DEAR Reader, it is our pleasure to present to you Proceedings of the 17th Conference on Computer Science and Intelligence Systems (FedCSIS 2022), which took place on September 4-7, 2022, in Sofia, Bulgaria, and in the hybrid mode.

The main Conference Chair of FedCSIS 2022 was Stefka Fidanova, while Nina Dobrinkova acted as the Chair of the Organizing Committee. This year, FedCSIS was organized by the Polish Information Processing Society (Mazovia Chapter), IEEE Poland Section Computer Society Chapter, Systems Research Institute Polish Academy of Sciences, Warsaw University of Technology, Wrocław University of Economics and Institute of Information and Communication Technologies, Bulgarian Academy of Sciences.

FedCSIS 2022 was technically co-sponsored by: IEEE Bulgarian Section, IEEE Poland Section, IEEE Czechoslovakia Section Computer Society Chapter, IEEE Poland Section Systems, Man, and Cybernetics Society Chapter, IEEE Poland Section Computational Intelligence Society Chapter, IEEE Poland Section Control System Society Chapter, Committee of Computer Science of the Polish Academy of Sciences, Mazovia Cluster ICT, Poland and Bulgarian Section of SIAM.

Moreover, last year the FedCSIS conference series formed the strategic alliance with QED Software, a Polish software company developing AI-based technologies and acting as the technological co-founder in the AI-driven start-ups. This collaboration has been continued.

During FedCSIS 2022, the keynote lectures were delivered by:

- Krassimir Atanassov, Bulgarian Academy of Sciences, Sofia, Bulgaria: “*Remarks on Index Matrices*”,
- Chris Cornelis, Ghent University, Department of Applied Mathematics, Computer Science and Statistics: “*Hybridization of Fuzzy Sets and Rough Sets: Achievements and Opportunities*”,
- Ivan Lukovic, University of Belgrade, Faculty of Organizational Sciences, “*Organizational Capability for Information Management – Do We Feel a Big Data Crisis?*”,
- Stefano Mariani on behalf of Franco Zambonelli (due to serious health issues encountered right before the conference), University of Modena e Reggio Emilia, Italy: “*Individual and Collective Self-development*”.

Moreover, this year, two special guests delivered invited talks:

- Bogusław Cyganek, who was awarded the 2021 Wiley-IEEE Press Award, for his recent book “*Introduction to Programming with C++ for Engineers*”,
- Andrzej Skowron, who delivered the talk: “*Rough Sets Turn 40: From Information Systems to Intelligent Systems*”, which was devoted to the 40th anniversary of introduction, by late Professor Zdzisław Pawlak, of the theory of Rough Sets.

FedCSIS 2022 consisted of five Tracks and a special event for Doctoral School Students. Within each Track, topical Technical Sessions have been organized. Each Technical Session was split into fully on site and fully on-

line sub-sessions. The on-site part of the conference took place in the facilities of the Crisis Management and Disaster Response Centre of Excellence in Sofia, Bulgaria.

Some of Technical Sessions have been associated with the FedCSIS conference series for many years, while some of them are relatively new. The role of the technical Sessions is to focus and enrich discussions on selected areas, pertinent to the general scope of each Track. The list of Tracks, and topical Technical Sessions organized within their scope, was as follows.

- **Track 1: Advanced Artificial Intelligence in Applications (17th Symposium AAIA'22)**
 - Artificial Intelligence for Next-Generation Diagnostic Imaging (1st Workshop AI4NextGenDI'22)
 - Artificial Intelligence in Machine Vision and Graphics (4th Workshop AIMaViG'22)
 - Personalization and Recommender Systems (1st Workshop PeRS'22)
 - Rough Sets: Theory and Applications (4th International Symposium RSTA'22)
 - Computational Optimization (15th International Workshop WCO'22)
- **Track 2: Computer Science & Systems (CSS'22)**
 - Computer Aspects of Numerical Algorithms (15th Workshop CANA'22)
 - Concurrency, Specification and Programming (30th International Symposium CS&P'22)
 - Multimedia Applications and Processing (15th International Symposium MMAP'22)
 - Scalable Computing (12th Workshop WSC'22)
- **Track 3: Network Systems and Applications (NSA'22)**
 - Complex Networks - Theory and Application (1st Workshop CN-TA'22)
 - Internet of Things – Enablers, Challenges and Applications (6th Workshop IoT-ECAW'22)
 - Cyber Security, Privacy, and Trust (3rd International Forum NEMESIS'22)
- **Track 4: Advances in Information Systems and Technology (AIST'22)**
 - Data Science in Health, Ecology and Commerce (4th Workshop DSH'22)
 - Information Systems Management (17th Conference ISM'22)
 - Knowledge Acquisition and Management (28th Conference KAM'22)
- **Track 5: Software and System Engineering (S3E'22)**
 - Cyber-Physical Systems (9th International Workshop IWCPS'22)
 - Model Driven Approaches in System Development (7th Workshop MDASD'22)
 - Software Engineering (42nd IEEE Workshop SEW'22)
- **7th Doctoral Symposium on Recent Advances in Information Technology (DS-RAIT'22)**

Each contribution, found in this volume, was refereed by at least two referees and the acceptance rate of regular full papers was slightly below 19% (55 accepted contributions, out of 290 general submissions).

During FedCSIS 2022, for the second time, the Zdzisław Pawlak award was presented to the best papers from across the whole conference. It was done to further underscore the fact that scientific achievements of Professor Pawlak had gone far beyond Artificial Intelligence. The following contributions have been awarded in three categories:

- In the category **Best Paper**: Kamil Rybiński (Warsaw University of Technology, Poland) and Michał Śmiąlek (Warsaw University of Technology, Poland) for the paper: “*Beyond Low-Code Development: Marrying Requirements Models and Knowledge Representations*”.
- In the category **Industry Cooperation**: Ghada Moualla (Orange Labs, France), Sebastien Bolle (Orange Labs, France), Marc Douet (Orange Labs, France) and Eric Rutten (INRIA, France) for the paper: “*Self-adaptive Device Management for the IoT Using Constraint Solving*”.
- In the category **Young Researcher**: Eyad Kannout (University of Warsaw, Poland), Michał Grodzki (University of Warsaw, Poland) and Marek Grzegorowski (University of Warsaw, Poland) for the paper: “*Utilizing Frequent Pattern Mining for Solving Cold-Start Problem in Recommender Systems*”.

Moreover, the Award Committee decided to fund two extra **Young Researcher** distinctions:

- Aleksandra Bączkiewicz (University of Szczecin, Poland) for the paper: “*Towards Temporal Multi-Criteria Assessment of Sustainable RES Exploitation in European Countries*”.
- Aleksandra Weiss (Scientific Circle of Robotics UWM in Olsztyn, Poland), Marcin Młyński (Scientific Circle of Robotics UWM in Olsztyn, Poland) and Piotr Artiemjew (University of Warmia and Mazury, Poland) for the paper: “*About Classifiers Quality Assessment: Balanced Accuracy Curve (BAC) as an alternative for ROC and PR Curve*”.

All the above awards and distinctions were jointly sponsored by the Mazovia Branch of the Polish Information Processing Society and by QED Software.

FedCSIS’22 also hosted the **Data Mining Competition** (already for the 5th time during the history of the FedCSIS conferences) co-organized by QED Software at the online platform KnowledgePit, and sponsored by Control System Software, a Polish company which develops decision support and optimization systems in the areas of transportation, spedition, and logistics.

The competition attracted 130 teams from 24 countries. The papers describing the most interesting solutions submitted to the competition were included in the FedCSIS 2022 proceedings in the special section of **Track 1**. The following papers represent the best solutions awarded by Control System Software:

- Paper describing **the winning solution**: Dymitr Ruta (Khalifa University, UAE), Ming Liu (Khalifa University,

UAE), Ling Cen (Khalifa University, UAE), Quang Hieu Vu (VNG Corporation, Vietnam), “*Diversified gradient boosting ensembles for prediction of the cost of forwarding contracts*”

- Paper describing **the 2nd best solution**: Haitao Xiao, (Chinese Academy of Sciences, China), Yuling Liu (Chinese Academy of Sciences, China), Dan Du (Chinese Academy of Sciences, China), Zhigang Lu (Chinese Academy of Sciences, China), “*An Approach for Predicting the Costs of Forwarding Contracts using Gradient Boosting*”
- Paper describing **the 3rd best solution**: Quang Hieu Vu (VNG Corporation, Vietnam), Ling Cen (Khalifa University, UAE), Dymitr Ruta (Khalifa University, UAE), Ming Liu (Khalifa University, UAE), “*Key Factors to Consider when Predicting the Costs of Forwarding Contracts*”
- Paper describing **the most practical solution**: Sławomir Pioroński (Adam Mickiewicz University, Poland), Tomasz Górecki (Adam Mickiewicz University, Poland), “*Using gradient boosting trees to predict the costs of forwarding contracts*”

The program of FedCSIS 2022 required a dedicated effort of many people. We would like to express our warmest gratitude to all Committee members, of each Track and each Technical Session, for their hard work in attracting and later refereeing 290 submissions.

We thank the authors of papers for their great contribution to the theory and practice of computing and intelligence systems. We are grateful to the invited speakers for sharing their knowledge and wisdom with the participants.

Last, but not least, we thank Stefka Fidanova and Nina Dobrinkova. It should be stressed that they made all the preparations to organize the conference in Bulgaria for three years in a row, while only in 2022 the conference actually happened there. They also worked with us diligently to adapt the conference formula to organize it in hybrid mode. We are very grateful for all your efforts!

We hope that you had an inspiring conference. We also hope to meet you again for the 18th Conference on Computer Science and Intelligence Systems (FedCSIS 2023) which will take place in Warsaw, Poland on September 17-20, 2023.

Co-Chairs of the FedCSIS Conference Series:

Maria Ganzha, Warsaw University of Technology, Poland, and Systems Research Institute Polish Academy of Sciences, Warsaw, Poland

Leszek Maciaszek, Macquarie University, Sydney, Australia and Wrocław University of Economics, Wrocław, Poland

Marcin Paprzycki, Systems Research Institute Polish Academy of Sciences, Warsaw, Poland, and Warsaw Management University, Warsaw, Poland

Dominik Ślęzak, Institute of Informatics, University of Warsaw, Poland, and QED Software, Warsaw, Poland

Proceedings of the 17th Conference on Computer Science and Intelligence Systems

September 4–7, 2022. Sofia, Bulgaria

TABLE OF CONTENTS

CONFERENCE INVITED CONTRIBUTIONS

KEYNOTE PAPERS

- Two new operations over extended index matrices and their applications in Big Data** 1
Krassimir Atanassov, Veselina Bureva
- Hybridization of Fuzzy Sets and Rough Sets: Achievements and Opportunities** 7
Chris Cornelis
- Individual and Collective Self-Development: Concepts and Challenges** 15
Marco Lippi, Stefano Mariani, Matteo Martinelli, Franco Zambonelli

ANNIVERSARY PAPER

- Rough Sets Turn 40: From Information Systems to Intelligent Systems** 23
Andrzej Skowron, Dominik Ślęzak

IEEE AWARD PAPER

- Modern C++ in the era of new technologies and challenges—why and how to teach modern C++?** 35
Bogusław Cyganek

17TH INTERNATIONAL SYMPOSIUM ON ADVANCED ARTIFICIAL INTELLIGENCE IN APPLICATIONS

- Call For Papers** 41
- A novel link prediction approach on clinical knowledge graphs utilizing graph structures** 43
Jens Dörpinghaus, Tobias Hübenthal, Jennifer Faber
- Deep Learning Transformer Architecture for Named Entity Recognition on Low Resourced Languages: State of the art results** 53
Ridewaan Hanslo
- Demand forecasting in the fashion business — an example of customized nearest neighbour and linear mixed model approaches** 61
Joanna Henzel, Łukasz Wawrowski, Anna Kubina, Marek Sikora, Łukasz Wróbel
- Improving Re-rankCCP with Rules Quality Measures** 67
Piotr Jezusek, Aleksandra Karpus
- Using Transformer models for gender attribution in Polish** 73
Karol Kaczmarek, Jakub Pokrywka, Filip Graliński
- A Comparative Study of Short Text Classification with Spiking Neural Networks** 79
Piotr S. Maciąg, Wojciech Sitek, Łukasz Skonieczny, Henryk Rybiński

Rule-based approximation of black-box classifiers for tabular data to generate global and local explanations	89
<i>Cezary Maszczyk, Michal Kozielski, Marek Sikora</i>	
Automatic detection of potential customers by opinion mining and intelligent agents	93
<i>Raúl Moreno, Alberto Fernandez-Isabel, Isaac Martín De Diego, Javier M. Moguerza, Carmen Lancho, Marina Cuesta Santa Teresa</i>	
An Automated Algorithm for Fruit Image Dataset Building	103
<i>Horea-Bogdan Mureşan</i>	
NiaNet: A framework for constructing Autoencoder architectures using nature-inspired algorithms	109
<i>Sašo Pavlič, Iztok Fister Jr., Sašo Karakatič</i>	
Aspects of autonomous drive control using NVIDIA Jetson Nano microcomputer	117
<i>Kacper Podbucki, Tomasz Marciniak</i>	
Temporal Language Modeling for Short Text Document Classification with Transformers	121
<i>Jakub Pokrywka, Filip Graliński</i>	
An End-to-end Machine Learning System for Mitigating Checkout Abandonment in E-Commerce	129
<i>Md Rifatul Islam Rifat, Md Nur Amin, Mahmud Hasan Munna, Abdullah Al Imran</i>	
Reinforcement Learning for on-line Sequence Transformation	133
<i>Grzegorz Rypeś, Łukasz Lepak, Paweł Wawrzyński</i>	
Applying SoftTriple Loss for Supervised Language Model Fine Tuning	141
<i>Witold Sosnowski, Anna Wróblewska, Piotr Gawrysiak</i>	
About Classifiers Quality Assessment: Balanced Accuracy Curve (BAC) as an alternative for ROC and PR Curve	149
<i>Aleksandra Weiss, Marcin Młyński, Piotr Artiemjew</i>	
Extending Word2Vec with Domain-Specific Labels	157
<i>Miloš Švaňa</i>	

1ST WORKSHOP ON ARTIFICIAL INTELLIGENCE FOR NEXT-GENERATION DIAGNOSTIC IMAGING

Call For Papers	161
Development of an AI-based audiogram classification method for patient referral	163
<i>Michał Kassjański, Marcin Kulawiak, Tomasz Przewoźny</i>	
Canine age classification using Deep Learning as a step towards preventive medicine in animals	169
<i>Szymon Mazurek, Maciej Wielgosz, Jakub Caputa, Rafał Frączek, Michał Karwatowski, Jakub Grzeszczyk, Daria Łukasik, Anna Śmiech, Paweł Russek, Ernest Jamro, Agnieszka Dąbrowska-Boruch, Marcin Pietroń, Sebastian Koryciak, Kazimierz Wiatr</i>	

4TH INTERNATIONAL WORKSHOP ON ARTIFICIAL INTELLIGENCE IN MACHINE VISION AND GRAPHICS

Call For Papers	173
On the Feasible Regions Delimiting Natural Human Postures in a Novel Skeletal Representation	175
<i>Simon Hengeveld, Antonio Mucherino</i>	
A lightweight approach to two-person interaction classification in sparse image sequences	181
<i>Włodzimirz Kasprzak, Van Khanh Do, Paweł Piwowarski</i>	
Geometry-Aware Keypoint Network: Accurate Prediction of Point Features in Challenging Scenario	191
<i>Tomasz Nowak, Piotr Skrzypczyński</i>	
Analysis of Brain Tumor Using MRI Images	201
<i>Lewi Uberg, Seifedine Kadry</i>	

Insights into Neural Architectures for Learning Numerical Concepts from Simple Visual Data	205
<i>Andrzej Śluzek</i>	

1ST WORKSHOP ON PERSONALIZATION AND RECOMMENDER SYSTEMS

Call For Papers	211
User Experience and Multimodal Usability for Navigation Systems	213
<i>Lumbardha Hasimi, Aneta Poniszewska-Marańda</i>	
Utilizing Frequent Pattern Mining for Solving Cold-Start Problem in Recommender Systems	217
<i>Eyad Kannout, Michał Grodzki, Marek Grzegorowski</i>	
Learning edge importance in bipartite graph-based recommendations	227
<i>Robert Kwieciński, Tomasz Górecki, Agata Filipowska</i>	
Personality Prediction from Social Media Posts using Text Embedding and Statistical Features	235
<i>Seiyu Majima, Konstantin Markov</i>	

4TH INTERNATIONAL SYMPOSIUM ON ROUGH SETS: THEORY AND APPLICATIONS

Call For Papers	241
Three-way Learnability: A Learning Theoretic Perspective on Three-way Decision	243
<i>Andrea Campagner, Davide Ciucci</i>	
On Multiplicative, Additive and Qualitative Pairwise Comparisons	247
<i>Ryszard Janicki, Mahmoud Mahmoud</i>	
Malware Evolution and Detection Based on the Variable Precision Rough Set Model	253
<i>Manel Jerbi, Zaineb Chelly Dagdia, Slim Bechikh, Lamjed Ben Said</i>	
Multi-Criteria Decision-Making with Linguistic Labels	263
<i>Alicja Mieszkowicz-Rolka, Leszek Rolka</i>	
Fuzzy Quantifier-Based Fuzzy Rough Sets	269
<i>Adnan Theerens, Chris Cornelis</i>	
Feature Selection and Ranking Method based on Intuitionistic Fuzzy Matrix and Rough Sets	279
<i>Bich Khue Vo, Hung Son Nguyen</i>	

15TH INTERNATIONAL WORKSHOP ON COMPUTATIONAL OPTIMIZATION

Call For Papers	289
GaMeDE2 — improved Gap-based Memetic Differential Evolution applied to multi-modal optimisation	291
<i>Michał Antkiewicz, Paweł Myszkowski, Maciej Laszczyk</i>	
A chance-constraint approach for optimizing social engagement-based services	301
<i>Michel Bierlaire, Edoardo Fadda, Lohic Fotio Tiotsop, Daniele Manerba</i>	
Independent Component Analysis Based on Jacobi Iterative Framework and L1-norm Criterion	305
<i>Adam Borowicz</i>	
The electric vehicle shortest path problem with time windows and prize collection	313
<i>Antonio Cassia, Ola Jabali, Federico Malucelli, Marta Pascoal</i>	
Analyzing longitudinal Data in Knowledge Graphs utilizing shrinking pseudo-triangles	323
<i>Jens Dörpinghaus, Vera Weil, Johanna Binnewitt</i>	
Agricultural System Modelling with Ant Colony Optimization	329
<i>Stefka Fidanova, Ivan Dimov, Denitsa Angelova, Maria Ganzha</i>	

A GPU approach to distance geometry in 1D: an implementation in C/CUDA	333
<i>Simon B. Hengeveld, Antonio Mucherino</i>	
A Multi-objective Cluster-based Biased Random-Key Genetic Algorithm with Online Parameter Control Applied to Protein Structure Prediction	337
<i>Felipe Marchi, Rafael Stubs Parpinelli</i>	
Team Orienteering Problem with Time Windows and Variable Profit	347
<i>Eliseo Marzal, Laura Sebastia</i>	
Subcaterpillar Isomorphism: Subtree Isomorphism Restricted Pattern Trees To Caterpillars	351
<i>Tomoya Miyazaki, Kouichi Hirata</i>	
Improving N-NEH+ algorithm by using Starting Point method	357
<i>Radostaw Puka, Bartosz Łamasz, Iwona Skalna</i>	
Boosting a Genetic Algorithm with Graph Neural Networks for Multi-Hop Influence Maximization in Social Networks	363
<i>Camilo Chacón Sartori, Christian Blum</i>	
Stackelberg Strategies for Weighted Load Balancing Games	373
<i>Neta Stein, Tami Tamir</i>	
Intuitionistic Fuzzy Model of the Hungarian Algorithm for the Salesman Problem and Software Analysis of a Shipping Company Example	383
<i>Velichka Traneva, Deyan Mavrov, Stoyan Tranev</i>	
Software Implementation of the Optimal Temporal Intuitionistic Fuzzy Algorithm for Franchisee Selection	387
<i>Velichka Traneva, Deyan Mavrov, Stoyan Tranev</i>	
<hr/>	
DATA MINING COMPETITON	
Call For Papers	391
KnowledgePit Meets BrightBox: A Step Toward Insightful Investigation of the Results of Data Science Competitions	393
<i>Andrzej Janusz, Dominik Ślęzak</i>	
Predicting the Costs of Forwarding Contracts: Analysis of Data Mining Competition Results	399
<i>Andrzej Janusz, Antoni Jamiołkowski, Michał Okulewicz</i>	
Considering various aspects of models' quality in the ML pipeline - application in the logistics sector	403
<i>Eyad Kannout, Michał Grodzki, Marek Grzegorowski</i>	
Prediction of the Costs of Forwarding Contracts with Machine Learning Methods	413
<i>Stanisław Kaźmierczak</i>	
XGBoost meets TabNet in Predicting the Costs of Forwarding Contracts	417
<i>Aleksandra Lewandowska</i>	
Using gradient boosting trees to predict the costs of forwarding contracts	421
<i>Sławomir Pioroński, Tomasz Górecki</i>	
Predicting the Costs of Forwarding Contracts Using XGBoost and a Deep Neural Network	425
<i>Lukasz Podlódowski, Marek Kozłowski</i>	
Diversified gradient boosting ensembles for prediction of the cost of forwarding contracts	431
<i>Dymitr Ruta, Ming Liu, Ling Cen, Quang Hieu Vu</i>	
Application of Diversified Ensemble Learning in Real-life Business Problems: The Case of Predicting Costs of Forwarding Contracts	437
<i>Milena Trajanoska, Pavel Gjorgovski, Eftim Zdravevski</i>	
Key Factors to Consider when Predicting the Costs of Forwarding Contracts	447
<i>Quang Hieu Vu, Ling Cen, Dymitr Ruta, Ming Liu</i>	
An Approach for Predicting the Costs of Forwarding Contracts using Gradient Boosting	451
<i>Haitao Xiao, Yuling Liu, Dan Du, Zhigang Lu</i>	

COMPUTER SCIENCE AND SYSTEMS

Call For Papers	455
Block Subspace Iteration Method for Structural Analysis on Multicore Computers <i>Sergiy Fialko</i>	457
Flexible user query order for the speculative query support in RDBMS <i>Anna Sasak-Okoń</i>	467

15TH WORKSHOP ON COMPUTER ASPECTS OF NUMERICAL ALGORITHMS

Call For Papers	473
Automatic code optimization for computing the McCaskill partition functions <i>Włodzimierz Bielecki, Marek Palkowski, Maciej Poliwoda</i>	475
Influence of loop transformations on performance and energy consumption of the multithreaded WZ factorization <i>Beata Bylina, Jarosław Bylina, Monika Piekarcz</i>	479
A short note on post-hoc testing using random forests algorithm: Principles, asymptotic time complexity analysis, and beyond <i>Lubomír Štěpánek, Filip Habarta, Ivana Mala, Luboš Marek</i>	489

30TH INTERNATIONAL SYMPOSIUM ON CONCURRENCY, SPECIFICATION AND PROGRAMMING

Call For Papers	499
An observation on pure strategies in Security Games <i>Marek Adrian, Gianluigi Greco</i>	501
Formal analysis of timeliness in the RaSTA protocol <i>Billy Naumann, Christine Jakobs, Matthias Werner</i>	505
Channel-Less Process Communication <i>Tomas Plachetka</i>	515
Improvement of design anti-pattern detection with spatio-temporal rules in the software development process <i>Łukasz Puławski</i>	521

15TH INTERNATIONAL SYMPOSIUM ON MULTIMEDIA APPLICATIONS AND PROCESSING

Call For Papers	529
A Modified ICP Algorithm Based on FAST and Optical Flow for 3D Registration <i>Konrad Koniarski, Andrzej Myśliński</i>	531
Hierarchical data structures in rendering scenes containing a massive number of light sources <i>Andrzej Lamecki, Krzysztof Kaczmarek, Joanna Porter-Sobieraj</i>	535
Encrypting JPEG-compressed images by substituting Huffman code words <i>Marek Parfieniuk</i>	545

12TH WORKSHOP ON SCALABLE COMPUTING

Call For Papers	551
Khaos: Dynamically Optimizing Checkpointing for Dependable Distributed Stream Processing <i>Morgan Geldenhuys, Ben Pfister, Dominik Scheinert, Lauritz Thamsen, Odej Kao</i>	553
Increasing data availability and fault tolerance for decentralized collaborative data-sharing systems <i>Kamil Jarosz, Łukasz Opióła, Łukasz Dutka, Renata G. Słota, Jacek Kitowski</i>	563

NETWORK SYSTEMS AND APPLICATIONS

Call For Papers	567
An Integer Programming Approach Reinforced by a Message-passing Procedure for Detecting Dense Attributed Subgraphs	569
<i>Arman Ferdowsi</i>	
Location Accuracy of a Ground Station based on RSS in the Rice Channel	577
<i>Jarostaw Michalak</i>	

1ST WORKSHOP ON COMPLEX NETWORKS: THEORY AND APPLICATION

Call For Papers	581
The effectiveness analysis of selected IT tools for predictions of the COVID-19 pandemic	583
<i>Paweł Dymora, Mirosław Mazurek, Kamil Łyczko</i>

Abstract—The Index Matrices (IMs) are extensions of the matrices of algebra. Over the IMs different operations, relations and operators are defined. In the present paper, two new operations over IMs are defined and some of their properties are studied. An application of these operations for describing of Big Data procedure is discussed. Hortonworks Data Platform (HDP) is used to provide capabilities for data warehouse processing in the Big Data environment. Apache Hive is selected for data warehouse construction and querying. Firstly, data warehouse for product sells is implemented. The tables for employees, customers, products and product sells are created. Thereafter the new index matrix operations for difference between two IMs are executed for the first time in the Big Data environment. SQL queries are written to demonstrate the operations. The new index matrix operations are executed using SQL JOIN notation and logical operator NOT EXISTS.

Index Terms—Big Data, Extended index matrix, Operation.

I. INTRODUCTION

THE CONCEPT of Index Matrix (IM) was introduced in 1984 and in more details - in 1987 [2], but the full description of the research over them was published in [3] exactly 30 years later.

Different extensions and modifications of the concept of an IM are described in [3]. One of them is an Extended IM (EIM), introduced firstly in [4]. They include as partial cases standard IM with elements of real or complex numbers, the (0, 1)-IM with elements from set {0, 1}, the logical IM with elements variables, propositions or predicates, the intuitionistic fuzzy IMs. The elements of the EIM can be each objects, in this number - whole IMs.

Different relations, operations and operators are defined over IMs and more general - over EIM. Only part of them have analogues in the theory of the standard matrices (see, e.g., [6], [7]).

Here, two new operations over EIMs are defined and some of their properties are studied. It will be obvious that these new operations can be transfer over each one of the partial cases of the EIM.

Firstly, we give the definition of an EIM.

Let \mathcal{I} be a fixed set of indices,

$$\mathcal{I}^n = \{(i_1, i_2, \dots, i_n) | (\forall j : 1 \leq j \leq n)(i_j \in \mathcal{I})\}$$

and

$$\mathcal{I}^* = \cup_{1 \leq n \leq \infty} \mathcal{I}^n.$$

Let \mathcal{X} be a fixed set of some objects. In the particular cases, they can be either real numbers, or only the numbers 0 or 1, or logical variables, propositions or predicates, etc.

Let operations $\circ, * : \mathcal{X} \times \mathcal{X} \rightarrow \mathcal{X}$ be fixed and let $(\mathcal{X}, \circ, e_\circ)$ and $(\mathcal{X}, *, e_*)$ be groups with unit elements e_\circ and e_* , respectively. For example, when operation “ \circ ” is “+” or “ \cdot ”, e_\circ will be 0, while when it is “ \times ” or “ \cdot ” – it will be 1. In some cases, it is suitable to define the unit element by \perp and it to be an empty object.

An EIM with index sets K, L ($K, L \subset \mathcal{I}^*$) and elements from set \mathcal{X} is called the object (see, [4], [3]):

$$[K, L, \{a_{k_i, l_j}\}] \equiv$$

		l_1	\dots	l_j	\dots	l_n
k_1	a_{k_1, l_1}	\dots	a_{k_1, l_j}	\dots	a_{k_1, l_n}	
\vdots	\vdots	\dots	\vdots	\dots	\vdots	
k_i	a_{k_i, l_1}	\dots	a_{k_i, l_j}	\dots	a_{k_i, l_n}	
\vdots	\vdots	\dots	\vdots	\dots	\vdots	
k_m	a_{k_m, l_1}	\dots	a_{k_m, l_j}	\dots	a_{k_m, l_n}	

where $K = \{k_1, k_2, \dots, k_m\}$, $L = \{l_1, l_2, \dots, l_n\}$, for $1 \leq i \leq m$, and $1 \leq j \leq n : a_{k_i, l_j} \in \mathcal{X}$.

In [3], for the IMs $A = [K, L, \{a_{k_i, l_j}\}]$, $B = [P, Q, \{b_{p_r, q_s}\}]$, operations that are analogous to the usual matrix operations of addition and multiplication are defined, as well as other, specific ones. Here, we give only three of these operations, that will be used below.

Addition

$$A \oplus_{(\circ)} B = [K \cup P, L \cup Q, \{c_{t_u, v_w}\}],$$

where

$$c_{t_u, v_w} = \begin{cases} a_{k_i, l_j}, & \text{if } t_u = k_i \in K \text{ and } v_w = l_j \in L - Q \\ & \text{or } t_u = k_i \in K - P \text{ and } v_w = l_j \in L; \\ b_{p_r, q_s}, & \text{if } t_u = p_r \in P \text{ and } v_w = q_s \in Q - L \\ & \text{or } t_u = p_r \in P - K \text{ and } v_w = q_s \in Q; \\ a_{k_i, l_j} \circ b_{p_r, q_s}, & \text{if } t_u = k_i = p_r \in K \cap P \\ & \text{and } v_w = l_j = q_s \in L \cap Q \\ 0, & \text{otherwise} \end{cases}$$

Structural subtraction

$$A \ominus B = [K - P, L - Q, \{c_{t_u, v_w}\}],$$

where here and below “ $-$ ” is the set-theoretic difference operation and

$$c_{t_u, v_w} = a_{k_i, l_j}, \text{ for } t_u = k_i \in K - P \text{ and } v_w = l_j \in L - Q.$$

Projection

$$pr_{M, N} A = [M, N, \{b_{k_i, l_j}\}],$$

where $M \subseteq K$, $N \subseteq L$, and for each $k_i \in M$ and each $l_j \in N$, $b_{k_i, l_j} = a_{k_i, l_j}$.

II. DEFINITIONS OF THE TWO NEW OPERATIONS

Let the two EIMs $A = [K, L, \{a_{k_i, l_j}\}]$ and $B = [P, Q, \{b_{p_r, q_s}\}]$ are given.

The first, simpler, operation is defined by

$$A \overset{\bullet}{\underset{1}{\circ}} B = [K \div P, L \div Q, \{c_{u_v, w_t}\}],$$

where and below for every two arbitrary sets X, Y :

$$X \div Y = (X - Y) \cup (Y - X);$$

$$c_{u_v, w_t} = \begin{cases} a_{k_i, l_j}, & \text{if } u_v = k_i \in K - P \text{ and } w_t = l_j \in L - Q \\ b_{p_r, q_s}, & \text{if } w_t = p_r \in P - K \text{ and } w_t = q_s \in Q - L \\ \perp & \text{otherwise} \end{cases}$$

The second operation is defined by

$$A \overset{\bullet}{\underset{2}{\circ}} B = [K \cup P, L \cup Q, \{c_{u_v, w_t}\}],$$

where

$$c_{u_v, w_t} = \begin{cases} a_{k_i, l_j}, & \text{if } u_v = k_i \in K - P \text{ and } w_t = l_j \in L \\ & \text{or } u_v = k_i \in K \text{ and } w_t = l_j \in L - Q \\ b_{p_r, q_s}, & \text{if } w_t = p_r \in P - K \text{ and } w_t = q_s \in Q \\ & \text{if } w_t = p_r \in P \text{ and } w_t = q_s \in Q - L \\ \perp & \text{otherwise} \end{cases}$$

The geometrical interpretations of both operations are shown on Figures 1 and 2.

From the definitions and geometrical interpretations of both operations we see immediately that the following assertions are valid.

Theorem 1. For every two EIMs A and B , for each operation \circ , and for operation $*$ defined for every two $x, y \in \mathcal{X}$ by $x * y = e_*$ there are follows:

$$A \overset{\bullet}{\underset{1}{\circ}} B = (A \ominus B) \oplus_{(\circ)} (B \ominus A),$$

$$A \overset{\bullet}{\underset{2}{\circ}} B = A \oplus_{(*)} B.$$

Proof. For the definitions of the operations \ominus and \oplus_{\circ} we obtain

$$\begin{aligned} (A \ominus B) \oplus_{(\circ)} (B \ominus A) &= [K - P, L - Q, \{c_{t_u, v_w}\}] \oplus_{(\circ)} [P - K, Q - L, \{d_{e_f, g_h}\}] \\ &= [(K - P) \cup (P - K), (L - Q) \cup (Q - L), \{c'_{t'_{u'}, v'_{w'}}\}] \\ &= [K \div P, L \div Q, \{c'_{t'_{u'}, v'_{w'}}\}] = A \div B, \end{aligned}$$

because

$$c'_{t'_{u'}, v'_{w'}} = \begin{cases} c_{t_u, v_w} = a_{k_i, l_j}, & \text{for } t'_{u'} = t_u = k_i \in K - P \text{ and } v'_{w'} = v_w \\ d_{e_f, g_h} = b_{p_r, q_s}, & \text{for } t'_{u'} = e_f = p_r \in P - K \text{ and } v'_{w'} = g_h \end{cases}$$

Obviously, operation \circ cannot be applied over the elements of both EIMs because there are not at least two elements from the both EIMs that have equal indices.

The second equality is proved by a similar way. \square

Theorem 2. For every two EIMs A and B , for each operation \circ :

$$A \overset{\bullet}{\underset{1}{\circ}} B = pr_{K-P, L-Q} A \oplus_{(\circ)} pr_{P-K, Q-L} B,$$

$$\begin{aligned} A \overset{\bullet}{\underset{2}{\circ}} B &= pr_{K-P, L} A \oplus_{(\circ)} pr_{K \cap P, L \div Q} A \oplus_{(\circ)} pr_{P-K, Q} A \\ &= pr_{K, L-Q} A \oplus_{(\circ)} pr_{K \div P, L \cap Q} A \oplus_{(\circ)} pr_{P, Q-L} A. \end{aligned}$$

The proof is similar to the above one.

Let \mathcal{M} be the set of all EIMs with elements from \mathcal{X}^1 .

Let

$$I_{\emptyset} = [\emptyset, \emptyset, \{\perp\}].$$

Theorem 3. $(\mathcal{M}, \overset{\bullet}{\underset{1}{\circ}}, I_{\emptyset})$ is a commutative group.

Proof. From the definition of operation “ $\overset{\bullet}{\underset{1}{\circ}}$ ” it follows directly that for each two EIMs $A, B \in \mathcal{M}$, $A \overset{\bullet}{\underset{1}{\circ}} B \in \mathcal{M}$.

