable choice of the gain L, such as in our case study $L = -1 < 0.0387$,we can conclude that always the system is stable, therefore $\tilde{e}_1(t) \xrightarrow{yields} 0$, and also $\hat{z}_1(t) \xrightarrow{yields} z_1(t)$ as $t \xrightarrow{\Delta} \infty$.

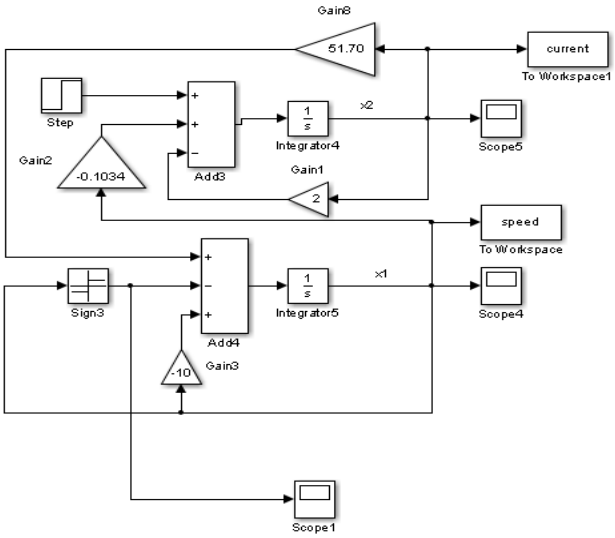

Fig. 3 DC servomotor state space-representation of nominal model in MATLAB/SIMULINK

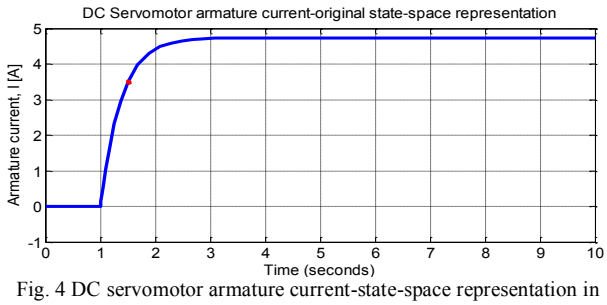

Fig. 4 DC servomotor armature current-state-space representation in MATLAB/SIMULINK

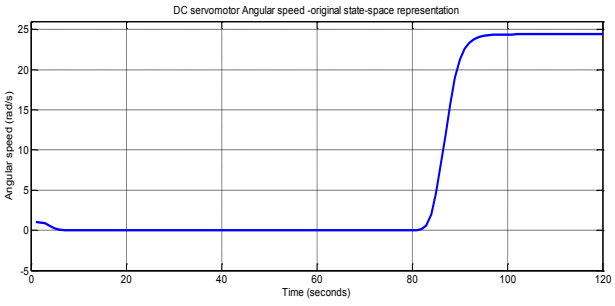

Fig. 5 DC servomotor angular speed- original state-space representation model in MATLAB/SIMULINK

In figure 12 is captured much more commutations around the sliding line:

$$S_w: \frac{de_2}{dt} = 0, e_2 = 0$$

and is shown the time switching control function

$$\vartheta = sgn(\hat{z}_2 - z_2) = sgn(e_2(t)), M = 1,\ L = -1.$$

Secondly, we build a classical Utkin observer with linear injection that is used in next section to introduce a constructive sliding mode observer design framework.

V. SLIDING MODE OBSERVER FOR LINEAR DC SERVOMOTOR WITH MODEL OR DISTURBANCE UNCERTAINTY

For the uncertain system (2) we define the following observer described in state-space representation [1]-[2], [4]-[5] by the following equations:

$$\frac{d\hat{x}}{dt} = A_{n\times n}\hat{x} + B_{n\times m}u - G_{L,n\times p}C_{p\times n}e(t) + G_{N,n\times p}\vartheta \quad (13)$$

where the error $e(t)$ is

$$e(t) = \hat{x}(t) - x(t) \quad (14)$$

ϑ is a discontinuous switching function about the sliding hyperplane:

$$S_w = \{e \in R^n | Ce = 0)\} \quad (15)$$

and the precise structure of injection signal matrices gains $G_{L,n\times p}, G_{N,n\times p}$ is to be determined.

The existence conditions for a SMO of the form (13) that rejects the uncertainty class $\Psi(x,u,t)$: $R_+ \times R^n \times R^m \to R^n$ of dc servomotor load torque $T_{Load} = 10sint(t)$ described in (2) are given in [1]-[2], [4]-[5]:

- $rank\,(C \times D) = q = 1,\ 1 = q \le p < n = 2$ (16)
- any invariant zeros of the original nominal system matrices (A, D, C) given in (2) must lies in the half left complex plane C_- (stable).

For a square nominal linear system these two conditions require that the triplet (A, D, C) to be relative degree one and minimum phase. Furthermore, the existence conditions depend upon a specific selection of the uncertainty channel and the observer design will be directly determined by the uncertainty distribution matrix D. The necessary and sufficient conditions for existence of a sliding mode observer (SMO) together with the canonical form provide a pathway to a constructive method for observer design [2], [4], [5].

The original nominal system (2) is converted in the canonical form (3) using a possible change in coordinates $z_c = T_c x$ through a canonical transformation matrix T_c given in (8):

$$A_c = T_c A T_c^{-1} = \begin{bmatrix} -2 & -0.1034 \\ 51.70 & -10 \end{bmatrix} = \begin{bmatrix} A_{11c} & A_{12c} \\ A_{21c} & A_{22c} \end{bmatrix}$$

$$B_c = T_c B = \begin{bmatrix} 2 \\ 0 \end{bmatrix} = \begin{bmatrix} B_{1c} \\ B_{2c} \end{bmatrix} \quad (17)$$

$$C_c = CT_c^{-1} = [0 \quad 1] = [C_{1c} \ \ C_{2c}]$$

$$D_c = T_c D = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}\begin{bmatrix} 1 \\ 0 \end{bmatrix} = \begin{bmatrix} 0 \\ 1 \end{bmatrix} = \begin{bmatrix} D_{1c} \\ D_{2c} \end{bmatrix}$$

In this structure all the required existence conditions mentioned in [2] to design a SMO are satisfied. The matrix gain $\bar{L}$ defined in [Sarah] for our case study becomes $\tilde{L} = \bar{L} = 0$.

Define now a new nonsingular matrix T_L of the following structure [2], [4], [5]:

$$T_L = \begin{bmatrix} I_{n-p} & \bar{L} \\ 0 & D_2 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad (18)$$

that converts the system from canonical form (17) in the following state-space representation:

$$z_L = T_L x_c$$

$$A_L = T_L A_c T_L^{-1} = A_c = \begin{bmatrix} -2 & -0.1034 \\ 51.70 & -10 \end{bmatrix}$$

$$A_L = \begin{bmatrix} A_{11,L} & A_{12,L} \\ A_{21,L} & A_{22,L} \end{bmatrix}$$

$$B_L = T_L B_c = \begin{bmatrix} 2 \\ 0 \end{bmatrix} = \begin{bmatrix} B_{1,L} \\ B_{2,L} \end{bmatrix}, \quad (19)$$

$$C_L = T_L^{-1} C_c = C_c = [0 \quad 1] = [C_{1,L} \ \ C_{2,L}]$$

$$D_L = T_L D_c = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}\begin{bmatrix} 0 \\ 1 \end{bmatrix} = \begin{bmatrix} 0 \\ 1 \end{bmatrix} = \begin{bmatrix} D_{1,L} \\ D_{2,L} \end{bmatrix},$$

and so, by chance, the same structure as in the canonical form.

The system triplet (A_L, C_L, D_L) can be put in the following form [1], [2]:

$$\frac{dz_{1,L}}{dt} = A_{11,L}z_{1,L}(t) + A_{12,L}z_{2,L}(t) + B_{1,L}u(t)$$

$$\frac{dz_{2,L}}{dt} = A_{21,L}z_{1,L}(t) + A_{22,L}z_{2,L}(t) + B_{2,L}u(t) + \cdots$$

$$D_{2,L}\Psi(x,u,t) \quad (20)$$

$$y(t) = C_{2,L}z_{2,L}(t) = z_{2,L}(t)\ ,$$

and so we can write also the following equivalent equation:

$$\frac{dy(t)}{dt} = A_{21,L}z_{1,L}(t) + A_{22,L}y(t) + B_{2,L}u(t) + \cdots$$

$$D_{2,L}\Psi(x,u,t) \quad (21)$$

The corresponding observer is described by the following equations:

$$\frac{d\hat{z}_{1,L}}{dt} = A_{11,L}\hat{z}_{1,L}(t) + A_{12,L}\hat{y}(t) + B_{1,L}u(t) - A_{12,L}e_y(t)$$

$$\frac{d\hat{y}(t)}{dt} = A_{21,L}z_{1,L}(t) + A_{22,L}\hat{y}(t) + B_{2,L}u(t) - \cdots$$

$$\left(A_{22,L} - A_{22,L}^s\right)e_y(t) + \vartheta \quad (22)$$

$$e_{2,L}(t) = \hat{z}_{2,L}(t) - z_{2,L}(t) = \hat{y}\,(t) - y(t) = e_y(t)$$

where $A_{22,L}^s$ is a stable design matrix, let us to take it $A_{22,L}^s = -2$. Let us to consider also a symmetric positive definite matrix for $A_{22,L}^s$, $P_2 \in R^{p\times p}$, that is a unique solution of the Lyapunov equation:

$$(A_{22,L}^s)^T P_2 + P_2(A_{22,L}^s) = -Q_2 \quad (23)$$

with $Q_2 \in R^{p\times p}$ a symmetric positive definite design matrix. For a particular selection of matrix $Q_2 = 4$ we get:

$$-4P_2 = -4 \to P_2 = 1 \quad (24)$$

Now a robust observer design is well defined and can be described by the following equations:

$$\frac{d\hat{x}}{dt} = A_{L_{n\times n}}\hat{x} + B_{L_{n\times m}}u - G_{L\_L,n\times p}C_{L_{p\times n}}e(t) + G_{N\_L,n\times p}\vartheta$$

$$\hat{y}(t) = C_{L_{p\times n}}\hat{x}(t) \quad (26)$$

$$e(t) = \hat{x}(t) - x(t)$$

$$e_y(t) = \hat{y}(t) - y(t)$$

where the gain matrices have the particular form [1], [2],[4], [5]:

$$G_{L\_L,n\times p} = T_c^{-1}\begin{bmatrix} A_{12,L} \\ A_{22,L} - A_{22,L}^{s} \end{bmatrix} = \begin{bmatrix} -8 \\ -0.10348 \end{bmatrix}$$

$$G_{N\_L,n\times p} = ||D_2||\, T_c^{-1}\begin{bmatrix} 0 \\ I_p \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \end{bmatrix} \quad (27)$$

Corresponding to a particular selection of canonical coordinates transform, $T_c = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$.