Using the well-known equality for every three sets X, Y and Z :

$$(X \div Y) \div Z = X \div (Y \div Z),$$

for every three EIMs $A, B, C \in \mathcal{M}$, where

$$C = [D, E, \{c_{d_f, e_g}\}]$$

we obtain

$$\begin{aligned} (A \overset{\bullet}{\underset{1}{\circ}} B) \overset{\bullet}{\underset{1}{\circ}} C &= ([K, L, \{a_{k_i, l_j}\}] \overset{\bullet}{\underset{1}{\circ}} [P, Q, \{b_{p_r, q_s}\}]) \overset{\bullet}{\underset{1}{\circ}} [D, E, \{c_{d_f, e_g}\}] \\ &= [K \div P, L \div Q, \{x_{u_v, w_t}\}] \overset{\bullet}{\underset{1}{\circ}} [D, E, \{c_{d_f, e_g}\}] \end{aligned}$$

¹When \mathcal{X} is a set (class) in the sense of NBG-set theory of all predicates, then \mathcal{M} will be a set (class).

Fig. 1. Geometrical interpretation of operation $\dot{\bullet}_1$ Fig. 2. Geometrical interpretation of operation $\dot{\bullet}_2$

(where each element x_{u_v, w_t} is some element a_{k_i, l_j} or some element b_{p_r, q_s})

$$= [(K \div P) \div D, (L \div Q) \div E, \{y_{\alpha\beta, \gamma\delta}\}]$$

(where each element $y_{\alpha\beta, \gamma\delta}$ is some element a_{k_i, l_j} or some element b_{p_r, q_s}), or some element c_{d_f, e_g})

$$= [K \div (P \div D), L \div (Q \div E), \{y_{\alpha\beta, \gamma\delta}\}]$$

$$= ([K, L, \{a_{k_i, l_j}\}] \dot{\bullet}_1 ([P \div D, Q \div E, \{z_{\varepsilon\zeta, \eta\theta}\}]))$$

(where each element $z_{\varepsilon\zeta, \eta\theta}$ is some element b_{p_r, q_s}), or some element c_{d_f, e_g})

$$= [K, L, \{a_{k_i, l_j}\}] \dot{\bullet}_1 ([P, Q, \{b_{p_r, q_s}\}]) \dot{\bullet}_1 [D, E, \{c_{d_f, e_g}\}].$$

Now, for EIM I_\emptyset we obtain

$$A \dot{\bullet}_1 I_\emptyset = [K \div \emptyset, L \div \emptyset, \{c_{u_v, w_t}\}]$$

(where each element c_{u_v, w_t} coincides with the element a_{k_i, l_j} from A for $u_v = k_i, w_t = l_j$)

$$= [K, L, \{a_{k_i, l_j}\}] = A.$$

Analogously is checked that

$$I_\emptyset \dot{\bullet}_1 A = A.$$

From the well-known equality $X \div Y = Y \div X$ it follows that

$$A \dot{\bullet}_1 B = [K \div P, L \div Q, \{c_{u_v, w_t}\}]$$

$$m = [P \div K, Q \div L, \{c_{u_v, w_t}\}] = B \dot{\bullet}_1 A,$$

i.e., the operation $\dot{\bullet}_1$ is commutative.

Finally,

$$A \dot{\bullet}_1 A = [K \div K, L \div L, \{x_{u_v, w_t}\}] = [\emptyset, \emptyset, \{x_{u_v, w_t}\}] = I_\emptyset,$$

because of lack of indices, element x_{u_v, w_t} must be \perp . \square

Theorem 4. $(\mathcal{M}, \dot{\bullet}_2, I)$ is a commutative monoid.

The proof is similar to this of Theorem 3, without the last part, i.e., as above, we can check that $(\mathcal{M}, \dot{\bullet}_2, I)$ is a commutative monoid, but it is not a group because the fact that there is not a set Y that for some non-empty set X to be valid $X \cup Y = \emptyset$.

III. AN EXAMPLE OF DIFFERENCE OPERATIONS IN THE BIG DATA ENVIRONMENT

Hortonworks Data Platform (HDP) is an open source framework for distributed storage and processing of huge datasets retrieving from different sources. HDP is used to discover insights from structured and unstructured data in the cloud or on-premises. It includes Big Data tools as Hadoop,

The screenshot shows the Ambari web interface for Hive. The top navigation bar includes 'Ambari', 'Sandbox', 'ops', 'alerts', 'Dashboard', 'Services', 'Hosts', 'Alerts', and 'Admin'. The main header is 'HIVE' with a '+ New' button. Below the header, there are tabs for 'QUERY', 'JOBS', 'TABLES', 'SAVED QUERIES', 'UDFs', and 'SETTINGS'. The 'TABLES' tab is active, showing a search bar with 'bigdatadb' and a 'Browse' button. Below the search bar, there are icons for 'customers', 'employees', 'productsales', and 'products'. The 'productsales' table is selected, and its structure is displayed in a table format:

COLUMN NAME	COLUMN TYPE	COMMENT
sn	int	
employeeen	int	
customern	int	
productn	int	
quantity	int	

Fig. 3. Data warehouse bigdatadb view in Apache Hive environment

Yarn, MapReduce, Hbase, Hive, Flume, Kafka, Druid [5]. The example of the difference operations is performed in the environment of Apache Hive. Apache Hive is a data warehouse used for reading, writing, and managing large amounts of data stored in distributed storage in SQL. Apache Hive flexibility can be extended using the used-defined functions (UDF) [1]. In the current investigation a data warehouse for product sells is implemented. The tables are uploaded using previously prepared csv files. Apache Hive supports only the sets operations *Union All* and *Union [Distinct]*. The *Intersect* and *Except (Minus)* operations are not included. In the current investigation for the first time the new index matrix operations performing operation difference will be applied by the analogy of the SQL *JOIN* clause and the logical operator *NOT EXISTS* in the Big Data environment. The tables *Customers* and *Employees* from *bigdatadb* data warehouse (Fig. 3). The authors will not compare the indexed field Number – the comparison will be performed using the columns for the first name and the last name of the tables. There are from the same data type. The tables *Employees* (Fig. 4) and *Customers* (Fig. 5) have the following from:

An example of the standard JOIN operation has the following form:

```
SELECT FName, Lname, CFname, CLName
FROM Employees JOIN ProductSales
ON Employees.Number=ProductSales.EmployeeN
JOIN Customers
ON Customers.CNumber=ProductSales.CustomerN
```

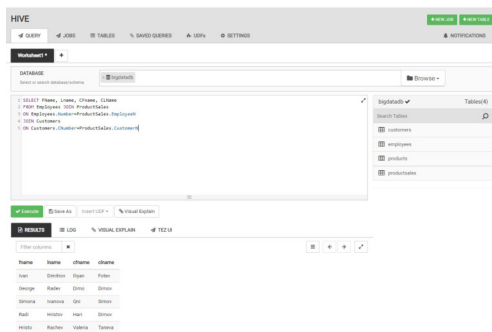

Fig. 6. Execution of standard JOIN operation

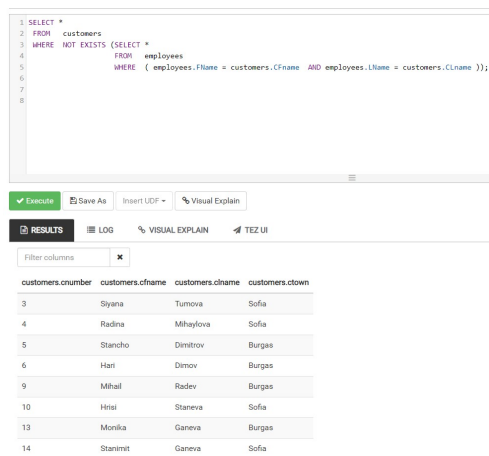

Fig. 7. SQL query for difference operation – case 1

Fig. 8. SQL query for difference operation – case 2

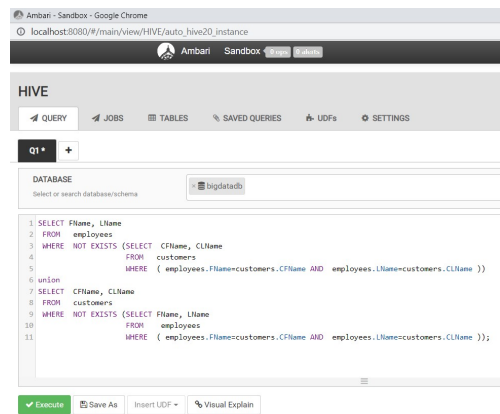

Fig. 9. SQL query for difference operation – case 3

The result presents the names of the customers and the employees. The SQL query in the Apache Hive environment is presented on the Fig. 6.

The simulation of difference operation is performed using the *NOT EXIST* logical operator in the *SELECT* statement and comparison of the desired columns from the tables in the sub-query (Fig. 7).

```
SELECT * FROM customers
WHERE NOT EXISTS (SELECT *
FROM employees
WHERE (employees.FName = customers.CFname
AND employees.LName = customers.CLname)
);
```

The result of the query presents customers not included in the list of the employees. The columns for first names and last names are compared.

The same query with replaced tables in the query and sub-query can be executed to receive the employees not included in the table of the customers (Fig. 8).

The result of the query is presented on the Fig. 10. It combines the employees that are not customers and the customers that are not employees.

The combination of the previous queries using the UNION operator is executed (Fig. 9).

IV. CONCLUSION

Two new operations are introduced in the paper. In future, other properties of them will be studied and some other applications will be discussed. A part of them will be related to Big Data and Data Mining as continuation of the discussed in the present paper.

Abstract—Fuzzy rough sets are the fruit of an intense and long-lasting collaboration effort between fuzzy set theory and rough set theory. Seminal research on the hybridization originated in the late 1980’s, and has inspired generations of researchers from around the globe to address both theoretical and practical challenges. In this paper, we gauge the state-of-the-art in this domain and identify opportunities for further development. In particular, we highlight the potential of fuzzy quantifiers in creating new robust fuzzy rough models, we advocate closer integration with granular computing as a stepping stone for designing rule induction algorithms, and we contemplate the role of fuzzy rough sets vis-à-vis explainable artificial intelligence.

I. INTRODUCTION

FUZZY ROUGH SETS emerge as a combination of fuzzy sets (Zadeh [62], 1965) and rough sets (Pawlak [43], 1982): while the former model vague information by recognizing that membership to certain concepts, or logical truth of certain propositions, is a matter of degree, the latter handle potentially inconsistent information by providing a lower and upper approximation of a concept, using the equivalence classes of an indiscernibility relation as building blocks. Both frameworks can be integrated from at least three different perspectives:

- 1) Concepts may be fuzzy rather than exact, allowing that objects belong to it to varying degrees. For example, in a data set containing information about hotels, one may be interested to characterize the concept of hotels considered as “expensive”, an inherently vague predicate. Then, each hotel’s membership to the fuzzy concept “expensive hotel” will be expressed using a value between 0 (not belonging to the concept at all, i.e., not expensive) and 1 (fully meeting the concept’s membership conditions, i.e., definitely expensive).
- 2) The indiscernibility relation, expressing that objects may or may not be distinguished from each other, may be gradual rather than strict; this reflects the intuitive idea that some objects are more similar to each other than others, and therefore they should be related to a higher degree (again a value between 0 and 1).

- 3) The condition for belonging to the lower and upper approximation may be expressed using *fuzzy quantifiers*. For example, classically an object is a member of the lower approximation of a concept if *all* objects indiscernible from it also belong to the concept. Here, instead of the traditional universal quantifier (\forall), one may use a fuzzy quantifier like “most”. The purpose of such a relaxation is to introduce a measure of tolerance towards inconsistency into the approximations, making them more robust.

The first two principles were already present early on in the work of Fariñas del Cerro and Prade [17], and Dubois and Prade [16], while the third one was first explored in 2007 by the theory of vaguely quantified rough sets [5] and recently revived by the introduction of Choquet-based fuzzy rough sets [49]. In this paper, we want to highlight the potential of fuzzy quantifiers in designing robust and interpretable fuzzy rough set models, which are in particular relevant for applications in data analysis [52]. The latter are becoming more and more widespread, and include, amongst others, feature selection [8], [13], [39], instance selection [29], [50], [51], instance-based classification [25], [30], [32], [33], cognitive networks [37], imbalanced classification [47], [54], multi-instance classification [53] and multi-label classification [35], [55].

Given that many of the aforementioned applications are instance-based or greedy approaches, whereas most successful applications of the rough set paradigm are rule based systems (see e.g. [23], [24]), it may be argued that the full potential of the hybrid theory has not yet been tapped (some notable exceptions are [22], [65], [66]), taking into account also the vast body of existing research on fuzzy rule based systems [2], [18], [26]. An important key to this logical next step lies in the field of granular computing [4], [59], an information processing paradigm centered on the segmentation of complex information into smaller pieces called information granules. Both rough sets and fuzzy sets relate to granular computing; it is well-known that the lower and upper approximation can be represented as unions of simple sets or granules induced from data [60], while Zadeh [64] identified fuzziness as a key part of the granulation in human cognition, and with

This work was supported by the Odysseus programme (grant number G0H9118N) of the Research Foundation – Flanders (FWO).

the help of fuzzy granules, a fuzzy rule based system may be set up. An important advantage of fuzzy rules, and of fuzzy logic in general, is that they allow for explanations using linguistic expressions. This property can be utilized for the development of interpretable machine learning algorithms, a research direction which is currently attracting a lot of researchers' attention [36].

The remainder of this paper is structured as follows: in Section II, we recall important preliminaries from both rough set and fuzzy set theory, while in Section III, we outline the main steps and results of the hybridization process. In Section IV, we pay attention to robust fuzzy rough set models, which play an important role for practical applications of the theory. Finally, in Section V, we offer an informal discussion of ongoing challenges and new opportunities for the hybrid theory.

II. PRELIMINARIES: FUZZY SETS AND ROUGH SETS

A. Rough sets

We first recall Pawlak's definition [43] of rough sets, which is also called the Indiscernibility-based Rough Set Approach (IRSA).

Definition 2.1: Let U be a set of objects and E an equivalence relation expressing indiscernibility, i.e., E is

- reflexive: $(u, u) \in E$,
- symmetric: if $(u, v) \in E$ then $(v, u) \in E$,
- transitive: if $(u, v) \in E$ and $(v, w) \in E$, then also $(u, w) \in E$.

For any $A \subseteq U$, the *lower and upper approximation* of A are defined as:

$$\underline{\text{apr}}_E(A) = \{u \in U : [u]_E \subseteq A\} \quad (1)$$

$$\overline{\text{apr}}_E(A) = \{u \in U : [u]_E \cap A \neq \emptyset\} \quad (2)$$

The couple $(\underline{\text{apr}}_E(A), \overline{\text{apr}}_E(A))$ is called the *rough set* of A . The equations (1) and (2) can be expressed equivalently using logical operators: for $u \in U$,

$$u \in \underline{\text{apr}}_E(A) \Leftrightarrow (\forall v \in U)((v, u) \in E \Rightarrow v \in A) \quad (3)$$

$$u \in \overline{\text{apr}}_E(A) \Leftrightarrow (\exists v \in U)((v, u) \in E \wedge v \in A) \quad (4)$$

It is also easily verified that $\underline{\text{apr}}_E(A) \subseteq A \subseteq \overline{\text{apr}}_E(A)$, which justifies the terms "lower and upper approximation". Moreover, the rough set approximations satisfy various other properties, for example set monotonicity:

$$A \subseteq A' \Rightarrow \underline{\text{apr}}_E(A) \subseteq \underline{\text{apr}}_E(A') \wedge \overline{\text{apr}}_E(A) \subseteq \overline{\text{apr}}_E(A') \quad (5)$$

which expresses that if a concept becomes larger, its approximations naturally should not decrease. On the other hand, relation monotonicity:

$$E \subseteq E' \Rightarrow \underline{\text{apr}}_E(A) \supseteq \underline{\text{apr}}_{E'}(A) \wedge \overline{\text{apr}}_E(A) \subseteq \overline{\text{apr}}_{E'}(A) \quad (6)$$

states that when equivalence classes become larger (more objects are indiscernible from each other), the lower approximation gets smaller, while more objects populate the upper approximation.

In case $\underline{\text{apr}}_E(A) = \overline{\text{apr}}_E(A)$, we call A an *exact set*. An equivalent way of expressing that A is exact is

$$A = \bigcup_{u \in A} [u]_E \quad (7)$$

In other words, A can be seen as a union of basic building blocks or granules, which correspond to equivalence classes of E . We call (7) the *granular representation* of A , and A is also called a *granularly representable set*. The following proposition highlights the special role of the lower and upper approximation as specific exact sets.

Proposition 2.2: For $A \subseteq U$, the greatest granularly representable set that is included in A is equal to $\underline{\text{apr}}_E(A)$, while the smallest granularly representable set that includes A is equal to $\overline{\text{apr}}_E(A)$.

On the other hand, the granular representation is also closely connected with the notion of consistency.

Proposition 2.3: Set $A \subseteq U$ is granularly representable if and only if it satisfies the consistency property, i.e., iff

$$(\forall u, v \in U)((v, u) \in E \wedge u \in A \Rightarrow v \in A) \quad (8)$$

Consistency expresses that if two objects are indiscernible and one of them belongs to a given concept A , the second object should necessarily also be part of the concept. This property is desirable in classification problems, where the goal is to establish meaningful patterns that allow to decide the membership of unseen objects to given decision classes. In this context, objects are also called instances and are characterized by their values for a number of attributes from a set \mathcal{A} . The domain of every attribute $a \in \mathcal{A}$ consists of a finite number of nominal values, and every instance $u \in U$ takes one of those values denoted with $a(u)$. Then, the equivalence relation E is constructed as

$$(u, v) \in E \Leftrightarrow (\forall a \in \mathcal{A})(a(u) = a(v)) \quad (9)$$

The granular representation of rough sets is in particular very useful from the perspective of rule induction. The problem of rule induction for classification tasks amounts to generating a set of rules which relate descriptions of objects by subsets of attributes with particular decision classes. Basic granules, from which rough sets are composed, can be interpreted as human readable "if..., then..." rules, and can be used to construct a rule based inference system as a prediction model. Well-known examples of rule induction algorithms are LEM2 [23] and MODLEM [24].

Pawlak's theory has been generalized in various different ways. For example, dropping the symmetry requirement from E leads to the Preorder-based Rough Set Approach (PRSA, [40]), which contains as a special case the Dominance-based Rough Set Approach (DRSA, [21]). In the latter, the domain of attributes now contains ordinal values, and the indiscernibility relation is replaced by a dominance relation. For clarity and brevity of the exposition, in the remainder of this paper we will focus on the indiscernibility-based approach, although many of the presented results remain valid for more general settings.

B. Fuzzy sets

Given a universal set U , Zadeh defined a fuzzy set A in U simply as a mapping from U to the unit interval $[0, 1]$, where $A(u)$ is called the membership degree of object u to A . It expresses to what extent u satisfies the vague property expressed by the fuzzy set A . For example, if U is a set of hotels from a given area, we may evaluate their expensiveness, based on their quoted nightly rate for a double room, as a fuzzy set A in U . Clearly, the assignment of membership degrees is both subjective and context-dependent, as it would depend for example on the budget of the person making the booking, and the area where the search is performed. However, an intuitive constraint in this case would be that the higher the quoted rate, the larger the membership degree should be. In this example, as in most practical applications of fuzzy set theory, there is an underlying numerical scale (a subset of the real numbers) on which the evaluation is made, and the ordering on that scale constrains the assignment of membership degrees.

In a similar vein, a binary fuzzy relation R in U is defined as a fuzzy set in U^2 , i.e., for any two objects u and v in U , $R(u, v)$ expresses the degree to which they relate. Fuzzy relations may be used for example to generalize the equivalence relation E from Section II-A, to establish to what extent two objects are *similar* (as opposed to a black-or-white assessment whether they are indiscernible or not). Such a fuzzy relation R should be at least reflexive and symmetric, i.e.,

$$R(u, u) = 1 \quad (10)$$

$$R(u, v) = R(v, u) \quad (11)$$

should hold for any u and v in U . In order to accommodate for the transitivity property, we first need an extension of the classical conjunction operator \wedge .

Definition 2.4: A triangular norm, or shortly t-norm, is a mapping $T : [0, 1]^2 \rightarrow [0, 1]$ that is commutative, associative, increasing in both arguments, and that satisfies the boundary condition $T(1, x) = x$ for all $x \in [0, 1]$.

Well-known representatives of the class of t-norms include the minimum, the product, and the Łukasiewicz t-norm defined by $T_{\mathbb{L}}(x, y) = \max(0, x + y - 1)$ for x, y in $[0, 1]$. The choice for a particular t-norm depends on the particular properties that one is interested in; for a comprehensive overview, we refer to [31].

Using a t-norm, we may now impose a kind of transitivity on fuzzy relations, and therefore extend the notion of an equivalence relation.

Definition 2.5: Let T be a t-norm. A fuzzy relation R in U that is reflexive, symmetric and satisfies

$$T(R(u, v), R(v, w)) \leq R(u, w) \quad (12)$$

for any u, v, w in U is called a fuzzy T -equivalence relation. Apart from logical conjunction, we will also require an extension of the boolean implication operator \Rightarrow .

Definition 2.6: An implicator is a mapping $I : [0, 1]^2 \rightarrow [0, 1]$ that is decreasing in its first argument and increasing

in its second one, and that satisfies the boundary conditions $I(0, 0) = I(0, 1) = I(1, 1) = 1$ and $I(1, 0) = 0$.

There exist numerous ways to construct implicators. Again, a detailed overview is out of the scope of this paper, and may be found in e.g. [3]. A popular approach is to associate implicators to t-norms by means of *residuation*, leading to the following definition of residuated implicators, or shortly R-implicators.

Definition 2.7: The R-implicator I_T associated to a t-norm T is defined by, for x, y in $[0, 1]$:

$$I_T(x, y) = \sup\{z \in [0, 1] \mid T(x, z) \leq y\} \quad (13)$$

As an example, the R-implicator associated to the Łukasiewicz t-norm can be obtained as $I_{T_{\mathbb{L}}}(x, y) = \min(1, 1 - x + y)$.

Finally, we recall that subsethood for fuzzy sets is defined as follows [62]: for fuzzy sets A and B in U ,

$$A \subseteq B \Leftrightarrow (\forall u \in U)(A(u) \leq B(u)) \quad (14)$$

III. HYBRIDIZATION: GENERAL FUZZY ROUGH SET MODEL

The equations (3) and (4) for determining membership to the classical lower and upper approximations can be “fuzzified” by making use of fuzzy logical connectives. This leads to the following definition [48], [6], [11].

Definition 3.1: Let A be a fuzzy set in U , R a fuzzy relation in U , I an implicator and T a t-norm. The lower and upper approximation of A are defined as, for $u \in U$,

$$\underline{\text{apr}}_R(A)(u) = \inf_{v \in U} I(R(v, u), A(u)) \quad (15)$$

$$\overline{\text{apr}}_R(A)(u) = \sup_{v \in U} T(R(v, u), A(u)) \quad (16)$$

The couple $(\underline{\text{apr}}_R(A), \overline{\text{apr}}_R(A))$ is called the *fuzzy rough set* of A . If $\underline{\text{apr}}_R(A) = A = \overline{\text{apr}}_R(A)$, A is called an exact fuzzy set.

Take note how these definitions extend their classical counterparts:

- 1) Object u belongs to the lower approximation of A to the extent that *for all* objects v , *if* v is related to u by R , *then* v should belong to A .
- 2) Object u belongs to the upper approximation of A to the extent that *there exists* an object v , such that *if* v is related to u by R , *and* v belongs to A .

In other words, the inf and sup operators naturally represent the \forall and \exists quantifier from Eq. (3) and (4), respectively, while the implicator I and t-norm T fulfil the role of the logical implication \Rightarrow and conjunction \wedge . When A is a classical, non-fuzzy set and R is a crisp equivalence relation, we again obtain Pawlak’s model. Depending on the specific choice of fuzzy connectives I and T , and the fuzzy relation R , some properties of this original model may or may not be preserved (see [12] for more details).

An important question is whether exact fuzzy sets possess a granular representation analogous to Eq. (7), as it would allow the above approximations to be used for generating fuzzy rules in a similar way as is done with crisp granules. Degang et al. [14] were the first to address this issue by formalizing the

notions of a fuzzy granule and granular representability of fuzzy sets.

Definition 3.2: Let R be a fuzzy T -equivalence relation in U for a given t-norm T and $\lambda \in [0, 1]$. The fuzzy granule corresponding to R , λ and T is the fuzzy set R_λ in U , defined by

$$R_\lambda(u) = \{(v, T(R(v, u), \lambda)); v \in U\} \quad (17)$$

We call a fuzzy set A in U granularly representable if

$$A = \bigcup \{R_{A(u)}(u); u \in U\} \quad (18)$$

In other words, A is granularly representable if it is the union of fuzzy granules $R_\lambda(u)$, where $\lambda = A(u)$ for each object u . The following proposition reveals that for particular choices of I and T , exact fuzzy sets indeed correspond to granularly representable ones, and vice versa.

Proposition 3.3: Let A be a fuzzy set in U , T a left-continuous t-norm and I its R-implicator. Then A is exact if and only if it is granularly representable.

Along the same lines, we can also generalize Proposition 2.2 and 2.3.

Proposition 3.4: For a fuzzy set A in U and a fuzzy T -equivalence relation, the greatest granularly representable fuzzy set that is included in A is equal to $\underline{\text{apr}}_R(A)$, while the smallest granularly representable set that includes A is equal to $\overline{\text{apr}}_R(A)$.

Proposition 3.5: Let R be a fuzzy T -equivalence relation. Fuzzy set A in U is granularly representable if and only if it satisfies the fuzzy consistency property, i.e., iff

$$(\forall u, v \in U)(T(R(v, u), A(u)) \leq A(v))$$

Note how fuzzy consistency provides us with a softened version of Eq. (8): the more similar u and v are, and the higher u 's membership to A , the more v should also belong to A .

IV. ROBUST FUZZY ROUGH SETS

The model of fuzzy rough sets described in the previous section offers considerable strength and flexibility, and lends itself very well for handling datasets with real-valued attributes, where fuzzy T -equivalence relations can be constructed by taking into account the distance between individual instances' attribute values. However, it may still be too rigid when applied in practical problems of data analysis, due to the occurrence of outliers. By the latter, we mean instances that do not follow the general data distribution, and which may negatively impact the quality of the fuzzy-rough approximations. In extreme cases, the lower approximation of a concept may be empty, while its upper approximation may contain all instances fully.

The root of the problem lies in the use of the inf and sup operators which, as we explained, correspond to the \forall and \exists quantifier, respectively. Because of this, an instance u will be fully excluded from $\underline{\text{apr}}_R(A)$ as soon as there exists another instance v such that $R(v, u) = 1$ and $A(v) = 0$, while on the other hand u will fully belong to $\overline{\text{apr}}_R(A)$ when an object

v can be found such that $R(v, u) = 1$ and $A(v) = 1$. This will occur independently of the choice of the implicator I and the t-norm T . While this effect may be mitigated by a thoughtful choice of the fuzzy relation R , it cannot be ruled out altogether as (partial) inconsistencies are commonplace in real applications.

In classical rough set theory, researchers also faced this problem, leading to probabilistic approaches like Ziarko's Variable Precision Rough Set (VPRS) model [67]. The latter relaxes Eq. (3) and (4) into

$$u \in \underline{\text{apr}}_E^p(A) \Leftrightarrow \frac{|[u]_E \cap A|}{|[u]_E|} \geq p \quad (19)$$

$$u \in \overline{\text{apr}}_E^q(A) \Leftrightarrow \frac{|[u]_E \cap A|}{|[u]_E|} > q \quad (20)$$

where $1 \geq p > q \geq 0$ are parameters of the model. In other words, an object belongs to the VPRS lower approximation if at least a fraction p of its equivalence class belongs to A , while it belongs to the upper approximation if more than a fraction q of $[u]_E$ is inside A . The model assumes that U is finite (which is not a problem considering that its application is in data analysis), and that $p > q$, to ensure that $\underline{\text{apr}}_E^p(A) \subseteq \overline{\text{apr}}_E^q(A)$. When $p = 1$ and $q = 0$, we recover Pawlak's original equations (3) and (4). In general, probabilistic rough set approaches have been exploited successfully for classification purposes, most notably within Yao's framework of three-way decisions [61].

Ziarko's VPRS model served as an inspiration source for different robust fuzzy rough set proposals. One of them, the Vaguely Quantified Rough Set (VQRS) model [5] softens the membership criterion for an object u to belong to the lower approximation of A into "most elements of $[u]_E$ are inside A ". Similarly, u belongs to the VQRS upper approximation of A to the extent that "at least some elements in $[u]_E$ belong to A ". To formalize this idea, the inherently fuzzy quantifiers "most" and "at least some" are modeled as specific fuzzy sets in the unit interval [63]:

Definition 4.1: A fuzzy set Q in $[0, 1]$ is called a regular increasing monotone (RIM) quantifier if Q is non-decreasing, $Q(0) = 0$ and $Q(1) = 1$.

The class of RIM quantifiers includes as special cases the existential and the universal quantifier:

$$Q_\exists(x) = \begin{cases} 0, & x = 0 \\ 1, & x > 0 \end{cases} \quad Q_\forall(x) = \begin{cases} 0, & x < 1 \\ 1, & x = 1 \end{cases}$$

Examples of RIM quantifiers that also take on values from the interior of the unit interval can be obtained using the following parametrized formula [5], for $0 \leq \alpha < \beta \leq 1$, and x in $[0, 1]$,

$$Q_{(\alpha, \beta)}(x) = \begin{cases} 0, & x \leq \alpha \\ \frac{2(x-\alpha)^2}{(\beta-\alpha)^2}, & \alpha \leq x \leq \frac{\alpha+\beta}{2} \\ 1 - \frac{2(x-\beta)^2}{(\beta-\alpha)^2}, & \frac{\alpha+\beta}{2} \leq x \leq \beta \\ 1, & \beta \leq x \end{cases}$$

For example, $Q_{(0.1, 0.6)}$ and $Q_{(0.2, 1)}$ could be used to represent the fuzzy quantifiers "at least some" and "most" from natural

Fig. 1. The RIM quantifiers $Q_{(0.1,0.6)}$ (left) and $Q_{(0.2,1)}$ (right)

language. They are depicted in Figure 1. In general, assuming RIM quantifiers Q_1 and Q_2 such that $Q_1 \subseteq Q_2$, we may define the VQRS approximations of A : for $u \in U$,

$$\underline{\text{apr}}_E^{Q_1}(A)(u) = Q_1\left(\frac{|[u]_E \cap A|}{|[u]_E|}\right) \quad (21)$$

$$\overline{\text{apr}}_E^{Q_2}(A)(u) = Q_2\left(\frac{|[u]_E \cap A|}{|[u]_E|}\right) \quad (22)$$

The above definition has the peculiarity that although both the set to be approximated and the equivalence relation are non-fuzzy, the resulting approximations may well be fuzzy. The reasoning behind this is that for example the membership degree in Eq. (21) evaluates the degree of fulfilment of the condition “ Q_1 elements of $[u]_E$ are in A ”. Note that if $Q_1 = Q_\forall$ and $Q_2 = Q_\exists$, we again arrive at Pawlak’s lower and upper approximation, while the VPRS equations (19) and (20) are also special cases of (19) and (20) using the RIM quantifiers

$$Q_1(x) = \begin{cases} 0, & x \leq p \\ 1, & x \geq p \end{cases} \quad Q_2(x) = \begin{cases} 0, & x < q \\ 1, & x > q \end{cases}$$

The VQRS equations may be further generalized to a fuzzy set A and a fuzzy relation R ; for details, we refer to [5]. Despite its intuitive appeal, the VQRS model has an important shortcoming which it shares with the VPRS model: it does not satisfy relation monotonicity, Eq. (6). This is in particular problematic in applications where the (fuzzy) indiscernibility relation is iteratively refined by adding more information (additional attributes). For example, in [7] it is shown how this affects the operation of the greedy QuickReduct feature selection algorithm.

A solution to this problem can be found by revisiting the equations (15) and (16) and replacing the inf and sup operators by less extreme ones. First note that for finite universes, inf and sup correspond to min and max, respectively. So, the lower approximation (15) is determined solely by the smallest one among all $I(R(v, u), A(u))$ values, and the single largest value $T(R(v, u), A(u))$ will set the upper approximation. A more balanced evaluation is offered by using ordered weighted average (OWA) operators [57]: given an input vector of $n \geq 1$ real values $\langle a_1, \dots, a_n \rangle$ and a weight vector $W = \langle w_1, \dots, w_n \rangle$ such that each $w_i \in [0, 1]$ and $\sum_{i=1}^n w_i = 1$, we first order the input values a_i from large to small obtaining $\langle c_1, \dots, c_n \rangle$ and then compute

$$OWA_W \langle a_1, \dots, a_n \rangle = \sum_{i=1}^n w_i c_i \quad (23)$$

This leads to the definitions of the OWA-based lower and upper approximation [9]:

$$\underline{\text{apr}}_R^{W_1}(A)(u) = OWA_{W_1} \underbrace{I(R(v, u), A(u))}_{v \in U} \quad (24)$$

$$\overline{\text{apr}}_R^{W_2}(A)(u) = OWA_{W_2} \underbrace{T(R(v, u), A(u))}_{v \in U} \quad (25)$$

Using $W_1 = \langle 0, \dots, 0, 1 \rangle$ and $W_2 = \langle 1, 0, \dots, 0 \rangle$, we obtain the original Eq. (15) and (16). Because of the monotonicity properties of T , I and the OWA operator, relation monotonicity is guaranteed, and moreover it always holds that

$$\underline{\text{apr}}_R(A) \subseteq \underline{\text{apr}}_R^{W_1}(A) \text{ and } \overline{\text{apr}}_R^{W_2}(A) \subseteq \overline{\text{apr}}_R(A) \quad (26)$$

In other words, OWA-based fuzzy rough sets indeed relax the original definitions, enlarging the lower approximation and restricting the upper one. In [56], different weighting schemes were discussed and evaluated experimentally.

Recently, in [41] it was shown that for certain choices of the t-norm T (including the product and Łukasiewicz t-norm, but not minimum), the OWA-based lower and upper approximations of any fuzzy set A are exact sets, i.e.

$$\underline{\text{apr}}_R(\underline{\text{apr}}_R^{W_1}(A)) = \overline{\text{apr}}_R(\underline{\text{apr}}_R^{W_1}(A)) = \underline{\text{apr}}_R^{W_1}(A) \quad (27)$$

$$\underline{\text{apr}}_R(\overline{\text{apr}}_R^{W_2}(A)) = \overline{\text{apr}}_R(\overline{\text{apr}}_R^{W_2}(A)) = \overline{\text{apr}}_R^{W_2}(A) \quad (28)$$

This means in particular that these approximations possess a granular representation, and can be used as a basis for fuzzy rule induction algorithms, as discussed in the next section.

V. DISCUSSION: CHALLENGES AND OPPORTUNITIES FOR FUZZY ROUGH SETS

Even though the VQRS model, considering its violation of the relation monotonicity property, has been mostly abandoned in favour of the OWA-based approach, its interpretation of membership to the fuzzy-rough approximations in terms of fuzzy quantifiers expressing “most” and “at least some” is arguably more intuitive and transparent than the one using the rather less compact representation of OWA weight vectors.

Yet this does not mean that OWA fuzzy rough sets are isolated from vague quantification. In fact, as explained in [49], from any OWA weight vector $W = \langle w_1, \dots, w_n \rangle$, a corresponding RIM quantifier Q can be derived by setting

$$Q(x) = \sum_{i \leq xn} w_i \quad (29)$$

and, vice versa, for every RIM quantifier Q and $n \geq 1$, the associated OWA weights w_i ($i = 1, \dots, n$) are determined by

$$w_i = Q\left(\frac{i}{n}\right) - Q\left(\frac{i-1}{n}\right) \quad (30)$$

As such, the weight vectors W_1 and W_2 featured in Eq. (24) and (25) are mutually interchangeable with their VQRS counterparts Q_1 and Q_2 . The resulting membership degrees, however, carry a different meaning; for example, $\underline{\text{apr}}_R^{W_1}(A)(u)$ should be understood as the truth value of the statement “for

most objects in U , it holds that if they are indiscernible from u , then they also belong to A "; in other words, the quantification also takes into account objects completely unrelated to u (i.e., fully discernible from u), while for the computation of the membership to the VQRS lower approximation, these objects are excluded.

A more serious limitation of the OWA fuzzy rough set model lies in the fact that it treats all objects symmetrically during the aggregation process, i.e., an individual object's impact is determined merely by its fulfillment of a specific logical formula. In practice, this means that we hypothesize that "a limited amount" of objects are outliers, and that their effect will be cancelled out by the chosen weighting scheme. Suppose however that we have specific knowledge that some specific objects are in fact certainly outliers, e.g., based on an outlier score that was calculated for them separately. Then, a more natural way to evaluate whether an object u belongs to the lower approximation of concept A is by checking if all objects indiscernible from u , *except* perhaps those which are considered outliers, belong to A .

In order to accommodate the above and other related use case scenarios, new definitions were proposed for the fuzzy-rough lower and upper approximation in [49] recently. They are based on the Choquet integral, a generalization of the classical Lebesgue integral to non-additive measures which has become popular as an aggregation function in decision making [20]. It was shown how the resulting Choquet-based fuzzy rough sets (CFRS) contain the OWA-based model as a special case, while inheriting some of its desirable properties, including set and relation monotonicity. At the same time, they also maintain the intuitive interpretation in terms of vague quantification. Considering that most of the existing fuzzy rough set models still rely on "traditional" approaches to fuzzy quantifiers such as those proposed by Zadeh [63] and Yager [58], which were shown to suffer from some serious conceptual flaws [19], this opens up exciting research opportunities involving more recent developments (see e.g. [15] for an overview).

An important unresolved question about the new CFRS model is whether it still conforms to the granular structure that the OWA-based model from Eq. (24) and (25), and the traditional fuzzy rough set model from Eq. (15) and (16) exhibit, in other words: whether its approximations are exact fuzzy sets in the sense of Eq. (18). While technical in nature, if this question can be answered positively, it opens the doors to fuzzy rule induction methods based on these fuzzy-rough approximations. Indeed, the fuzzy granules corresponding to the approximations can be used inside the antecedent part of fuzzy rules, and an unseen test object's membership in them may be interpreted as the firing strength of the corresponding rule.

As a concrete example, let us consider rule-based classification. In this case, U is partitioned into a number of decision classes (concepts). Let C be one such decision class, and denote its lower approximation, computed according to one of the models discussed in this paper, by $\underline{apr}(C)$. Then, if

$\underline{apr}(C)$ is granularly representable, by Eq. (18) a corresponding decision rule will be generated for every training object u , such that for a given test object v , the firing strength of this rule is obtained as

$$T(R(v, u), \underline{apr}(C)(u)) \quad (31)$$

in other words, as a conjunction between $R(v, u)$, the observed similarity between u and v , and $\underline{apr}(C)(u)$, the membership of the training object u to the lower approximation.

Decision rules based on the lower approximation are usually called "certain" rules, while we refer to those based on the upper approximation as "possible" rules, distinguishing their relative strength. More generally, fuzzy decision rules can be derived from any granularly representable fuzzy set associated to decision classes, for instance from the so-called granular fuzzy-rough approximation introduced in [42], which is defined as the closest granularly representable fuzzy set (w.r.t. a certain loss function) to a given concept, and which is obtained as the result of a linear programming problem.

In practice, however, generating one rule per training object is not a viable approach, and an important challenge is therefore to design proper rule induction algorithm that can at the same time reduce the number of rules, as well as maximize the number of objects that each rule covers. Such a strategy was already pursued in [28], where it was combined with fuzzy rough set guided feature selection, and various other attempts (see e.g. [22], [38], [65], [66]) have also been made to integrate fuzzy rough sets and rule induction; yet, a convincing proposal of a "fuzzy LEM" classification algorithm is still missing and could represent a breakthrough in this domain, not in the least from the perspective of interpretable machine learning.

Indeed, the generation of compact fuzzy rules benefits the human understanding of classification algorithms based on them, as rule-based models are some of the most interpretable models, and they closely resemble human cognition [1]. In [2], various criteria were distinguished for interpretability at different levels of a fuzzy rule-based system, including linguistic variables and fuzzy granules. An integration of these criteria with fuzzy-rough rule induction is therefore at hand to develop a coherent and compact model of interpretable granular computing. Apart from the granules themselves, an important role should again be reserved for fuzzy quantifiers, as they are useful to summarize knowledge in a concise, linguistic way.

Individual and Collective Self-Development: Concepts and Challenges

Marco Lippi, Stefano Mariani, Matteo Martinelli, Franco Zambonelli

 Email: name.surname@unimore.it

Abstract—The increasing complexity and unpredictability of many ICT scenarios will represent a major challenge for future intelligent systems. The capability to dynamically and autonomously adapt to evolving and novel situations, with a partial or limited knowledge of the domain, both at the level of individual components and at the collective level, will become a crucial need for smart devices acting in many application domains. In this paper, we envision future systems able to self-develop mental models of themselves and of the environment they act in. Key properties will include: learning models of own capabilities; learning how to act purposefully towards the achievement of specific goals; and learning how to act in the presence of others, i.e., at the collective level. In our work, we will introduce the vision of self-development in ICT systems, by framing its key concepts and by illustrating suitable application domains. Then, we overview the many research areas that are contributing or can potentially contribute to the realisation of the vision, and identify some key research challenges.

Index Terms—Self-development, sense of agency, learning, self-adaptation, self-organization.

I. INTRODUCTION

HUMAN infants, since their early months, start experiencing with their own body, moving hands, touching objects, and interacting with people around. Such activities are part of an overall process of self-development (a.k.a. autonomous mental development), which lets them gradually develop cognitive and behavioural capabilities [1]. These skills include the capability to recognize situations around, the sense of self, the sense of agency (i.e., understanding the effect of own actions in an environment), the capability to act purposefully towards a goal, and some primitive social capabilities (i.e., knowing how to act in the presence of others).

The possibility of building ICT systems capable – as humans – of self-developing their own mental and social models and to act purposefully in an environment, is increasingly recognized as a key challenge in many areas of artificial intelligence (AI), such as robotics [2], intelligent IoT and smart environments [3], [4], autonomous vehicles management [5], [6].

Indeed, for small-scale and static scenarios, and for simple goal-oriented tasks, it is possible “hardwire” a model of the environment within a system, alongside some pre-designed plans of action. However, for larger and dynamic scenarios, and for complex tasks, individual components of ICT systems should be able to autonomously (i.e., without human supervision): (i) build environmental models and continuously update them as

situations evolve; (ii) develop the capability of recognizing and modelling the effect of their own actions on the context (which variables of the environment can or cannot be directly affected by which actuators, which variables and actuators relate to each other); and (iii) learn to achieve goals on this basis and depending on the current situation; (iv) learn how to organize and coordinate actions among multiple distributed components whenever necessary.

The main contribution of this paper is to frame the key concepts of self-development in ICT systems and to identify challenges and promising research directions. More in particular: Section II introduces a general conceptual framework for the (continuous and adaptive) process of self-development, both at the individual and at the collective level, and sketches key application scenarios; Section III analyzes the most promising approaches in the area of machine learning, multiagent systems, and collective adaptive systems that can contribute with fundamental building blocks towards realizing the vision of self-development, each *per se* challenging; Section IV identifies additional horizontal challenges to be attacked, emphasizing the key role that the self-adaptive and self-organizing research community could play. Finally, Section V concludes by sketching our current and future research work in the area.

II. FRAMEWORK AND APPLICATIONS

The term “self-development” is used to indicate the process carried out by infants during the early stages of their life [1] but, more generally, it can be also associated to the developmental nature of agents that live and interact with a novel environment. The idea of our framework is depicted in Figure 1. At the *individual* level, the first contacts an agent has with a new environment are through *embodiment and perception*: it typically tries to move and interact, in order to test the effect of its own action, so as to acquire a *sense of agency*. Only after these skills have been sufficiently developed, the agent can start behaving in a *goal-oriented* way, by choosing the sequence of actions that can bring to the fulfilment of a goal.

Clearly, the individual level quickly turns into a *collective* one, where the agent has to face other agents, which are not under its control: thus, the agent learns to recognize *self and non-self*, as well as to develop *strategic thinking*, by choosing its own actions by taking into account the behaviour of the other agents. As the complexity grows, the agent will need to

Fig. 1: The conceptual framework of self-development.

understand whether it can *communicate* with others, and with which protocols, as well as *coordinate* in order to jointly act towards a common goal, possibly through the creation of an *institution*.

The whole development, at both the individual and collective level, can be seen as a never-ending, cyclic process, where agents have to continuously adapt to new situations and environments.

A. The Individual Level

At the individual level, an agent \mathcal{X} immersed in an environment can observe (or sense) a set of variables $\mathcal{V} = \{v_1, v_2, \dots, v_n\}$. Internal variables that describe the status of the agent are included in this set as well. The agent can interact with the environment through a set of “actions” $\mathcal{A} = \{a_0, \dots, a_{n-1}, null\}$, including the *null* action.

Embodiment and Perception. Initially, the agent needs to autonomously identify and recognize the components of sets \mathcal{A} and \mathcal{V} : this means that it should get acknowledged of its actuating and sensing skills. Even without resorting to complex AI techniques, methods from the reflective and self-adaptive programming systems can effectively apply in this phase [7] to let the agent dynamically self-inspect its capabilities and start analyzing the observed variables. Still in this phase, the agent can also start acquiring some understanding of the relations between the observed variables over time, as well as some simple prediction capabilities.

Sense of Agency. After the first phases that are mostly dealing with perception, the agent needs to understand what are the effects of each $a_j \in \mathcal{A}$ on \mathcal{V} . This can happen even by chance, with random actions, thus trying to apply actions, without any goal in mind, just to see their effects [2]. Throughout this process, the agent will eventually recognize that, given a current state v^t and the application of an action a_i , the environment will reach (with some probability) a different state v^{t+1} . This mechanism enables the construction of the basic sense of agency [1], and of the sense of causality.

Goal-orientedness. As the agent acquires more sophisticated skills, it can start applying \mathcal{A} with a specific goal in mind. Given the current state v^t and a desired future state v^g (the desired “state of the affairs”), the agent applies the acquired sense of agency by applying the actions that can possibly lead to v^g . This also involves achieving the capability of planning the required sequence of actions to achieve a specific goal.

Self and Non-Self. After an individual agent starts interacting with the environment and testing the effects of its own actions \mathcal{A} , it recognizes that such actions have effect on the environment. As an immediate consequence, it also understands that there are effects that are not under its own control. That is, there are “non-self” entities acting in the environment, too. By learning how to apply \mathcal{A} , the agent also learns the limits of such actions because of non-self entities affecting v^t .

Strategic Thinking. Once the agent has built a world model (how \mathcal{A} affects v^t) and has included the mental models of others (non-self) [8], it can start designing strategies. That is, it can recognise that there are goals that it can possibly (or hopefully) attain only by accounting for the actions of others.

Once again, we remark that self-development is not to be conceived as a “once-and-for-all” process. Rather, it is a life-long process: environments can be dynamic, new variables may become available and thus enable more detailed observations. Also, new actions may become feasible or, the other way round, be no longer be available. This requires the agents to re-tune their learnt sense of agency, and re-think how to achieve goals in isolation and in the presence of non-self entities.

B. The Collective Level

As multiple agents enter the arena, each of them quickly recognizes that there are goals that cannot be achieved in isolation or by simply applying strategic thinking, but they rather need a deep interaction among all the actors. Therefore, as part of their individual self-development, also need to develop some forms of “autonomous social engagement”.

Communication. A first, necessary, step is to identify the way in which agents can communicate and exchange messages. Agents should thus be provided with a specific set of “communication actions”, which could take the form of explicit communication acts (messages) or implicit actions that aim at influencing the others, i.e., by leaving signs in the environment (stigmergy) or by acting in a way that is easily noticeable by others (behavioural implicit communication)[9]. In some cases, the agent has to learn how to receive and send such messages, as a social form of action and perception.

Coordination. When evaluating the possible communication actions, each agent understands the way in which such acts can be exploited to control some environmental variables, and even those that are not (fully) controllable by itself alone. Therefore, such explorative behavior enables the learning of basic forms of coordination, which can be thought of as a social form of learning the sense of agency.

Institution. After exploring coordination protocols, the agents can eventually “institutionalize” their way of interacting. That is, they will learn those acceptable social patterns of coordination, and the set of social norms and social incentives, that enables them to systematically achieve goals together [10].

As in the single-agent setting, a dynamic environment or an evolving agent population may require the above collective process to assume a continuous cyclic nature. We hereby remark that the communication, coordination, and institution stages are not necessary to promote complex goal-oriented collective actions [11]. Yet, whenever communication protocols exist, the self-development process will naturally and gradually learn how to exploit them.

C. Application Scenarios

There are diverse application scenarios that can potentially take advantage of systems capable of self-development.

Robotics is the area which first identified the profitability of building robots capable of self-development [12]. In particular, it is necessary when the robot gets damaged while in operation, and has to develop a novel understand of what it can do according to its residual operational capabilities. At the collective level, the autonomous evolution of communication and coordination capabilities can be of fundamental importance to acquire the capability of the collective to act in unknown and dynamically changing scenarios [13].

Smart factories, as collective robotic systems, can be seen as an aggregated group of components that act together in order to achieve a production goal. Beside their basic scheme of functioning, defined at design time, if one component of the manufacturing system breaks or has some unexpected behaviour, the manufacturing system should ideally adapt to the new situation, and self-develop capabilities of acting so as to overcome the problem without undermining production [14]. The need for adaptability and flexibility is indeed explicitly recognized as a key challenge in Industry 4.0 initiatives [15].

Smart homes can facilitate our interactions with the environment and increase our safety and comfort. We envision

that once a new home is built, its smart devices could start exploring their own individual and collective capabilities, so as to eventually learn how they can affect the home environment, and apply such capabilities once users will start populating it. This will also require to continuously adapt to habits and preferences of users, accommodate new devices and services, tolerate partial failures. Our preliminary experience suggests the feasibility of the vision [3].

Smart cities as well can potentially take advantage of self-development approaches [16]. However, unlike in a smart home, a smart city is not a system free to explore the effect of its actions and interactions, and eventually become capable to act in a goal-oriented way. Thus, for this scenario (but most likely also for smart factories), simulation-based approaches should probably be exploited: system components will be made self-developing in a simulated environment, before being eventually deployed in the real world [6].

III. RESEARCH APPROACHES

The idea of self-development, at both the individual and collective level, has been widely investigated in areas such as cognitive psychology, neuroscience, philosophy, and ethics [2]. We hereby focus on the computational perspective, and in particular on the most recent approaches that can contribute to realise the self-development vision (Figure 2). Although most of these approaches can play a fundamental role and are already providing precious insights on the problems, they still have to attack several challenges to become practical tools for future self-developing systems.

We do not focus here on the basic levels of individual self-development, i.e., perception and embodiment, in that tools already exist to give agents sophisticated sensing abilities (e.g., convolutional neural networks to recognize objects, scenes, and activities [17]) and the capability of controlling their own actuators purposefully.

A. Goal-oriented Learning

The broad area of reinforcement learning shares with our vision the objective of training machines to act in a goal-oriented way in a specific context. However, despite the amazing recent results in the area, in particular with deep Q-learning [18], most current approaches do not aim at building systems with a sense of agency and capable of developing an interpretable world model, but rather at achieving goals based on explicit, domain-based rewards, that are named *extrinsic*. This makes most approaches highly ineffective in scaling up to learning tasks in complex contexts, or across domains, or despite the ever-changing dynamics of the environment.

Curriculum-based approaches to machine learning go somewhat in the direction of gradually developing the capability to act in complex scenarios [19]. The agent is first trained on simple tasks, and the gained knowledge is accumulated and exploited in increasingly complex scenarios, where further skills can thus be effectively learnt. Yet again, most of these approaches do not focus on the development of a world model and of an explicit sense of agency.

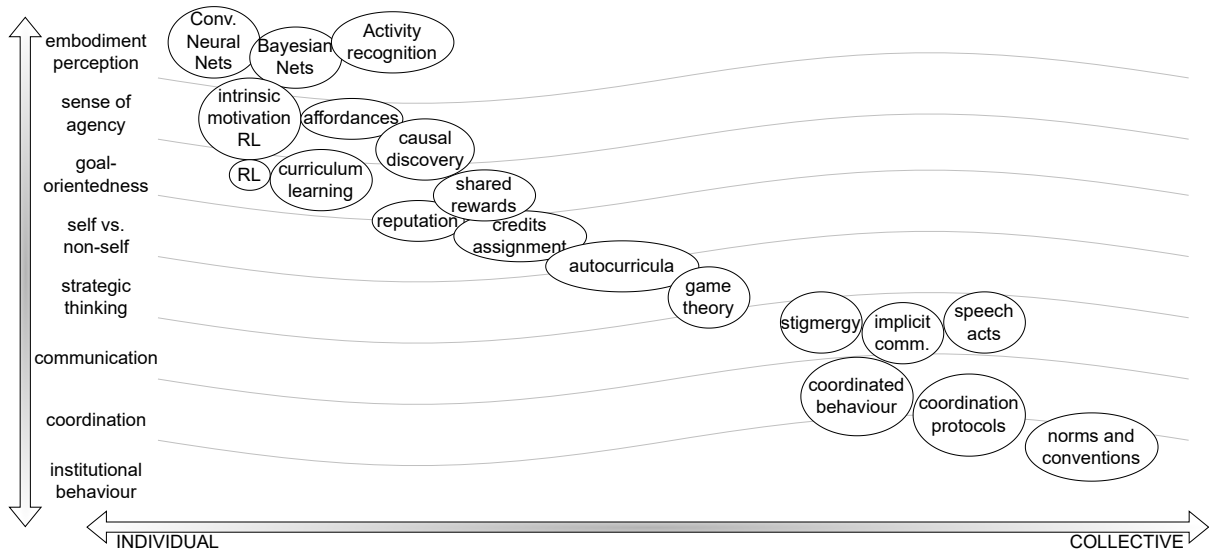

Fig. 2: Key techniques for self-development.

Reinforcement learning approaches based on *intrinsic* rewards [20], instead, more closely exploit the idea of exploring the world to develop a sense of agency. In fact, while extrinsic rewards are typically designed by a “teacher” (e.g., the score in a videogame) intrinsic rewards are developed by the agent itself to satisfy its curiosity (i.e., when it discovers how to achieve specific tasks). For example, in [21] intrinsic rewards are computed as the error in forecasting the consequence of the action performed by the agent given its current state.

Recent approaches based on the theory of affordances [22] propose to have agents gradually learn the effects of their actions. By having them act in constrained environments where only a limited set of actions apply, they eventually develop an explicit sense of agency, i.e., a model of how their actions affect the environment.

In any case, all these approaches face the key challenge of building general conceptual and practical tools to: (i) learn to effectively act in an environment by exploiting the power of model-free sub-symbolic (deep learning) approaches; and, at the same time, (ii) learn incremental and reusable causal models of the world. The latter being increasingly recognized as a key ingredient for intelligence and self-development.

B. Learning causality

Understanding and leveraging *causality* is recognized as a key general challenge for AI in the coming years [23]. Judea Pearl [24] has proposed the idea of a “causal hierarchy” (also named “ladder of causation”) to define different levels of causality recognition and exploitation by an intelligent agent. The first level consists in simply detecting causal relations as associations, whereas the second one assumes the possibility to intervene in the environment and observe the effects of the taken actions. Finally, the third level enables reasoning and planning on the basis of counterfactual analysis. Such layers correspond to some of the phases of the self-development

loop we defined: the first one is mostly involved in the perception phase, whereas the second one is associated to the development of a sense of agency and to recognition of self and non-self. The final layer clearly enables goal-oriented behaviour, strategic thinking, and collective coordination.

Bayesian and causal networks are among the models that are most widely exploited in order to build interpretable causal models of the world [24]. A recent contribution that is in line with the ideas we envision for self-development is the application of curriculum learning to the problem of learning the structure of Bayesian networks [25]. On a pure sub-symbolic level, on the other hand, another recent work proposes to learn causal models in an online setting [26], with the aim to find (and strengthen) causal links between input and output variables.

We argue that key challenges in this area concern, again, understanding how to synergetically exploit symbolic and sub-symbolic approaches to learn, represent, and evolve causal models in self-development scenarios, and how to use them to adaptively achieve goals.

C. Autocurricula

When multiple agents act in a shared environment, their actions and their effectiveness in achieving goals are affected by what others do. Game-theoretic approaches to strategic thinking have deeply investigated this problem and the decision-making processes behind [27]. In this context, it has also been shown that agents can effectively learn in autonomy to improve their performance in dealing with others [28].

However, when moving from theoretical settings (e.g., the prisoner’s dilemma) to complex and realistic scenarios where agents have complex goals (e.g., hide-and-peek in a building), peculiar phenomena arise. The more one agent learns, the more it challenges others, triggering a continuous increase in complexity of behaviour, ultimately enabling to incrementally learn

more sophisticated means to act. This somewhat resembles the increase of complexity that agents face in curricula approaches to reinforcement learning. The key difference being that, in the presence of multiple agents, the increase in complexity and capabilities of agents is promoted and self-sustained by the system itself, hence the term *autocurricula* [11].

Recently, autocurricula-based approaches have produced stunning results in multiagent environments, both cooperative and competitive (e.g., in the hide and seek scenario [29]). And we consider such approaches fundamental towards the self-development of complex agent societies. However, a deep understanding of the process that drives evolution of individual and collective behaviours is still missing, and is a key challenge for the next few years. To this end, providing agents an explicit modelling (possibly in causal terms) of the others' behaviour and of the overall societal behaviour, may be necessary [8]. Also, autocurricula approaches do not currently account for the possibility of interact with other agents, which may indeed be fundamental to improve collective learning.

D. Learning to communicate and coordinate

As already mentioned, agents may communicate and coordinate: by explicit messages, by leaving traces in the environment, or implicitly [9].

These forms of communication are already exploited in multiagent learning, mostly to improve the individual learning process by letting agents share information (e.g., for merging their individual causal models of the world [30]) and coordinate actions. However, these communication approaches are usually assumed as an *innate* capability of agents, rather than one to be learnt. That is, agents have an *a-priori* sense of agency with respect to communication actions, whereas in our self-development vision it should be developed by learning.

For example, with reference to explicit communication acts, [31] proposes a voting game to let agents learn to share a communication language and to develop a strategy to communicate. In [32], it is shown that reinforcement learning can be effectively applied to let agents learn how to communicate in order to achieve a specific effect. In the case of *implicit* communication, instead, forms of implicit behavioural communications have been shown to emerge in simple system components that purposefully move in an environment [33], as they learn to affect others with *ad-hoc* actions. Learning to use stigmergy to effectively coordinate is under-explored in the literature, which instead focuses on the opposite – using stigmergy to boost learning.

In any case, the development of general approaches to let agents develop fully-fledged forms of communication and coordination is still an open challenge, which may call for agents to develop not only a model of the world, but an overall model of the society (i.e., a social sense of agency). as a sort of social sense of agency.

E. Emergence of Institutions

Whereas learning to communicate is about understanding how to use communication to coordinate actions with others,

enabling and sustaining global collective achievement of goals requires “institutionalized” means of acting at the collective level, i.e., a set of shared beliefs and of shared social conventions and norms aimed at ruling collective actions [34]. The mechanisms leading to the spontaneous emergence of institutions in human society, there included the mechanisms to promote and sustain altruistic and cooperative behaviour (e.g., reputation and shared rewards), have been widely investigated [35]. However, most approaches to building multiagent systems assume such mechanisms as *explicitly designed* [34].

Yet, some promising studies related to the emergence of institutionalised behaviour in multiagent systems have been undertaken (see [10] for a recent survey). For instance, [36] proposes a collective learning framework where agents learn to adopt norms in repeated coordination, i.e., agents eventually *learn* that a social norm has emerged, and “institutionalize” their behaviour in their (social) decision making processes by complying to the norm. Another interesting work [37] integrates rational thought, reinforcement learning, and social interactions to model norms emergence in a society: agents incrementally develop a social behaviour (a social norm) while *internalising* it within their cognitive model.

However, the development of general models and tools to support the proper learning and evolution of institutionalised mechanisms of coordination in ICT and multiagent systems is still missing, and so are the solutions to the many problems involved in this process. For instance: how to avoid that an agent learns that free-riding is better than abiding norms; or how to avoid inconsistencies and misunderstandings in their interpretation.

IV. HORIZONTAL CHALLENGES

The presented approaches and techniques are still at the research stage, and many research challenges have been identified for each of them. In addition, it is possible to identify several additional “horizontal” challenges, i.e., of a general nature independently of the specific approach.

The specific nature of such challenges, in our opinion, makes them specifically suited for being pursued by the self-adaptive and self-organising research community, i.e., the ACSOS community at large.

Engineering. Many of the presented approaches are grounded in machine learning, a discipline with plenty of years of research behind, but in which good engineering practice is often neglected, and traditional software engineering problems are sometimes considered mundane. Systems are often developed *ad-hoc* for a specific task or problem domain, with little attention to modularity, reusability, dependability, thus missing the flexibility to adopt them across different domains, tasks, datasets [38]. In addition, given that the diverse approaches presented can each contribute important pieces to the overall vision of self-development, sound engineering approaches are needed to try to integrate such a heterogeneous plethora into a coherent whole. These represent multi-faceted and horizontal research challenges that, in our opinion, could and should be profitably attacked by the self-adaptive and self-organising

research community, due to its inherent software engineering endeavour.

Controlling evolution. Self-development raises the issue of somewhat controlling how behaviours evolve, as individual learns new skills and tasks, and as the collective learns new way of coordinating and acting together. How can we *steer* a learning process towards desired outcomes without putting bias in it? How can we *constrain* the boundaries within which individual and collective behaviours should stay (e.g., in terms of safety)? What *interventions* can we make to re-direct an agent or a collective that has taken an unpredictable or unsafe self-development path? Experience in self-adaptive components based on feedback, as well as in the study of emergent behaviours in self-organising systems and definitely help in finding proper technical answers, and – why not – *ethical* ones [39].

Humans in the Loop. The more self-development technologies will advance, the more humans will have to actively interact with them. This interaction will raise technical issues (will we have “handles” to control or block such systems in some ways and to some extent?) and ethical problems (will we be rather “handled” by these systems and subjects to their decisions?). Some of these problems already emerged, like in the *moral machine* experiment [40] or in AI-based hiring technology. Technical challenges will be meat for the HCI and distributed systems communities (there included the self-organising systems one). Ethical and moral ones will be meat for politicians and lawyers, although deep joint work with technical experts will always be necessary. A key ingredient involves institutions, since they represent humans as a group: laws and regulations need to be developed to regulate the global actors into the day-by-day technology usage. Nevertheless, a deeper interaction between researchers in science and technology and public institutions is needed to support the regulation design phase.

Sustainability. Algorithms for self-development will most likely require extensive computational resources. For example, the mentioned “hide and seek” experiment by OpenAI involved a distributed infrastructure of 128,000 pre-emptible CPU cores and 256 GPUs on GCP [29]: the default model optimised over 1.6 million parameters taking 34 hours to reach the fourth stage over six of agents skills progression. This example is a sort of best-in-class projects; anyway, it is clear that if self-developing systems will be based on similar learning approaches, they will require massive amounts of computational resources. Therefore, a key challenge for the community will be to devise algorithmic and system-level means to make self-development systems sustainable, and affordable by others other than the big technology players.

Explainability. Being able to inspect and explain the decision making process of AI systems is already a hot topic, so much that an entire research field (XAI, from eXplainable AI) has born. We already commented several times how such problems should be compulsory accounted for also for self-development, possibly with the help of causal models. This is indeed a key challenge for self-adaptive and, especially,

for self-organising research, too, where explaining global behaviours, patterns, and configurations emerging from local interactions is mostly still considered the “holy grail”.

V. CONCLUSIONS, CURRENT AND FUTURE WORK

In this paper, we have elaborated upon the vision of self-development, at both the individual and collective level. Although the road towards fully-realizing the vision is still a long one, several ideas in the areas of learning, causality, multiagent systems, are already showing its potential feasibility.

From our side, we are currently experimenting with Bayesian networks and causal models to learn dependencies between variables that represent sensors and actuators within a smart environment. In a simplified smart home setting, we showed how an agent is able to learn the effect of one of its own actions, thus acquiring the sense of agency, the necessary precondition towards goal-orientedness [3]. The training set consists of a collection of observations where the agent performs random actions and observes their effect on the rest of the environment. Once the learning phase is completed, the agent is eventually able to understand what to do to reach the desired state of affairs. At the collective level, our preliminary experiments show how different agents are able to learn to cooperate to achieve a goal they could not achieve individually. We assumed that the agents can share their observations, thus providing training examples to a single data set that can be used to learn a single, general model. By learning from the joint set of observations and actions, the two agents learn that they need to cooperate and to coordinate their actions.

As a continuation of this strand of research, we are now moving to a distributed learning setting, where agents do not fully share their observations to agree on a single global (causal) model of their shared environment. Rather, they cooperate to refine their own local causal models whenever they recognize partial, missing, or wrong information, by organising a coordinated distributed intervention protocol meant to obtain the additional information needed to disambiguate, refine, complete, or correct their own local models.

As part of our future work we plan to investigate how digital twins could enable the learning paradigms described so far. In particular, in many application domains such as smart factories, one could envisage a hierarchical architecture where digital twins collect and integrate data coming from heterogeneous physical devices, building more and more abstract models and representations.

Abstract—The theory of rough sets was founded by Zdzisław Pawlak as a framework for data and knowledge exploration. His seminal paper titled “Rough Sets” was published in 1982, in *International Journal of Computer and Information Sciences*. One of the key aspects that lets us use rough sets in practical scenarios is the notion of information system, which comes from even earlier Professor Pawlak’s works. Information systems are the means for data and knowledge representation. They constitute the input to rough set mechanisms aimed at computing approximations of concepts and deriving compacted, interpretable decision models. In particular, the fundamental notion of the indiscernibility relation is defined on the basis of a given information system. Accordingly, we discuss to what extent information systems can serve as the basis for intelligent systems. We claim that in many cases it is not enough to treat a data set – represented as an information system – as a purely abstract object with no linkage to the data origins. Oppositely, we should give ourselves a technical possibility to construct information systems dynamically, taking into account interaction with physical environments where the data comes from. With this respect, we refer to the notions of interactive granular computing and we generally consider together the paradigms of rough sets, information systems, and information granulation.

Index Terms—Rough Sets; Information Systems; Data Mining; Big Data; Interactive Granular Computing; Intelligent Systems

I. INTRODUCTION AND BASIC CONCEPTS

ZDZISŁAW Pawlak (1926-2006) founded the theory of rough sets with the aim of analyzing incomplete information by means of approximations [1]. His book published in 1991 [2] established worldwide recognition of rough sets as an approach which can model complex problems using simple constructs. The idea of rough sets originated from earlier Professor Pawlak’s research on knowledge representation and information retrieval [3], [4]. The key observation was that we often operate with objects (cases, instances) which are indistinguishable from each other, so approximating the sets of objects by using indistinguishable “blocks” is the most reasonable thing we can do. A need for reaching such simple solutions was important for Professor Pawlak during his entire scientific career which included far more achievements than just rough sets [5]. It is also interesting to note that the basic models he used working in different fields, such as conflict analysis [6] or concurrency [7], were based on information systems. In the same time, his personal interests were going far beyond computer science and science in general [8].

The updated (after 25 years) viewpoint on rough sets was presented in [9], [10], [11]. As it happens with every theory, it took time to understand the actual contribution of rough sets with respect to other approaches. Firstly, rough sets were compared with the theory of fuzzy sets [12]. Over the years, it turned out that these two theories can be successfully combined because they offer complementary granules understood as computational building blocks for approximations [13], [14]. In the next sections, one can see a number of examples of such combinations. Another thread of comparisons was devoted to the principles of information granulation and granular computing (GrC) [15], [16], whereby it is generally assumed to operate on groups of objects / instances / items gathered together into granules. In this case, the relationship turned out to be even more natural because such granules (or generally, various frameworks and layers of granular information) are a natural input for calculations related to rough sets.

Nowadays, rough sets are particularly popular in the area of learning decision models from the data. There are many rough set methods aiming at feature selection and interpretable decision model construction [17], [18], [19]. However, the principles of rough sets have much broader influence. They have an impact on various methodologies of decision making, *e.g.* multi-criteria decision making [20] or three-way decision making which strongly relies on rough set positive, negative and boundary regions [21]. Moreover, rough sets are employed to enhance expressive and algorithmic capabilities of many approaches to data mining and knowledge discovery. A good example here is an extension of standard data clustering toward rough clustering (whereby we search and operate with lower and upper approximations of rough data clusters) and its fuzzy hybridizations [22], [23], [24]. Another example corresponds to formal concept analysis [25] which has this year its 40th anniversary exactly like rough sets. With that respect, there are many approaches to constituting rough set approximations of formal concepts or in other words, formal concepts which comprise of rough set approximations [26]. Rough sets turned out to be useful also in other fields of science and industry. For instance, they were adopted in design of database engines and solutions, with respect to query language extensions (which can be referred as rough querying) and acceleration of commercial database software performance [27], [28].

In all above scenarios, rough set methods (or mechanisms that adopt rough set principles) require an input to derive approximations of concepts, relations, etc. In [1], Professor Pawlak discussed several examples of domains, whereby the inputs to rough set methods could take different forms. One of those forms corresponded to the notion of an information system [3]. In the framework proposed by Professor Pawlak, information systems are aimed at representing the underlying data, information or knowledge that we want to use to describe (and approximate) the concepts of practical interest. An information system comprises of objects, attributes and the values of attributes over those objects. Information systems resemble data tables in the theory of relational databases. It should be noted that data tables, in particular decision tables, have been studied and used in many applications since 60-ties of the XX-century [29], [30]. Still, we need to remember that Professor Pawlak's goal to operate with information systems was to represent information (including information derived from the data) rather than focus on the data itself [2]. This topic is actually wider and one can find analogies between information systems and data / information / knowledge representation frameworks in some other theories [25], [31], [32].

The complete idea of information systems has been created thanks to cooperation of Professor Pawlak with other scientists [4], [33]. At that time, there was a great demand for constituting the foundations for information representation and retrieval [34]. All those works were reaching beyond a standard understanding of data storage and processing, particularly with respect to incompleteness, imprecision and indeterminism of information that one needs to handle in practice. Over the years, the concept of non-deterministic information systems evolved in many interesting directions [35], [36]. Going back to the principles of information granulation [16], one may say that such information systems comprise of descriptions – also called signatures – of granules (composed in different ways, specific to different applications) in terms of available attributes, where those signatures are not always precise.

Operating with granules introduces a useful abstraction, a kind of border between granules' signatures (being the inputs to further computations) and granules' internals, whereby one can locate guidelines about *how* and / or *what for* those signatures are derived from physical data sources. This is why in this paper, we are interested equally in: (i) rough sets as the methodology for deriving concept approximations and compacted decision models, (ii) information systems which provide the input to those derivations, and (iii) the paradigms of GrC and information granulation, as various forms of granules can be "hidden right under" the abstract descriptions that information systems consist of. We focus particularly on the methodology of interactive granular computing (IGrC) [37] and interactive information systems [38], where the above-mentioned abstraction was explicitly introduced in terms of complex granules (c-granules) with the embedded control mechanisms that decide how their signatures are derived.