Also, the discontinuous switching function ϑ about the sliding hyperplane S_w (15) is given by:

$$\vartheta = \begin{Bmatrix} -\rho(t,y,u)||D_{2,L}|| \dfrac{P_2 e_y(t)}{||P_2 e_y(t)||} \Big| e_y(t) \neq 0 \\ 0 \Big| e_y(t) = 0 \end{Bmatrix} \quad (28)$$

Remark: A big advantage of this development in this formulation of the sliding mode observer (SMO) design framework is that there is no requirement for (A, C) to be observable [2].

On the state components the developed robust observer given in (26) can be written in the following form:

$$\frac{d\hat{x}_1}{dt} = -2\hat{x}_1(t) - 0.1034\hat{y}(t) + 2u(t) + 8e_y(t) - \cdots$$
$$\rho(t,y,u)sign(e_y(t)) \quad (29)$$
$$\frac{d\hat{y}(t)}{dt} = 51.70\hat{x}_1(t) - 10\hat{y}(t) + 0.1034e_y(t)$$

with the dynamical errors described by following equations:

$$\frac{de_1(t)}{dt} = A_{11,L}e_1(t) = -2e_1(t)$$
$$\frac{de_y(t)}{dt} = A_{21,L}e_1(t) + A_{22,L}^{s}e_y(t) + \vartheta - D_{2,L}\Psi(x,u,t)$$
$$= 51.70e_1(t) - 2e_y(t) + \vartheta - \Psi(x,u,t)$$
$$e_1(t) = \hat{x}_1(t) - \hat{x}_1(t) \quad (30)$$
$$e_y(t) = \hat{y}(t) - y(t)$$

where the uncertainty function $\rho(t,y,u)$ is bounded by:

$$\rho(t,y,u) \geq r||u(t)|| + \alpha(y,t) + \delta \geq 12r + 10sin(t) + \delta$$

For a particular selection according to [Sarah]:

$$r = 0.7 > 0, \delta = 1.6 > 0, \alpha(y,t) = -10\sin(t), \quad (31)$$

the equations become:

$$\frac{d\hat{x}_1}{dt} = -2\hat{x}_1(t) - 0.1034\hat{x}_2(t) + 2u(t) + 8e_y(t) -$$
$$\ldots - 20sign(e_y(t)) \quad (32)$$
$$\frac{d\hat{y}(t)}{dt} = 51.70\hat{x}_1(t) - 10\hat{y}(t) + 0.1034e_y(t)$$

where the scalar function $\rho(t,y,u)$ is bounded by:

$$\rho(t,y,u) \geq 20 \quad (33)$$

5.1 SIMULATION RESULTS

The dynamics errors of the Sliding mode Observer model (30) attached to the dc Servomotor actuator with disturbance uncertainty (the load torque, $T_{Load} = 10sint(t)$) are modeled in SIMULINK and shown in figure 13. Their dynamic evolution, i.e. armature current residual (e_1) and angular speed residual(e_y), is shown in figures 14 and 15.

The SMO control switching function around sliding line ϑ is calculated according to (28) and (31) and is shown in figure 16. The state-space representation of the robust Sliding Mode Observer model (26) in canonical form is represented also in SIMULINK, and the evolution of the both model and estimated states, namely the angular output speed $(y(t), \hat{y}(t))$ and the armature current $(x_1(t), \hat{x}_1(t))$ are shown in figures 17 and 18, for open-loop system for the same setting $u(t) = 12\,[V]$. From the last two figures we observe that after approximately 2 seconds, visually perfect replication of the true and estimated states is taking place. To demonstrate the robustness of the nonlinear observer tracking the output from the dc Servomotor when the initial conditions of the true states and observer states are deliberately set to different values. If the nonlinear component is removed by setting $\rho(t,y,u)$ to zero, the resulting Luenberger Observer [2] behaves as simple observer without sliding motion.

VI. SLIDING MODE OBSERVER REAL-TIME IMPLEMENTATION

In control systems literature rarely we find details about the real-time software and hardware implementation aspects, and no sufficient attention is given about the algorithms and the sampling time selection. Usually the implementation aspect and real-time control systems design are connected together but in the most cases this connection is always ignored. Furthermore the real-time control systems design is treated from control perspective ignoring the implementation aspects of the control algorithms. Fortunately, recently the real-time implementation and design aspects get a considerable attention from part of control engineering community due to the introduction of new software tools like MATLAB/SIMULINK with its RTW (Real-Time Workshop) and the RTWT (Real-Time Windows Target) Toolboxes. The real-time platform used to perform these real-time simulations is a MATLAB R2013a with SIMULINK running on two processors WINDOWS OS machine. Certainly these new real-time platforms do the implementation of real-time experiments easier and save much time but on the other hand they have some drawbacks regarding a good perception of the real-life problems that could appear during the real-time implementation of the control systems.

VII. CONCLUSIONS

In this paper, we have studied the possibility of using a Sliding Mode Observer strategy design to a dc Servomotor actuator with disturbance uncertainty that is integrated in the same control system structure. The implementation in real time of SMO proposed control strategy will be very useful for our future developments in fault detection and isolation (FDI) control applications based on the equivalent signal injection principle [1]-[4]. This new FDI control strategy will be design in the future work based on the injection signal principle [1]-[2], [4]-[5]. The main contributions in our research are summarized briefly as follows:

(a) Comparison of performance capabilities and advantages of real-time implementation of a Sliding Mode Observer (SMO) versus Sliding Mode Control (SMC),
(b) Implementation in real time a Sliding Mode Observer of a linear dc Servomotor actuator without uncertainty,
(c) Implementation in real time a Sliding Mode Observer for a linear dc Servomotor actuator with bounded disturbance uncertainty.

***Abstract*—Multimedia devices are widely used in professional applications as well as personal purposes. The use of computer vision systems enables detection and extraction of important features exposed in images. However constantly increasing demand for this type of video with high quality requires simple however reliable methods. The objective of presented research is to investigate applicability of heuristic method for real-time video frames capturing and correction.**

***Index Terms*—Video Stream Correction, Real-time Processing, Heuristic Method.**

I. Introduction

MULTIMEDIA devices are widely used in professional applications as well as personal purposes. We can find cameras applied in security systems present in CCTV (Closed Circuit TeleVision) applications where several cameras are detecting motion to supervise it against criminal actions and unlawful activities. Various types of these are used in financial institutions like banks, airports and any other railway/bus stations, sport stadiums and culture institutions like cinemas, theaters and concert places. Similarly to these, video recording is very useful for houses and car-parks where we use vision systems to prevent robbery. Recent years have also shown that modern video technologies with their various multimedia applications are also supported by international and national organizations and authorities which are exploring possibilities of implementations of computer aided analysis in order to assist i.e. law officers on duty. For these reasons it is paramount to develop automated systems that can actively improve precision of capturing in real time in various conditions, lightening and other factors that can actively influence CCTV.

Therefore in this article we want to discuss a new tracking model for image capturing, where dedicated version of heuristic attempt is applied to assist in detecting proper camera orientation in real time. Research presented in this work tend to move toward development of such a model.

A. Related Works

Image capturing and feature extraction efficiency in multimedia applications have been investigated in various research projects. Pope and Lowe proposed probabilistic approach to the problem of various 3-D object recognition [1], while Grycuk et al. proposed approach to use SURF for video key features detection for following frames [2]. With development in technology it became possible to evaluate more features with higher precision. Drozda et al. presented proposition of different orderings for visual sequences alignment implemented as algorithms for image classification [3]. Knop et al. discussed improvements in application of neural methods into video compression based on dedicated scene change detection algorithm [4], while Capizzi et al. proposed novel attempt to process images of oranges to be classified by proposed neural network architecture [5], Stateczny et al. discussed application of intelligent methods for image processing in batymetric systems [6]. Intelligent methods are also widely adapted into detection processes: Starzyk developed visual saccades for object recognition [7], Pabiasz et al. proposed three–dimensional facial landmarks recognition [8] and novel approach to 3D face images processing [9]. Similarly heuristic methods, as newly developed algorithms inspired by nature, gave new possibilities to multimedia streaming aspects. Panda et al. developed edge magnitude solution, where classic heuristic approach based on Cuckoo Search Algorithm was implemented to search over multilevel thresholding [10]. Mishra et al. proposed heuristic attempt to watermarking on gray-scale images by application of Firefly Algorithm [11]. Heuristic methods are extensively examined in recent years, and various new or hybrid methods are developed for multimedia applications in detection and image capturing systems. Woźniak and Połap presented extensive comparison of efficiency in key-points extraction between developed Cuckoo Search Algorithm and classic methods like SIFT and SURF [2], [12]. Similarly Firefly Algorithm application was proposed by Woźniak and Marszałek [13]. Walendzik et al. reported development in gaming technologies for automatically generated evaluation [14] and Swiechowski et al. discussed self adapting strategies to gaming reality [15]. Decision making systems widely use adaptive strategies to simulate intelligent data streaming processing as reported by Rutkowski et al. [16].

Multimedia processing by possible applications of various methods of Computational Intelligence started important trend in nowadays technology. Multimedia storing systems are applied to manage visual information [17]. Korytkowski et al.

proposed boosted fuzzy classifiers for captured images [18].

In this article we propose novel approach to implement heuristic method to work as real-time detector for cameras and vision systems.

II. Proposed Frame Processing Technique

Computational Intelligence (CI) methods widely use various soft computing techniques for detection and extraction of features. One of these processes is frame capturing. It is non-trivial to preform this operation in real-time along with correction of quality. Proposed in this article technique is based on application of CI method, in particular dedicated versions of bio-inspired heuristic approach, as a dedicated solution to improve vision tracking in CCTV systems or any image recognition systems that use this or similar type of vision capturing.

In this type of bio-inspired simulation approach we can adapt birds, fish or any other species which together as a cluster behave in a very specific way. The population adapts to given initial conditions of the environment following to the destination. This type type of behavior is very useful in various applications, i.e. where we want to search object space for specific features.

A. Ad-hoc Filtering Method

Before application of heuristic detection we need to extract features from video frames. These features will serve as objects, which will be traced along rotation of the camera. To extract features we have applied simplified filtering method, which is run ad-hoc to filter video frames and extract objects to be forwarded to heuristic tracking method. In proposed filtering we introduce evaluation of the luminosity to extract edges of the traced objects. Extraction leaves pixels of high luminosity which extract shapes as bright pixels over dark background. We simply approximate both dimensions of the luminance gradient along exes of the video frame.

1) Applied Operator: Extraction of objects is based on idea to use directional differential operator $\vec{\nabla}$ on brightness ϕ as:

$$\vec{\nabla}\phi \cdot d\mathbf{x_i} = [\partial_1\phi, \partial_2\phi] \cdot [dx_{i,1}, dx_{i,2}]\,, \tag{1}$$

where partial derivatives $\partial_1\phi$ and $\partial_2\phi$ are computed for video frame points $\mathbf{x_i}$ according to each coordinate.

Proposed ad-hoc frame filtering is using luminance intensity matrix L to compute function

$$\begin{cases} \tilde{\phi}(\mathbf{x_i}) = \sqrt{\sum_{k=1}^{2} \phi_k^2(\mathbf{x_i})} \\ \phi_k(\mathbf{x_i}) = \sum_{m,n=1}^{3} \max_{k=1,2}(M_{mn}^k \cdot L(x_{i,1}+m-2, x_{i,2}+n-2)) \end{cases} \tag{2}$$

as convolution of matrices

$$\begin{cases} M^1 = \begin{pmatrix} -1 & -2 & -1 \\ 0 & 0 & 0 \\ 1 & 2 & 1 \end{pmatrix} \\ M^2 = \begin{pmatrix} -1 & 0 & -1 \\ -2 & 0 & 2 \\ -1 & 0 & 1 \end{pmatrix} \end{cases}. \tag{3}$$

Matrix M^1 is applied for vertical extraction and matrix M^2 is applied for horizontal extraction, however application of $\max_{k=1,2}(\cdot)$ returns only highest convolution value to the output bit of video frame points $\mathbf{x_i}$ to enable faster shape features extraction. Composed in this way filtered frame is forwarded to applied heuristic method for tacking.

B. Proposed Bio-Inspired Heuristic Approach

The main idea of bio-inspired heuristic approach is to simulate entire population of mapped organisms into implemented algorithm. During iterations we assume that individuals can exchange information to find destination. This make the implemented population act similarly to swarms of fish, birds or other species. This assumptions are composed into mathematical model, where destination of the swarm in each iteration is the object traced by the CCTV camera. The algorithm is implemented to search the following video frames for destination objects by matching trajectories of individuals (particles) and therefore trace the object in real-time. Each of individuals is a vector of coordinates that move along the rotation of the camera tracing the object.

Movement of tracing individuals is based on stochastic and deterministic approach, where we combine random walk toward optimum with deterministic distance between particles. The knowledge about traced object is updated in each iteration according to positions of particles that correctly detected traced object. This information serves as a staring location for further iteration, where particles compare new situation to previous frame and follow the best situated individual to the destination.

1) Applied Model: To keep the randomness of movements along with so called "communications between particles" we introduce deterministic and random factors along with the following assumptions:

- Tracing points are moving along the captured video frames in search of the object,
- Each individual is referring to it previous position while tracing the object,
- At the end of each iteration, all the individuals exchange information,
- Number of tracing individuals is constant.

Each tracing individual position is denoted as $\mathbf{x}_i^t$ whose i components correspond to dimensions of the video frame and t is iteration in the algorithm. Move is denoted as $\mathbf{m}_i^t$ with appropriate symbols for each iteration t according to the formula:

$$\mathbf{m}_i^{t+1} = \mathbf{m}_i^t + \alpha \cdot \epsilon_1 \cdot [g_*^{t-1} - f(\mathbf{x}_i^t)] + \beta \cdot \epsilon_2 \cdot [\mathbf{x}_*^t - \mathbf{x}_i^t], \tag{4}$$

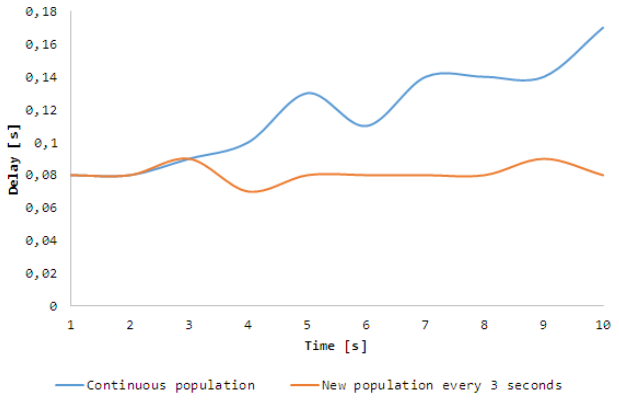

Fig. 1. Image capturing process in real-time improvements in two examined solutions: blue line for continuous usage of the same population of $tracing\_individuals$, orange line for new population of $tracing\_individuals$ introduce in each 3 sec.

where the symbols are: $\mathbf{m}_i^t$ – tracing move of i individual in t iteration, α – optimum value memory factor, β – optimum individual position memory factor, $\epsilon_1, \epsilon_2 \in [0, 1]$ – random values, g_*^t – previous position of the tracing individual at the frame in $t-1$ iteration, $f(\mathbf{x}_i^t)$ – present position of the tracing individual at the frame in t iteration, $\mathbf{x}_*^t$ – position of best situated individual in t iteration, $\mathbf{x}_i^t$ – position of tracing individual i in t iteration.

For that modeled trace move we perform movements of all tracing individuals using formula:

$$\mathbf{x}_i^{t+1} = \mathbf{x}_i^t + (-1)^K \cdot \mathbf{m}_i^t, \tag{5}$$

where the symbols are: $\mathbf{x}_i^t$ – position of tracing individual i in t iteration, $\mathbf{m}_i^t$ – trace move i particle in t iteration according to (4), K–random factor applied to randomize direction of movements.

Equations (4) and (5) allow trafing of objects in real-time using implementation of the proposed Algorithm 1. To start tracing we place initial population of individuals at random over first video frame. While camera is rotating along the axis implemented However, to improve tracing abilities we can also apply some boundary criteria to enable additional movements control.

III. Experimental Results

In the experimental tests we have applied two sample video streams. First was captured at one of polish parks. Second was captured in egyptian pyramid. The task for proposed system was to follow rotation of the camera to trace the object in real-time and therefore improve quality of video recording. Based on tests, the maximum displacement of particles between two frames has been appointed as 5 pixels. With this value, the amount of calculations in the proposed algorithm is significantly minimized - in the last stages of the algorithm only circles of radius equal to 5 are analyzed. Results of proposed real-time heuristic tracking are presented in Fig. 2. Chart of the delay for both solutions is presented in Fig. 1.

Algorithm 1 Heuristic Approach to Video Frames Processing in Real-Time

Define coefficients: α – memory factor, β – position memory factor, $generation$ – number of iterations, $tracing\_individuals$ – number of individuals in swarm,
while video frames are captured from rotating CCTV camera **do**
  Capture 2 following video frames with a delay of 1 sec,
  Perform Ad-hoc Filtering Algorithm on each of them,
  Start tracing using first video frame,
  Create at random initial population,
  t:=0,
  while $t \leq generations$ **do**
    Move $tracing\_individuals$ according to (5) and (4),
    Sort $tracing\_individuals$ according to brightness,
    Evaluate $tracing\_individuals$ and take $best\_ratio$ of them to next $generation$,
    Rest of $tracing\_individuals$ take at random,
    Next $generation$: $t++$,
  end while
  Place $tracing\_individuals$ from last $generation$ over second filtered video frame,
  Divide this frame into 4 parts,
  Take this part where we have highest concentration of $tracing\_individuals$,
  for $-5 \leq \alpha \leq 5$ **do**
    for $-5 \leq \beta \leq 5$ **do**
      Move $tracing\_individuals$ using correction (α, β),
      Calculate percentage of all points whose adaptation is the same as for the first frame,
      Save point for which the percentage is highest,
      $\beta++$,
    end for
    $\alpha++$,
  end for
  Determine the direction on the basis of selected point.
end while

A. Conclusions

In the experimental tests we have compared two attempts for proposed solution: to continue heuristic processing using only one population of $tracing\_individuals$ and to change population in each 3 seconds. Comparing results of benchmark tests we can see that introduction of new population in regular intervals can increase efficiency of the real-time processing. Chart presented in Fig. 1 show relation of delay between two compared solutions. With increasing time of video processing newly introduced population tends to reduce delay what influence efficiency of tracking, therefore proposed processing becomes faster and even more adapted for CCTV real-time video systems.

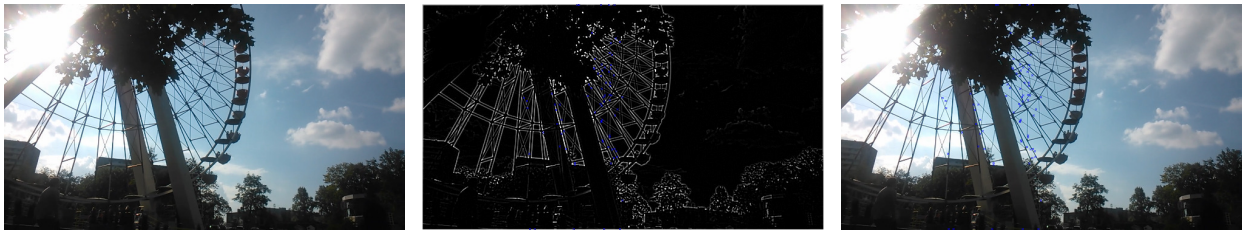

Fig. 2. Image capturing process of wheel in in real-time improvements. From left to right: original frame, filtered with heuristic points, original with heuristic points.