IGrC raised from the observation that traditional ways of computing do not take into account how the process of

perceiving attribute values is realized, *where* and *when* to access the concerned objects in a physical space, and *why* particular attributes are selected. This kind of awareness / attention / agency [39] is important for designing intelligent systems which are supposed to deal with complex phenomena in the real physical world [40]. This becomes even more important when one realizes that unexperienced data scientists often treat the available data sets as an ultimate baseline without investigating how those sets were collected.

In the above considerations, we evolved from information systems toward intelligent systems. We referred to the concepts of awareness and perception (perceiving attribute values), we can also refer to the concept of cognition. With this respect, let us cite the following statement of Leslie Valiant¹, which is particularly relevant when extending GrC toward IGrC:

A fundamental question for artificial intelligence is to characterize the computational building blocks that are necessary for cognition.

The above computational building blocks can be treated as a generalization of granules known from GrC [15]. (In particular, indistinguishable blocks / indiscernibility classes known from rough sets can be treated as atomic granules.) Naturally, such granules / blocks / classes have been already studied within GrC in the context of cognition [14]. However, when moving from blocks to computational building blocks, it is indeed useful to rely on IGrC because therein, the aforementioned c-granules are aimed at more tasks than just storing their signatures. Such c-granules build the relevant configurations of physical objects, initiate and modify interactions between them, so they are generally responsible for perceiving the physical world. They link physical objects with abstract objects used to represent the instances of decision making from the viewpoint of models working on information systems.

In the next sections, we consider some examples of challenges with respect to which IGrC can be worth adapting. For now, let us mention just one of them, namely hierarchical learning [41], [42]. From a logical viewpoint, one can think about it as learning satisfiability relations at different levels of hierarchy [43], [44]. This includes learning logical structures (e.g. relational structures or models), as well as logical formulas and their semantics expressed using those structures. The current methods of hierarchical learning are often based on GrC, with a special emphasis on designing hierarchies of information systems by basing on domain knowledge [45], [46]. However, granules on which the corresponding reasoning pipelines are performed, cannot neglect the underlying hierarchies of physical objects that are crucial for perception processes. Also, different layers of hierarchy can be connected to different types of sensors and actuators. Thus, the IGrC framework can be helpful indeed to embrace both, the relationships between information systems at different levels of hierarchy and the relationships between particular systems and the associated physical-object-related information sources.

¹people.seas.harvard.edu/~valiant/researchinterests.htm

In the rest of the paper, in Section II, we refer to some selected literature on rough sets. This section is quite extensive given the anniversary flavor of the paper. In Section III, we go back to the discussion about the importance of information systems. We emphasize a need of operating with information systems (and the results of rough set computations over information systems) considered in a wider context of interactions between abstract and physical objects of different sorts. We go through several aspects of applications, whereby this kind of interaction is needed. We show to what extent the paradigms of IGrC can be helpful. We also refer to some concepts known from the domain of big data in order to put our discussion into other contexts. In Section IV, we conclude the paper.

Let us reemphasize the retrospective context of this paper. Besides the 40th anniversary of rough sets (which is our major focus) and the 40th anniversary of formal concept analysis (which was mentioned above), there are two more celebrations worth mentioning. The first of them refers to the rough set workshop series which “visited” the FedCSIS conferences for the first time 10 years ago² and which is now back to the program of technical sessions³. Secondly, this year’s FedCSIS hosts the 30th International Symposium on Concurrency, Specification and Programming (CS&P 2022)⁴. The topics related to rough sets and information systems have been always visible at the CS&P events. In particular, the above-cited papers [36], [40], [44] come from CS&P.

II. SELECTED RELATED WORK ON ROUGH SETS

In order to provide a better viewpoint of the theory and applications of rough sets, we refer to two events from the past. These references will also constitute a better background for our major goal in this paper, which is the review of new advances on rough-set-related information systems.

A. Rough Sets at FedCSIS 2012

The first considered event is FedCSIS 2012 held 10 years ago in Wrocław, Poland⁵. As already mentioned, that was the first time when rough sets occurred so intensively at a FedCSIS conference. Let us start outlining the FedCSIS 2012 rough-set-related publications from [47], [48]. The first paper equips the Variable Precision Rough Set (VPRS) approach [49] with a Bayesian background [50]. The second paper combines VPRS with fuzzy rough set methods [24] in order to produce flexible decision rules. In summary, both papers deal with information imprecision – modeled by probabilities (which is the domain of VPRS) and fuzziness (which can be used to work *e.g.* with partial matching of rules’ antecedents) – and attempt to extract interpretable decision models from the data [11].

The topic of rough-set-driven decision rules is considered also in one more FedCSIS 2012 publication [51]. In general, one will see throughout our whole paper that rough set principles fit the field of rule induction very well [18], [31].

This relationship is evident not only at a technical algorithmic level but also with respect to the common assumption of looking at the data through the glasses of information granules [16]. For more examples of connections between the worlds of rules and rough sets, let us refer *e.g.* to [17], [52].

Going further, papers [53], [54] introduce new heuristic measures that can be used during attribute reduction. It is worth noting that attribute reduction – or in other words algorithmic elimination of redundant attributes from the constructed set of attributes – is an important contribution of rough set research to knowledge discovery and in particular to its phase of feature selection [55]. As a complement to typical feature selection algorithms which attempt to add the most useful attributes, rough set methods take as input the sets of attributes produced by those typical algorithms and attempt to additionally compact them by eliminating unnecessary or approximately unnecessary elements. The additional aspect of attribute elimination occurs in just a few machine learning methodologies worldwide [56], so we can indeed say that this is an important rough sets’ contribution to this area.

Papers [57], [58] continue the topic of attribute reduction. The first of them proposes greedy algorithms for deriving so-called superreducts from data sets with multivalued decision attributes (target variables). It is one more example of dealing with information imprecision in rough set frameworks. Superreducts are the subsets of attributes which are sufficient to induce values (or as in this case, the sets of possible values) of decision attributes. It is also important to note that the notion of superreduct is equivalent to the notion of test in the test theory [31]. The second paper compares the notions of decision bireduct (aimed at deriving both the sets of attributes and the sets of data objects for which those attributes are sufficient to construct rule-based decision models) and approximate reduct (aimed at eliminating as many attributes as possible, even if the ability to induce decisions is not fully preserved). This comparison was later extended in [17].

The next two papers extend the topic of feature selection toward some of modern data challenges, namely high-dimensionality and large data volumes. Paper [59] combines attribute reduction with attribute clustering. Attributes are first grouped using some rough-set-inspired measures and then the methods of attribute reduction work iteratively on cluster representatives. This allows for decreasing the complexity of attribute reduction for high numbers of attributes and it also improves interpretability of results. These methods were later extended to let them work with attribute groups which can be set up for many reasons, including heterogeneity of data sources that are required to derive attribute values [60].

Paper [61] copes with big data volumes by putting attribute reduction and decision tree induction into a relational database framework, whereby the corresponding algorithms are implemented in SQL. The authors extend some previous ideas in this field [19] and, in particular, employ an open source database engine called Infobright Community Edition to run experiments. Infobright Community Edition is an example of using rough sets to optimize other types of data computations,

²fedcsis.org/2012/rsa.html

³fedcsis.org/2022/rsta

⁴fedcsis.org/2022/csp

⁵fedcsis.org/2012/

in this case – query execution in relational databases⁶. This emphasizes that rough sets can be successfully used not only for machine learning and data mining but also for other tasks of big data processing. We refer to [62] for current developments related to Infobright Community Edition. We also refer to [63], where the Infobright’s technology performance is explained in terms of rough set operations on specifically aggregated (granulated) multivalued information systems.

The last two rough-set-related publications are interesting from the information systems’ viewpoint as well. In [64], the source of building an information system is a transformed ontological graph which encodes our knowledge about a given area [65]. The rules derived using the Dominance Rough Set Approach (DRSA) [20] express useful regularities within the original graph. This is actually an illustration of the fundamental idea behind information systems, namely, that such systems may contain not only the empirical data but they may also integrate it with domain knowledge [11], [43].

Finally, paper [66] presents the real-world application of rough sets to explore medical data. Herein, the information system – the input for rough-set-based model learning methods – does not correspond directly to the original data measurements. It is rather a result of a sequence of time-window-driven data aggregations which are typical for building hierarchical information systems describing complex objects [45], [67]. This work applied in particular a rough-set-based software system for machine learning and data mining – called RSES – which is now available in a library format [68] (see also the RSES extension targeted at spatio-temporal concepts⁷). It is also one more practical use case of deploying the Infobright Community Edition database engine to run the underlying operations over granulated and compressed data sets.

B. Rough Set Contest at PP-RAI 2022

The second considered event is the PP-RAI 2022 conference held this year in Gdynia, Poland⁸. The chairs of PP-RAI 2022 decided to celebrate the 40th anniversary of rough sets by organizing the contest for the most influential article on rough sets co-authored by Polish researchers in 2020 or later⁹. Let us discuss below the articles submitted to this contest.

Papers [69], [70] operate at the edge of rough sets and formal concept analysis [25]. The first paper adopts the principles of attribute reduction (or more generally, model compaction) to simplify so-called fuzzy concept lattices, introduced as the means for representing patterns and regularities hidden in numerical data [71]. The second paper is actually an extension of the previously-cited work [36]. The authors attempt to put classical rough sets, formal concept analysis and the DRSA-style extensions of rough sets [20] into a unified conceptual pipeline aimed at transforming the data – through various forms of (possibly multivalued) information systems [33] – to knowledge. Within such a universal framework, the authors

reconsider special cases of rough set operators known from different approaches. Therefore, one may say that this paper is a direct continuation of the ideas introduced in [1].

Papers [72], [73] link rough sets with logical foundations. The first paper shows how to express reasoning based on the VPRS-style extensions of rough sets [49] within the framework provided by a probabilistic extension of PROLOG [74]. The second paper shows how to reason about the properties of various types of rough set approximations within the framework provided by Mizar – a powerful system for automated proving [75]. Needless to say, such foundations are crucial for every theory, including reasoning within the theory and reasoning about the theory. We refer to [76] for more information about logical background of rough sets.

Papers [77], [78] present further advances in the previously-discussed popular rough set approaches such as the above-mentioned DRSA and fuzzy rough sets, respectively. The first paper uses the statistical learning machinery [79] to give new insights into parameters of probabilistic extensions of DRSA. The second paper, somewhat analogously, attempts to provide new interpretation of fuzzy rough set parameters. This is done by considering a new form of fuzzy granules [80], which consequently leads toward more intuitive derivation of fuzzy rough decision rules. One can say that these two articles fall into the same thematic categories as the previously-considered FedCSIS 2012 publications [47] and [48], respectively.

Papers [81], [82] continue the topic of feature selection. The first paper refers to heuristic attribute evaluation measures and data discretization techniques analogous to those reported in [10], [19]. The second paper seems to be particularly interesting as it extends the already-discussed topic of rough set software packages and libraries [24], [68] toward hardware optimizations that are specific for high performance computing. Such optimizations should be further compared and integrated with other acceleration opportunities, *e.g.* adaptation of MapReduce [60] and analytical database engines [61].

Papers [83], [84] refer to rough set software too. The first paper reports one more package delivering rough set methods for data mining and knowledge discovery. The second paper is about the application of that package to biomedical data mining. This second paper – besides its important experimental results – touches the aspects of visual data analytics [85], [86] and a need of understanding both, the analytical processes and their outcomes by subject matter experts [87], [88].

Papers [89], [90], [91] illustrate more real-world applications of rough set methods in the area of biomedicine. The first paper uses rough set approximations built over neighborhood-based information granules [92]. The remaining two papers confirm the expressive power of the DRSA-based decision rules. They also compare the accuracy of rule-based models with other approaches (such as random forests and logistic regression [93]) and show how to derive the attribute importance (see *e.g.* [94]) from the considered rules.

Papers [95], [96] continue the topic of rule induction. The first paper can be compared to [35], as both of them deal with deriving probabilistic rules from incomplete information sys-

⁶en.wikipedia.org/wiki/Infobright

⁷mimuw.edu.pl/~bazan/roughice/?sLang=en

⁸pp-rai2022.umg.edu.pl/

⁹roughsets.org/newspage/events/

tems, assuming several types of incompleteness. The second paper applies both rough-set-based [18] and fuzzy-set-based [12] rules in the task of posture detection. This is an example of real-world application, whereby the multi-stage solution needs to integrate sensor calibration, sensor data acquisition, inducing rules from the acquired data, as well as rule-based inference. With respect to making all such layers working together, this work can be compared to [43], [66], [67].

Papers [97], [98] deal with ensembles of decision models. The first paper employs so-called Dominance-based Rough Set Balanced Rule Ensemble for fraud detection. Herein, it is worth adding that rough set methods and applications include also examples of operating with ensembles of the aforementioned approximate reducts [99] and bireducts [17], [58] which correspond to bigger collections of rules. The second paper shows how to negotiate between classifiers and actually refers to the aforementioned conflict analysis model proposed by Professor Pawlak [6], [100]. On the other hand, the mechanism of voting in the third paper relies on the aforementioned three-way decision making [21]. It is worth emphasizing that solutions described in both papers attempt to provide a deeper insight into the ensemble decisions.

Paper [101] remains in the area of ensembles of decision models but it also touches an important aspect of incremental learning in dynamic data environments [102]. Herein, it is worth recalling a gentle difference between reasoning about objects or states in a repetitive fashion (whereby the values of attributes in information systems need to be cyclically updated) and reasoning about temporal objects or phenomena (which require different construction of information systems with attributes reflecting changes and trends) [103], [104].

Finally, papers [105], [106] combine the principles of rough sets and GrC with popular machine learning methods, referring to decision model ensembles as well. The idea is to prepare compacted data inputs – called granular reflections [15] – for the algorithms responsible for learning decision models such as *e.g.* neural networks or random forests (see [93] again). From a conceptual perspective, it corresponds to the aforementioned studies on aggregated / granulated / summarized information systems [63], [66]. This topic has also interesting relationships with some branches of approximate computing [107] and compressed image recognition [108].

III. INFORMATION SYSTEMS AND IGrC

As we have already emphasized, rough sets are based on data / information granulation. Both the original rough set approach and its extensions, need granules (and their descriptions / signatures) as inputs to compute approximations. The same applies to rough set methods of constructing decision models, *e.g.* rule-based models [52], [95]. On the other hand, granules can take different forms and have different origins. They can be partition blocks (induced by combinations of attribute values or ranges), dominance classes or neighborhoods [20], [89], relationships based on fuzzy (dis)similarity and (in)discernibility [78], [80] and so on. In information systems, granules can take different information signatures such as

precise values, value sets, ranges and distributions [35], [57]. Those signatures can be computed using different aggregation mechanisms, often assuming non-trivial interdependencies with processes and devices that produce the data [63], [66]. The reliability and accessibility of information – therefore also reliability and accessibility of the outcomes of calculations over information systems – requires a careful analysis of all phases of forming the contents of such systems.

In Section I, we highlighted that the IGrC framework [37], [40] could be helpful to keep information systems aligned with respect to practical needs of operations on them in different contexts. In the next subsections, we will elaborate on several aspects of such alignment. As already discussed, IGrC uses so-called *c*-granules in order to create configurations of physical objects and control interactions between them so as to achieve computational objectives. Now let us add that the control mechanisms embedded within *c*-granules rely on one more type of granules – informational *c*-granules (*ic*-granules) which include both abstract (informational) and physical layers. They contain specifications how to link the abstract and physical worlds, whereby the abstract world corresponds in particular to (the networks of) information systems. The perceived properties of physical objects can be used to transform the current configurations of *ic*-granules, *i.e.* to modify interactions between objects. Such mechanisms require a design of new methods of reasoning about *where*, *when*, *what*, and *how* to perceive using different sensors or actuators. New methods for judging membership (alignment, matching) of the perceived situations in (with) rough set approximations of complex concepts are needed too.

A. Reliability of Information

This kind of reliability is studied in many fields. In the domain of big data, it is referred as one of the “V’s” – Veracity [109]. Actually, we have already dealt with some of other “V’s” in the previous sections, *e.g.* Volume [61], Velocity [101] and Variety [60]. However, without addressing Veracity, *i.e.* assuring data quality that is transformed into information reliability, any solutions focused on those other “V’s” cannot guarantee anything useful. Another popular term related to this problem is “garbage data”. It refers to the fact that if a machine learning method is executed on improper data, then the resulting models cannot be expected to work successfully. The causes of data being garbage data may be connected to problems with *e.g.* sensor measurements, data parsing, or even data labels acquired from human experts [67], [110].

A technical solution to cope with garbage data is often to filter them out by using validation procedures (*e.g.* checking sensor scales) [99]. However, in many applications – such as [66] (Subsection II-A), [96] (Subsection II-B) or just-mentioned [67] – it would lead toward disqualifying too broad data fragments, if any formalized validation is possible at all. Another approach is to *live* with the unreliable data and moreover, to take such unreliability into account while conducting any computations. With this respect, non-deterministic information systems have some tools to express uncertainty

by replacing precise values with sets, intervals, etc. [35], [63]. However, (a degree of) reliability remains something different, as it refers to the way the data was acquired from the physical world rather than the specification of attribute values.

The IGrC framework is quite natural when it comes to reasoning about such an additional layer of information. Interactive granular computations can be actually extended toward adaptive searching strategies for the most relevant and reliable data, spatio-temporal windows pointing out to fragments of the physical world where the most reliable measurements and / or actions should be performed, and so on. This kind of reasoning may be also associated with the domain of data governance which extends towards data and information security, accessibility, as well as the protocols of interactions between intelligent systems and humans [111], [112]. On the other hand, the discussed physical-world-related aspects can be an additional contribution of IGrC to data governance. Moreover, IGrC can be helpful to operate with often softly expressed regulations about data integrity and timeliness.

It is also worth referring the above discussion to the meanings of aleatoric and epistemic uncertainties in machine learning [113]. From this perspective, a limited reliability of the contents of information systems can be treated as one of ingredients of the epistemic uncertainty, as it puts together both, the model and the data deficiencies. However, we believe that these two sources of deficiencies should be kept separately, with the third type of experimental / physical uncertainty explicitly considered. The analysis of this third type of uncertainty should be taken into account when assessing the efficiency and stability of machine learning models, especially given the fact that in some practical scenarios the inputs to the learning algorithms can be unreliably extracted for the purpose of *e.g.* accelerating computations [114].

B. Acquisition of Information

In order to talk about information reliability, we first need to assure that information can be gathered at all. In practice, there is often a great variety of data available but it does not mean yet that the corresponding information is sufficiently complete to perform any kind of analysis. (This relates to one more “V”: Value.) Some promising approaches to data enrichment refer to the paradigm of active learning [115], which can be further extended toward establishing an interactive loop within which subject matter experts label data objects that are of the highest interest to the machine learning algorithms. One just needs to think about controlling the quality of such labels [110].

Similarly, the data enrichment processes can rely on connecting information systems with physical systems [116]. Actually, it is worth pointing out that humans can be considered as a special kind of physical objects that interact with decision support systems and / or intelligent systems. This refers to a broader topic of the information and communication technologies (ICT) systems [39] which put together the aspects of hardware (*e.g.* sensors), software (*e.g.* machine learning methods), the data (including domain knowledge), and the system users (in particular subject matter experts).

The above ideas require a firm layer that connects information systems with the physical world where the data comes from. In IGrC, every granule should have an access to instructions how to compose the values of particular attributes for particular objects [38], [40]. Moreover, it is important for this layer to log a history of attempts to calculate particular fragments of an information system. Such history may let us avoid mistakes and misinterpretations related to the data acquisition processes. That history may be also useful while assessing reliability of the current contents of an information system. Such mechanisms can be adopted also from the architectures of granular database engines [62], [107], whereby the aspects of information completeness and reliability are equally important as in the field of machine learning.

Going back to the framework of active learning, let us claim that subject matter experts can assist us not only in enriching the data with labels but also enriching the data mining algorithms with domain insights. As an example, let us think one more time about the task of feature selection. There are various techniques of measuring and visualizing attribute importance [88], [90], [94] but they are usually applied to report to humans the final results instead of “inviting” them into a more interactive dialogue on feature selection process. In this regard, we refer to [85] where incrementally constructed information systems are employed to guide subject matter experts through such an interactive process, letting them share their recommendations about the most relevant attributes.

Last but not least, when it comes to decision problems related to complex phenomena, it is worth attempting – using the elements of active learning and human-computer interaction – to acquire from subject matter experts even more advanced knowledge, expressed in terms of hierarchical structures and dependencies. This fits the paradigm of computing with words [117] (which also corresponds to the foundations of information granulation with respect to decomposing complex problems onto their smaller components) and, in particular, the following challenge formulated by Judea Pearl [118]:

Traditional statistics is strong in devising ways of describing data and inferring distributional parameters from sample. Causal inference requires two additional ingredients: a science-friendly language for articulating causal knowledge, and a mathematical machinery for processing that knowledge, combining it with data and drawing new causal conclusions about a phenomenon.

C. Accessibility and Cost of Information

In practical deployments, there is always a risk that some of data sources – which are needed to calculate some of attributes being inputs to a decision model – will be temporarily unavailable (because of *e.g.* physical connection problems or dissatisfaction of some data governance rules) or unreliable (as discussed in Subsection III-A). Feature selection [56], including contribution of rough set methods to elimination / reduction of redundant attributes [10], can be a remedium to this problem – less attributes require less aspects of data to be

calculated. Moreover, it is possible to diversify data sources needed to derive attributes that are used by particular models in an ensemble [17], [55]. This increases a chance that at least some of models would be usable in a given situation.

However, it is not only about the accessibility, sometimes it is also about the cost. For instance, in the recent contests organized at one of online data mining competition platforms¹⁰ [119], [120], the participants purposefully did not take into account some of the available data sources (modalities) because – according to them – derivation of attributes from those sources would be too expensive computationally. Going further along this path, one may say that even if such “expensive” attributes are included into a model, its deployed version should have a choice to decide dynamically which of them (and at what level of precision [114]) are necessary to be calculated. This is important the more so as in intelligent systems dealing with complex phenomena, the most adequate selections and meanings of attributes can be changed over time [40].

Going even further, if appropriate metadata is maintained on the side of an information system, the same attribute values can be derived from different information sources or using different data modalities, perhaps subject to different cost and precision [43], [67]. This is well-aligned with the IGrC assumptions discussed in the previous subsections. The point is to pass to information granules the decision power in regard to how they produce information that they are responsible for, and make decision models responsible for timely asking those granules for particular information pieces [38], [116].

The above discussion can be extended toward a broader topic of whether the data / information updates should be rather “pushed” or “pulled” in the computational pipelines which involve learning and applying the learnt models. A common assumption is that any change in the underlying information should be more or less quickly transmitted to the inputs of a model, causing its recalculation or at least modification of its behavior [101], [102]. However, in big data scenarios it is not so obvious – it may be safer to leave such decisions in hands of information granules equipped with well-designed triggers and internal cost models [37], [107].

D. Networks of Information Systems

Continuing with the topic of intelligent systems aimed at reasoning about complex phenomena, we already know that data sources required to learn the underlying decision models cannot be acquired in a single-step process. It is necessary to provide such systems with permanent links to relevant fragments of the physical world and keep adapting (actively but also reasonably, from the computational perspective) the induced models following changes in the perceived situation. Recalling our comments about logical reasoning related to hierarchical systems [43] (see the end of Section I), one should also be aware that these hierarchical structures are dynamically changing in time and the relevant reasoning methods should allow to the system to perform the necessary reasoning about

such dynamical structures. This seems to be aligned with the following opinion expressed by Frederick Brooks [121]:

Mathematics and the physical sciences made great strides for three centuries by constructing simplified models of complex phenomena, deriving, properties from the models, and verifying those properties experimentally. This worked because the complexities ignored in the models were not the essential properties of the phenomena. It does not work when the complexities are the essence.

The starting point is to work with environments which create, maintain and synchronize multiple dynamic information systems. Such networks of information systems would be still a kind of abstraction of the real world but on the other hand, they would reflect it more accurately than single systems.

Let us first focus on the aforementioned hierarchical systems. We have already referred to the approaches whereby domain knowledge – expressed in terms of ontologies of concepts associated with a particular decision problem – is utilized to decompose that problem onto simpler components located within a hierarchical schema and then, to aggregate perceived information along that schema [45], [117]. To facilitate such aggregation process, it is indeed convenient to design a hierarchy of information systems whose objects (and therefore also attributes) correspond to different levels of conceptual granularity. This idea is actually analogous to modeling the data by means of multi-table relational database structures [114], [119], and it can be observed in quite a few applications mentioned earlier [46], [66], [67], [103].

Somewhat “orthogonal” aspect of thinking about multiple information systems refers to concurrency and distributed computations. From this perspective, at each level of the above-discussed hierarchies, we may actually imagine a group of systems working collectively and exchanging information. Herein, it is important to refer to the models proposed by Professor Pawlak [7], as well as the history of the aforementioned conferences on Concurrency, Specification and Programming (CS&P). Furthermore, it is useful to refer also to the works on the networks of information systems linked by so-called infomorphisms [32], [122]. Some relevant realizations can be found also in other domains. For instance, the already-considered granular database engine [107] contained a mechanism of distributed execution of analytical queries, whereby particular computational nodes could exchange with each other some approximate partial answers and, basing on such understood rough set approximations, decide autonomously whether it is worth requesting for the precise results.

Once we have a hierarchy / distribution of information systems, we can extend their network with the IGrC-based connections to the physical world [38], [123]. This implies a number of challenges, as the above-discussed coordination between particular information systems needs to be combined with coordination of each single system with its physical “alter ego”. For instance, we can consider a more active version of the tasks of attribute selection and extraction [56], [60], whereby it is required to develop new methods of

¹⁰knowledgepit.ai

selection and construction of sensors. At a more general level, the whole idea requires a distributed control of *c*-granules, whereby specific reasoning methods (related to cooperation / competition between granules) need to express the expected behavioral patterns of the whole “society” of granules. Herein, one can seek for inspirations in the previously discussed conflict analysis [6]. The requirements of the aforementioned ICT systems [39], web intelligence [65] or *e.g.* IoT analytics [124] – whereby there are a number of federated learning scenarios involving distributed agents (and their underlying information systems) – can be a useful analogy as well.

IV. CONCLUSIONS AND FUTURE DIRECTIONS

The first goal of this paper was to expose the current progress of the theory and applications of rough sets – the methodology founded by Zdzisław Pawlak with the aim of deriving and expressing important patterns and dependencies subject to limited (incomplete, imprecise) information about the concepts of practical interest [1], [9]. We examined connections of rough sets with decision making [20], [21], logics [73], [76], probability [47], [72], statistical / machine learning [77], [105], data mining [19], [23], fuzzy sets [13], [48], formal concept analysis [26], [69], and other data / information / knowledge representation methodologies [31], [32]. We discussed some of rough set techniques aimed at attribute selection / reduction treated as a component of knowledge discovery processes [10], [17], with particular emphasis on computational scalability challenges [60], [82]. We paid special attention to rough set approaches to construction of interpretable (explainable by design) rule-based decision models [18], [48], [52], [97]. We referred to rough set software packages for data mining and machine learning [24], [68], [83], as well as other technologies which utilize rough set approximation principles for their internal purposes [62]. We also recalled several (out of many) applications of rough set methods in real-world data analysis, including biomedical and healthcare applications whereby interpretability of decision models is of special importance [66], [67], [84], [91].

Our second goal was to address the progress in the area of information systems [3], [4]. We referred to their extensions [33], [70] and we outlined a number of applications which use specifically formed information systems as the means for representing (granulated / aggregated) data, (uncertain / imprecise) information, and (appropriately transformed) knowledge structures [35], [43], [63], [89]. We pointed out that information systems – especially their hierarchies and networks – constitute the means for reasoning about complex spatio-temporal phenomena [45], [104]. We also claimed that information systems can be a medium to conduct interactive data analytics involving subject matter experts [85] and support interactions between multiple data exploration processes [123]. That led us toward discussing the current challenges (often referred as the big data “V’s”) in front of information systems understood as the means for representing and delivering data required for the learning processes [102], [109], [110], [119]. Accordingly, we examined whether the principles of so-called interactive

granular computing (IGrC) [37], [116] can help us to face those challenges and to what extent they are aligned with some of emerging trends in machine learning [115], [124].

It was important for us to discuss the principles of granular computing – including IGrC – together with rough sets and information systems, as these three domains interfere with each other in many interesting ways [11], [14], [15], [40]. In particular, IGrC may have future implications for the design of intelligent systems, *e.g.* when it comes to so-called perceptual rough sets¹¹. If one wants to build rough set approximations of complex concepts in real-world environments, then it is required to design a dynamic space of granules which are able to reason about complex approximation constructions. The corresponding reasoning methods will need to be far richer than the ones considered so far in rough set applications.

Some other future directions for rough sets and information systems refer to continuation of development of real-world applications, focused on *e.g.* images and video recordings [22], [46], [120], as well as signals and sensor measurements [99], [96], [103]. This kind of development should emphasize strong assets of rough sets, such as straightforward interpretability of the derived decision models, even when it comes to modeling very complex and dynamic situations [11], [101]. Needless to say, interpretability is now the key objective for a great majority of machine learning applications [87], [88].

When thinking about the future it is also worth referring to the history. That reflected one more objective: acknowledging the 40th anniversary of rough sets [1], their founder [5], as well as some of relevant past and present events such as FedCSIS 2012 (rough set papers published exactly 10 years ago) [47], [48], [51], [53], [54], [57], [58], [59], [61], [64], [66], the PP-RAI 2022 rough set contest [69], [70], [72], [73], [77], [78], [81], [82], [83], [84], [89], [90], [91], [95], [96], [97], [98], [101], [105], [106] and celebration of the 30th CS&P – the event series whereby this paper’s topics have been regularly addressed [36], [40], [44], [103], [116], [123].

In the end, let us recall that this is not the first anniversary corresponding to rough sets in the history of the FedCSIS conferences. Indeed, FedCSIS 2016 (Gdańsk, Poland) hosted the international panel discussion in memoriam of the 90th anniversary of the birth and the 10th anniversary of the death of Professor Pawlak¹². The previously-cited publications [4], [8], [100] were prepared specially for that panel.

Abstract—Computers are one of the most important inventions in human history, and computer languages enable human-computer communication. Undoubtedly, C++ is one of the most important and influential in this group. Nevertheless, new technologies and related industry challenges place high demands on C++ and foster the development of new computer languages that meet new needs. For this reason, and thanks to the dynamically operating ISO standardization group, C++ is constantly updated while maintaining its backward compatibility. However, all this complicates and hinders not only the teaching of beginners but also the use by professionals. In this article, we briefly discuss the goals as well as proposed methodologies and techniques for teaching contemporary C++ in the age of new technologies and challenges.

Index Terms—C++, modern technologies, compilers, teaching programming, computer science curricula

I. INTRODUCTION

C++ is a multi-paradigm, imperative, procedural, functional, object-oriented, generic, and modular language invented in early 1980s and further developed by Bjarne Stroustrup [5][10] [29]. Since 1991 standardization of C++ is supported by the ANSI International Organization for Standardization (ISO), with the latest standard version published in December 2020 [21]. With performance and efficiency in mind, C++ extends and is compatible with the C programming language, while to incorporate the object-oriented and abstraction mechanisms it draws from Simula. This hybrid approach has proven extremely useful over the years, especially in such domains as systems programming, embedded systems, resource constrained platforms, large computing and simulation libraries, machine learning & artificial intelligence (ML/AI) and many others.

Nevertheless, there are industries such as web applications that favor the development of other languages as well. While the popularity rankings of programming languages are in some ways superficial and may be misleading, they provide some

insight into future trends in the IT industry and can help students decide which language they want to learn. From these the TIOBE Programming Community index shows the popularity of programming languages based on 25 search engines [16]. At its top are Python, C, Java, and C++, which together are well ahead of the others, as shown in Fig. 1. In the last two years, Python and C have swapped between 1st and 2nd places in the ranking. Also C++ is gaining in popularity and tends to surpass Java.

Aug 2022	Aug 2021	Change	Programming Language	Ratings	Change
1	2	▲	 Python	15.42%	+3.56%
2	1	▼	 C	14.59%	+2.03%
3	3		 Java	12.40%	+1.96%
4	4		 C++	10.17%	+2.81%
5	5		 C#	5.59%	+0.45%

Fig. 1 An excerpt from the TIOBE list of the top-ranked programming languages in 2022 (from [16]).

On the other hand, in the Popularity of Programming Language Index (PYPL), which shows how often language tutorials are searched on Google, C/C++ are ranked 5th together (Aug. 2022) [17]. However, neither of the above indexes is about the best programming language or the language in which most lines of code have been written.

A detailed analysis of various languages and their applications is far from the scope of this paper, nevertheless we can observe that while scripting tasks surely fall into the realm of Python, and web development for Java, then vast majority of high performance applications falls into the domain of C/C++.

The latter are also the only languages in this group that compile their code directly into the machine language. Although, there are contenders such as Rust and the recent Carbon [11][12], C++ endowed with hundreds of libraries, tools, and many years of experience, and a superset of C in a sense, *is and will probably be the most important and productive language today*, especially for large and performance demanding systems. Therefore, C++ is surely worth learning. However, the more extensive the specification of modern C++ becomes, the more critical the requirement to properly teach modern C++ to new generations of programmers becomes. In this article, we tackle this issue in an attempt to shed more light on why and how to teach modern C++.

There are relatively large Internet resources [30][10][13] and literature [27][20][23] about C++ and its features. However, when it comes to teaching modern C++, the situation is not bright. There are only few online presentations [2][3][4], web services and books to recommend [28][29]. Nevertheless, even these are a bit dated considering new C++17 and C++20 standards. To fill this gap the new book was written, *Introduction to Programming with C++ for Engineers*, which was published by Wiley-IEEE Press in 2021 [6]. It contains teaching materials, from elementary to advanced level, intended for the three-semester study cycle. Based on this, this article provides an overview of methodology and techniques for teaching modern C++.

It is worth mentioning that the problem of teaching and disseminating knowledge about modern C++ also found wide interest in the language committee. In this context, the SG20 group arose, whose aim is to prepare and provide guidelines for content to be covered by C++ courses [31]. Their main document is a resource for instructors to assist in the preparation of C++ courses in a variety of environments, including universities, colleges, and industry.

The rest of the paper is organized as follows. An overview of the methodologies and techniques of teaching the C++ language is presented in Section II. It is organized into four subsections. Section III provides scenarios for the different levels of C++ learning. Section IV discusses the role of good examples in the teaching process. Section V deals with the issue of teaching for real life challenges. The paper ends with conclusions in Section VI.

II. AN OVERVIEW OF TEACHING METHODOLOGIES & TECHNIQUES

In this section the basic methodologies and techniques for teaching modern C++ are outlined. The main issue is to list the most important steps in class preparation and to focus on the most important factors.

A. Preparing for Teaching

First, there are some key factors to consider before starting your class. The following is a list of them:

- Get to know your students – what are their backgrounds, what are their motivations, whether they are kids or students of electronics and telecommunication, computer science students, or students of non-technical faculties (biology, humanistic, etc.); or professionals

who want to expand their skills in modern C++? What have they already learned, math, python, basics of computer science?

- Organize your classes well – individual or group work (some activities such as lectures can be for a group, but some – such as tutorial – should be individual), group sizes, etc. Have a plan but actively respond to students' progress and expectations, have close contact and react actively, similarly to the *agile* methodology for software development. But also control the attitude and experience of other fellow teachers in the group (in many universities often the lecturer and laboratory teacher are different people).
- Plan your time – how many hours for a lecture, for a lab, for joint work, and for an individual project. Consider time for individual consultations.
- Organize the class work well – consider exercises for personal work as well as projects for *team work*.
- Teaching materials – students have access to various sources, but they rely on your opinions, therefore the correct selection of book(s), internet materials, video(s), etc. is very important.