IV. Final Remarks

Proposed solution enabled us to obtain the direction of camera movement at the time of recording. The proposed method uses heuristic processing and ad-hoc filtering. Due to simple implementation and low number of operations it is possible to perform it all in real-time during video recording, when CCTV system is already loaded. The results, i.e. the average delay is constant over time, allow for practical use in various applications such as sport equipment or systems of the virtual view. Moreover, such a solution in conjunction with the navigation system GPS can create real guidance system.

In future work, it is planned to reduce the calculations and the inclusion of additional factors such as navigation system in order to create an easy-to-use solutions for a variety of purposes.

8th Workshop on Scalable Computing

THE Workshop on Scale Computing (WSC) is a result of evolution in the world of computing. It originated (as Workshop on Large Scale Computing in Grids; LaSCoG) in 2005. Next, cloud computing became popular and, in response to this new trend, Workshop on Scalable Computing in Distributed Systems (SCoDiS) emerged. The two workshops (under a joint name LaSCoG-SCoDiS) have been organized till 2014 (information about past events can be found here). However, the world of large-scale computing continuously evolves. In particular, data-intensive computations (known as “Big Data") brough a completely new set of issues that have to be solved (in addition to those that exist since late 1990th and that still deserve our attention). Therefore we have decided to refresh the name of the event (to better represent the scope of interest). This is how the Workshop on Scalable Computing (WSC) came to being.

TOPICS

- General issues in scalable computing
  - Algorithms and programming models for large-scale applications, simulations and systems
  - Large-scale symbolic, numeric, data-intensive, graph, distributed computations
  - Architectures for large-scale computations (GPUs, accelerators, quantum systems, federated systems, etc.)
  - Data models for large-scale applications, simulations and systems
  - Large-scale distributed databases
  - Security issues for large-scale applications and systems
  - Load-balancing / intelligent resource management in large-scale applications, simulations and systems
  - Performance analysis, evaluation and prediction
  - Portals, workflows, services and collaborative research
  - Data visualization
  - On-demand computing
  - Virtualization supporting computations
  - Self-adaptive computational / storage systems
  - Volunteer computing
  - Scaling applications from small-scale to exa-scale (and back)
  - Computing for Big Data
  - Business applications
- Grid / Cloud computing
  - Cloud / Grid computing architectures, models, algorithms and applications
  - Cloud / Grid security, privacy, confidentiality and compliance
  - Mobile Cloud computing
  - High performance Cloud computing
  - Green Cloud computing
  - Performance, capacity management and monitoring of Cloud / Grid configuration
  - Cloud / Grid interoperability and portability
  - Cloud / Grid application scalability and availability
  - Economic, business and ROI models for Cloud / Grid computing
  - Big Data cloud services

***Abstract*—The paper presents modeling and simulation of energy consumption of two types of parallel applications: geometric Single Program Multiple Data (SPMD) and divide-and-conquer (DAC). Simulation is performed in a new MERPSYS (Modeling Efficiency, Reliability and Power consumption of multilevel parallel HPC SYStems using CPUs and GPUs) environment. Model of an application uses the Java language with extensions representing message exchange between processes working in parallel. Simulation is performed by running threads representing distinct process codes of an application, with consideration of process counts. Instead of running time consuming calculations, their times are simulated using functions representing computational time dependent on input data sizes. The simulator considers performance and power consumption values for compute devices stored in its database. We performed verification of running the two applications on up to 512 and 1024 processes respectively on a large cluster from Academic Computer Center in Gdansk demonstrating a high degree of accuracy between simulated and measured results.**

I. Introduction

IN TODAY'S High Performance Computing (HPC) landscape performance and power consumption are key factors, both of which are of key concerns in design of future systems. As of today, Tianhe-2 is the most powerful computing cluster on the TOP500 list with performance of over 33 PFlop/s at 17.8 MWs of power consumption. Tianhe-2 uses the hybrid architecture that couples multicore CPUs and accelerators within a single node. Examples of accelerators used today are GPUs or coprocessors such as Intel Xeon Phi. These are used in the top high performance clusters listed on the TOP500 list. The recently announced Tesla P100 offers 5.3 TFlop/s double-precision performance with Thermal Design Power (TDP) 300 Watts[1]. Intel® Xeon Phi™ Coprocessor 7120P offers 1.2 TFlop/s theoretical peak double-precision performance[2] with TDP 300 Watts[3].

As computational power of HPC systems comes from engaging more and more processing cores and consequently increasing the sizes of compute devices and the number of compute devices within a system, there is often a need for assessment of not only performance but also power consumption of such systems. A typical use case is when the user or system owner already know several applications that are run in their contexts or environments and need to assess performance and power consumption of an HPC system after an upgrade or after a new HPC system is to be purchased.

This paper focuses on a model and methodology for assessment of power and energy consumption of parallel applications adopted in the MERPSYS simulation environment[4]. This work follows modeling execution time of parallel applications in MERPSYS that is presented in [1].

II. Related Work

In terms of applications, energy consumption and its reduction is very important. Proper techniques involving load shifting and machine management may result in energy bill savings [2]. Paper [3] analyzes optimization of energy consumption for large virtualized service centers.

In work [4], authors present a workflow that allows prediction of energy and power consumption of HPC applications using available data for a given application regarding power and energy consumption for specific values of nodes used. Then, based on a predictor, that uses the available data and proper interpolation, predicted values can be found. The paper shows a high degree of accuracy of the predictor for Hydro (computational fluid dynamics) and EPOCH (plasma physics simulation) benchmarks executed on the SuperMUC (near Munich, hence MUC) HPC platform.

In paper [5], experiments with Co-Design Molecular Dynamics (CoMD) and Livermore Unstructured Lagrangian Explicit Shock Hydrodynamics (LULESH) codes were performed on a system with host Xeon E5 CPUs and Xeon Phi 5110P coprocessors with measurements of energy and power for the whole system, CPUs and Xeon Phis. Results were used to obtain parameters of theoretical model coefficients with high confidence (R^2 coefficient). Results were presented for host frequency scaling as well as problem size scaling.

In paper [6] authors used neural networks to train models that predicted power and energy consumption when running high performance computing codes. It has been shown that

[1]http://wccftech.com/nvidia-pascal-gpu-gtc-2016/

[2]http://www.intel.com/content/www/us/en/benchmarks/server/xeon-phi/xeon-phi-theoretical-maximums.html

[3]http://ark.intel.com/products/75799/Intel-Xeon-Phi-Coprocessor-7120P-16GB-1_238-GHz-61-core

[4]http://merpsys.eti.pg.gda.pl/

after training, using various versions of codes, it is possible to predict power consumption and energy usage of CPUs and DIMMs with less that 5.5% error for LU factorization, Jacobi and matrix multiplication.

In work [7] authors have presented a detailed energy usage model for parallel master-slave applications, including modeling energy consumption of communication operations, based on execution times. Furthermore, the model was verified in a real environment with a master and 4 or 6 slaves for single or dual core configurations with error rate lower than 4% across the tested configurations.

In paper [8] authors investigated execution times and energy used when running MPI-only and hybrid MPI with OpenMP codes such as Parallel Multiblock Lattice Boltzmann or Gyrokinetic Toroidal Code. In particular, on the largest configurations tested with 8 nodes and a total of 32 cores, hybrid versions showed better execution times and energy consumption than MPI-only codes. Energy used was broken into CPU, memory, disk and motherboard energy.

In paper [9] authors, following analysis performed for Amdahl's law, present a general energy speed-up model in a parallel environment, for multicore systems. Furthermore, authors present specific results for three various power consumption models for a multicore CPU, based on the number of cores used: in the first one all cores are always on, the second with consideration of active cores only and the third with base power, active and idle core power values.

Modeling power consumption of cluster nodes depending on the number of threads active with verification against real measurements were presented in [10]. This showed an idle system power consumption and a non-linear increase until a saturation point. Such a model has been incorporated into the MERPSYS simulator. In work [1], modeling and verification of performance of parallel applications in MERPSYS was presented for computation of vector similarities along with verification in a real parallel environment.

For some types of applications, such as embarrassingly parallel ones, volunteer computing may be an alternative to clusters. Clusters and volunteer systems are different in terms of locality (centralized vs distributed), payer of infrastructure and electrical bill cost, involvement (or lack thereof) of society, security. Comparison of performance and power consumption as well as computational efficiency of cluster based systems and volunteer based systems which use distributed volunteers' computers is presented in [11]. For the latter, sets of volunteer hardware configurations were taken from BOINC projects and `http://cpubenchmark.net/` benchmarks for relevant CPUs and TDPs were used. On average performance/power consumption ratio for modern CPU based clusters turned out to be 2-3 times better than for machines in volunteer based systems.

In [12] authors statistically analyze average CPU utilization and draw a conclusion that in the typical operating region of between 10 and 50% of utilization, energy efficiency is low and aim at designing energy proportional machines that would consume energy proportional to the executed work.

Modelling energy consumption of distributed systems can be useful for exploring the time-energy trade-off, defined in [13]. The authors consider the relationships between execution time, energy consumption and power draw for a set of chosen applications, both on shared memory devices such as Intel Xeon Phi coprocessor and Intel Xeon processor, as well as the Vesta IBM Blue Gene/Q cluster. Formal formulation of the multi-objective code optimization problem is presented, as well as evidence that the energy-performance trade-offs exist in practice.

Paper [14] analyzes energy and makespan trade-offs as a Pareto front in heterogeneous computing systems. Pareto fronts for the multi-objective optimization problem can be determined using mathematical modeling and linear programming [15]. However, such model has to closely match the characteristics of the real executions, which can significantly vary depending on the application model (i.e. synchronization scheme, communication overlapping). Additionally, the model may require defining the execution times of each type of task on each type of hardware beforehand. Thus, for more accurate modeling of various application executions on various hardware, it is important to develop a more flexible method which can give an approximate result with a possibility to quickly modify the application and hardware models.