Certainly, these are only propositions based on many years of our observations and conducted classes. However, for different groups and teachers, the list and importance of each factor may differ.

B. Choice of the Vital Language Features – the 20/80 Rule

What works well in our 25 years teaching experience is getting the right preparation and then focusing on the most important and productive features of the language at the given teaching stage that allow students to quickly comprehend and become proficient in basic programming techniques. As a result, it allows the students to create useful and well-organized programs as quickly as possible. The choice of features can be arbitrary, but is best if these are based on the experience of the teacher(s). As we have noticed, for this purpose *the Pareto 20/80 principle* is worth considering [14][6].

Fig. 2 The 20/80 rule states that many activities are not evenly distributed and some contribute more than others. This idea can be used to prepare 20% of the most important C++ features for the students' classes.

The 20/80 paradigm, known also as the Pareto rule or law of the vital few, states that in many life situations, 20% of causes is responsible for roughly 80% of consequences, or results, as shown in Fig. 2. This heuristic observation was probably first noticed by the mentioned Italian economist Vilfredo Pareto, who noted that at that time 80% of the land in Italy was owned by 20% of the population. Interestingly, this can also be observed in computers, which is usually manifested that 20% of bugs contribute 80% of crashes, or that 80% of the CPU time is spent on 20% of the code, etc.

Hence, the idea is to use this rule to prepare the most important 20% of features to be taught in the beginning. This approach can result in much better productivity and allows students to faster reach the level of solid understanding of basic programming constructs and techniques, compared e.g. to the linear approach, as shown in Fig. 2.

C. The Spiral Development Model

As originally proposed by Boehm [1][15], the spiral model of software development is associated with iteratively repeated processes while managing risk for its active reduction, as shown in Fig. 3.

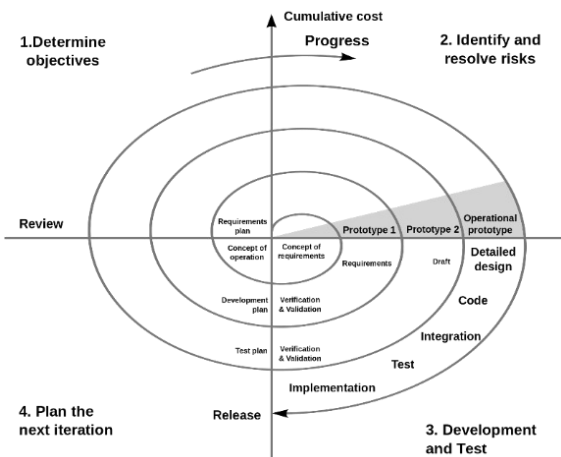

Fig. 3 The spiral model, originally proposed by Boehm for development of software, can be also applied to the C++ teaching process (from [1]).

However, it appears that the C++ teaching process is in many ways similar to this spiral model. Namely, many topics are, and should be, repeated with wider scope and level of details. Risk management in this case means strict control of the students' absorption of previous material before presenting an advanced version of a topic. This also applies to the gradual increase in the complexity of student developed projects.

III. EXEMPLARY TEACHING SCENARIOS

Some scenarios for teaching modern C++ are discussed here. Assuming classes organized in the semester periods (14/15 weeks per semester), and organized in the form of a lecture per week, a laboratory per week for the half of the semester, as well as the student's own project and consultations

for the remaining part of the semester, the following scenarios are presented for the entire three-semester C++ teaching cycle:

1. Introduction to programming with C++ (the beginners program), followed by basics of C++.
2. Object-oriented design & programming with C++, followed by advanced memory management.
3. Advanced C++ concepts, followed by basics of parallel programming.

A possible organization of classes in the form of a state diagram is shown in Fig. 4. Each of the three semesters consists of *two building states* – the idea here is that the second state in a semester is optional, i.e. it is undertaken if there is enough time and the group have achieved good results in the first state.

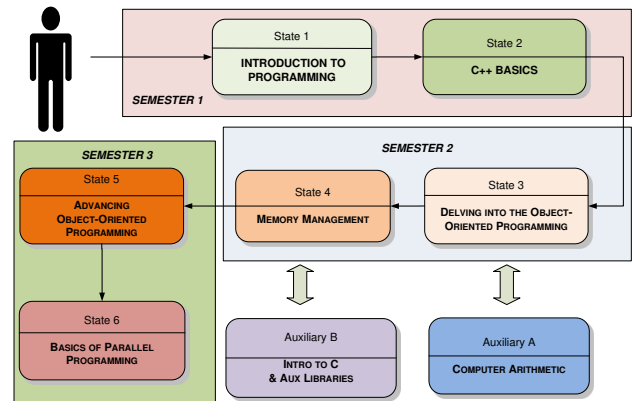

Fig. 4 Possible C++ teaching scenarios organized for the three semesters. Each semester consists of two stages – compulsory and optional, which is carried out if there is enough time and the group has demonstrated significant progress in learning. Also visible are auxiliary topics “A” for computer arithmetic and “B” for low-level features, such as the C programming language and introduction to additional libraries.

These are supplemented with the auxiliary states, which can be included to the program of teaching semesters depending on the needs and progress of the students. Supporting topics include: “A” computer arithmetic and “B” introduction to programming in C and a supplemental introduction to using libraries such as QT, FLTK, OpenGL, OpenMP, OpenCV, etc., depending on the students' needs and the profile of their faculties.

However, before providing some more concrete lists of features for each teaching scenario, let's highlight the following issues and hints that should be considered:

- Well define the main goals of the classes.
- For each semester well define a minimal set of C++ features to be acquired by students; for this purpose the 20/80 rule can be applied.
- Throughout the term: stick to the developed teaching plan (the curriculum) but actively respond to students' progress – this resembles the *agile* concept, applied to the teaching process.

Not surprisingly, the aforementioned teaching scenarios follow chapter layout in the book [6]. The more detailed teaching scenarios are outlined in the following subsections.

A. Scenario for Beginners

Following the plan outlined in Fig. 4 let's analyze a possible minimal set of C++ features. This can be defined as follows.

1. Introduction to the computer API and the basic C++ development tools (editor, compiler, linker, IDE, etc.).
2. The `main` function.
3. Minimal libraries (`#include`), using directive.
4. Printing texts `std::cout`.
5. Defining and *initializing* variables: `int` and `double` (explain the difference).
6. Entering values to the variables `std::cin`.
7. Conditional statement `if` and how to provide a logical condition.
8. `std::vector`
9. `std::string`
10. The loop: "classical" `for` and "range" `for`

Especially for beginners it is important to provide diagrams and ready recipes for project organization, tools, build process, particularly compiling and dealing with compilation errors as well as basics of debugging. Active support from the teacher is essential at this stage. A possible diagram of an exemplary program in the single `main` function is shown in Fig. 5.

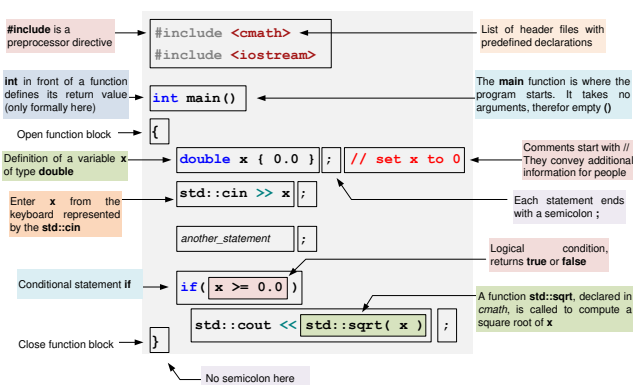

Fig. 5 A diagram showing basic constructions of a C++ program for absolute beginners (from [6]). Many projects for beginners can be written on the canvas of a single `main` function.

Although very simple, the code based on a single `main` function can be used successfully in many beginner projects.

B. Scenario for C++ Basics

A possible scenario for teaching the basics of C++ may include the following topics.

1. The most common built-in data types, their applications and initialization.
2. Code debugging techniques.
3. Basic members and applications of `std::vector`.
4. A matrix as a vector of vectors.

5. Basics of `std::string`.
6. `auto` and when to use it.
7. Common standard algorithms (`std::copy`, `std::find`, `std::generate`, `std::accumulate`, etc.).
8. Structures as data containers with `struct`.
9. References.
10. Statements (the role of braces).
11. Functions (argument passing, recursive, lambdas).
12. Intro to (separate) classes: `struct` vs `class` + constructor and member functions.
13. Basic of software testing.
14. Operators.

The beginners and basics scenarios constitute teaching material for the 1st semester (Fig. 4).

C. Scenario for Object-Oriented Programming in C++

A natural follow up is introduction to the OOP domain with C++. At this stage a possible list of topics can look as follows.

1. Intro to OOP.
2. Anatomy of a class (e.g. extended matrix class).
3. Right references.
4. Classes with all special functions – move semantics explained (e.g. extending matrices into tensors).
5. Templates and generic programming (functions, classes, member templates).
6. Virtual mechanism.
7. Some design patterns (e.g. wrapper, handle-bode/bridge, proxy).
8. Memory management (RAII, `std::unique_ptr`, `std::shared_ptr`, `std::weak_ptr`).

The virtual mechanisms and polymorphism should be shown on class hierarchies. However, the more complex are postponed to the advanced level, as discussed in the next section. Nevertheless, the introduction to the OOP and topics of memory management constitute material for the 2nd semester.

D. Teaching Advanced Topics of C++

After completing the OOP and memory management parts of the course, the last stage can be coined "advanced C++". However, it is not less difficult to define what actually should be included and how to teach such advanced concepts. Nevertheless, a possible list of topics can be formed as follows.

1. Designing class hierarchies.
2. C++ filesystem.
3. Forward/universal references.
4. Regular expressions (`std::regex`).
5. Graphical user interface (various libraries, QT, MFC, FLTK, ...).
6. System clock and time measurement (`std::chrono`).
7. Intro to functional programming and the `std::ranges`.
8. Intro to expression parsing – the interpreter DP, building the syntax trees, composite DP, visitor DP.
9. State machine pattern.
10. Advanced generic programming techniques.

11. Basics of parallel programming (`std::par`, `std::thread`, OpenMP).

Certainly, all the aforementioned teaching scenarios are just simple propositions [6]. They can be easily adjusted to best suit the level and needs of the students as already discussed.

IV. THE IMPECCABLE ROLE OF GOOD EXAMPLES

As it is not possible to teach swimming without entering the water, it is also not possible to teach programming without writing code and developing projects by students. Hence, the role of good code examples cannot be overestimated. However, let's consider what factors should be taken into account when preparing code examples for teaching. A good example of code should be:

- comprehensible,
- not too long,
- touch on 'real' problems,
- can serve as a starting point for student's project; i.e. it can be used in an incremental development and the spiral model in action.

The examples are very important because not only do they illustrate some code concepts, but they provide "thought patterns" that the developer evokes and then modifies while working on a similar problem.

There are different ways students can use the code examples, for instance:

- Compile, make it run, debug to observe the results.
- Re-type an example and make it run.

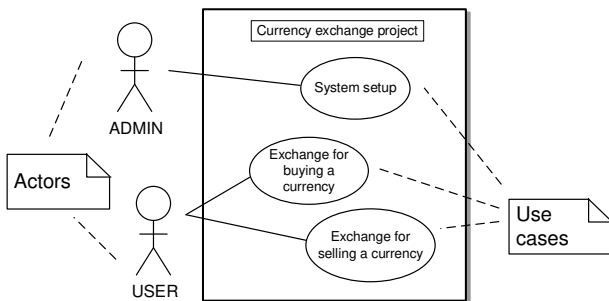

Fig. 6 Teaching software development is about more than showing C++ code. The entire process should be presented, starting e.g. with the UML diagrams and the complete development process, from design, till code unity tests and deployment. Here is a UML use case diagram of the currency exchange exemplary project (adopted from [6]).

- Don't use the example – create your own version, instead; then compare.
- Use as a 'startup' for your own project/example.

It is also important for educators to realize that teaching programming should encompass *the deeper context of software development*. This means that instead of showing only parts of C++, a teacher should present the entire development process,

starting with problem analysis, resulting UML diagrams such as in Fig. 6, software design, code unity tests, deployment, etc.

However, we'd like to emphasize that not less important is the process of consultations between the student and her/his teacher. Such a code refinement process enables comprehension of proper coding techniques.

V. TEACHING FOR THE REAL-LIFE CHALLENGES

The world did not start today, and there are millions of lines of the legacy code that still need to be maintained, deployed, refactored or extended. Therefore, teachers should ask themselves questions such as how to prepare students to cope with the existing code, as well as how to respond to the expectations of employers. The problem is even deeper – there is an ongoing discussion on mismatch between computer science curricula and industry needs [22][24][25][26][32], which generally is out of the scope of this paper. However, when confining this to teaching modern C++ the teachers should be aware of the *what* to address and *how* to go about, as well as of the *short time span* issues.

Returning to the task of teaching modern C++ in the light of the legacy code, we need to introduce the lower-level constructions of C++ (such as pointers, unions, raw memory/string operations, etc.), sometimes also at least the basics of C. Certainly, the set of these low-level features depends on the needs of the students. However, the most important are the proper moments in the teaching scenarios when these low-level features are taught. That is, low-level features should be introduced *after* instilling good programming habits in using *modern* features of C++, not the other way around.

The low-level features will be inevitable when preparing students to work with operating systems such as Linux or FreeRTOS, or to use many common libraries, such as OpenMP, OpenCV, OpenGL, QT or games with Unreal Engine, etc. But even to explain at some point what is `int main(int argc, char ** argv)` the teacher has to face how to introduce the pointers. So the question is not "if" but "when".

VI. CONCLUSIONS

The paper contains a short overview of the challenges related to promoting the interest in modern C++, as well as in teaching modern C++ to various groups of learners in the era of new technological challenges. The subject is very wide and we only scratched the surface.

Every three years, the C++ standardizing committee, supported by thousands of enthusiasts, publishes a new specification for the language. Thanks to this, it gained dozens of new features, which makes it very efficient and effective. However, such a dynamically changing environment also raises some problems especially in terms of the *stability* of language features as well as their presentation and acceptance from the world C++ programming community.

This also makes teaching modern C++ a real challenge. Accordingly, this paper introduces some teaching methodologies and techniques, such as the 20/80 principle, as well as some modifications to the software development

methodologies, such as the spiral model and agile approach, which were brought into the teaching domain. Further on, the overviews of some teaching scenarios for different groups of learners were provided. More detailed versions are available in the book *Introduction to Programming with C++ for Engineers* [6], whereas the code examples and additional materials are available from the Internet [8][9].

In the end, the following list summarizes the main postulates and guidelines for effective teaching of modern C++:

- As C++ programmers we are all students and many of us are, or become, teachers.
- When teaching, get to know your students, get to know their needs and wishes, then organize the classes well.
- At each stage think about selecting the appropriate C++ features for teaching, keeping in mind *the 20/80 rule*.
- Provide good and practical examples! They constitute “mental patterns” for your students.
- Keep things simple and in right order – but be *agile* and actively react to students’ progress.
- Teach in a repeated way, gradually introduce more advanced concepts and techniques, raising the level – apply the *spiral* development model.
- Teach not only C++ itself, but C++ across *the entire computer science framework*: show steps of software design, UML, data structures, algorithms, design patterns, development tools, software testing, etc.
- Do not forget about the programmers/companies reality, the legacy code, etc. Provide information on lower-lever features, teach basics of C if necessary, but at the right time.
- Pay attention to the self-education, always improve the skills of not only your students, but also yourself and your team, watch/participate in lectures, conferences, read books, etc.

With the increasing demands on high performance systems, the embedded world moving from C to C++, the revolution in big data, parallel computations, etc., undeniably C++ is, and probably will be, the most powerful modern computing language for many years to come. Therefore, there is no doubt that *C++ should be taught to a wide range of students*, especially of technical faculties. However, this should be well organized as *one of the important topics* in wisely prepared computer science curricula, containing *a combination of various programming languages*, that respond to the needs of industry in the era of new technologies and challenges.

As a concluding remark let's remember that: *The quality of the software of the future depends on the quality of education today.*

ACKNOWLEDGMENT

The author expresses his gratitude to Prof. Dominik Ślęzak for his invitation and encouragement to write this paper.

The author also commends Wiley-IEEE Press for the 2021 Wiley-IEEE Press Professional Book Award for the book *Introduction to Programming with C++ for Engineers* (<https://ieeepress.ieee.org/wiley-ieee-press-awards/>) and for financial support in participation in FedCSIS'22.

17th International Symposium Advances in Artificial Intelligence and Applications

THIS track is a continuation of international AAIA symposiums, which have been held since 2006. It aims at establishing the synergy between technical sessions, which encompass wide range of aspects of AI. With its longest-tradition threads, such as WCO focusing on Computational Optimization, it is also open to new initiatives categorized with respect to both, the emerging AI-related methodologies and practical usage areas. Nowadays, AI is usually perceived as closely related to the data, therefore, this track's scope includes the elements of Machine Learning, Data Quality, Big Data, etc. However, the realm of AI is far richer and our ultimate goal is to show relationships between all of its subareas, emphasizing a cross-disciplinary nature of the research branches such as XAI, HCI, and many others.

AAIA'22 brings together scientists and practitioners to discuss their latest results and ideas in all areas of Artificial Intelligence. We hope that successful applications presented at AAIA'22 will be of interest to researchers who want to know about both theoretical advances and latest applied developments in AI.

TOPICS

Papers related to theories, methodologies, and applications in science and technology in the field of AI are especially solicited. Topics covering industrial applications and academic research are included, but not limited to:

- Decision Support
- Machine Learning
- Fuzzy Sets and Soft Computing
- Rough Sets and Approximate Reasoning
- Data Mining and Knowledge Discovery
- Data Modeling and Feature Engineering
- Data Integration and Information Fusion
- Hybrid and Hierarchical Intelligent Systems
- Neural Networks and Deep Learning
- Reinforcement Learning
- Bayesian Networks and Bayesian Reasoning
- Case-based Reasoning and Similarity
- Web Mining and Social Networks
- Business Intelligence and Online Analytics
- Robotics and Cyber-Physical Systems
- AI-centered Systems and Large-Scale Applications
- AI for Combinatorial Games, Video Games and Serious Games
- Evolutionary Algorithms and Evolutionary Computation
- Artificial Intelligence for Next-Generation Diagnostic Imaging (1st Workshop AI4NextGenDI'22)

- Artificial Intelligence for Patient Empowerment with Sensor Systems (1st Workshop AI4Empowerment'22)
- Artificial Intelligence in Machine Vision and Graphics (4th Workshop AIMaViG'22)
- Intelligent Ambient Assisted Living Systems (1st Workshop IntelligentAAL'22)
- Personalization and Recommender Systems (1st Workshop PeRS'22)
- Rough Sets: Theory and Applications (4th International Symposium RSTA'22)
- Computational Optimization (15th Workshop WCO'22)

TRACK CHAIRS

- **Zdravevski, Eftim**, Ss. Cyril and Methodius University, Macedonia
- **Szczuka, Marcin**, University of Warsaw, Poland
- **Matwin, Stan**, Dalhousie University, Canada

PROGRAM CHAIRS

- **Corizzo, Roberto**, American University, USA
- **Sosnowski, Łukasz**, Systems Research Institute, Polish Academy of Sciences, Poland
- **Świechowski, Maciej**, QED Software, Poland

Abstract—This paper presents a novel approach towards link prediction in clinical knowledge graphs. They play a central role in linking data from different data sources and are widely used in big data integration, especially for connecting data from different domains. We present a knowledge graph initially built on data from a clinical trial on Spinocerebellar ataxia type 3 (SCA3), which is a rare autosomal dominant inherited disorder. The contributions of this paper are (1) to create a feasible data representation schema capable of handling clinical imaging data in a knowledge graph and to (2) convert the data efficiently into a knowledge graph. Due to the limited amount of patient-nodes usually common methods for link prediction and graph embeddings are problematic and thus we will (3) present a novel approach for link prediction utilising graph structures and Conditional Random Fields. In addition, we present (4) an extensive evaluation underlining the importance of (a) data management and (b) further research on link prediction using graph structures.

I. INTRODUCTION

KNOWLEDGE graphs have been shown to play an important role in recent knowledge mining settings, for example in the fields of life sciences or bioinformatics. Contextual information is widely used for NLP and knowledge discovery tasks since it highly influences the exact meaning of expressions and also queries on data. Here we will present some results on link prediction in knowledge graphs in the field of personalised medicine which aims for matching certain risk groups and possibly yet unknown subgroups to treatments, ultimately optimising patients' responses, mainly to available drugs. For this purpose, collected primary data of the examined persons have to be linked with data from secondary sources like publications or databases in an application-oriented way.

As part of the European Spinocerebellar Ataxia Type 3 Initiative (ESMI), SCA3 mutation carriers, their first-degree relatives, and healthy controls were prospectively studied using standardised clinical assessment as well as MRI imaging and biosampling.

Spinocerebellar ataxia type 3 (SCA3) is a rare autosomal dominant inherited disorder. The onset of the disease is in adulthood. Patients develop ataxia, which is a disorder of coordination of target movements that affects gait, fine motor skills and speech. The disease is progressive and patients in the advanced stages are usually dependent on the use of first a walking aid and later a wheelchair. Not only the gait

disorder has a strong influence on everyday activities. Also the independent preparation of meals, tool use of e.g. eating utensils and an increasingly unclear speech severely restrict the patients in their everyday life. Although SCA3 mutation carriers are not yet symptomatic, disease activity is already evident, for example, in atrophy of certain areas of the brain where neuropathological changes are predominant, as well as elevated blood levels of non-specific markers for neuron loss. The data set contains not only patient data but also digital imaging data [1], [2].

The goals of this paper are (1) to create a feasible data representation schema capable of handling clinical imaging data in a knowledge graph, see Figure 1, and to (2) convert the data efficiently into a knowledge graph. Since the overall amount of participants in clinical trials is usually not high, employing common methods for link prediction and graph embeddings is problematic [3]. We will (3) present a novel approach to link prediction utilising graph structures and (4) its evaluation.

This paper is divided into six sections. After an introduction, the second section gives a brief overview of the state of the art, related work and backgrounds used for our novel approach. Therefore, we will refer to both knowledge graphs and dedicated algorithms. In the third section, we present our approaches regarding data integration and data schema. The fourth section describes the novel approach to link prediction, with the experimental results on both artificial and real-world scenarios in the subsequent section.

Our conclusions and outlooks are drawn in the final section. We will propose a novel CRF-field based approach which presents promising performance. While the results at first glance do not seem to be a significant improvement for new algorithms for knowledge discovery on clinical data they clearly show the importance of (a) data management and (b) further research on link prediction using graph structures. We also provide a short outlook for extensions of our work.

II. RELATED WORK AND BACKGROUND

Clinical research is more and more relying on data-intensive approaches, thus facing increasingly complex challenges. Expert systems, for example, provide users with several methods for knowledge discovery. They are widely used to find relevant

was generalised to achieve interoperability with clinical data.

In our case, the first step taken is the integration of data from a very complex clinical trial. We will provide a data integration schema in the next section. The data schema should be capable of further data integration, for example *Gene Ontology* or data from scientific documents like *PubMed*. The software importer should be as generic as possible to work on multiple data sources. This helps to provide experimental results on data which is not affected by data protection regulations.

The experimental results are carried out using a Neo4j graph database on a HPC environment utilising parallel learning on several machines. We have provided a generic importer capable of handling different data sources. It makes use of a configurable ini-file which offers a predefined structure and is read-in by the generic importer. All software is available online¹.

III. DATA INTEGRATION AND DATA SCHEMA

The actual data schema for the graph on which this work is based is presented in Figure 2. For this purpose, the data used was first considered, taking into account the underlying data structure. This data structure is formalised and published in the *Registry of DICOM Data Elements*². There the different categories of objects within the *DICOM* metadata are listed, described and linked. The underlying tree structure of the information object definitions (IOD) and their sub-trees consisting of other IODs, modules and attributes is very well displayed in the *DICOM Standard Browser*³. Our data schema was significantly influenced by these sources and represents the inherent data structure using nodes, edges and attributes. The given selection and arrangement of the individual nodes has been made by the author as an exemplary instance. By adjustments in the configuration file also other schemes arise. However, for the graph used in this work it was necessary to decide on a schema. First, it was important to keep the four-level hierarchy of the *DICOM* data. This can be observed in Figure 2 in the middle strand. Each patient has his or her own node linked to his or her studies. These in turn contain the associated series, which then contain the images. In addition to this main strand within the schema, additional information is then annotated. All modules classified as mandatory (M) are included. In addition, at least one module from the classes conditional (C) and user optional (U) was also used. For (C) the class *Contrast/Bolus* is chosen, for (U) we decided on *Patient Study*. Within the data schema, the IOD modules used, which form their own node groups, are highlighted in yellow for visualisation, and the attributes in red. The blue line *Node Group = True* implies that the nodes listed below belong to the node group of the heading. These are represented as triangles in the graph, but are shown here as node groups for clarity. As an example, the *Manufacturer* node

can be considered. It belongs to the node group *General Equipment* and forms a triangle in the graph with the node *General Equipment* and the node *General Series*. An example is shown in Figure 3.3. In contrast, the *General Series* node, for example, has attributes such as *Modality*, *Series Instance UID*, and others stored as node-owned attributes rather than as separate nodes.

However, such specifications can be freely designed and modified via the configuration file, as explained in the section before. In addition to the data contained in the *DICOM* files, two more nodes have been added. *Source* specifies the source of the data. For the given data, this is stored under the tag (0013, 1010). *File* stores the file name of the image and therefore serves as a kind of provenance, allowing the nodes to be uniquely assigned to a respective file. To ensure that said two nodes can be included, it is important for the configuration of the importer that the patient is contained in the graph as a node. This means a minor restriction in the sense of free configuration, however, such a graph without patients should be difficult to justify in terms of content.

Due to data protection rules, we will present results using a second data source, which is open-source and also supports the generic usability of the importer. The *SIMBA Image Management and Analysis System*⁴ is used as our source. From the projects listed there, the *ELCAP Database* and from it again the *Zero-Change Dataset* were selected. The data comes from the *Public Lung Database to Assess Drug Response*, as can be seen from the website. A second configuration file named *dev2.ini* is created for them, which partly contains different nodes from the first one. Since the only purpose is to show conceptually that the script works for other data sets and configurations, only a much smaller total number of node types is used in the configuration file.

IV. LINK PREDICTION

A. Scores based on the topology of the graph

Link prediction belongs to the field of computational analysis of a network, where the nodes represent persons or entities and the edges represent relations. These networks are dynamic and change over time. The link prediction problem deals with a section of such a network at a time t_0 and asks for the most accurate predictions possible for edges that do not yet exist at time t_0 and will be added at a later time t . Among other things, the network's own topology plays a crucial role. To be able to quantify this topology different neighbourhood measures from graph theory and their relative effectiveness are investigated.

In [13] a so-called score is used for the measure of this effectiveness. It is calculated in different ways. Examples are:

- **Common Neighbours:** Given a graph $G = (V, E)$, $Score(x, y) := |\Gamma(x) \cap \Gamma(y)|$ describes the number of common neighbours of two nodes $x, y \in V$. Here, $\Gamma(v)$ denotes the direct neighbourhood of a node $v \in V$. [13]

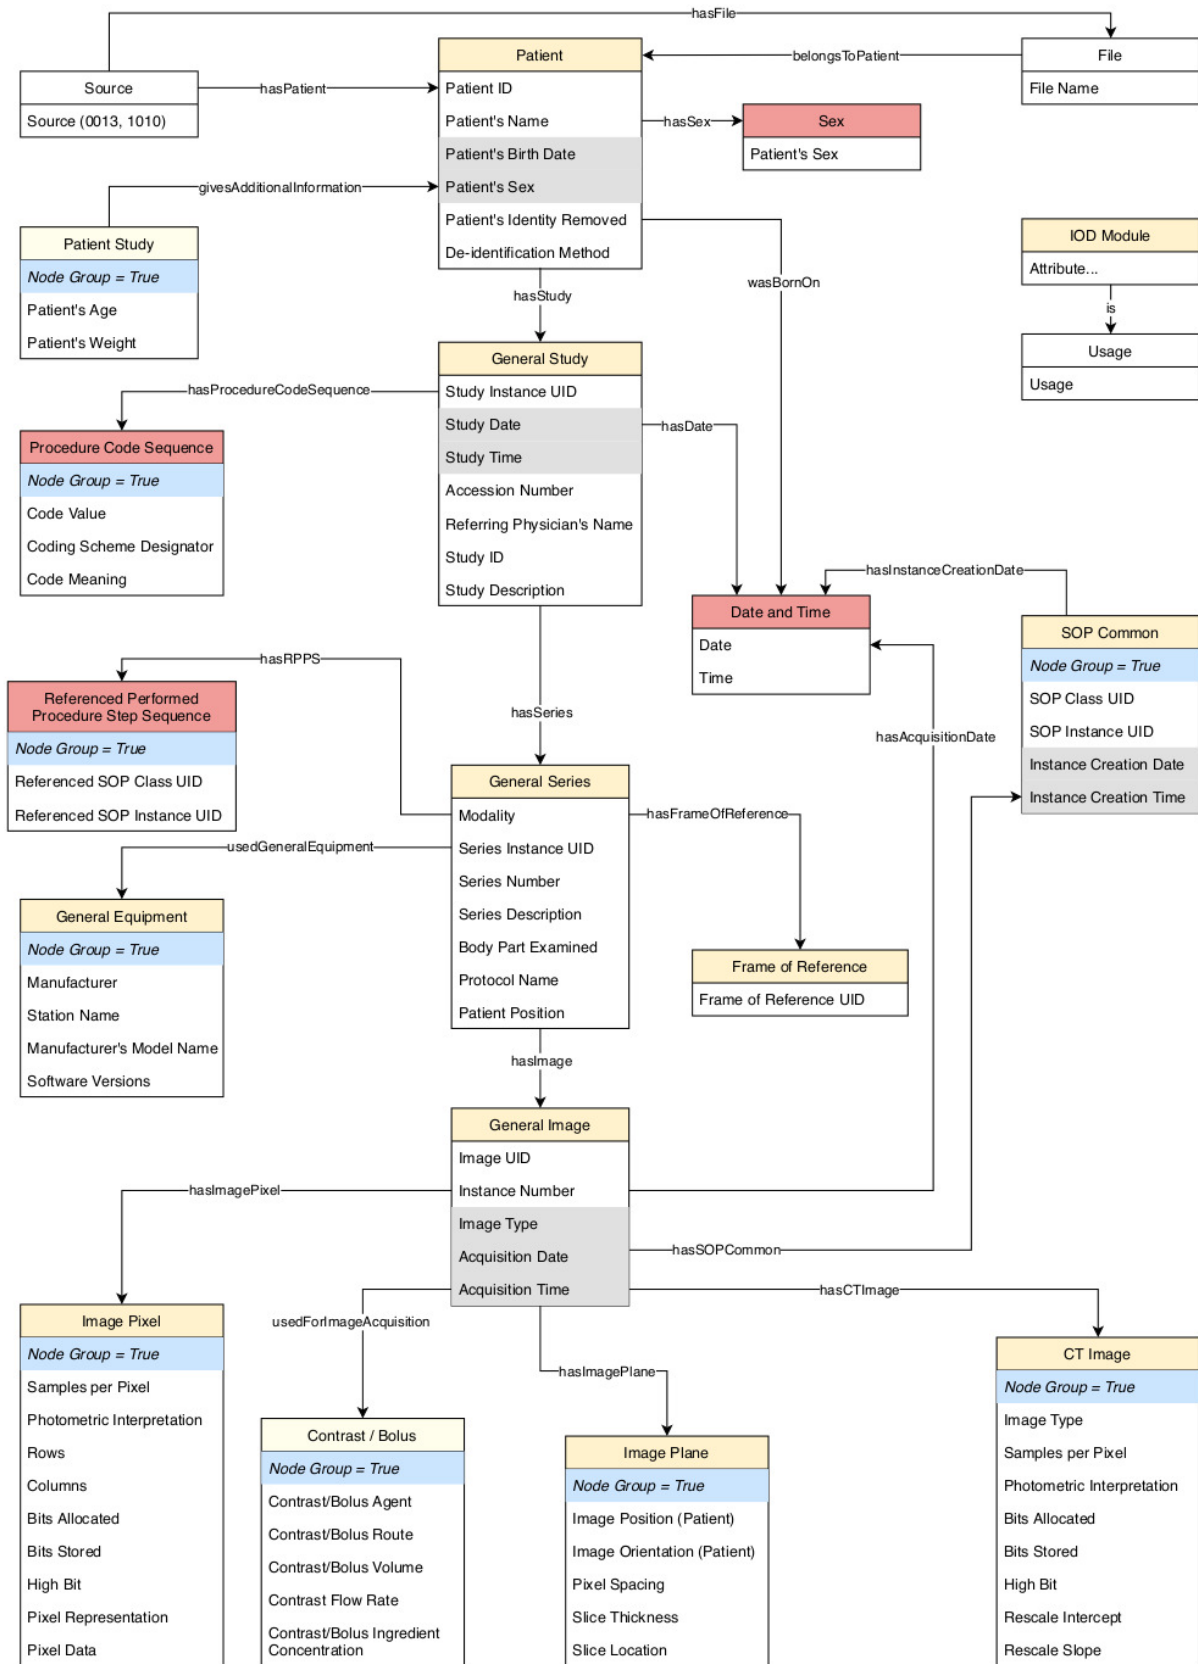

Fig. 2. Data schema for the import of DICOM files.

Fig. 3. Partial section of the graph: Exemplary triangle in the graph between the named example nodes Manufacturer (red), General Equipment (blue) and General Series (orange).

- Preferential Attachment: Given again a graph $G = (V, E)$. The underlying premise is the assumption that the probability that a new edge contains the node $x \in V$ is proportional to $|\Gamma(x)|$. Since the measure was originally conceived for predicting future collaborations between two authors, this yields $Score(x, y) := |\Gamma(x)| \cdot |\Gamma(y)|$. This builds on the idea that nodes with many edges have a higher probability of even more edges. [13]
- Adamic/Adar: The coefficient found here originally yields a measure that two homepages are strongly connected. For this purpose, features z are computed from a feature base set F of the two nodes, here web pages, and the commonality is defined as:

$$\sum_{z:\text{features shared by } x,y} \frac{1}{\log(\text{frequency}(z))}$$

This gives less weight to more frequent features than to less frequent ones. If features are to be left out and only the topology of the graph is to be considered, the following score is used for two nodes $x, y \in V$ of a graph $G = (V, E)$:

$$Score(x, y) = \sum_{z \in \Gamma(x) \cap \Gamma(y)} \frac{1}{\log(|\Gamma(z)|)}$$

These measures belong to methods based on node adjacency. [13]

They are presented in the Neo4j database in two ways as the basis of link prediction within the graph used there. First, there is the possibility of making the addition of a new edge conditional on whether the above score exceeds a pre-specified bound. If it does, the edge is added. On the other hand, the scores can be combined with supervised learning: They are used as features to train a binary classifier. This then predicts whether a particular pair of nodes will be connected by an edge with high probability in the future. To train and evaluate the classifier, the graph used is divided into training, testing and validation sets. Then training is performed within the training graph and the result is applied to the test graph. During validation, promising results are shown for the use case. With this work, as will be explained later, a different approach is

taken, but one that also uses these scores as features or as a criterion for choosing a label.