Paper [16] considers tuning of application execution by proper tiling in the code (cache usage) and CPU frequency. It considers impact on the execution time and energy usage using an example of Poisson's equation with stencil computations.

In work [17] a methodology and experiments were presented for a distributed KernelHive [18] system that is aimed at parallelization of computations in a heterogeneous environment that consists of potentially several clusters each with multicore CPUs and accelerators such as GPUs. Based on an imposed power consumption limit, an optimizer is able to select compute devices such that the total power consumption does not exceed the threshold and execution time is minimized taking into consideration application configuration (including OpenCL's kernel NDRange configurations for GPUs and CPUs), network parameters etc. Dependence of execution times against power consumption limits were shown for a real environment.

As demonstrated in paper [4], a model for prediction of power and energy usage in an HPC system can potentially be very desirable e.g. for budget estimation and prediction of peak requirements in terms of power consumption.

In work [19] authors presented Energy Efficient Task Duplication Schedule (EETDS) algorithm with a grouping and energy efficient group allocation schedule phases of a DAGs (Directed Acyclic Graphs) onto a parallel environment. The algorithm was compared, in terms of energy consumption, to Task Duplication Scheduling algorithm (TDS), Non-Duplication Scheduling algorithm (NDS) and Energy-Efficient Non-Duplication Scheduling (EENDS) strategies for Gaussian Elimination and FFT for various values of communication to computation ratio (CCR) demonstrating benefits of EETDS for larger CCR values.

In paper [20] optimization of hybrid MPI/OpenMP parallel application execution is considered in terms of execution efficiency. Algorithms used consider Dynamic Concurrency Throttling (DCT) and Dynamic Voltage Frequency Scaling (DVFS), also in a combined setting. It is demonstrated that the proposed approach results in savings in energy usage with little loss in performance or even gains.

III. Motivations and Problem Statement

Motivations for simulation of execution of parallel applications on large systems stated for the MERPSYS environment, involving execution time and energy consumption, include:

1) Finding good configurations for running parallel applications i.e. specific compute devices in the available environment, numbers of nodes as well as application parameters such as data packet sizes etc.
2) Testing various potential (e.g. from a database of available components) hardware configurations for running a set of applications. MERPSYS allows instant substitution of one component by another e.g. exchanging a CPU or a GPU for another CPU or GPU model, similarly for interconnects.
3) Simulations of a set of applications in a distributed multi-level system composed of clusters and volunteer based systems in order to find approximately optimal hardware allocation, task mapping and scheduling.

In view of the aforementioned works and challenges, *the goal of this paper is to define and verify a model of energy consumption of a parallel application run on a parallel system that would return acceptably accurate results from fast running simulations of parallel runs*. Specifically, this requires finding the following function

$$\text{energy consumption}(\text{parallel application}, \text{parallel system}, \text{input data})$$

It should be noted that there are two possible ways of how energy consumption is calculated. In one, within the makespan of the application only energy used for duration of computations on particular nodes, only when these are used by the application, is accounted for. In the latter, energy of all nodes is integrated over the makespan irrespective of how many application processes/threads run there, considering idle energy consumption if none processes/threads are active. MERPSYS adopted the second method.

In essence, the function mentioned above can be expressed in terms hardware count, thread count, time of effective application execution (stress time) and time of ineffective processor work (idle time) as follows:

$$\begin{aligned}\text{energy consumption}(\text{parallel application}, \text{parallel system}, \\ \text{input data}) = \\ \sum_{i=1}^{Hardware_{count}} (t_{application} PW[i]_{idle} + \\ \sum_k t_{exec}[i,k](PW[i]_{stress}(threadcount[i,k]) - \\ PW[i]_{idle}))\end{aligned}$$

which considers hardware used and power consumption in idle state multiplied by execution time as well as additional power consumption under stress when running a given number of threads on particular hardware multiplied by activity period.

IV. Modeling Energy Consumption

We modeled energy consumption in a supercomputer Galera Plus located in Academic Computer Centre in Gdansk (CI TASK). This supercomputer consists of 192 computational nodes each containing two Intel Xeon Six-core processors. We used two models of parallel applications: a Single-Program-Multiple-Data application model and a Divide-And-Conquer application model.

Before energy modeling, we modeled the time of a application execution dependency on the number of processors used for calculation. We proved that our timing model is valid using MERPSYS simulation environment (described in the next section). In our simulation, we assumed usage of 1, 8, 27, 64, 125 ... 512 processes for the SPMD application and 1, 2, 4, 8, ... 1024 processes for the DAC application. We achieved results of modeling in a high accordance to the real execution times (see Figure 1) [21].

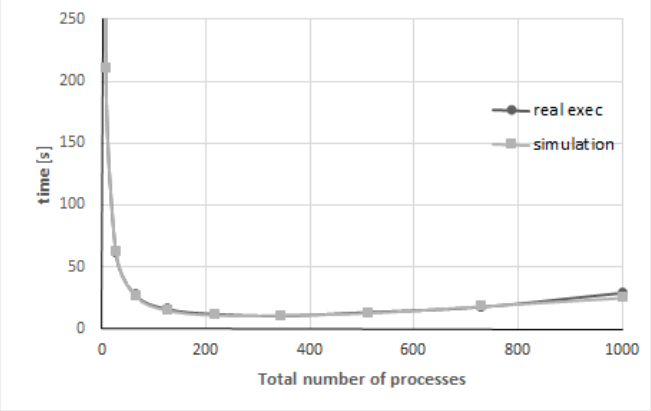
In the first application, all used computational nodes are almost equally loaded during the whole time of application execution. So energy consumption should be a simple multiplication of execution time and the power used by computational nodes involved in calculations. However in our testbed environment only 32 nodes were assigned to experiments. We assumed in our model that when the modeled number of processes was smaller than 32, each process runs on a separate node, and only a part of computational nodes are used. If the modeled number of processes is equal or greater than 32, the processes are distributed among all the available computational nodes, and all the computational nodes are used. So energy consumption in the SPMD application can be expressed as a sum of energy consumed by active nodes (E_{an}) and inactive nodes (E_{in}):

$$E = E_{an} + E_{in}$$

where the energy consumed by active and inactive node are evaluated as:

$$E_{an} = N_{an} \cdot P_{an} \cdot t_{exec}$$
$$E_{in} = N_{in} \cdot P_{in} \cdot t_{exec}$$

(a)



(b)

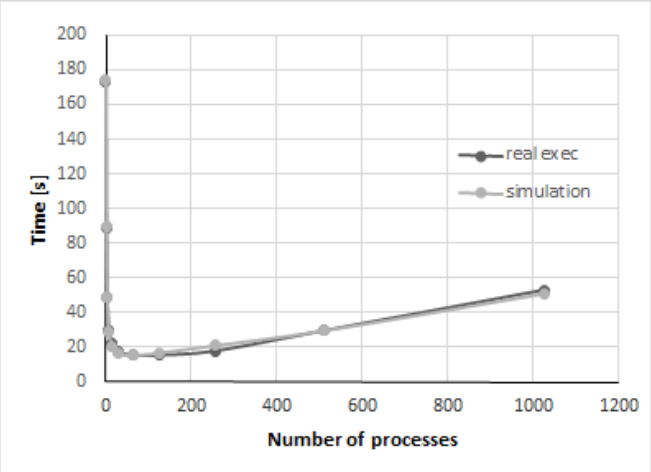


Fig. 1. Execution time modeling of (a) SPMD application and (b) DAC application

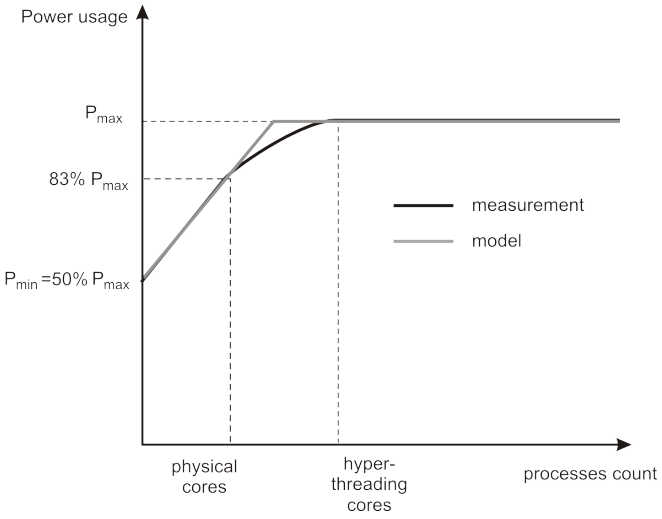

Fig. 2. Power usage on a single node depending on processes count

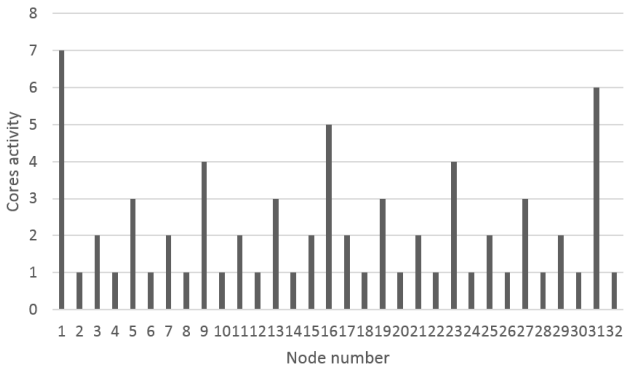

Fig. 3. Model of cores activity in DAC application consecutive steps

The number of active nodes (N_{an}) and the number of inactive nodes (Nin) are simply:

$$N_{an} = min(N_{proc}, N_{total})$$
$$N_{in} = N_{total} - Nan$$

where:

N_{proc} is the number of processes in application,
N_{total} is the total number of computational nodes (here 32),
P_{an} is modeled power usage at one active node,
P_{in} is modeled power usage at inactive node.