B. Link prediction for paths based on node attributes

The approach adopted in this paper makes use of Conditional Random Fields. Therefore, their origin is briefly examined here and an introduction is given.

a) *Markov chain*: First, a simple Markov chain of order n is considered. The idea is to be able to calculate the probability of future states occurring. The order indicates on how many previous states the next one depends. In a first-order Markov process, the next state depends only on the current state. At the beginning, the system is in the initial state. [19]

Definition IV.1. A Markov process is understood to be a tuple (S, A, δ) . Here S describes the finite set of states, A the set of possible actions, and δ the state transition function. [19]

For each pair (s_t, a_t) with $s_t \in S, a_t \in A$ the state s_t transitions via $\delta(s_t, a_t)$ to the state s_{t+1} . The transitions in this case are usually given in probabilities. The choice of action depends on the current state and can be represented as a function $\pi : S \rightarrow A; \pi(s_t) = a_t$. It is also called a strategy. [19]

b) *Hidden Markov models*: Hidden Markov models are used to represent probability distributions over sequences of observations. A distinction is made between the observation X_t and the state Z_t at time t . The latter is hidden, hence the name of the model. Here, as in the 1-step Markov chains, the so-called Markov property is assumed: Z_t at time t depends only on Z_{t-1} at time $t-1$. An example of this can be seen in Figure 4. The time t need not be an explicit time and can also be implicitly considered as a location within the sequence. The overall probability distribution of a sequence of states and observations can be expressed as an equation as follows:

$$P(Z_{1:N}, X_{1:N}) = P(Z_1)P(X_1|Z_1) \prod_{t=2}^N P(Z_t|Z_{t-1})P(X_t|Z_t)$$

Since the states are hidden and only the observations are considered, which in turn depend on the states, the probability of an N-element sequence is represented by a product of

Fig. 4. Example of a hidden Markov model: Z_t describes the state and X_t the observation dependent on it at time t .

conditional probabilities. Moreover, except for the initial state, each state depends on the previous one. [20], [21], [22]

According to [20], [21], there are five elements that characterise a hidden Markov model:

- the number K of states that can be assumed in the model. The states are represented as $K \times 1$ vectors with binary values such that the k -th state at time t takes the value 1 in the k -th row and 0 everywhere else.
- the number Ω of distinct observations that can be observed in the model. Analogous to the states, an $\Omega \times 1$ vector is used.
- the state transition model A : This is also called the state transition probability distribution and describes the probability of changing from a state $Z_{t-1,i}$ to a state $Z_{t,j}$ within one time step. Here $i, j \in 1, \dots, K$. This can be formulated as follows:

$$A_{i,j} = P(Z_{t,j} = 1 | Z_{t-1,i} = 1)$$

Each row of A sums up to 1 in this case.

- the observation model B is an $\Omega \times K$ matrix whose elements $B_{j,k}$ give the probability of making the observation $X_{t,k}$ given the state $Z_{t,j}$:

$$B_{j,k} = P(X_t = k | Z_t = j)$$

- the initial state distribution π is a $K \times 1$ vector with $\pi_i = P(Z_{1,i} = 1)$.

The model is often abbreviated in literature as $\lambda = (A, B, \pi)$. [20], [21]

c) *Markov Random Fields*: Let $G = (V, E)$ be an undirected graph. The nodes $v \in V$ correspond to the random variables which can assume the states. Here, these depend only on the states of the random variables u of their Markov cover $B_v := \{u : (v, u) \in E\}$. This is expressed in the following equation:

$$P(x_1, \dots, x_n) = \frac{1}{Z} \prod_{c \in C} F_c(x_c)$$

Here C is the set of maximal cliques of the graph. The functions F are non-negative and depend on the variables within a clique c . For normalisation, a function $Z = \sum_{x_1, \dots, x_n} \prod_{c \in C} F_c(x_c)$ is used so that the distribution sums up to 1 overall. [23]

d) *Conditional Random Fields*: Conditional Random Fields are a special case of Markov Random Fields and belong to the field of supervised learning. Instead of only considering the probability for a label sequence y , here the probability of a label sequence y , conditioned by an observation sequence x , is determined:

$$P(y|x) = \frac{1}{Z(x)} \prod_{c \in C} F_c(x_c, y_c),$$

$$Z(x) = \sum_{y \in Y} \prod_{c \in C} F_c(x_c, y_c)$$

The normalisation function $Z(x)$ now also depends on x .

In other literature, the definition of a (linear chain) Conditional Random Field is the conditional probability

$$p(y_{1:n} | x_{1:n}) = \frac{1}{Z} \exp \left(\sum_{n=1}^N \sum_{i=1}^F \lambda_i f_i(y_{n-1}, z_n, x_{1:N}, n) \right).$$

Within the exponential function, the first sum is over $n = 1, \dots, N$, which indicates the position of a word, or here a node, within the sequence. The second sum iterates the features f_i weighted by the scalars λ_i , $i = 1, \dots, F$. The values for the weights must be given or learned by the CRF model. They ensure that certain labels are preferred or even avoided. [24] For a given sequence, several features can be active at the same time, i.e., not equal to 0. This is called overlapping features. This can happen because, unlike in hidden Markov models, it is also possible to look at subsequent or previous elements of the sequence. [24] To train, fully labelled training sequences $(x^{(1)}, y^{(1)}), \dots, (x^{(m)}, y^{(m)})$ are required, where $x^{(i)} = x_{1:N}^{(i)} \forall i \in 1, \dots, m$. Thus, the conditional probability of the training data is maximised:

$$\sum_{j=1}^m \log p(y^{(j)} | x^{(j)})$$

This is computed by default employing algorithms that use the gradient descent method. [24]

To assess the quality of the prediction, the F1-score (also balanced F-score or F-measure) is used. This can be regarded

Fig. 5. The input path p consists of the nodes v_i , $i = 1, \dots, n$ highlighted in grey. The white nodes u_j , $j = 1, \dots, m$ serve as labels of the nodes of p .

as a weighted average of the precision and the recall. The best value is 1 and the worst value is 0. The formulas used for this are:

$$F1 = 2 \cdot \frac{\text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}},$$

$$\text{Precision} = \frac{TPR}{APR},$$

and:

$$\text{Recall} = \frac{TPR}{APS}.$$

Here TPR means true positive results, APR means all positive results and APS are all samples that should have been identified as positive.

e) Learning Paths: Link prediction is used to predict possible, initially non-existent edges for the previously constructed graph. For this purpose, the graph is imported from *Neo4j* into *Python* via the *py2neo* library⁵. Then, using a query, paths are read in from the graph to be used as input for the conditional random fields and link prediction. The paths are converted to NER-compatible (named entity recognition) form. Thus, a path p is considered first. Then, for each node v contained in p , all neighbouring nodes $u \in \Gamma(v)$ are taken as possible labels. Thus, each node can be used both as a node of a path and as a label for other nodes, see Figure 5.

In the next section, we describe and evaluate different scenarios.

C. Creating one-node paths

The simplest form offers a path of length one, i.e. a single node and its direct neighbourhood. For this purpose, these one-node paths are read from the graph. It is specified which node type is considered, e.g. patients or images. Then a graph query is used to find the direct neighbourhood $\Gamma(v)$ of these nodes $v \in G$ and Γ is stored as a set of labels $l(v)$ for v . Since the CRF library can only assign one label to each node v at a time, criteria must be used for selection. For this purpose, section IV-A is used here to select nodes with, for example,

⁵see <https://py2neo.org/2021.1/>

TABLE I

EXCERPT FROM THE OUTPUT OF QUERY Q1. THE TERM SCORE REFERS TO THE VALUE CALCULATED FOR THE NODE AND ITS LABEL BY NEO4J'S COMMON NEIGHBOURS ALGORITHM.

patientNode	labelNode	score
CT-Training-BE001	SPIE-AAPM Lung CT Challenge	251.0
CT-Training-BE001	1.2.840.113704.1.111.2112.1167842143.1	2.0
CT-Training-BE001g	Patient_Study	2.0
CT-Training-BE001	073Y	1.0
CT-Training-BE001	1-001.dcm	1.0
...		

the highest score in one of the link prediction algorithms available in *Neo4j*. Later, alphabetical sorting is also given as an alternative. The choice of the method for probing the labels on the one hand influences the result and on the other hand also the runtime of the queries. First, single patient nodes are considered. As their label the neighbour with the highest score first at Common Neighbours and then at Total Neighbours is chosen. Afterwards we consider two other nodes, namely General Image and Date. The queries used for this are the following (Since some queries did not terminate they are left out):

```
(Q1) MATCH (p:Patient)-[]-(a) RETURN p.nodeUID
as patientNode, a.nodeUID as labelNode,
gds.alpha.linkprediction.commonNeighbors(p, a)
AS score ORDER BY p.nodeUID, score
DESC, a.nodeUID
```

```
(Q2) MATCH (p:Patient)-[]-(a) RETURN p.nodeUID
as patientNode, a.nodeUID as labelNode,
gds.alpha.linkprediction.totalNeighbors(p, a)
AS score ORDER BY p.nodeUID, score, a.nodeUID
```

```
(Q4) MATCH (p:General_Image)-[]-(a) RETURN
p.nodeUID as imageNode, a.nodeUID as labelNode
ORDER BY p.nodeUID, a.nodeUID
```

```
(Q5) MATCH (p:Date)-[]-(a) RETURN p.nodeUID
as dateNode, a.nodeUID as labelNode ORDER BY
p.nodeUID, a.nodeUID
```

See table I for an example output for query Q1. The algorithm we use for applying the *CRFs* to the paths from the graph consists of the following steps:

Algorithm 1 INTEROPERABLE-DATA

Require: Graph G in *Neo4j*

Ensure: Label prediction, Measurement of prediction success

- 1: readNodePathsFromGraph(G)
 - 2: splitValidationAndTrainingData()
 - 3: for all P in AP :
 - 4: assignFeaturesToNodesInPaths($N(P)$)
 - 5: assignLabelsToNodes($N(P)$)
 - 6: trainUsingCRFs(AP)
 - 7: evaluateResultByComparingToValidationData()
 - 8: **return** predictionVector, F1-Score, Precision, Recall
-

Here $N(P)$ denotes the set of nodes in path P while AP denotes the set of all paths read from the graph. The set of output values consists of a prediction vector as well as the F1 score, the precision and recall.

TABLE II
DETAILS FOR QUERY Q1

node	precision	recall	f1-score	support
SPIE-AAPM Lung CT Chall...	1.0000	1.0000	1.0000	14
accuracy			1.0000	14
macro avg	1.0000	1.0000	1.0000	14
weighted avg	1.0000	1.0000	1.0000	14

V. EVALUATION

A. Runtime

This subsection deals with the consideration of the achieved runtimes of the link prediction programmes. First, the runtime result of the queries Q1 - Q5 is presented. Within the programme, times are measured for all individual sections. The problematic part of the programme is the `sent2features()` method. For illustration the runtime of the time-relevant parts is shown in Figure 6. All other parts of the programme have a negligible very small runtime. This is especially evident for Q4. In this query, the `General Image` node is in the centre, which compared to other nodes such as `Patient` has already got a lot of neighbours due to the structure of the graph. The runtime, which is almost completely generated by `sent2features()`, amounts to a total of slightly less than 11 hours.

B. Quality

The first attempts at link prediction are carried out with single-node paths. Here the focus is initially on the patient. For Q1 link prediction shows the association of the data with the associated study *SPIE-AAPM Lung CT Challenge*. In this case a F1-score of 1 is obtained. This prediction is very accurate, however this is not surprising given the data. The patient node has a very limited type and number of neighbours. Sorting by number of common neighbours leaves only the source. This is also reflected in the detailed look at the labels, as can be seen in Table II.

In these tables, available labels are shown under the heading node. Precision, recall and the F1-score are shown to the right. The value at support indicates the frequency of the find. The opposite results are obtained for sorting by Total Neighbours. Here a F1-score of 0 is obtained. Thus, the prediction has completely failed here. The result can be seen in Table III. Again, the actual result is not surprising considering the data. The patients have different ages and due to the small group of individuals, clustering is unlikely.

The penultimate one-node path query is Q4. Here labels for the node `General Image` are being examined. The label selection is based on alphabetical order. From a biological point of view, a different weighting may be more appropriate, but several methods of label selection should be tried for scientific reasons. For Q4, a nominally very good value of 0.7737 was obtained for the F1-score. The detailed consideration of the result is presented in excerpts in Table IV. It shows that different labels were selected for the images in the prediction, with priority given to the label -1024. For the last query Q5

there is only a limited set of available nodes and edges of the graph due to the node selection and the given data. The programme nominally returns a very high value with an F1-score of 0.9819. The label predicted for the node `Date` is `SOP_Common`. The values of precision and recall compared to the F1-score are shown for the queries Q1 - Q5 in Figure 7 and Figure 8. The former relates precision and recall to each other. The contour lines provide a visual impression of the corresponding F1-score. The latter shows the three values for precision, recall and F1-score side by side,

VI. CONCLUSION AND OUTLOOK

Our studies pursued several goals. The first and second were to create a feasible data representation schema capable of handling clinical imaging data in a knowledge graph and the generic approach for importing imaging data into a graph. *Neo4j* provides an easy way to import large amounts of data with bulk import and we provide the source code of our solution online. This can be individually configured by the user with the help of the script presented here and the associated configuration file. The design of the graph can be very much defined by the user. For the combination with already existing graphs and data systems an interface can be formed with few lines of code. To do so, only the possibly overlapping node types have to be identified. The corresponding CSV files of the programme presented here can be read in a subsequent programme and the node IDs can be stored in sets. Thus, our solution could also be integrated in analysis workflows, for example utilising text mining.

The third goal was to present a novel approach for link prediction utilising graph structures and applying NER and

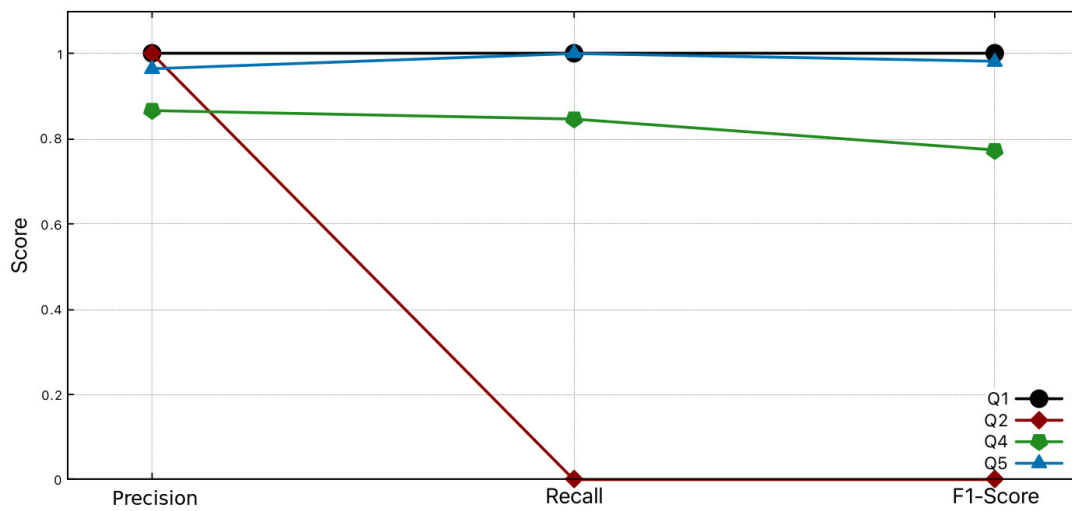

Fig. 8. Comparison of precision, recall and F1-score of queries Q1 - Q5.

CRFs to paths from a graph. For single-node paths, excellent results were obtained for the selected nodes. But we could also show the importance of data management and further research on link prediction using graph structures. For Q1 we could provide trivial results and this clearly underlines the need for data literacy, understanding the structures is essential. Our proposed approach also states the importance of an evaluation with state-of-the-art graph embedding technologies to prove the advantage of keeping graph structures for AI approaches on graphs as [16] proposed.

The next step would be considering multi-node paths which will show an increasing runtime for large data sets. Querying features from the graph in our experimental setting turned out to be very time consuming and scales accordingly with the amount of data. The second problem is the increasing runtime for machine learning as the number of nodes used in the input path grows. At the same time, the requirements for the available main memory also increase enormously. However, both are related not only to the length of the input path, but also to the local environment of the paths. We assume that sparsely populated locations of the graph allow better predictions and provide faster results.

While our proof of concept is both functional and generic, extending the knowledge graph, e.g. with data from text mining on scientific documents, is feasible and just a matter of modelling connectors to the relevant sources since the software is prepared for running in a workflow.

ACKNOWLEDGMENT

We thank the Regional Computing Center of the University of Cologne (RRZK) for providing computing time on the DFG-funded (Funding number: INST 216/512/1FUGG) High Performance Computing (HPC) system CHEOPS as well as support.

Deep Learning Transformer Architecture for Named-Entity Recognition on Low-Resourced Languages: State of the art results

Ridewaan Hanslo
University of Pretoria
Gauteng, South Africa
Email: ridewaan.hanslo@up.ac.za

Abstract—This paper reports on the evaluation of Deep Learning (DL) transformer architecture models for Named-Entity Recognition (NER) on ten low-resourced South African (SA) languages. In addition, these DL transformer models were compared to other Neural Network and Machine Learning (ML) NER models. The findings show that transformer models substantially improve performance when applying discrete fine-tuning parameters per language. Furthermore, fine-tuned transformer models outperform other neural network and machine learning models on NER with the low-resourced SA languages. For example, the transformer models obtained the highest F-scores for six of the ten SA languages and the highest average F-score surpassing the Conditional Random Fields ML model. Practical implications include developing high-performance NER capability with less effort and resource costs, potentially improving downstream NLP tasks such as Machine Translation (MT). Therefore, the application of DL transformer architecture models for NLP NER sequence tagging tasks on low-resourced SA languages is viable. Additional research could evaluate the more recent transformer architecture models on other Natural Language Processing tasks and applications, such as Phrase chunking, MT, and Part-of-Speech tagging.

Index Terms—Named-Entity Recognition, Natural Language Processing, Neural Networks, Sequence Tagging, XLM-R, Machine Learning, Transformer Models.

I. INTRODUCTION

NATURAL Language Processing (NLP) which has been in existence for more than 70 years, is a branch of Artificial Intelligence [7]. NLP uses computational techniques for the analysis and representation of naturally occurring texts to achieve human-like language processing for various applications and tasks. Machine Translation (MT) was the first computer-based NLP application [7]. Thereafter, applications utilizing NLP such as Information Retrieval, Information Extraction (IE), and Question-Answering (QA) were introduced [7]. These IE applications include sequence tagging tasks such as Named-Entity Recognition (NER) and Part-of-Speech (POS) tagging.

NER is a task that processes natural language, classifying and grouping, for example, words into categories (also known as phrase types) [20]. With the advent of big data and large datasets, classifying natural language in these datasets has become increasingly important. For example, organiza-

tions are able to apply NER in customer support, content classification, and search and recommendation engines [21]. Furthermore, NER findings may be transferred to other NLP tasks such as MT, automatic text summarization, and knowledge base construction [20]. Lack of data severely impedes performance on NER tasks with low-resourced languages [20].

Recently, within NLP research, the use of Neural Network (NN) architectures, also referred to as Deep Learning (DL) architectures, has generated state-of-the-art results for MT, IE, and QA tasks [2], [8]. NN has seen several additions in the past few decades, from Convolutional Neural Networks (CNN) and Recurrent Neural Networks (RNN) to Transformer architectures [3], [4], [8]. CNN is an extensively studied DL architecture inspired by the visual perception mechanisms of living creatures [11]. RNN is concerned with sequential data that display correlations between data points within a time sequence [12]. Transformers are prominent NN architectures in NLP research, surpassing RNN and CNN in model performance [13].

Transformers facilitate the creation of high-capacity models that are pre-trained on large corpora. These transformers capture long-range sequence features that facilitate parallel training, and the pre-trained models are easily adapted to specific tasks with good performance [13]. XLM-Roberta (XLM-R) is a recent transformer model that has reported state-of-the-art results for NLP tasks and applications, such as NER, POS tagging, phrase chunking, and MT [2], [9].

NLP sequence tagging tasks such as NER and POS tagging have been extensively researched [1]-[7], [9], [10]. However, within the past few years, new DL transformer architecture models such as XLM-R, Multilingual Bidirectional Encoder Representations from Transformers (M-BERT), and Cross-Lingual Language Model (XLM) lower the time needed to train large datasets through greater parallelization. This allows low-resourced languages to be trained and tested with less effort and resource costs while achieving state-of-the-art results for sequence tagging tasks [1], [2], [9]. M-BERT, a single language model pre-trained from monolingual corpora, performs cross-lingual generalization very well [14]. Furthermore, M-BERT is capable of capturing multilingual representations [14]. On the other hand, XLM pre-training has led to solid

This work is based on the research supported by the National Research Foundation of South Africa (Grant Number 138325).

improvements in NLP benchmarks [15]. Additionally, XLM models have contributed to significant improvements in NLP studies involving low-resourced languages [15]. These transformer models are usually trained on very large corpora with datasets that are terabytes (TB) in size.

II. BACKGROUND

A recent study by [1] researched whether NN's are viable for NLP sequence tagging (POS tagging and NER) and sequence-to-sequence (Lemmatization and Compound Analysis) tasks for resource-scarce languages. These resource-scarce languages are ten of the 11 official South African (SA) languages, with English being excluded. The languages are considered low-resourced, with Afrikaans (af) being the more resourced of the ten [1], [10]. This recent study compared two Bidirectional Long Short-Term Memory with Auxiliary Loss (bi-LSTM-aux) NN models to a baseline Conditional Random Fields (CRF) model. The annotated data used for the experiments are derived from the National Centre for Human Language Technology (NCHLT) text project. The results suggest that NN architectures such as bi-LSTM-aux are viable for sequence tagging tasks for most SA languages [1]. However, within the study by [1], NN's did not outperform the CRF Machine Learning (ML) baseline NER model. Rather the CRF model performed better on NER than the bi-LSTM-aux models. Loubser and Puttkammer [1], therefore, advised further studies to be conducted using NN transformer models on resource-scarce SA languages. Additionally, because of the considerable variation in performance per language during their study, [1] suggests conducting further research on the variation in performance per language.

Similarly, a previous study by [18] evaluated XLM-R transformer models for NER on low-resourced languages. However, the fine-tuning of the transformer models was at the model level and not the language level. In other words, a transformer model was fine-tuned on, for example, the Afrikaans (af) language. Thereafter, the model with the fine-tuned parameters for the Afrikaans (af) language was applied to the other remaining nine SA languages. The reason for this decision was due to resource capacity constraints. As a result, the study by [18] produced only a couple higher F-scores than the CRF and bi-LSTM-aux baseline models. Albeit, the CRF model retained the highest average F-score for the ten languages.

For this reason, this study builds upon these previous studies by evaluating the performance of DL transformer architecture for NER on low-resourced languages with fine-tuning of the model applied at the language level. Therefore, the purpose of this study is to evaluate the performance of the NLP NER sequential task using two XLM-R transformer models applying fine-tuning to each model and language combination. In addition, the experiment results are compared to previous research findings.

A. Research Hypotheses

H₁ – There is a performance improvement for NER on the low-resourced SA languages using fine-tuned XLM-R transformer models.

H₂ – Fine-tuned XLM-R transformer models outperform other neural network and machine learning models on NER with the low-resourced SA languages.

B. Paper Layout

The remainder of this paper comprises of the following sections: Sect. III provides information on the languages and datasets while Sect. IV presents the language model architectures. The experiment settings are presented in Sect. V. The results and a discussion of the research findings are provided in Sect. VI and Sect. VII respectively. Section VIII concludes the paper, providing practical implications, limitations of this study and recommendations for future research.

III. LANGUAGES AND DATASETS

As mentioned by [1], SA is a country with at least 35 spoken languages. Of those languages, 11 are granted official status. The 11 languages can further be broken up into three distinct groups. The two West-Germanic languages, English and Afrikaans (af). Five disjunctive languages, Tshivenda (ve), Xitsonga (ts), Sesotho (st), Sepedi (nso) and Setswana (tn) and four conjunctive languages, isiZulu (zu), isiXhosa (xh), isiNdebele (nr) and Siswati (ss). A difference between SA disjunctive and conjunctive languages is the former has more words per sentence than the latter. Therefore, disjunctive languages have a higher token count than conjunctive languages. For further details on conjunctive and disjunctive languages and examples thereof, see [1].

The datasets for the ten evaluated languages are available from the South African Centre for Digital Language Resources online repository (<https://repo.sadilar.org/>). These annotated datasets are part of the NCHLT Text Resource Development Project, developed by the Centre for Text Technology (CTeX, North-West University, South Africa) with contributions by the SA Department of Arts and Culture. The annotated data is tokenized into five phrase types. These five phrase types are:

1. LOC - Location
2. MISC - Miscellaneous
3. ORG - Organization
4. OUT - not considered part of any named-entity
5. PER - Person

The LOC, ORG and PER phrase types are entity names and are the main named entity category used in this study. The MISC phrase type as explained by [10] are for phrase types that form part of either the number expressions or temporal named entity categories so as not to lose the opportunity to annotate the data, which can be further annotated in the future [10].

It is important to note that this annotated data is the same dataset used by the previous studies [1], [10], [18]. However, the studies by [10] and [18] clearly indicates the inclusion of the MISC phrase type whereas, the study by [1] does not.

The previous studies made use of the CoNLL-2003 shared task protocol for data tagging [19]. Additionally, the named entities are further annotated with the beginning [B], inside [I], and outside [O] labelling scheme, which is posited to be ideal for sequence tagging training [10].

The datasets consist of SA government domain corpora. Therefore, the SA government domain corpora are used to do the experiments and comparisons. Eiselen [10] provides further details on the annotated corpora.

IV. LANGUAGE MODEL ARCHITECTURES

A. XLM-R

XLM-Roberta (XLM-R) is a transformer-based multilingual masked language model [2]. This language model trained on 100 languages uses 2.5 TB of CommonCrawl (CC) data [2]. From the 100 languages used by the XLM-R multilingual masked language model, it is noted that Afrikaans (af) and isiXhosa (xh) are included in the pre-training.

As indicated by [2], the benefit of this model is training the XLM-R model on cleaned CC data increases the amount of data for low-resourced languages. Further, because the XLM-R multilingual model is pre-trained on many languages, low-resourced languages improve performance due to positive transfer [2].

The study by [2] reports the state-of-the-art XLM-R model performs better than other NN models such as mBERT and XLM on QA, classification, and sequence labelling. For this research study, two transformer models are used for NER evaluation. The XLM-R_{Base} NN model and the XLM-R_{Large} NN model. The XLM-R_{Base} model has 12 layers, 768 hidden states, 12 attention heads, 250 thousand vocabulary size, and 270 million parameters. The XLM-R_{Large} model has 24 layers, 1024 hidden states, 16 attention heads, 250 thousand vocabulary size, and 550 million parameters [2]. Both pre-trained models are publicly available (<https://bit.ly/xlm-rbase>, <https://bit.ly/xlm-rlarge>).

These pre-trained models (XLM-R_{Base} and XLM-R_{Large}), as mentioned in Sect. I allow low-resourced languages to be trained and tested with fewer resource costs and effort. Therefore, they were fed into this study's DL transformer architecture NER model as part of the NER evaluation process. The model was developed with the Python programming language, the PyTorch ML framework, the Facebook AI Research Sequence-to-Sequence Toolkit (written in Python), and the PyTorch Transformers library. The developed model incorporated the AdamW PyTorch algorithm (optimizer) with warm-up scheduling was trained, validated and then evaluated on the test data. Section V discusses the model's experimental settings.

B. CRF

Conditional Random Fields (CRF) is used for building probabilistic models for segmentation and labelling of sequence data [5]. CRF as ML models are simple, yet, successfully used for NLP sequence tagging tasks, such as NER and POS tagging [4]. Before the use of CRF, Hidden Markov Models (HMM) and stochastic grammars were widely used probabilistic models for tagging tasks [5]. The benefit of using CRF as a sequence modelling framework is it addresses label biases much better than HMM [5]. Additionally, CRF also provides for better stochastic context-free grammar generalization. More information on the CRF ML model is provided by [5].

Eiselen [10] used a CRF ML model for NER on the ten low-resourced SA languages, and [1] included this model as the baseline to compare their two bi-LSTM-aux NN architecture models. Loubser and Puttkammer's [1] findings show that the bi-LSTM-aux models were almost on par with the CRF model, meaning that the NN models did not outperform the ML model. For this reason, this study includes the CRF model as it would be good to compare the DL models with ML models that consistently performs well on NLP sequence tasks. The code for this model is publicly available (<https://taku910.github.io/crffp>).

C. bi-LSTM-aux

Bidirectional Long Short-Term Memory with Auxiliary Loss (bi-LSTM-aux) NN models have been reported as successful with NLP sequence modelling tasks [3]. Modelling tasks include POS tagging, NER, sentiment analysis, and dependency parsing [3]. While both LSTM and bi-LSTM models are classified as RNN, bi-LSTMs implement a backward and forward pass through the sequence before proceeding to the next layer within the network [3]. The inclusion of the auxiliary loss function in the model is to help improve performance gains for rare words used within the corpora [3]. The bi-LSTM-aux model was trained on 22 languages, using polyglot embeddings, and data obtained from the Universal Dependencies project [3]. Additional details on the model are obtainable from [3]. The findings from the study by [3] using their novel bi-LSTM-aux model for POS tagging suggests that the model is as effective as HMM and CRF tagging models. Loubser and Puttkammer [1] used bi-LSTM-aux and bi-LSTM-aux with embeddings model variations for their study. The code for these models is publicly available (<https://github.com/bplank/bilstm-aux>).

V. EXPERIMENTAL SETTINGS

The experimental settings for the XLM-R_{Base} and XLM-R_{Large} models are described next, followed by the evaluation metrics and the corpora descriptive statistics.

TABLE I.
FINE-TUNED PARAMETERS PER LANGUAGE AND MODEL COMBINATION

Language	Model	Learning Rate	Warmup Proportion	Dropout
Afrikaans (af)	Base	6e-5	0.0	0.0
	Large	6e-5	0.0	0.2
isiNdebele (nr)	Base	6e-5	0.0	0.0
	Large	6e-5	0.0	0.0
isiXhosa (xh)	Base	6e-5	0.0	0.2
	Large	6e-5	0.1	0.2
isiZulu (zu)	Base	6e-5	0.1	0.2
	Large	6e-5	0.0	0.2
Sepedi (nso)	Base	7e-5	0.1	0.3
	Large	7e-5	0.1	0.3
Sesotho (st)	Base	6e-5	0.0	0.2
	Large	6e-5	0.1	0.2
Setswana (tn)	Base	6e-5	0.1	0.3
	Large	6e-5	0.0	0.0
Siswati (ss)	Base	6e-5	0.0	0.2
	Large	6e-5	0.0	0.2
Tshivenda (ve)	Base	6e-5	0.0	0.2
	Large	6e-5	0.0	0.2
Xitsonga (ts)	Base	6e-5	0.0	0.2
	Large	6e-5	0.0	0.0

A. XLM-R Settings

The training, validation, and test dataset split was 80%, 10%, and 10%, respectively. Table I provides the fine-tuned parameters at the model and language level while the shared settings across the models and languages are as follows:

- Gradient accumulation steps: 4
- Maximum sequence length: 128
- Training batch size: 32
- Training epochs: 10

B. Evaluation Metrics

Precision, Recall and F-score are evaluation metrics used for text classification tasks, such as NER. These metrics are used to measure the model’s performance during the experiments. The formulas for these metrics leave out the correct classification of true negatives (tn) and false negatives (fn), referred to as negative examples, with greater importance placed on the correct classification of positive examples such as true positives (tp) and false positives (fp) [16]. For example, correctly classified spam emails (tp) are more important than correctly classified non-spam emails (tn). In addition, multi-class classification was used for the research experiments to classify a token into a discrete class from three or more classes. The metric’s macro-averages were used for evaluation and comparison. Macro-averaging (M) treats classes equally, while micro-averaging (μ) favors bigger classes [16]. Each evaluation metric and its formula as described by [16] are listed below.

Precision M : “the number of correctly classified positive examples divided by the number of examples labeled by the system as positive” (1).

$$\frac{\sum_{i=1}^l \frac{tp_i}{tp_i + fp_i}}{l} \quad (1)$$

Recall M : “the number of correctly classified positive examples divided by the number of positive examples in the data” (2).

$$\frac{\sum_{i=1}^l \frac{tp_i}{tp_i + fn_i}}{l} \quad (2)$$

Fscore M : “a combination of the above” (3).

$$\frac{(\beta^2 + 1)Precision_M Recall_M}{\beta^2 Precision_M + Recall_M} \quad (3)$$

C. Corpora Descriptive Statistics

Table II provides descriptive statistics for the language’s training data. As mentioned earlier, disjunctive languages have a higher token count than conjunctive languages. Albeit, the unique phrase type and named entity count for conjunctive languages are, on average, higher than the disjunctive languages.

TABLE II.
THE TEN LANGUAGES TRAINING DATA DESCRIPTIVE STATISTICS

Language	Writing System	Tokens	Phrase Types	Named Entities
af	Mixed	184 005	22 693	21 100
nr	Conjunctive	129 577	38 852	25 030
xh	Conjunctive	96 877	33 951	15 185
zu	Conjunctive	161 497	50 114	25 216
nso	Disjunctive	161 161	17 646	19 163
st	Disjunctive	215 655	18 411	19 211
tn	Disjunctive	185 433	17 670	18 993
ss	Conjunctive	140 783	42 111	21 403
ve	Disjunctive	188 399	15 947	14 119
ts	Disjunctive	214 835	17 904	24 376

VI. RESULTS

Fig. 1 depicts the precision scores for the ten low-resourced SA languages under the five NER models. The Afrikaans (af) language has the highest precision score with 81.74% for the XLM-R_{Large} model, while the Sesotho (st) language has the lowest precision score of 50.31% for the bi-LSTM-aux emb model. Table III displays the precision scores of the two XLM-R transformer models compared to

models used by [1] and [10]. The XLM-R models share five of the ten highest precision scores, with the highest average score belonging to the CRF model with 75.64%. The bold scores in Tables III, IV, V and VI show the highest evaluation metric score for each language and the model with the highest average score.

Fig. 1 The precision % for the 10 low-resourced SA languages visual representation

Fig. 2 depicts the recall scores for the ten SA languages under the five NER models. As with the precision evaluation metric, the Afrikaans (af) language has the highest recall scores for three of the five models, with an 87.07% for the XLM-R_{Large} model. Sesotho (st) has the lowest recall score of 55.56% for the bi-LSTM-aux model. Table IV displays the recall scores for the ten low-resourced SA languages. The XLM-R models share the highest recall scores for seven of the ten languages, with the highest average score belonging to the XLM-R_{Base} model with 76.34%.

Fig. 2 The recall % for the 10 low-resourced SA languages visual representation

Fig. 3 depicts the F-scores for the ten languages under the five NER models. The Afrikaans (af) language has the highest F-scores for three of the five models, with 84.25% for the XLM-R_{Large} model. Sesotho (st) has the lowest F-score of 53.77% for the bi-LSTM-aux emb model. Table V displays the F-score comparison. The XLM-R models produced the highest F-scores for six of the ten languages, with the highest average score belonging to the XLM-R_{Base} model with 73.64%.

VII. DISCUSSION

This section discusses the research findings concerning hypotheses testing. The first alternate hypothesis is accepted or rejected based on the XLM-R transformer model’s performance using the three-evaluation metrics. The second hypothesis is accepted or rejected based on the XLM-R transformer model’s performance compared to the CRF and bi-LSTM-aux models used in previous SA NER studies.

H₁ – There is a performance improvement for NER on the low-resourced SA languages using fine-tuned XLM-R transformer models.