We measured that power usage at Intel Xeon processors in inactive node (P_{in}) equals approximately 50% of maximum power usage (P_{max}) which is consumed when all the cores are active [10]. We simplified the function of power usage due to number of active cores as a linear broken function (see Figure 2).

The model of energy consumption in the DAC application is much more complex. Computational nodes are unevenly loaded in consecutive steps of application. At the beginning all needed cores are active. In following steps every second core goes to an idle state (see Figure 3). Thus energy consumption must be evaluated in each step separately. It means that not only the number of active/inactive cores (and active/inactive nodes), but also the time of execution in each application step must be evaluated.

In the DAC application active and inactive energy is expressed by the following formulas:

$$E_{an} = \sum_{k=1..N} E_{an}(k)$$
$$E_{in} = \sum_{k=1..N} E_{in}(k)$$
$$E_{an}(k) = N_{an}(k) \cdot P_{an}(k) \cdot t(k)$$
$$E_{in}(k) = N_{in}(k) \cdot P_{in}(k) \cdot t(k)$$

where:

N is the number of steps in the application process,
k is the index of step,
$t(k)$ is time of execution of the k^{th} step,

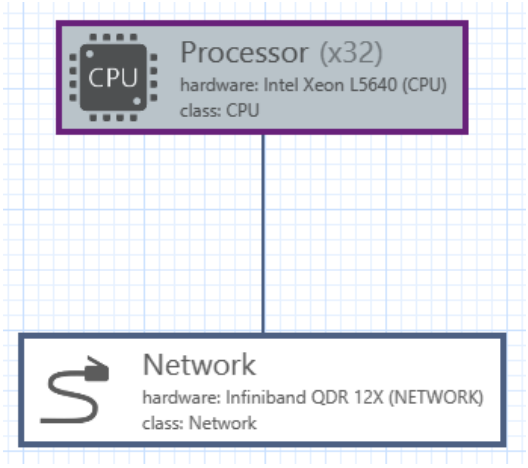

Fig. 4. Sample model of supercomputer architecture in MERPSYS

$P_{an}(k)$ is power used on an active node in the k^{th} step,
$P_{in}(k)$ is power used on an inactive node in the k^{th} step,
$N_{an}(k)$ is number of active nodes in the k^{th} step,
$N_{in}(k)$ is number of inactive nodes in the k^{th} step,
$E_{an}(k)$ is energy used on all active nodes in the k^{th} step,
$E_{in}(k)$ is energy used on all inactive nodes in the k^{th} step,

We are aware that the above model, where the total energy used for computations depends on the number of computational nodes and their usage, ignores the energy used by the whole infrastructure (e.g. cooling system), but this payload was beyond our research at this time.

V. Simulation Environment

We modeled time of execution and energy consumption in the MERPSYS simulation environment. MERPSYS enables modeling of a calculation environment (by drawing an architecture model diagram) and simulation of application execution in this environment (by writing an application model as a simulation program).

The architecture model is a graph diagram in which nodes model key architecture components, and edges model connections between components. As we modeled the Galera Plus supercomputer with homogeneous nodes our diagram consisted of two nodes: one single node modeling all computational components (all processors) and the second node modeling the internal Infiniband network connecting the computational components (see Figure 4). Next we specified component instances count (i.e. the number of computational nodes in the modeled supercomputer). Afterwards MERPSYS looked up to its component database and assigned timing parameters to components.

The application modeling program is written in the Java language, with the use of a special simulator interface, accessible by the `sim` object. We can see a sample fragment of simulation program in Figure 5. The simulation program is not the application itself. To create the simulation program we had to translate the application written in C

```
if (tag.equals("center"))      {

   sim.computation(boundary_cells_size,// computing boundary cells
         ComputationType.CPU,
         SoftwareStack.Undefined,
         1,
         linearComplexity,
         OperationType.Calculations,
         OptimizationType.None);
   sim.p2pCommunicationSend(ysize, "right");
   sim.p2pCommunicationSend(xsize, "bottom");
   sim.p2pCommunicationSend(ysize, "left");
   sim.p2pCommunicationSend(xsize, "top");
```

Fig. 5. Sample fragment of simulation program in MERPSYS

programming language to the simulation Java language. However, the simulation program is much simpler than the corresponding application program. All computational routines are modeled as sim.Computation method invocations. Interprocess communication is modeled as sim.p2pCommunicationSend/sim.p2pCommunicationReceive or one2oneCommunicationSend/one2oneCommunicationReceive invocations. All the researcher has to do is to determine the data count and the computational routines complexity.

VI. Experiments and Results

As we have mentioned above we modeled and simulated time of execution and energy consumption of two parallel applications (SPMD and DAC) in the Galera Plus supercomputer. The applications were written in C using MPI library. We compared the results of simulation with real application execution measured in this supercomputer.

A. Testbed Environment

The testbed consists of a number of identical computation nodes provided by the Academic Computer Center in Gdansk University of Technology in Poland. Each node is based on two Intel(R) Xeon(TM) CPU 2.27GHz processors (EM64T) with 6 physical processing cores with HyperThreading, 12MB cache, running Linux kernel version 2.6.32. Each node has 16 Gigabytes of RAM and they are composed in the cluster architecture, with fast (QDR, 40Gbps) Infiniband interconnection. The power meters of the cluster are served by the specialized, autonomous management subsystems: HP Integrated Lights-Out 3 (iLO 3)[5].

B. Testbed Applications

The first of the tested application is a geometric SPMD application. This kind of application can be used to solve such problems as weather prediction, heat distribution or other physical phenomena. The evaluated 3D geometric space is divided to many cuboidal regions, each region is evaluated by a separate node. The evaluation process is repeated in many iterations, between each iteration the calculation nodes interchanged data corresponding to regions borders. Data is

[5]http://h20565.www2.hpe.com/hpsc/doc/public/display?docId=emr_na-c02714903&lang=en-us&cc=us

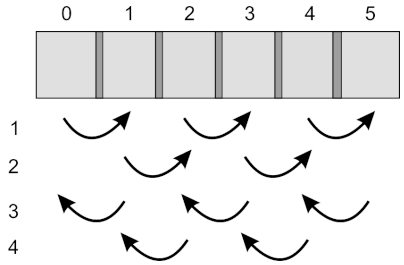

Fig. 6. The schematic inter-process data exchange in the SPMD application

interchanged in 4 steps for each dimension. Considering X dimension in the first step even nodes send data to their right neigbours, next odd nodes send data to their right neighbours, next odd nodes send data to their left neighbours, and at last event neighbours send data to their left neighbours (see Figure 6 for illustration).

Sample fragments of the SPMD application are shown below. In the beginning some common data variables are defined following by four auxiliary routines (getdata, setdata, compute_cell, and cell_to_rank). The main simulation logic is iterated in four nested *for* instructions. The most external loop iterates for an arbitrary number of steps, the internal loops iterate in the three dimensions of the geometric space. After a process has computed an associated cuboidal region in the three dimensions, the process sends data to its neighbors using the scheme shown in Figure 6.

```
double *data;
int X,Y,Z;
int procx,procy,procz;
int proccount;
...
// single data cell get method
double getdata(int x,int y,int z)
{
 return data[...];
}

// single data cell set method
void setdata(int x,int y,int z,double val)
{
 data[...]=val;
}

double compute_cell(int x,int y,int z)
{
 // computes the value of the cell
}

int cell_to_rank(int x,int y,int z)
{
// returns the rank of a process
// that owns cell (x,y,z)
}
```

```
main(int argc,char **argv)
{
 ...
 // the main simulation loop
 for(t=0;t<steps;t++)
 {
  for(i=myminx;i<=mymaxx;i++)
  for(j=myminy;j<=mymaxy;j++)
  for(k=myminz;k<=mymaxz;k++)
  {
   setdata(i,j,k,
           compute_cell(i,j,k));
  }
  // exchange data in X direction
  if (myblockx%2)
  {  // receive from left
    MPI_Recv(..., YZ_wall,
    cell_to_rank(myminx-1,myminy,myminz),
    ...);
  }
  else
  {
   // send to right
   if (myblockx+1<procx)
     MPI_Send(..., YZ_wall,
     cell_to_rank(mymaxx+1,myminy,myminz),
     ...);
  }
  ...
  // do the same for Y direction
  // and Z direction
 }// end of the iteration loop
 MPI_Finalize();
 exit(0);
}
```

The second test application is a Divide-and-Conquer merge-sort algorithm implementation. The first node, which gets the large data set, divides the data into two parts and sends one part to its free neighbor node. This process is repeated in parallel until the size of each partition reaches its limit. Then each node sorts its part of data and "odd" nodes return the sorted fragments to their "parent" nodes. The "parent" nodes merge two sorted data fragments and the process repeats until all data flow to the first node when they are merged to one sorted set (see Figure 7).