The XLM-R_{Large} and XLM-R_{Base} transformer models produced F-scores that ranged from 53.77% for the Sesotho (st) language to 84.25% for the Afrikaans (af) language. In addition, many of the models recall scores were greater than 75% whereas, the precision scores were averaging at 70%. Remember, in this instance, the recall metric emphasizes the average per-named-entity effectiveness of the classifier to identify named entities, and the precision metric compares the alignment of the classifier’s average per-named-entities to the named entities in the data. All F-scores were above 60% except the Sesotho (st) language, which for both XLM-R models were below 60%.

A previous study by [18] was only able to achieve F-scores of 39% for the Sesotho (st) language and proposed that using different hyper-parameter tuning (fine-tuning) and dataset splits could produce higher F-scores. Further, [18] also suggested that further studies could implement the transformer models with discrete fine-tuning parameters per language to produce higher F-scores. The findings of this study show that transformer models with discrete fine-tuning parameters per language generate higher F-scores (see Table VI). The fine-tuned transformer models produced an average F-score 6% higher than the previous transformer models.

Therefore, the alternative hypothesis is accepted as there is a performance improvement on NER with the low-resourced SA languages using fine-tuned XLM-R transformer models. It is important to note that the previous study by [18] was not included in the comparative analysis with previous SA NER studies because the experimental results were insignificant when compared to the average F-scores of the [1] and [10] studies (see Table V).

H₂ – Fine-tuned XLM-R transformer models outperform other neural network and machine learning models on NER with the low-resourced SA languages.

The fine-tuned transformer models (see Table I) were also compared to the findings of previous studies. In particular, [10] used the CRF ML model to do NER sequence tagging on the ten resource-scarce SA languages. Furthermore, [1] implemented bi-LSTM-aux NN models both with and without embeddings on the same datasets. The comparative

* As reported by [18]. ** The model was unable to produce scores for Sepedi.

analysis reveals the performance improvement of implementing DL transformer architecture for NLP sequence tagging tasks such as NER. For example, when analyzing the F-scores, the XLM-R models have the highest F-scores for six of the ten languages, and the CRF model has three of the highest F-scores (see Table V). Meanwhile, the bi-LSTM-aux models had only one of the highest F-scores (see Table V).

This study's result is an improvement for NER research in the SA context because the previous studies by [1] and [18] could not outperform the CRF ML model implemented by [10] until now. Albeit, not all the SA languages are good candidates for DL architectures. For example, the isiXhosa (xh) and Tshivenda (ve) languages consistently underperform compared to the CRF ML model. Additionally, the comparative analysis identified the Sesotho (st) language as the lowest-performing language across the

NN models, with an average F-score of 56%, making it an outlier and an unviable language for current DL architectures for NER.

Therefore, the alternative hypothesis is accepted as fine-tuned XLM-R transformer models outperform other neural network and machine learning models on NER with the low-resourced SA languages (see Table V and Table VI).

This study reveals that the fine-tuned XLM-R transformer models perform relatively well on low-resourced SA languages with NER sequence tagging. Noticeably, there is no distinct performance difference between disjunctive and conjunctive languages. In addition, Afrikaans (af) outperform the other languages using the transformer models. As mentioned earlier, the outlier is the Sesotho (st) language, with the CRF baseline model F-score being 14% more than the XLM-R models and 18% more than the bi-LSTM-aux models. In confirmation with [18], including a language, such as isiXhosa (xh) during the transformer model pre-training does not guarantee good performance during evaluation.

Further, [10] suggested excluding the MISC phrase type to determine whether recall can be improved upon, however, this study revealed that even with the inclusion of the MISC type, the transformer models increased the recall scores considerably. Nonetheless, this is not to say that re-evaluation using an updated list of named entities will not produce higher metric scores.

VIII. CONCLUSION

This research reports on the implementation of Neural Network (NN) and Machine Learning (ML) models to evaluate Named-Entity Recognition (NER) sequence tagging on the ten low-resourced languages of South Africa (SA). The models were trained, validated, and tested using SA government domain corpora. Given the findings, the XLM-R transformer models performed better than the CRF and bi-LSTM models on recall and F-score. The transformer models produced higher F-scores for six of the ten SA languages, while the CRF model had only three of the highest F-scores. The CRF remained dominant on precision, averaging around 75%.

In addition, both the hypotheses were accepted (see Section VII). Firstly, using fine-tuned XLM-R transformer models improves performance on NER for low-resourced SA languages substantially. Secondly, fine-tuned XLM-R transformer models outperform other neural network and machine learning models on NER for the low-resourced SA languages. Therefore, NN transformer models are feasible for sequence tagging tasks, such as NER.

The implications of this study for research and practice of NER using NN transformer models are that such models are not only viable for low-resourced languages but advisable given they require less effort and resource costs. Furthermore, this approach to NER tasks benefits other downstream NLP tasks and applications. These tasks and

applications include question answering, machine translation, and machine reading comprehension.

A limitation of this research is not evaluating the more recent XLM-RXL and XLM-RXXL models on the NER sequence tagging task. Furthermore, the datasets could be re-evaluated using an updated list of named entities.

Additional research could evaluate transformer models on other NLP applications and tasks. Further, NLP tasks and applications could be tested using a linear-complexity recurrent transformer variant and a frozen pre-trained transformer model.

Abstract—The fashion industry is characterised by the need to make demand forecasts in advance and for highly volatile products for which we often have no sales history at the time the forecasts are made. For this reason, it is necessary to propose forecast mechanisms that can cope with the given conditions. Such forecasts can be based on expert predictions for generalized product categories. In this case, the task of machine learning forecasting methods would be to divide the aggregate prediction into forecasts for individual products, in each colour and size. In the paper, we present several approaches to this specific task. We present the use of the naive method, custom nearest neighbour approach, parametric linear mixed model and an ensemble approach. Overall, the best results we obtained for the ensemble method. Our research was based on real data from fashion retail.

I. INTRODUCTION

DEMAND forecasting in the fashion industry is characterised by specific conditions. In this industry, it is necessary to be able to forecast for a long horizon in time. This is because many products are ordered from other parts of the world, where they are produced on a large scale. Products must be ordered in advance so that the entire process of production, delivery, promotion and distribution to shops in different countries can take place on time.

On the other hand, fashion products are highly variable over time. Rarely are products sold for several seasons. Most of them appear on sale only in one sales season, which translates into a very short sales history for a particular product. This relates to natural seasonality due to changing seasons, but also to trends that can vary significantly from one year to the next.

The combination of the need to order products in advance and the volatility of the products being sold means, that we have to make predictions of demand for products that mostly have not previously been on sale. These are difficult conditions for making forecasts. Sales forecasts could be made by experts based on their domain knowledge, but such experts would

also have difficulty determining future sales of a particular product, in a particular size and colour, each week of the following season. Additionally, with many shops, this would be a very time-consuming process. In this case, a good idea is to use automated forecasting methods, which would be based on statistical models or machine learning models.

The research described in this article dealt with the problem of sales forecasting in the fashion industry. What is important, in our research we obtained sales forecasts for product categories and our task was to build on these general predictions the forecasts for individual products (described by specific product type, colour and size). Sales forecasts were made on weekly aggregates. Forecasts for individual categories were provided to us by a business partner and are proprietary. They are not the subject of this article. However, it should be noted that the forecast data could be provided by an expert. Making assumptions about aggregate sales within more general product categories should be a more manageable and less time-consuming task for an expert.

In this paper, we would like to present several approaches to making demand forecast for the specific products from fashion retail based on higher level forecasts. We present naive method, custom nearest neighbour approach, parametric linear mixed model and an ensemble approach.

II. RELATED WORK

Demand forecasts are the basis of most decisions in supply chain management. Forecasting methods applied to this problem are based on both domain knowledge and historical data analysis. In the former approach, the retailers knowledge is utilised to develop demand prognosis. In the later approach statistical and machine learning based methods are intensively used [1]–[3].

Our research is focused on the data describing the demand in a fashion sector. In this area, research on machine

learning methods application were carried out. In the article [4] the authors present the use of deep neural networks for sales forecasting in fashion industry, especially forecasting the sales of new fashion products. They compare the deep learning approach with other algorithms e.g. Decision Trees, Random Forest, Support Vector Regression, Artificial Neural Networks and Linear Regression. The authors found deep learning models to have good performance, however for some metrics the models were not significantly better than some simpler techniques. It shows that in this sector the simpler and interpretable methods may obtain good results.

Pre-season forecasting in fashion retail was also discussed in [5]. The authors point out, that the typical time-series methods can be introduced for this problem, however in most cases the retailers need to forecast new products, so in historical data there is no time-series linked precisely to the forecast product. It means that the retailers need to base on their intuition and the historical data of similar products. The authors also highlight the need for creating explainable forecasting models. Because of explainability and interpretability, many stakeholders still use a very simple and naive approach for forecasting new products — averaging sales of similar products for the new product. If AI method could be used in this sector it is important to give explanation, how the decision was made.

The authors of [6] focus on fast fashion sales forecasting where the data is limited and within limited time. The authors propose a novel algorithm — Fast Fashion Forecasting (3F) — which combines extreme learning machine (ELM) and the grey model (GM). Extreme learning machine was also used for fashion retailing forecasting in the [7]. In the aspect of Fast-Moving Consumer Goods (FMCG), the authors of [8] showed benefits of applying Machine Learning methods in creating demand forecasting models.

III. PROBLEM STATEMENT

In our research, we were working with the specific problem of forecasting demand for fashion products. From our business partner, we obtained their forecasts of sale for pre-defined categories of products. Our task was to divide these forecasts to the forecasts for each separate product that belongs to the category. A unique product is described by a unique combination of attributes: product type, colour and size. The most important requirement was to use provided forecasts, not to create from scratch forecasts for each separate product. The second important assumption was the horizon of the forecasts. We were working with long-term predictions — forecasts had to be made for 29 weeks ahead. Predictions were made for weekly sale aggregates.

In the obtained dataset, we had real historical sale data from a fashion brand with a shop chain. The dataset contained sale data from January 2016 to November 2021. For the period from April 2021 to November 2021, we got from our business partner not only predictions for the whole category, but also their predictions for unique products. Because of this, we considered this part of a dataset as our test dataset, on which the experiment's result will be calculated. The data before

were our train dataset. In the data, we could observed strong seasonality — big peaks of sales before summer. It should also be noted that data contains sales from COVID-19 pandemic and lock-downs connected with this phenomena. Figure 1 presents demand for an example product.

Fig. 1. Demand of selected product

In the data preparation process we created new attributes, that could be defined for new products, that would be in sale many weeks ahead. Because of forecasting demand with a long time-horizon, we couldn't use data about weather or information about sale from weeks just before the forecast week. In our dataset, each observation described one week of a sale of a specific product (a unique product described by a unique combination of attributes: product type, colour and size). Each week, for each product, was described by the attributes listed below.

- Attributes connected with a product in sale: product type, size, main colour and colour undertone.
- Attributes connected with time of a sale (describing the week of an observation): week number, season, quarter of a year, number of days to the closest event (Christmas, Easter, national holiday, Valentine's Day etc.), number of days that passed from the closest event, number of events/holidays that happened during the considered week, number of events/holidays that happened during three weeks — in the week under consideration, the preceding week and following week, binary feature that described if it is the last week of a year.
- Attributes connected with sale: number of sold units, number of sold units within category, fraction of the sale in a given category that account for the sale of the product concerned.
- Attributes connected with trend and seasonality: we used prophet tool [9] to decompose data from train dataset into trend and seasonality for each product. Obtained results were utilized for test dataset.
- ID attributes: product name, category name, date of a first day from a considered week.

In our dataset, we didn't have information about price or planned promotions.

IV. METHODS

In this chapter, we want to present some selected approaches for breaking down the higher level forecasts (forecasts for one category of products) into lower level forecasts (per product forecasts). We present naive method, non-parametric custom nearest neighbour approach, parametric linear mixed model and an ensemble approach. The experiments were performed using R and Python languages.

A. Naive

Firstly, we proposed a naive method of splitting the forecast for the whole category into a forecast for the individual product. This involved finding the weight by which the category forecast was to be multiplied to produce the product forecast.

Suppose the forecast was made for the week n of year Y for a selected product p . The product belongs to category c . In such case, we looked up the sale of the product in week n in the previous year ($Y - 1$). Then, we divided it by the total sales in the category c in week n in the previous year. The given fraction was the weight by which the forecast for the category for week n of year Y was multiplied. The result is the forecast for the product.

An extension of this proposed solution was to determine weight based not only on the week the year before, but also on its week preceding and the week following. This ensured that the weights were averaged and minimized the impact of outliers on the resulting forecast. The forecast for the product was calculated as follows:

$$y_{p,n,Y} = \frac{1}{3} \sum_{i=-1}^1 \frac{s_{p,n+i,Y-1}}{s_{c,n+i,Y-1}} y_{c,n,Y} \quad (1)$$

where s means real sale, y is a forecast, p is a product, for which we calculate the forecast, c is a category of a product, n is a week number, Y is a year. For example, if the year before the forecast week, sale of a product was 2% of total category sale, while the week before it was 6%, and the following week it was 7%, the final weight by which the forecast for the entire category was multiplied was the average of these values — 0.05. A naive method with averaged weights was considered in further stages of the work.

The presented naive approach has one big disadvantage — it works only on a product with history of sale. The naive method could be used for new products only with expert's help. The expert could indicate which product, with historical sales, the new product is similar to. Then, we would assume, that we could use the weight obtained from historical sale of a similar product, to get the forecast for a new product. However, we felt that it would be useful to focus on a solution that would allow us to forecast the demand for new products, with minimal expert involvement in the process.

B. Nearest neighbour (KNN)

As a more advanced forecasting procedure, we propose a nearest neighbour (KNN) approach. This is a non-parametric technique widely used in classification tasks, however we used

it as a method for finding similar observation from historical data. This algorithm, given an input vector, calculates distance (based on a chosen distance metric) to observations from a training dataset. The one observation, whose conditional attribute vector is most similar to the new feature vector, is considered to be its nearest neighbour.

In this approach, we used the dataset described in section III. In order to use some attributes in the KNN approach, additional input data had to be provided. This situation has occurred for "size" attribute. Our dataset included different fashion products, e.g. shirts, bras and socks. These products have different clothing sizes. In order to calculate distance between different observations using the attribute "size", we changed original sizes to numerical values based on our training set, i.e. historical data. We divided the historical dataset by size — a separate subset for each category of products, which have different clothing sizes. Then, for each of the sizes in the set, we determined the percentile values within those subsets. That is, if we forecasted sales for socks in size 36/38, we converted size 36/38 into the numerical value — percentile that this size represented in the historical data.

Additional input data was also provided for attribute "product type". This attribute had nominal values, that were identifiers of the fashion types — the values did not hold any additional meaning. In order to calculate distance between different product types, we proposed using *product types dissimilarity table*. In our *product types dissimilarity table*, we provided the distance between different product types. The distance was equal to 0, if we calculated the distance between products that had the same product type. The distance was equal to 0.5, if we calculated the distance between products that belonged to the same clothe category but are of different product type, e.g. both products were shirts, but they were of different type. The distance was equal to 1, if we calculated the distance between products that belonged to different clothe category, e.g. one product is a shirt and the other is socks.

In the KNN approach, we used the following attributes: week, product type, size, main colour, colour undertone, season, quarter of a year, number of days to the closest event, number of days that passed from the closest event, number of events/holidays that happened during the considered week, number of events/holidays that happened during the week under consideration, the preceding week and following week.

The schema of the proposed procedure is presented in Figure 2. The KNN method is called with the parameter $k=3$. This parameter value was selected from the set of values $k=\{1,2,3\}$, as the value giving the best model results.

It can be noted that this method is based on a similar assumption as our naive method. In the naive approach, we looked for the weight in the history of a given product exactly one year before. In the KNN method, the weight is determined in the same way — it is a fraction of the product's sales to sales in the entire category. The difference is that in the KNN method, we refer to a week that did not necessarily occur exactly one year earlier. Additionally, the nearest neighbour (the nearest "week") may refer to historical data for a different

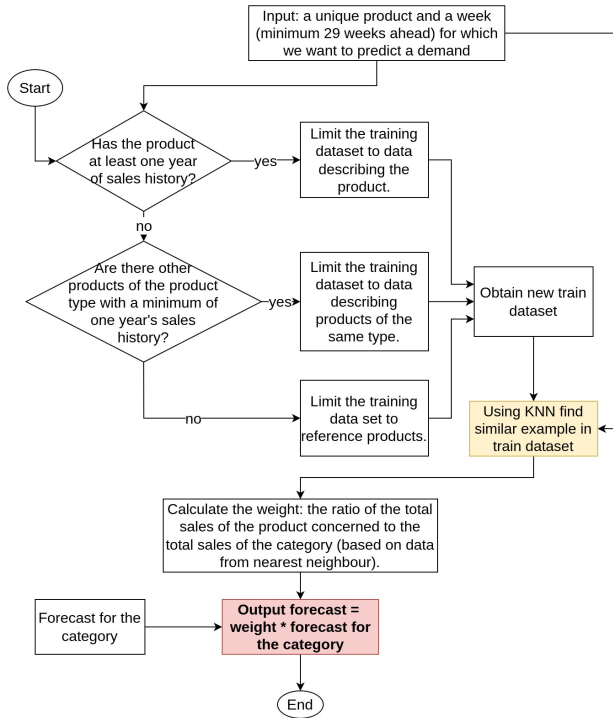

Fig. 2. The schema of the custom nearest neighbour procedure for obtaining the forecasted demand of a product.

product than the one for which the forecast is made.

C. Linear mixed model (LMM)

Linear mixed models are an extension of simple linear regression models and can be used for data with a hierarchical structure which is observed in fashion. These models incorporate fixed and random effects:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u} + \boldsymbol{\varepsilon} \quad (2)$$

where \mathbf{y} is a vector of outcome variable, \mathbf{X} is a matrix of predictors, $\boldsymbol{\beta}$ is a vector of fixed-effects regression coefficient, \mathbf{Z} is a design matrix for random effects, \mathbf{u} is a vector of random effects and $\boldsymbol{\varepsilon}$ is a vector of residuals [10].

In this approach, a model for each product group was estimated with random effects defined by product, size, and color. In groups where there was only one product, random effects were estimated only for size and color. Due to strong asymmetry of outcome variable (forecast weight) Box-Cox transformation [11] was applied.

We assure that there are significant differences between outcome variable and groups defined by product, size, and color using ANOVA. The significance of random effects was confirmed based on the permutation test.

As predictors in linear mixed models, we used attributes connected with product in the sale, time of a sale, trend, and seasonality (described in section III).

D. Ensemble approach

In the ensemble approach, we combined the results from the non-parametric KNN method with the results from the parametric linear mixed model. The forecast returned was the average of forecasts provided by these two models.

V. RESULTS

In this section, we present results obtained using methods described in section IV. We predicted demand for 7 categories of products and aimed for a reduction of mean absolute error (MAE) relative to baseline. Detailed results are presented in table I.

TABLE I
MEAN ABSOLUTE ERROR OF PREDICTED DEMAND IN TEST DATASET

Product category	Baseline	Naive	KNN	LMM	Ensemble
Category 1	3.23	3.77	3.67	3.52	3.59
Category 2	9.68	11.61	11.01	9.29	9.72
Category 3	6.86	7.04	7.12	6.96	6.71
Category 4	6.44	8.43	8.64	7.74	8.12
Category 5	20.23	17.48	20.33	21.09	19.77
Category 6	11.55	11.51	11.48	11.05	10.70
Category 7	4.17	4.70	4.46	4.04	4.07

For the second and seventh categories the best results were obtained for LMM method. For categories third and sixth the lowest errors were obtained for ensemble approach. In the sixth category, we obtain gain in precision for all methods. In the case of the seventh category, both LMM and ensemble approaches have lower errors. For the fifth category also naive approach performed better than the baseline. The first and fourth categories were a little bit problematic because any of the proposed methods do not perform better than baseline. Overall, the biggest improvement is observed for the ensemble methods because for 4 from 7 categories this approach gave better results than the baseline.

In the next step, we tried to investigate what could be a possible reason for such results. Figure 3 presents differences between real and predicted demand for each method and category.

We observed that the fourth and fifth categories were characterized by a much lower number of observations compared to the rest categories. The small sample size could be one of the reasons why it was impossible to obtain a lower MAE than the baseline result for the fourth category. In the case of the fifth and sixth categories, we noticed a few outlier values and a flattened distribution of these errors compared to other categories. In the rest categories, the average of differences between true and predicted demand is close to 0.

The last part of the study was the analysis of stability over time. The Figure 4 shows differences between real demand (bold black line) and forecasts obtained with different approaches for one selected product.

In this particular case, the lowest MAE was obtained for the LMM approach. We can observe that almost all methods predicted lower than actual demand just before summer. The best estimation in this period was observed for KNN method,

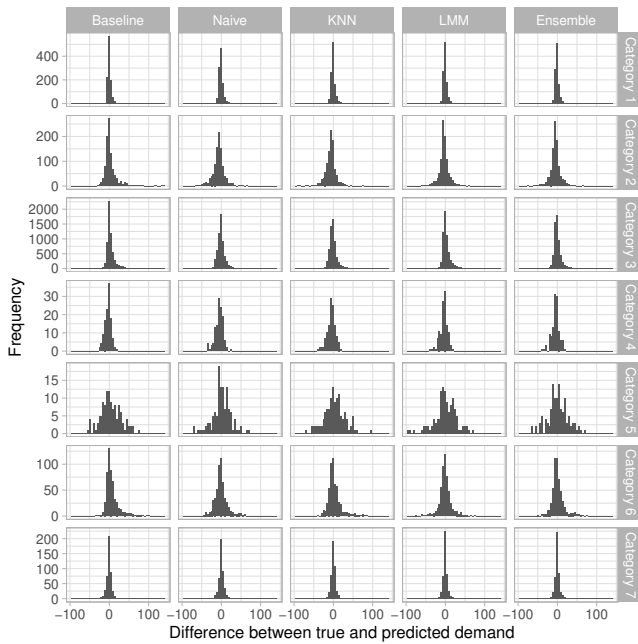

Fig. 3. Distribution of differences between true and predicted demand

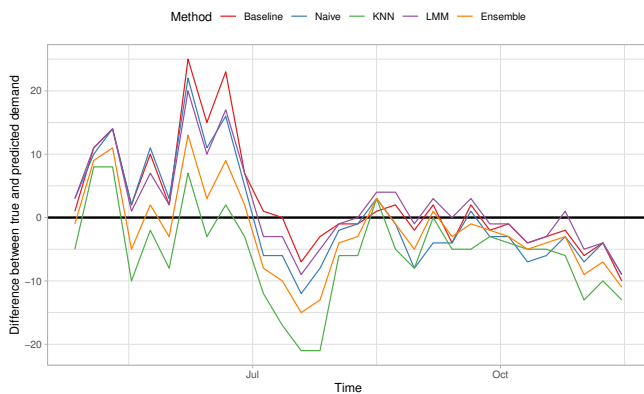

Fig. 4. Differences between true and predicted demand for selected product

however it gives the biggest error in summer. Generally, the proposed approaches underestimate seasonal peaks for all products in our dataset.

VI. CONCLUSIONS AND FUTURE WORKS

Demand forecasting in the fashion business could be problematic due to short product history — in many cases, product is sold for one season. In our case we have access to longer time series nevertheless this data contains unexpected issues connected with COVID-19 such as lock-downs and changing habits of customers.

The proposed solution was based on the share of sale estimation and multiplication of the result by the provided forecast for the category. In almost all cases, utilized methods gave better results than the baseline provided by our business

partner. However, it should be noted that in such an approach we can highlight two sources of possible error — firstly at the method level connected with historical data and predictions and secondly at the category forecast level which differ from real category demand.

Future works explore further the topic of demand forecasting in various business cases: what to do in case of short historical data or how to forecast demand for a totally new products using existing data. We will also investigate other statistical methods designed for this purpose and optimize scope of conditional attributes used by techniques presented in this work.

ACKNOWLEDGMENT

The work was carried out in part within the project co-financed by European Funds entitled “Decision Support and Knowledge Management System for the Retail Trade Industry (SensAI)” (POIR.01.01.01-00-0871/17-00). The research leading to these results received funding by Young Researchers funds of Department of Computer Networks and Systems, Faculty of Automatic Control, Electronics and Computer Science, Silesian University of Technology, Gliwice, Poland (project no.: 02/120/BKM22/0021). This work was partially supported by the European Union through the European Social Fund (grant POWR.03.05.00-00-Z305).

Abstract—Recommender Systems are software tools and techniques which aim at suggesting new items that may possibly be of interest to a user. Context-Aware Recommender Systems exploit contextual information to provide more adequate recommendations. In this paper we described a modification of an existing contextual post-filtering algorithm which uses rules-like user representation called Contextual Conditional Preferences. We extended the algorithm by taking into account rules quality measures while recommending items to a user. We proved that this modification increases the quality of recommendations, measured with *precision*, *recall* and *nDCG*, and has no impact on the execution time of the original algorithm.

I. INTRODUCTION

RECOMMENDER Systems (RS) were created as a response to the information overload problem, which we suffer from nowadays. These software tools and techniques aim at suggesting new items that may possibly be of interest to a user [1]. An item could be a movie (Netflix), a song (Pandora), a job (LinkedIn) or a friend (Facebook). In everyday life we interact with RS when we search for information using Google or when we buy something through the Internet.

Context-aware RS (CARS) are a particular category of RS which exploit contextual information to provide more adequate recommendations [2]. For example, a movie recommendation for a Saturday evening with your friends should be different from one suggested for a Sunday afternoon with your family. It has been proven that adding contextual information in the process of recommendation can highly increase prediction accuracy and user satisfaction [3]. Adomavicius and Tuzhilin [2] distinguish three main types of context-aware recommender systems, i.e. contextual pre-filtering, contextual post-filtering and contextual modeling. The paradigms differ in the way they incorporate context in the recommendation process. More details are given in Section II.

Karpus et al. [4] proposed a context-aware re-ranking algorithm (re-rankCCP) which utilizes user model called Contextual Conditional Preferences (CCPs). CCPs are special kind of rules which are learned from past user ratings and used to reorder items in a primary recommendation list. This method seems promising in making user explanations for recommendations due to the use of rules that are easy to understand by a human. However, this solution has a big disadvantage. While using CCP, an algorithm only checks its relevance to a current user context, not taking into consideration the quality of an induced preference. Thus, better CCPs can be

omitted during reordering what would lead to a reduction in the recommendation accuracy and user satisfaction.

In this paper we propose a method for determining the CCP quality using rules quality measures, i.e. *coverage*, *support* and *confidence* and apply it in the modification of the re-rankCCP. We proved that this modification increases the quality of recommendations, measured with *precision*, *recall* and *nDCG*, and has no impact on the execution time of the re-rankCCP. The main contribution of this paper can be summarized as follows:

- We propose a way to measure quality of CCP with usage of rules quality measures.
- We improve re-rankCCP algorithm to take into account quality of CCPs while generating recommendations.
- We compare effectiveness of modified re-rankCCP on 2 baseline algorithms, 3 rules quality measures and 4 aggregate functions and show that there is a best configuration for the dataset used.

The rest of the paper is organized as follows. Related work and basic re-rankCCP are described in Sections II and III, respectively. Section IV provides technical details of the proposed modification and is followed by a description of the dataset used. Section VI introduces evaluation method while obtained results are presented in Section VII. Conclusions close the paper.

II. RELATED WORK

Adomavicius and Tuzhilin [2] distinguish three main types of CARS, i.e. contextual pre-filtering, contextual post-filtering and contextual modeling. The paradigms differ in the way they incorporate context in the recommendation process.

In contextual pre-filtering, we first do selection of ratings by taking only relevant context into account. Thus, we filter an initial set of ratings and return the contextualized data. After this preparation any known two-dimensional recommendation algorithm could be used to predict user preferences. Baltrunas et al. [5] introduced *micro profiles* which split a user profile into partitions depending on the values of context parameters. They showed that usage of such *micro profiles* gave a significant improvement in the prediction accuracy in the movie domain while considering time as a context variable. Pre-filtering approach which utilizes ontological user profiles was proposed by Karpus et al. [6]. Each user profile consists of many ontologies representing user preferences in

different context and domain. Ferdousi et al. [7], [8] tried to find a correlation between ratings and context in which they were given. They proposed a new context representation based on the Pearson Correlation Coefficient as well as a new pre-filtering technique based on this representation.

Contextual post-filtering applies context after traditional recommendation process. It means that from a predicted set of recommendations we select just those that match current user context. Bahramian et al. [9] proposed a new context-aware tourism recommender system based on an ontology approach where a spreading activation technique is used to contextualize user preferences and learns the user profile dynamically. Negre et al. [10] introduced a context-aware recommender system based on a contextual post-filtering for OLAP queries, where queries recommended by a classic log-based recommender system were contextualized.

Contextual modeling differs radically from previously described paradigms. In this kind of recommenders we incorporate a context in a prediction model. The recommendations are achieved directly from the model, taking into account current user-context situation. Iqbal et al. [11] introduced Kernel Context Recommender System, which is a flexible, fast, and accurate kernel mapping framework that recognizes the importance of context and incorporates the contextual information using kernel trick while making predictions. Zheng et al. [12] proposed method that combines context-aware and multi-criteria recommender systems. They evaluated their solution on an educational data and an extended TripAdvisor dataset. Authors tested different approaches for incorporating context in the recommendation process.

In the recent years, an application of artificial neural networks in CARS is getting more and more attention [13], [14], [15]. Hildebrandt et al. [15] proposed NECTR, a novel recommender system based on a tensor factorization model and an autoencoder-like neural network. A Deep Learning based model which learns customer similarity from the sequence to sequence similarity as well as item to item similarity by considering all features of the item, contexts, and rating components was introduced by Kala et al. [14]. The method uses Dynamic Temporal Warping distance measure for dynamic temporal matching and 2D-GRU (Two Dimensional-Gated Recurrent Unit) architecture.

III. BACKGROUND - RE-RANKCCP ALGORITHM

Contextual Conditional Preferences (CCPs) were introduced to provide compact and context-aware representation of user interests for RS [16], [4]. CCP is an expression of the form:

$$(\gamma_1 = c_1) \wedge \dots \wedge (\gamma_n = c_n) \mid (\alpha_1 = a_1) \succ (\alpha_1 = a'_1) \wedge \dots \wedge (\alpha_m = a_m) \succ (\alpha_m = a'_m)$$

with γ_i being contextual variables, α_i item attributes, and $c_1, \dots, c_n, a_1, a'_1, \dots, a_m, a'_m$ being exact values of these parameters. Symbol \succ denotes a preference relation, e.g. $x \succ y$ means that someone prefers x over y .

The above CCP is read as *given the context* $(\gamma_1 = c_1) \wedge \dots \wedge (\gamma_n = c_n)$ *I prefer* a_1 *over* a'_1 *for* α_1 *and* \dots *and* a_m *over* a'_m *for* α_m . An example of the CCP is shown below.

$$\begin{aligned} \text{time of day} &= \text{afternoon} \wedge \text{companion} = \text{with children} \\ &\mid \text{genre} \in \{\text{animated}, \text{family}\} \succ \text{genre} \in \{\text{thriller}\} \end{aligned}$$

It means that for a given context, i.e. in the afternoon and the company of children, a user prefers movies that belong to the genre “animated” or “family” to those with category “thriller”.

CCPs can be learned from explicit user ratings [17]. In order to elicit preference relations the dataset containing ratings, contextual parameters and item features is split into two parts, i.e. positive and negative, based on the value of the ratings. Then, both subsets are divided into smaller sets containing all of the contextual information and one of the item features. Such prepared data are an input for the Prism[18] algorithm. Final CCPs are obtained by merging rules with the same context.

An algorithm for generating a list of top k recommendations with CCPs, the re-rankCCP, was introduced by Karpus et al. in [4]. We describe it below.

For a certain user and his current context, first we generate a primary list of top m recommendations with some existing non-context-aware algorithm, e.g., UserKNN. The value of m has to be significantly greater than k , where k is the number of the recommendations in the final list. Then we have to find the best CCPs that will be further used in the reshuffling process.

The best CCPs are those which are most similar to the considered context. In order to count a contextual similarity between a CCP p and a current user context $ctx(u)$ we used the following measure:

$$\text{sim}(p, ctx(u)) = \sum_{(\gamma_i, c_i) \in p} \text{overlap}(ctx(u), (\gamma_i, c_i)) \quad (1)$$

We also used the overlap function defined as:

$$\text{overlap}(ctx(u), (\gamma_i, c_i)) = \begin{cases} 1 & (\gamma_i, c_i) \in ctx(u); \\ 0.5 & c_i = -1; \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

The overlap function returns 1 when we are sure that the pair (γ_i, c_i) is contained both in the contextual part of p and in the current user context $ctx(u)$. When it is uncertain, i.e. when the value c_i for the dimension γ_i is equal to -1 (the unknown value), it returns 0.5. Otherwise 0 is returned. Note that the current user context $ctx(u)$ is also a set of pairs (γ'_i, c'_i) , i.e. the name of the contextual variable and its value.

For each item in the primary recommendations list and each best CCP we have to compute how much an item i satisfies a CCP p . For this purpose, we have to use the *satisfiability* measure:

$$\text{sat}(i, p) = \frac{\sum_{\alpha \in a(p)} (\text{sim}(v_\alpha^m(p), v_\alpha(i)) - \text{sim}(v_\alpha^l(p), v_\alpha(i)))}{|a(p)|},$$

where sim denotes Jaccard similarity, α is the name of an item feature, $a(p)$ is the set of item attributes considered in

the CCP p , $v_\alpha(i)$ is the set of values of an attribute α for an item i . Similarly $v_\alpha^m(p)$ and $v_\alpha^l(p)$ denote the sets of values of an attribute α for a CCP p on both sides of the preference relation - m stands for *more preferred* and l for *less preferred*.

The *satisfiability* measure represents the difference between item similarities to the both sides of the CCP preference relation, i.e. the similarity to the most preferred part minus the similarity to the less preferred part. In this way we reward items that fit best to user preferences and penalize items that have features that user does not like. The size of a set of item attributes serves as a normalization factor. Thus, regardless of the number of item features, the value of *satisfiability* is always between 0 and 1.

The next step is to order the primary recommendations list according to the value of average *satisfiability* of the best CCPs. The last part is to cut off unneeded items from resulting recommendations list to receive top 5, top 10 or other top k ranking.

IV. ALGORITHM MODIFICATION

One of the key parts of the re-rankCCP algorithm is a selection of best CCPs for current user context based on the similarity measure from Equation 1. However, this measure does not take into account the quality of CCPs. Consequently, recommendation could be made based on less important user preferences. Therefore, we replaced the similarity with a weighted similarity sim_w :

$$sim_w(p, ctx(u)) = q(p)sim(p, ctx(u)) ,$$

where sim is the similarity measure from Equation 1 and $q(p)$ is a quality of a CCP p . Now, we need to define the quality of a CCP.

CCPs can be generated from rules induced with Prism algorithm. Thus, we decided to use rules quality measures, like *coverage* or *support*, to define quality of CCP. However, one CCP is created using many different rules. Therefore, we have to decide how to reasonably aggregate many rules quality values into one value characterizing CCP's quality.

In this paper we tested four aggregate functions, which we found the most reasonable, i.e. *minimum*, *maximum*, *sum* and *average*. The last one seems the most obvious because it simply takes quality values from all used rules and returns one normalized value for a CCP. We also obtain standardized quality for the first two functions which simply take the worst and the best rule quality value, respectively. The *sum* function additionally reflects the quantity of rules that are used for creation of a CCP. The more good rules were used, the higher the quality of a CCP would be.