The DAC application code is shown below. For simplicity it is assumed that the size of the vector to be sorted is a power of 2. The same applies to the number of processes.

```
...
int *mergelocal(...)
{
// a function for local merging
// (i.e. one process, one thread)
```

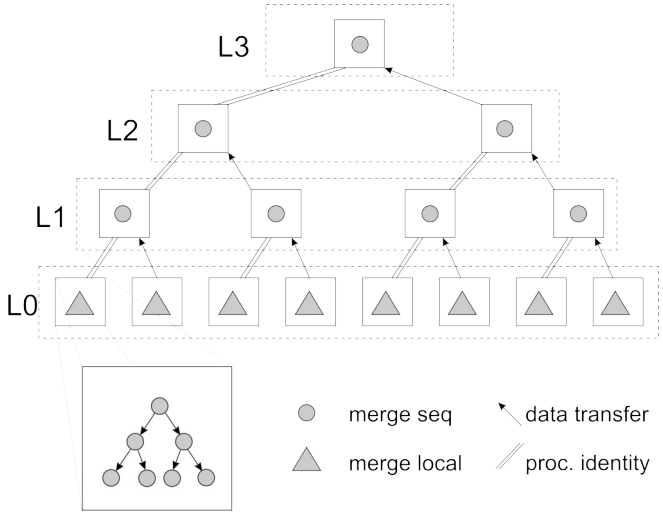

Fig. 7. The schematic algorithm of the SPMD application

```
}

int *mergeseq(int *arrayin,long length)
{
 // the main function for a sequential
 // merge (iterative)
 for(;currentlength*2<=length;
             currentlength*=2)
 {
  for(i=0;i<length;
              i+=2*currentlength)
   mergelocal(...);
   ...
 }
}

int main(int argc,char **argv)
{
 ...
 // in the first step each process needs
 // to sort its part of the array
 arrayout=mergeseq(arrayin, ...);

 // now send the data to an upper process
 if (myrank%2)
 { // then send the data
   // to process with rank myrank-1
   MPI_Send(...);
 }

 // now each process needs to check its
 // role in the divide-and-conquer tree
 // whether it should quit or receive data
 // from another process, merge and send
 // to another process
 int currentskip=2;
 // the current skip between process
 // ranks as in the above scheme
 for(;currentskip<=proccount;
       currentskip*=2)
 {
  if (!(myrank%currentskip))
  {
   // then I am involved in the given step
   // this means that I need
   // to receive the data
    MPI_Recv(...);

   // now merge data
    mergelocal(...);
    ...
   // and send to an upper process
   // if it is not the last iteration
    if (currentskip*2<=proccount)
    { // if not the last iteration
      // now check if I should
      // send the data or not
      if (myrank%(currentskip*2))
      { // then I should send the data
        // to process with rank
        // myrank-currentskip
        MPI_Send(...);
     ...
     break;
    }
   }
  }
 }
 MPI_Finalize();
}
```

C. Simulation Programs

Real calculations are not performed in the simulation program. Instead we invoke sim.computation method passing a string that descibes computational complexity. This string is composed in the simulation program as a JavaScript function that returns the number of operations. However we had to calibrate the result to the real application execution time measured in the testbed environment. It is represented by the last factor (60.94) in the computationComplexity function expression.

```
String computationalComplexity="function "
+ ConstVar.complexityFunctionName + "("
+ ConstVar.parameters + "){"
+ "return " + ConstVar.getDataSize
+"*60.94;"
+ "}";

for (t=0; t<steps; t++)
```

```
{
 sim.computation(compDataSize,
  ComputationType.CPU,
  SoftwareStack.Undefined,
  1,
  computationalComplexity,
  OperationType.Calculations,
  OptimizationType.None);
  ...
```

In the real MPI application each process is identified by a "rank" integer number. In the MERPSYS simulator we can not identify a single process. Instead we can identify a "role" of a process (with a "tag" string). So we mapped application process algorithm based on individual process number to simulation program algorithm based on process group role. We defined 7 roles for the SPMD application using relative processes position: "Center", "Left", "Right", "Top", "Bottom", "Front", and "Back". We replaced the four-step inter-process data exchange with send-receive simulation to the neighbor processes groups (see below):

```
// first send data to all neighbors
neighborTag = "center";
if (!tag.equals(neighborTag)
    && centerCount>0)
  sim.p2pCommunicationSend(wallSize,
                    neighborTag);

  ...

// then receive data from all neighbors
neighborTag = "center";
if (!tag.equals(neighborTag)
    && centerCount>0)
  sim.p2pCommunicationReceive
                    (neighborTag);
```

For the second application, we defined program roles as "levels" (from L0 to L10). We also had to define three computational complexity functions: InitComplexity, MergeSeqComplexity, and MergeLocalComplexity. Instead a peer-to-peer communication send function we used one-to-one communication send. In peer to peer communication, it is assumed that *all* pairs of processes communicate. In the DAC application *one* process sends data to *one* other process. At the same time a *half* of all the processes in the lower level send data to their corresponding processes in the upper level, so the time of one pair communication must be multiplied by sendersCount/2.

```
for (level=0;level<levelCount;level++)
{
 thisTag = "L"+Integer.toString(level);
 if (tag.equals(thisTag))
 {
  nextTag = "L"
          +Integer.toString(level+1);
  if (level==0)
  {
   sim.computation(...,
   InitComplexity,...);

   sim.computation(...,
   MergeSeqComplexity,...);
  }
  else
  {
   priorTag="L"
       +Integer.toString(level-1);
   sim.one2oneCommunicationReceive(
   priorTag);
   sim.computation(...,
   MergeLocalComplexity,...);
  }
  if (level<levelCount-1)
  {
    int sendersCount=
      sim.getNumberOfProcessesForTag
        (thisTag);
    dataSize = dataCount*4;
    sim.one2oneCommunicationSend
      (dataSize, nextTag, sendersCount/2);
  }
 }
}
```

D. Power Measurement

We measured power usage at a single node of a real execution cluster. Power usage was measured in Watts every 10 seconds of the application execution. We repeated the execution three times for each assumed processes count and then we averaged the measured values. The results are shown in Table I and Table II.

TABLE I
POWER USAGE ON A ONE NODE DURING SPMD APPLICATION EXECUTION

Processes count	Measured probes	Power usage on one node [W]	Standard deviation
8	17	84	0.68
27	5	84	0.00
64	2	93	1.49
125	1	106	0.00
216	1	126	0.00
343	1	147	4.71
512	1	159	4.71
729	1	48	0.00
1000	2	99	43.14

E. Simulation Results and Comparison

Having accurate time simulaton results (see Figure 1), we could base energy simulation on solid foundations. We evaluated energy consumption in the MERPSYS simulator and compared the results to the measured energy consumption.

TABLE II
POWER USAGE ON ONE NODE DURING DAC APPLICATION EXECUTION

Processes count	Measured probes	Power usage on one node [W]	Standard deviation
1	16	86.7	2.14
2	8	87.0	1.15
4	4	87.0	1.00
8	2	87.3	0.94
16	1	87.3	0.94
32	1	86.7	0.94
64	1	98.0	0.00
128	1	113	1.89
256	1	137	1.89
512	2	123	43.97
1024	4	134	41,20

TABLE III
REAL AND SIMULATED ENERGY CONSUMPTION IN SPMD APPLICATION

Proc. count	Active nodes count	Inact. nodes count	Real energy cons. [Wh]	Simul. energy cons. [Wh]
8	8	24	151.20	152.1
27	27	5	45.67	46.6
64	32	0	22.71	22.7
125	32	0	15.13	15.0
216	32	0	13.46	13.2
343	32	0	13.86	14.2
512	32	0	18.97	19.0

However as we measured energy consumption at a one node only, we had to recalculate the measured results according to the model of application. In the SPMD applications, as all nodes assigned to the application are active all the time, it was easy to calculate the energy consumption in the whole experimental environment. We show the compared results in Table III. However in the DAC application nodes are unevenly active. We applied the model of activity shown in Figure 3 and recalculated active and inactive nodes real energy consumption in all the applications steps separately, and next summarized them. As the results depend not only on the really measured energy consumption but on the model of activity as well, we call the results the "modeled" energy. Comparison between modeled energy consumption and simulated energy consumption is shown in Table IV.

TABLE IV
MODELED AND SIMULATED ENERGY USAGE IN DAC APPLICATION (COMPARISON)

Proc. count	Modeled energy usage at active nodes	Modeled energy usage at inactive nodes	Total modeled energy usage	Sim. energy usage
1	4.15	118.85	123.0	123.2
2	4.26	59.30	63.6	63.6
4	4.54	30.10	34.6	34.7
8	5.17	15.61	20.8	20.8
16	6.52	7.47	14.0	14.4
32	9.54	2.41	12.0	11.9
64	8.83	3.10	11.9	11.7
128	10.27	4.01	14.3	13.4
256	15.42	5.40	20.8	16.9
512	25.95	7.76	33.7	27.2
1024	47.11	12.83	59.9	55.9

VII. CONCLUSIONS AND FUTURE WORK

In the paper we presented a way to model parallel SPMD and divide-and-conquer applications within the MERPSYS environment including application and system models. Next, we presented verification of results obtained from the fast MERPSYS simulator against energy consumption that stemmed from consideration of power usage of real cluster nodes. We performed tests and calculations for up 512 and 1024 processes for SPMD and divide-and-conquer applications respectively reaching a high degree of accuracy. This allows to obtain results for these applications for other configurations such as input data sizes with ease without the need for rerunning the real application and much faster than the latter.

The future works should cover wider variety of the software and hardware systems. Different vendors and configurations should be tested as well as new simulated programs.

***Abstract*—Recent years have seen a growing trend towards the introduction of more advanced manycore processors. On the other hand, there is also a growing popularity for cheap, credit-card-sized, devices offering more and more advanced features and computational power.**

In this paper we evaluate Parallella – a small board with the Epiphany manycore coprocessor consisting of sixteen MIMD cores connected by a mesh network-on-a-chip. Our tests are based on classical genetic algorithms. We discuss some possible optimizations and issues that arise from the architecture of the board. Although we achieve significant speed improvements, there are issues, such us the limited local memory size and slow memory access, that make the implementation of efficient code for Parallella difficult.

I. Introduction

FOLLOWING the Manycore Revolution [1] and the popularity of small integrated, power consumption- and cost-oriented computing boards (for example, Raspberry Pi), it was expected that these two "directions" would merge at some point. One of the results of this "merge" is the Parallella board[1] [2], created by Adapteva. It is a small (credit card-sized) board, comprising of a 16-core Epiphany coprocessor and the main dual-core ARM processor.

Such boards are interesting for researchers due to their costs, simplicity, and the low level requirements for beginning work with them. Parallella has the benefits of being a standalone, plug-and-play coprocessor similarly to Intel Phi [3]. In this case, "standalone" means that it is a completely separate computer unit that can run independently of any other nodes. On the other hand, it is plug-and-play, because it only requires an Ethernet cable to connect to it.

In this paper we want to review the Parallella board as a simple and effective tool for implementing strictly computational systems. We do not expect the platform to provide higher performance than well established manycore architectures like GPGPU. However, it seems that the programming model and achievable efficiency are *good enough* for creating quick, low-cost hardware-accelerated parallel platforms for simulations and computations. We want to show that it is feasible to implement various execution strategies on the platform and demonstrate its possible weaknesses.

The work reported in this paper concentrates on the realization of genetic and evolutionary algorithms on the Parallella board. It is related to and extends our previous publications regarding the implementation of effective tools for running population-based computational intelligence systems [4], especially using the agent paradigm [5], [6] in both parallel and distributed [7], as well as heterogeneous environments [8].

In the following sections, we briefly introduce the Parallella platform and Epiphany manycore (Section II) and its memory and programming models. Then, in Section III, we discuss our benchmarks and introduced optimizations. In Section IV we present the results. Finally, these results are discussed in Section V, alongside introducing the next steps we are taking with Parallella.

II. Parallella

Parallella is a hardware platform built on top of the manycore Epiphany [2] coprocessor, created by Adapteva in 2011. It was funded by a Kickstarter campaign[2] The board was first presented in June 2014.

The Epiphany processor consists of a 2D array of nodes (known as "eNodes") connected by a mesh network-on-a-chip. Each node consists of a single RISC core (called "eCore"), a DMA engine, 32 kB of memory and a network interface. Each core includes a 32-bit floating point RISC CPU, local memory, a DMA engine, an event monitor and a network interface. The mesh connections on a 16-core processor are shown in Figure 1.

Each "eCore" contains a floating-point unit (FPU), an arithmetic logic unit (ALU) and a 64-word register file, as shown in Figure 2.

The address space in Epiphany is flat and consists of 2^{32} bytes. Each node has 32 kB of its own local range of memory aliased in addresses `0x0000–0x7FFF`. However, memory of each node can be accessed by prefixing the address with a globally addressable ID consisting of 6 bits for a row ID and 6 bits for a column ID (counted from 0) – thus giving a theoretical maximum of $64 \times 64 - 1 = 4095$ cores. For example, if a core wanted to access the memory of the core located in the second row and the third column (1,2) it would access addresses `0x04200000–0x04207FFF`.

Some specifics of the Epiphany architecture related to eMesh include:

[1] https://www.parallella.org/

[2] https://www.kickstarter.com/projects/adapteva/parallella-a-supercomputer-for-everyone

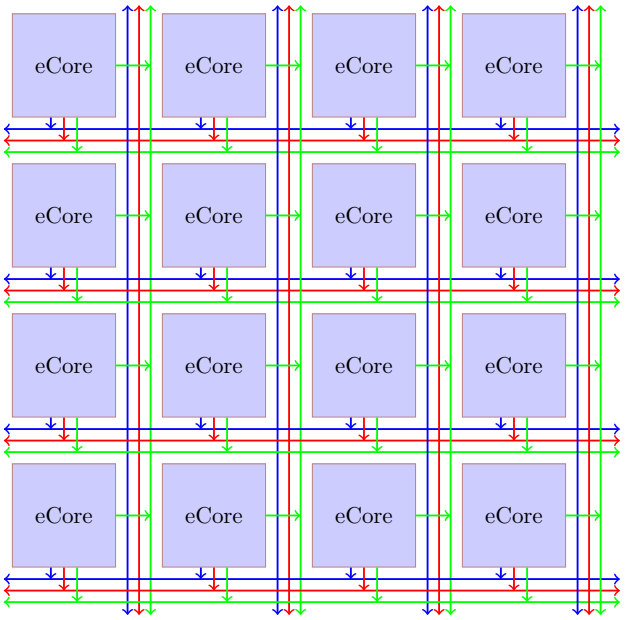

Fig. 1. eMesh Network-on-a-Chip. The blue lines indicate cMesh (used for on-chip writes), green — xMesh (off-chip writes), red — rMesh (read requests).

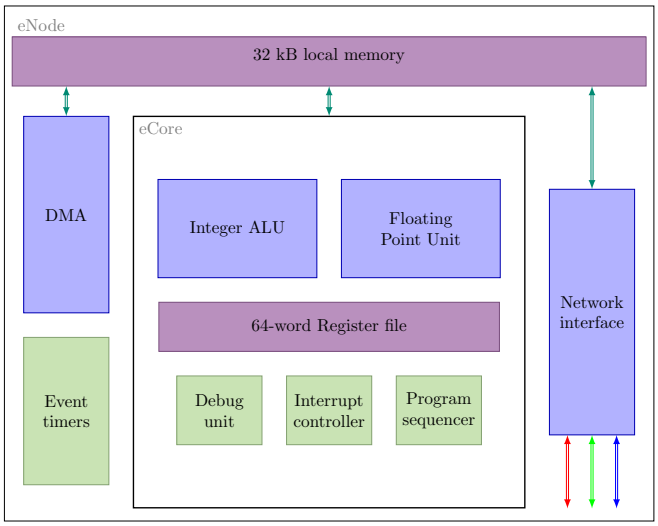

Fig. 2. eNode components. Each eNode has an eCore and 32 kB of local memory, a network router, a DMA engine and two event timers. Each eCore has a 64-word register file, FPU, ALU, interrupt controller, sequencer and debug unit.

- writes are preferred over reads – for a single read there need to be two transactions: one for a read request and one for an answer,
- non-local memory accesses are weakly ordered.

The main goals of the Epiphany architecture are: power efficiency (a single 16-core Epiphany processor consumes a maximum of 2 W, the whole Parallella board requires around 5 W), scalability, an easy programming model, and high performance (2 GFLOPS per single core).

Currently, there are 16- and 64-cores Epiphany processors available. However, 64-core versions have only been produced in limited numbers and are only available directly from Adapteva.

The Parallella board uses a 16-core Epiphany processor (E16G301), a Xillinx Zynq (models 7010 or 7020 with two ARM cores) and 1 GB of RAM. Additional components include: 1 Gbit Ethernet interface, USB and HDMI ports, and a MicroSD slot. The standard operating system (in this case – Linux) boots from the MicroSD card onto an ARM processor and can communicate with the Epiphany using an e-Link interface. 32 MB of memory is shared between ARM processors (host) and Epiphany. It is mapped in eNodes to `0x8E000000–0x8FFFFFFF` address space. eCores can use it in the same way as internal memory, however the performance will be lower as shown in Section IV-A1.

The memory size usable by the programmer is dependent on many factors. In the most common linker configuration the internal memory (32 kB) is used, for example, to store:

- program code,
- global variables,
- stack.

And a fragment of the external memory (32 MB) is used for the C standard library code, data and stack [9].

Programming on the Epiphany side is done in the usual way. The SDK supports the standard C library with mathematics functions. Additionally, it provides some specific utilities for managing hardware resources: registers operations, interrupts handling, timers, mutexes, barriers and DMA functions. The "workgroup" concept is supported and each created workgroup can have a different code loaded. The important thing to remember is that Epiphany is an MIMD processor and each core can execute a completely different code. There is no synchronization between cores (besides library functions and experimental `SYNC` instruction).

Alternative approaches to using the basic SDK are MPI [10] and OpenMP [11].

Epiphany does not provide double precision float operations in hardware. As such, these are emulated by a compiler and thus carry performance loss when used.

III. Programs

Our benchmark application was a simple genetic algorithm [12] with the fitness-proportional selection, mutation

enabled and using the two-dimensional Beale's function as a fitness function:

$$f(x,y) = (1.5 - x + xy)^2 + \left(2.25 - x + xy^2\right)^2 + \left(2.625 - x + xy^3\right)^2$$

The initial population was generated within $[-5.0, 5.0]$ boundary.

With this basic skeleton we prepared several versions of the implementation for the Parallella using different solutions and optimizations.

As we wanted to implement the whole algorithm on the Epiphany processor, we needed a separate pseudo-random number generator. We used a "tiny" version of the Mersenne Twister [13], [14] that requires only 127 bits of memory, and could be easily used with Epiphany.

A. Fitness computation offloading

The first and the simplest way to use the Epiphany processor is to offload what is usually the heaviest computation in genetic algorithms – the evaluation of the fitness function.

The main loop of the computation performs the following operations:

1) Generate a new population (on the host side).
2) Compute the fitness (on the Epiphany processor).
3) Find the best organism (on the host side).

The simplified version of the function initializing and starting Epiphany cores is shown in Listing 1. We perform the following steps:

1) reset workgroup,
2) load the device code,
3) write population and its size,
4) start the workgroup,
5) wait for all cores to finish working,
6) read the computed fitness values.

```
void epi_fitness_fill(
    simulation_t * simulation,
    e_platform_t * platform) {

  // Reset device and load code
  e_reset_group(&dev);
  e_load_group("e_main.srec", &dev, 0, 0,
    platform->rows, platform->cols,
    E_FALSE);

  // Write required data - size and population
  e_write(&e_size_mem, 0, 0, 0x0,
    &(simulation->size), sizeof(float));
  e_write(&e_population_mem, 0, 0, 0x0,
    simulation->population,
    simulation->population_size);

  // Send start interrupt
  e_start_group(&dev);

  // Wait for all cores to finish work
  epi_wait_for_status(STATUS_EXITED);

  // Read computed fitness
  e_read(&e_fitness_mem, 0, 0, 0x0,
    simulation->fitness.values,
    simulation->fitness_size);
}
```

Listing 1. Host part of fitness computation

For transferring the population we use an array of pairs of floats (with a size twice that of the population). The output (fitness values) is stored in a separate array of floats. In the basic version, both are located in the external memory.

B. Full population evaluation

In the second version we offloaded both the fitness computation and finding the best individual to the Epiphany cores. In this case, each core, finds the best individual in its fragment of the population. After computing all the fitness values, each core sends (using a 16-element `size_t` array) the index of the best individual that was found. The host collects these 16 elements and chooses the best among them. It also generates a new population.

C. Whole algorithm on Epiphany

In the final stage, we also implemented the whole algorithm on the Epiphany processor. Most of the implementation was straightforward, as the code flow could be similar. The main issue was handling large data with the small amount of local memory.

In order to handle a large number of organisms efficiently, for each iteration, we split the population into chunks each consisting of 16×1024 organisms (except the last one). Each core copies 1024 organisms from the external memory into its local memory. Then, it computes the fitness and generates a new population for this fragment and puts the new organisms to the external memory. After all cores perform these operations on all chunks, they load new organisms from the external memory and execute the next iteration.

A loss in the exchange of organisms between cores can be observed and we basically operate on subpopulations. However, to resolve (at least partially) this problem, we shuffle the population when copying organisms from the external memory. We do this efficiently using the DMA engine (see Section III-D3).