We decided to apply three commonly used rules quality measures, namely: *coverage*, *support* and *confidence* [19]. For this purpose, we had to slightly modify an algorithm for CCPs extraction to compute those measures. However, this algorithm is independent from the re-rankCCP. We also extended a CCP representation to contain information about its quality. Figure 1 shows modified CCP from the above example in the JSON format. The rest of the re-rankCCP remains the same.

```

1  {"CCPs":[
2    { "context":{"time of day":"afternoon", "companion":"with children"},
3      "MorePreferred":{"genre":["animated","family"]},
4      "lessPreferred":{"genre":["thriller"]},
5      "coverage":0.4924},
6    ...
7  ]}
```

Fig. 1. An example CCP in the JSON format with information about rule quality measured with the coverage.

V. DATASET

We performed experiments on the same dataset as authors of the original re-ranking algorithm, i.e. LDOS-CoMoDa dataset. The LDOS-CoMoDa dataset [20] was collected by a web application that enables contextual rating of a movie just after watching it. The dataset consists of 2296 ratings given by 121 users to 1232 items. It contains 30 variables among which 12 are contextual parameters. Other variables are basic information about user (user id, age, sex, city and country), a rating in a 5-star scale (higher values denote higher preference) and content information about multiple item dimensions (item id, director, country, language, year, 3 main genres, 3 main actors and budget). Unknown values are denoted by “-1”.

We chose users who rated at least 5 items. Then, we randomly selected 20% of items rated by each of these users to be included in the test set. The remaining data constitute the training set.

VI. EVALUATION METHOD

We re-implemented in Python the re-rankCCP algorithm, which was originally implemented in Java. We also performed new training and test sets split. Thus, because of the randomness of the split, we have different data in those sets than in the previous papers [4], [16].

The re-rankCCP is a post-filtering technique which means that it needs other algorithm to work. We decided to test two known methods, i.e. Bayesian Personalized Ranking (BPR)[21] and User k Nearest Neighbors (UserKNN)[22]. We had several reasons for this choice. First of all, inventors of re-rankCCP obtained the most promising results with BPR algorithm. Second of all, UserKNN was one of the most (or even the most) popular method in the field of RS. Last but not least is the way how these algorithms treat missing data. BPR tries to minimize its negative impact on the prediction accuracy, while UserKNN completely ignores missing data. Hereby, we obtained a representative sample of base algorithms.

For the re-rankCCP and base algorithms we had to set up some parameters. UserKNN used 50 neighbors to compute recommendations. Base algorithms generate lists of top 100 items while re-rankCCP produces the top 10 list. Rating greater than 3 is considered positive. We decided to choose three commonly used measures of recommendations quality, i.e. *precision*, *recall* and *nDCG* [23].

In addition to the impact of the modification on the quality of recommendations, we wanted to check its impact on the algorithm execution time. Since we slightly modified CCP representation, our method does not affect the time

of generating recommendations. However, it could have impact on the time needed to induce CCPs, since it is where the CCP quality is computed. In order to check it we performed an experiment for which we prepared 4 datasets from the LDOS-CoMoDa. The datasets consists of 3000, 5000, 7000 and 10000 rows respectively. For each dataset we performed CCPs generation for the re-rankCCP algorithm and its modifications. We collected results with *%time* function which is available in *ipython* environment.

VII. RESULTS

Table I shows values of *precision*, *recall* and *nDCG* obtained for different configurations of algorithms, rules quality measures and aggregate functions during our experiments. The best results for each algorithm and rules quality measure is marked with bold (locally best result), while the best results for each algorithm/base algorithm is marked with underline (globally best result considering division into two groups: BPR and UserKNN). It should be noticed that re-rankCCP always improves *precision*, *recall* and *nDCG* of its base algorithm. Nonetheless, re-rankCCP performs weaker than its modifications with rules quality measures.

For most of configurations of algorithms and rules quality measures, the best results were obtained by *minimum* and *average* functions. The first function was the best for *support* and *confidence*, irrespective of a base algorithm, while the latter works well with *coverage* and *support* on re-rankCCP with BPR algorithm. An exception appears in re-rankCCP with UserKNN algorithm and *coverage* measure. The best results for this configuration was obtained by the *maximum* function. The best results for *minimum* and *average* functions should not be surprising. While using *minimum* function, we assure that all other rules used to induce a CCP have greater quality values than the resulting value. We obtain similar effect for the *average*. On the contrary, for the *maximum* we could choose preference which is generated from rules from which one is strong and all others are weak. The same bad effect can happen for *sum* function. Modified re-rankCCP will prefer a CCP from many weak rules than a CCP from two strong rules. The smallest improvement in modified re-rankCCP was obtained with the *coverage* for both base algorithms. It can be justified by the fact that the *coverage* is not a proper quality measure for rules since it considers only antecedent of a rule.

To check the statistical significance of obtained results we performed Wilcoxon signed rank test with $\alpha = 0.05$. For the re-rankCCP with BPR as a baseline algorithm two results were statistically insignificant, i.e. for *coverage-minimum* and *confidence-maximum* pairs with p-value equals to 0.4375 and 0.5282, respectively. The re-rankCCP with UserKNN as a baseline and *support* measure has almost all results insignificant, i.e. for *maximum*, *average* and *sum* functions with p-values equal to 0.5745, 0.0625 and 0.1563 respectively. All other reported results are statistically significant.

Considering results presented in Table I and their statistical significance, we can conclude that objectively the best improvement to the re-rankCCP is obtained using the *support*

measure for rules quality and the *minimum* function for an aggregation. It should be noticed that UserKNN performs pretty weak on LDOS-CoMoDa dataset. This could be because of the data sparsity.

Table II shows times of generating CCPs for the re-rankCCP algorithm and its modification with the coverage. We obtained very similar results for support and confidence measures which is why we omitted it here. The differences in execution times are negligible. Thus, we can conclude that our modification does not increase execution time of re-rankCCP, and improves the quality of recommendations.

VIII. CONCLUSIONS

In this paper we proposed a way for measuring the CCP quality using rules quality measures and aggregate functions. To the best of our knowledge, this is the first attempt to compute a CCP quality. We also improved re-rankCCP algorithm by incorporating quality of CCPs into recommendation process and proved that this modification outperforms the re-rankCCP as well as both baseline algorithms, i.e. BPR and UserKNN. We compared its effectiveness on two baseline algorithms, three rules quality measures, i.e. *coverage*, *support* and *confidence*, and four aggregate functions, i.e. *minimum*, *maximum*, *sum* and *average*. Our experiments showed that the *support* measure aggregated with the *minimum* function is the best configuration for computing the CCP quality on LDOS-CoMoDa dataset. However, more experiments on other datasets and with more baseline algorithms are needed to check if these results could be generalized.

Abstract—Gender identification is the task of predicting the gender of an author of a given text. Some languages, including Polish, exhibit gender-revealing syntactic expression. In this paper, we investigate machine learning methods for gender identification in Polish. For the evaluation, we use large (780M words) corpus "He Said She Said", created by grepping (for author's gender identification) gender-revealing syntactic expressions and normalizing all these expressions to masculine form (for preventing classifiers from using syntactic features). In this work, we evaluate TF-IDF based, fastText, LSTM and RoBERTa models, differentiating self-contained and non-self-contained approaches. We also provide a human baseline. We report large improvements using pre-trained RoBERTa models and discuss the possible contamination of test data for the best pre-trained model.

I. INTRODUCTION

The task of *gender identification or attribution* consists in predicting the gender of an author of a given text. As such, it is an example of text classification, is usually tackled using supervised machine learning, and is relatively popular in the NLP community. Some recent example of experiments in automatic gender identification for various languages are: [17], [27], [2], [14]. For a critical analysis of gender detection systems and their limitations, see [18].

Collections of gender-labeled texts are required if a system based on supervised machine learning is to be trained. The usual approach is to use metadata such as information on authors (of books, papers, social media posts, etc.). Interestingly, some languages exhibit gender-revealing first-person expressions (cf. *soy polaco* vs *soy polaca* in Spanish), and such expressions can be used to automatically label texts as written by a male or female in order to create a data set. This approach (*distant supervised learning*, [21]) is similar to using emoticons for sentiment analysis tasks [23], [9].

Some languages (e.g. Slavic languages) are more amenable to this distant supervised approach than others (e.g. English or Chinese). The approach was applied to Polish to create a large collection of texts, the "He Said She Said" (HSSS) corpus [10]. In this paper, we (1) re-state the original challenge as a classification task with a probability-based evaluation metric, (2) report on large improvements on the gender detection task using pre-trained RoBERTa models, and (3) discuss the

TABLE I
 THE "HE SAID SHE SAID" CHALLENGE IN NUMBERS.

		characters	words	items
train	total	1,240,131,217	177,428,897	3,601,424
	male	628,793,876	89,795,752	1,800,712
	female	611,337,341	87,633,145	1,800,712
dev-0	total	51,080,450	7,158,683	137,314
	male	26,066,897	3,641,716	68,657
	female	25,013,553	3,516,967	68,657
dev-1	total	51,009,045	7,275,691	156,606
	male	25,579,703	3,641,568	78,303
	female	25,429,342	3,634,123	78,303
test-A	total	43,597,629	6,234,069	134,618
	male	22,253,841	3,175,881	67,309
	female	21,343,788	3,058,188	67,309

possible contamination of test data with the data on which RoBERTa models were trained.

In Section II, we discuss the HSSS challenge along with the modifications in the data set done for the purposes of this paper. In the main Section III, we discuss the methods we applied to tackle the challenge of gender identification. Section IV summarizes the results. Finally, we discuss the issues of training/testing data contamination in Section V.

II. HE SAID SHE SAID TASK

Polish is one of the languages with a high frequency of gender-specific first-person expressions. (Only the few languages with gender distinction in the first person, e.g. Ngala [24], might have a higher frequency of such expressions.) This fact was leveraged to create a large gender-labeled corpus for Polish: the "He Said She Said" corpus [10]. Simply CommonCrawl dataset was grepped, using morphological dictionaries and handcrafted rules, for gender-specific first-person expressions. Obviously, there were some issues that needed to be addressed, e.g. quotes, titles, SEO spam.

Later, the corpus was turned into a classification challenge hosted at the Gonito.net platform [11]. All feminine gender-

specific first-person expressions were changed to masculine forms in order to prevent classifiers from using the simple gender-revealing syntactic features. Obviously, without this normalization step, the challenge would be trivial. The corpus was randomly split into 4 sets: train set, two development (validation) sets (dev-0 and dev-1) and test set (test-A). The split was based on the websites from which the texts originated, i.e. texts from the same website would belong to the same set. Also, the sets were balanced so that 50%/50% distribution would be obtained, not just for the whole data set, but also for *each* website. For instance, let's consider a message board about pregnancy, in general, there are many more texts written by women there (at least judging by gender-marked first-person expressions), but for the challenge, the same number of male and female texts would be sampled from such a website. This, along with the fact that texts are short, makes the challenge rather difficult.

The challenge was presented [11] to showcase the Gono.net platform and was discussed there only briefly. For more detailed information about the challenge, see Table I.

For this paper, two changes have been made to the original challenge:

- 1) *Likelihood* metric was chosen as the main metric (instead of simple accuracy), Likelihood is defined as the geometric mean of probabilities assigned to the gold-standard classes – the motivation was that accuracy is not enough to distinguish solutions of varying quality and confidence;
- 2) some unwanted blank characters were removed.

Some initial experiments with learning classifiers based on the HSSS data set were presented in [12].

III. METHODS

We introduce the structure of our experiments as follows. Subsection III-A describes human baselines. Subsection III-B describes TF-IDF (term frequency-inverse document frequency) based methods. Subsection III-C describes some neural methods. Both III-B and III-C are self-contained. This means not including any data apart from training data available in HSSS task. Subsection III-D describes pre-trained transformer models. Table III presents all classifiers results.

- self-contained – we use only data available from the HSSS task: train on the training set, validate on the dev-0 (validation) set and report results on the test-A (test) set. We will use 256 sequence length which covers most (over 90%) of the HSSS data to speed up the training process.
- non-self-contained – we use publicly available models, which were pre-trained on large amounts of data (may be contaminated by examples from the test or validation set). We will use the sequence length that was saved for these models, which is usually 512.

TABLE II
RESULTS ON THE TEST SET SAMPLE OF SIZE 800 CREATED FOR HUMAN EVALUATION.

method	test accuracy
TF-IDF + logistic regression	0.68500
Polish RoBERTa base	0.77125
LSTM (constrained)	0.73375
human 1	0.65250
human 2	0.67375
human 3	0.66250
human 4	0.65625
human ensemble	0.68125

A. Human Baseline

Four people (two females and two males) made predictions for random sample sets of size 200 for development set and 800 for the test set. They were explained how the dataset was created and asked not to look for the answer on the internet. We rejected human 1 result based on the development dataset result and created a human ensemble with the remaining 3 people predictions using majority voting. The results are presented with the best TF-IDF based, self-contained and overall methods in the Table II.

B. TF-IDF based methods

Term frequency-inverse document frequency (TF-IDF) is a common vector representation of a document in natural language processing. We use the TfidfVectorizer library from Scikit-learn with standard parameters. This includes word-level, lowercasing, l_2 normalization. We did not restrict the vocabulary size and we used word-level splitting. The following classifiers were trained using TF-IDF vectors: Logistic Regression, XGBoost Classifier, SVM.

1) *Logistic Regression*: We used LogisticRegression from Scikit-learn library with standard parameters, except for the maximum number of iteration. We trained until classifier convergence.

2) *Support Vector Machine Classifier*: Support-Vector Network [5] is a common algorithm, that circumvents non-linear separability of data as well as separate samples from different categories. Although, in this case, we chose LinearSVC from Scikit-Learn, which uses a linear kernel. The reason is memory and computation issues related to the high dimension of TF-IDF representation and the number of samples in the HSSS task. Again, we used standard parameters, except for no maximum number of iteration, which led to convergence. We do not report likelihood due to the fact that SVM does not yield probabilities.

3) *XGBoost Classifier*: Tree boosting is an effective and popular method for regression and classification. We used XGboost library [3] with the choice of the parameters suited for better classifier quality.¹ This includes gbtrees booster,

¹Some of the parameters were taken from <https://www.kaggle.com/serigne/stacked-regressions-top-4-on-leaderboard>

learning rate set to 0.05 and max depth set to 3.

C. Neural Methods (*self-contained*)

1) *FastText*: FastText [15] is a shallow neural network library created for fast text classification model training and evaluation. We used a supervised setting with hyperparameter tuning, the word embeddings were initialized randomly. The best result was obtained with wordNgrams set to 2, word dimension set to 156, and context size window set to 5.

2) *LSTM*: Long Short Term Memory Networks [13] were used to obtain a state-of-the-art results on most NLP tasks before the era of Transformer language models [7]. In our tasks, for bidirectional LSTM, SentencePiece [19] tokenization performs better than word-level lowercase tokenization. Vocab size 50k was used with randomly initialized embeddings of size 100. We tried embedding size 300, but resulted in slightly worse classifier quality. We used one layer of 256 units, trained with Adam [16] optimizer with learning rate 0.001. The batch size used for training was 400 and sequences were trimmed and padded to 256 tokens.

3) *Transformer*: In the last time Transformer [26] and its modification like BERT [7], RoBERTa [20] or XLM-R [4] achieve state-of-the-art in the benchmarks such as GLUE [29] or SuperGLUE [28] benchmark. Most often used bidirectional Transformers are pre-trained on huge amounts of monolingual data in the Masked Language Model (MLM) process, where the model learns a bidirectional representation of tokens. Next, pre-trained models are finetuned to the specific task. This process reduces the time to train a new model from scratch and can be easily adapted to other tasks. In our case, the downstream task is classification, where the model uses a special token ([CLS], classification token), which represents the whole sentence and helps achieve better results.

We train self-contained classifier based on the RoBERTa model in two ways: with pre-training and without pre-training (train classifier from the scratch) stage. We only used the data that was available in the HSSS challenge to avoid any data leaks in the other data sets. To compare our methods we created Transformer with 8 layers, 8 heads, 256 sequence length and embedding size 512 and 2048 respectively for internal model representation and feed forward layer (after attention layer). We use 50k size vocabulary with Sentencepiece tokenization and randomly initialized embeddings of size 512. First, the model was pre-trained for 10 epochs with Masked Language Model (MLM) criterion and finetuned 10 epochs for the classification tasks. Second, the model was trained on the classification task for 20 epochs (comparing to the previous one, where it was 10 + 10 epochs for pre-training and classification) only. We pre-train and finetune with Adam optimizer with learning rate 0.0001 and 50 sentences per batch. Scores presented in the Table III show that the pre-training stage is the important element to achieve a better model for classification tasks.

D. Pre-trained Transformers

In this section we describe fine-tuning of models publicly available for Polish language: Polish RoBERTa [6] and multi-

lingual XLM-R [4] (which supports 100 languages including Polish). Both models are available in the two versions: base (with 12 layers) and large (with 24 layers). Monolingual models like RoBERTa are focused on achieving the best results in a given language. On the other hand, multilingual models support as many languages as possible with results similar to monolingual models. The disadvantage of multilingual models is the size of the vocabulary, which is several times larger than monolingual models like Polish RoBERTa. Bigger vocabulary needs more resources to fine-tune models, but may improve results by cross-language relationships.

1) *Polish RoBERTa finetuning*: We finetuned Polish RoBERTa [6] (base and large model) using fairseq library [22] for 5 and 3 epochs respectively for the base and large model. Further training resulted in lower development dataset accuracy. We used Adam optimizer with a learning rate 0.00001 and around 200k warmup steps. The maximum sequence we use is 512 as in original Polish RoBERTa.

2) *Polish RoBERTa finetuning with Monte-Carlo model averaging*: Common practice when using dropout is to scale weights during inference time. However, as described in [25] (section 7.5), further investigated in [8], this procedure is only an approximation of Monte-Carlo model averaging. We checked, whether the Monte-Carlo model averaging yields better results than standard weight scaling in our case. By setting Polish RoBERTa (both base and large) in the training mode (with active dropout), making predictions 12 times, and averaging likelihood, we obtained slightly better results in both cases.

3) *XLM-R finetuning*: We finetuned multilingual XLM-R [4] base and large for 1 epoch, further training does not improve results. Each of the models was trained with 512 tokens using Adam optimizer with a learning rate 0.00004. Batch size has been set to 10 and 25 for the base and large model. Results are available in the Table III.

4) *Polish RoBERTa last layer averaged*: For the evaluation of how much information about language Polish RoBERTa possesses, we conducted the following experiment. We extracted the last layer tokens and averaged them. Then, we trained logistic regression classifier with no Polish RoBERTa finetuning. This was done until classifier convergence.

5) *XLM-R last layer averaged*: We conducted the same experiment with XLM-R as in subsection III-D4.

6) *Polish RoBERTa fill mask*: In order to check the predicting power of only pre-trained Polish RoBERTa models, we conducted the following experiment. We masked all gender-revealing first-person expression and used the models in Masked Language Model setting. We choose one random expression and looked for the most probable word indicating gender in the first 10 model predictions. Only 6333 samples out of 137314 in the test set did not reveal first-person expression in the first 10 predictions. No training or development sets were used in this experiment. However, this method does not yield good results (though the trivial baseline was beaten).

IV. RESULTS

The self-contained models (BiLSTM and RoBERTa MLM + classifier) achieved better results than TF-IDF and fastText. The BiLSTM model achieves a bit better results than the Transformer base model, which suggests that the Transformer model needs more resources. The classifier trained from scratch (without pre-training) produces inferior results, and this shows again that the pre-training step is an important element in classification tasks. Neural methods achieve better results than the human baseline, but human results are comparable to TF-IDF.

Pre-trained models trained on the much larger data set than the HSSS data set achieve the best results. Monolingual and multilingual models achieve similar results, but XLM-R large achieve lower results than other pre-trained models, indicating that the bigger models may not improve results on the classification tasks. Polish RoBERTa large achieved similar results to the base version, which might mean that RoBERTa large needs more pre-training steps to get better results.

V. CONTAMINATION STUDY

Using a pre-trained language model (or any other solution not constrained to the train set provided with the challenge) raises the question of data contamination or train-test overlap, i.e. (1) was the test set represented in the training set of the language model?, (2) did it make the results better (e.g. due to memorization of test texts by the language model)? See [1] for the discussion of data contamination in the case of the GPT-3 model when used for popular English NLP test sets.

We carried out a contamination study on the solution based on the Polish RoBERTa model (the best solution so far). As the Polish RoBERTa was trained (among other sources) on CommonCrawl 2019/2020 [6], and the HSSS was prepared using CommonCrawl 2012-2015 (mostly 2012), the risk of contamination was real (a significant percentage of Web content from 2012-2015 could survive up to 2019).

We searched the contents of CommonCrawl 2019 (as provided to us by the authors of [6]²) for the six-gram fragments of the HSSS test set, obviously taking into account the fact that feminine gender-specific forms were modified during the preparation of the HSSS test set.

The summary of the contamination study is given in Table IV, where the results obtained with Polish RoBERTa are compared against the best constrained solution (an LSTM trained on the HSSS training set). The following conclusions can be made:

- results on the contaminated subset *are* better (and the difference of the Accuracy/Likelihood metrics on the contamination and not contaminated metric is significant), and this might indicate that the problem is real;
- still, the percentage of data contaminated is low (3%), hence the impact on the total is limited; if we were to lower the results on the contaminated subset to be

²Unfortunately, we were unable to check the other sources, though the probability of them contaminating the test set seems much lower

the same as on the uncontaminated subset, the accuracy would be lower only by a small margin;

- note that this is not a proof of contamination; the cause of better results on the contaminated subset might be different, for example it might have been caused by the fact that CommonCrawl 2019 for Polish RoBERTa was filtered by a language model, whereas for the HSSS data set — only using handcrafted heuristics, i.e. sentences might be longer and “proper” (e.g. say with fewer spam texts), hence easier for a classification task.

VI. CONCLUSIONS

We showed that a pre-trained Transformer model can obtain strong results for a challenging classification tasks on short texts. It turned out that predictions done by humans (even aggregated) were much worse. What is important is that influence of contamination of the training set was practically excluded.

Abstract—Short text classification is an important task widely used in many applications. However, few works investigated applying Spiking Neural Networks (SNNs) for text classification. To the best of our knowledge, there were no attempts to apply SNNs as classifiers of short texts. In this paper, we offer a comparative study of short text classification using SNNs. To this end, we selected and evaluated three popular implementations of SNNs: evolving Spiking Neural Networks (eSNN), the *NeuCube* implementation of SNNs, as well as the *SNN Torch* implementation that is available as the Python language package. In order to test the selected classifiers, we selected and preprocessed three publicly available datasets: 20-newsgroup dataset as well as imbalanced and balanced PubMed datasets of medical publications. The preprocessed 20-newsgroup dataset consists of first 100 words of each text, while for the classification of PubMed datasets we use only a title of each publication. As a text representation of documents, we applied the TF-IDF encoding. In this work, we also offered a new encoding method for eSNN networks, that can effectively encode values of input features having non-uniform distributions. The designed method works especially effectively with the TF-IDF encoding. The results of our study suggest that SNN networks may provide the classification quality is some cases matching or outperforming other types of classifiers.

Index Terms—short text classification, spiking neural networks, evolving spiking neural networks, *NeuCube*, *SNN Torch*, medical documents, PubMed documents

I. INTRODUCTION

EFFECTIVE text classification is a difficult task that often requires adaptation of special types of learning and encoding methods. Classification of short texts is often even more difficult due to the very limited length of documents that can be used as training input data. The already offered methods for short text classification include, for example, Support Vector Machines (SVM), naive Bayes classifier, decision trees [1] or the classifiers that include clustering of input data as a preprocessing step [2].

Spiking Neural Networks (SNNs) are a type of neural networks that are highly inspired by biological mechanisms of learning and cognition of a human brain. Surprisingly, there are no publications applying SNNs to short text classification. Thus, in this work we evaluate three selected implementations of SNNs applied by us to the short text classification task, namely: our prepared classifier that uses *evolving Spiking Neural Networks*, *eSNNs*, the *NeuCube* implementation of SNNs as well as the *SNN Torch* implementation.

Evolving Spiking Neural Network (eSNN) is a recently introduced classifier that was successfully applied in various domains: transportation prediction [3], air pollution prediction [4]–[6], recognition of moving objects [7], or anomaly detection [8], [9]. To the characteristic of eSNNs belongs: ability to process large amounts of data efficiently and insignificant memory requirements. As it was proven in the enumerated examples of eSNNs usage cases, they can effectively use the biologically inspired learning and prediction mechanisms in typical engineering applications.

The other implementation selected for this study is the *NeuCube* implementation of SNNs [10], [11]. Contrary to the eSNNs implementation, *NeuCube* consists of three layers of spiking neurons: input, whose aim is to encode input values into firing times, internal, which consists of a reservoir (cube) of hidden neurons, whose weights are trained in an unsupervised manner using synaptic-plasticity rules, and output, which contains neurons responsible for assigning decision classes to testing examples.

Finally, as the third implementation of SNNs we selected recently developed *SNN Torch* implementation available as a package of the Python language [12]. To the advantages of *SNN Torch* belong its flexibility to construct SNNs that can consist of many layers of neurons which combine not only neuronal models that are typically present in SNNs, such as the Leaky-Integrate-and-Fire (LIF) model, but also sigmoid neuronal models. In addition, *SNN Torch* can take advantage of a GPU-based processing in order to speed up training and classification procedures.

This paper provides the following contribution:

- To the best of our knowledge, for the first time in the literature we apply SNNs for classification of short texts and, especially, large sets of medical publications based on their metadata (such as a title or an abstract of a publication). To this end, we selected three types of SNNs: *eSNN* networks, the *NeuCube* implementation of SNNs as well as the *SNN Torch* implementation.
- As a part of our implementation of *eSNN* networks we propose a new input data encoding method. The proposed method first creates a histogram of input values of each feature F in the training dataset. The number of bins (subranges) of histogram is specified by a user-given parameter called B . Subsequently, the NI_{size} input

neurons of an eSNN are redistributed to encode the values of each bin of the histogram according to the cardinality of values in bins. As we present in the experiments, the offered encoding method provides much better classification accuracy than the other two encoding methods offered in the literature: a method that directly calculates the firing order of input neurons proposed in [5] and Gaussian Receptive Fields (GRFs) [13].

- We conduct experiments using the frequently-used *20-newsgroup* dataset¹ as well as two real PubMed datasets of medical publications selected from the website of the BioASQ competition². Since we focus on classifying short texts, from each document of the *20-newsgroup* we selected only 100 first words. In the case of two selected PubMed datasets, only a title of a publication is used as input data for each tested classifier.
- The obtained results of experiments suggest that SNN Torch implementation is more effective in short text classification than the other selected SNNs implementations. Additionally, for the selected PubMed datasets, SNN Torch gives results of classification slightly superior to the other classifiers tested in the experiments.

The paper is structured as follows. Section II presents the related work. Section III describes the SNNs implementations selected for this study. This section also describes the proposed encoding method for the eSNN networks. In Section IV, we give the description of the obtained datasets and applied preprocessing. Section V provides the results of experiments. Finally, in Section VI we conclude the work and discuss the results.

II. RELATED WORK

A. Short Text Classification

Effective classification of short texts is a topic intensively studied nowadays. The already offered methods offered for text classification include: various types of classifiers, such as Support Vector Machines (SVM), naive Bayes classifiers, decision trees or different types of neural networks [1]. [14] distinguishes two types of approaches that can be applied for text classification: the first one, in which the set of text is first represented using Document-Term Matrix (DTM), which can be obtained using feature extraction method, such as Bag of Words (BoW) or Term Frequency - Inverse Document Frequency (TF-IDF). Subsequently, DTM is used to train a selected classifier, such as SVM. The second approach skips the process of generating DTM matrix and directly provides the set of texts as training data for a deep neural network.

Majority of recent approaches to short text classification with neural network models focused on applying Recurrent Neural Networks (RNNs) and Convolutional Neural Networks (CNNs). [15] presented a classification model that is based on CNNs and incremental learning. In order to increase the classification accuracy, [15] applied an approach in which a

current short document of a pipeline of documents is classified not only based on its textual content but also based on obtained classification results of preceding documents.

[16] presented the results of experiments on the classification of one-sentence questions using CNNs. The dataset applied in [16] was obtained from the WikiAnswer and contained 608 650 questions grouped into several hundred categories. As the results of experiments of [16] suggest, CNN networks can classify questions with accuracy comparable or better than SVM classifier.

In [17], a model that combines CNNs networks with SVM classifier was applied to the classification of simple sentences expressing either positive and negative feelings. In the approach presented in [17], first, a word embedding method (such as Word2Vec) is used to obtain the vector representation of each word in the text corpus. Subsequently, each text in the corpus is represented as a sequence of vectors, each corresponding to one of the text's words. Such a representation of texts is next used as input data for CNN network that consists of convolutional, max-pooling and fully-connected layers. The results obtained from the fully-connected layer are used as training data for the SVM classifier. The results of experiments presented in [17] suggest that this approach can provide better classification results than separate CNNs and SVM classifiers.

The review of the other types of classifiers applied for (short) text classification (and in particular MESH dataset) can be found, for example, in [14], [18], [19].

B. Spiking Neural Networks for Text Classification

We are aware of only two other works adapting spiking neural networks for text classification. However, contrary to this work, both of them applied SNNs for long text classification. In order to classify longer texts, [20] offered a method consisting of two phases. The first phase consists of transforming a text into a vector of numbers using TF-IDF encoding and, subsequently, into a sequence of spikes. In the second phase, an SNN network is taught in an unsupervised way using the spikes generated in the first phase in order to generate spike-based low-dimensional representation of a text. Subsequently, the generated representation is used as input data for the training of logistic regression, which is responsible for the final classification of documents. Thus, in the approach of [20], an SNN network can be perceived as a dimensionality reduction technique of a TF-IDF text representation. While the approach of [20] was shown to provide superior text classification results to the other classifiers tested there, it used only logistic regression, which (as presented, for example, in our experiments) itself can be an effective text classifier.

[21] presents a comparison of classification results for different types of word embeddings (such as Word2Vec and GloVe [22]) and neuron types that were applied in SNN (such as the LIF neuronal model). The results obtained in [20] suggest that SNNs can be effectively applied to classify longer texts.

III. THE SELECTED IMPLEMENTATIONS OF SPIKING NEURAL NETWORKS

A. The Evolving Spiking Neural Networks Implementation

In Fig. 1, we present the architecture of our implementation of eSNNs. The designed eSNN network consists of groups of input neurons $\text{NI}^{(F_1)}, \dots, \text{NI}^{(F_m)}$ encoding values of m features $\mathcal{F} = \{F_1, \dots, F_m\}$ ³. The number of input neurons in each group $\text{NI}^{(F)}$ is the same and is specified by the user-given parameter NI_{size} . The output neurons in the repository NO are assigned decision classes present in the training dataset of texts \mathbf{D}_{tr} (we assume that each text in $T \in \mathbf{D}_{tr}$ has one and only one decision class). Thus, given L decision classes, the output neurons NO are organized into L groups. In the learning process of an eSNN network, a new candidate output neuron n_c is created for each training text $T \in \mathbf{D}_{tr}$ and either added to the repository NO or merged with the neurons already existing there.

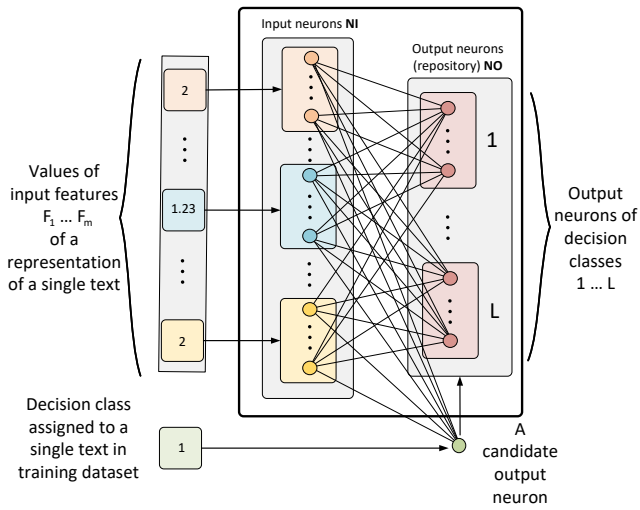

Fig. 1. The architecture of an eSNN network adopted in this study.

1) *Input Layer*: For the encoding of input values of features \mathcal{F} into spikes we develop a new encoding method. Our motivation to develop the presented method lies in the fact that the previously introduced methods dedicated for eSNNs⁴ (such as the GRFs method [24] or the method of [5]) do not work well with some text representations (such as the TF-IDF representation)⁵. Specifically, both the GRF method and the method of [5] are not able to effectively encode input values of features having non-uniform distributions. This can

³The number of features \mathcal{F} depends on the used text representation: for example, Word2Vec and Doc2Vec representations allow the user to specify the number of features [23].

⁴Unlike the other implementations of SNN networks, eSNN does not require exact firing times of input neurons to be propagated into the network. Rather than, it is enough to calculate the firing order of input neurons $\text{NI}^{(F)}$ encoding a value of each feature $F \in \mathcal{F}$.

⁵In fact, in Section V we present experiments comparing the mentioned encoding methods for eSNNs.

be explained by the fact that both of these methods divide the range of input values of a feature F into a number of equal subranges, the number of which is equal to the user-given number of input neurons NI_{size} . A center value of each of such subranges is associated with one input neuron. Given an input value to be encoded and the obtained center values of input neurons, the GRFs method and the method of [5] calculate Euclidean distances between the input value and the center values of input neurons. The non-decreasing order of such Euclidean distances between the input value and the center values of input neurons identifies the firing order of input neurons. In the case of non-uniform distributions of input values (such as a normal distribution or skewed distributions), it can often happen that a relatively high number of input values will be encoded using the same firing order of input neurons, while the values of other ranges will be associated with more distinguishing firing order of input neurons. To alleviate this problem, we offer the method presented below.

The proposed encoding method requires two user-given input parameters, which are the number of input neurons NI_{size} encoding values of each feature $F \in \mathcal{F}$ as well as the number of bins (subranges) B (where $B < NI_{size}$) used to create a histogram of values of each feature F . The proposed method first creates a histogram of input values of a feature F using solely the training dataset. Subsequently, the NI_{size} input neurons are allocated to encode the values of each bin of the histogram in the following way. First, each bin is assigned at least one input neuron of NI_{size} neurons. The rest of $NI_{size} - B$ input neurons is allocated as follows.

Let $Min^{(F)}$ and $Max^{(F)}$ be minimal and maximal values of feature F in training dataset \mathbf{D}_{tr} , respectively. The width of range of each bin equals $Bins_{width} = \frac{Max^{(F)} - Min^{(F)}}{B}$. The range of each bin is calculated as follows:

- $[Min^{(F)} + (i - 1) \cdot Bins_{width}, Min^{(F)} + i \cdot Bins_{width})$, for $Bin_i, i = \{1, \dots, B - 1\}$.
- $[Min^{(F)} + (B - 1) \cdot Bins_{width}]$, for Bin_B .

Subsequently, the number of values of a feature F in each bin is calculated and remembered as $Bin_i.\overline{Values}$. The number of neurons allocated to each bin is obtained using Proposition 1.

Proposition 1. Let $Bin_i.\overline{Neurons}$ represents a number of input neurons allocated to encode values of Bin_i and $\overline{\mathbf{D}_{tr}}$ be a number of training examples (texts):

- $Bin_i.\overline{Neurons} = \left\lceil \frac{Bin_i.\overline{Values}}{\overline{\mathbf{D}_{tr}}} \cdot (NI_{size} - B) \right\rceil + 1$, for $i \in \{1, \dots, B - 1\}$,
- $Bin_i.\overline{Neurons} = \left\lceil \frac{Bin_i.\overline{Values}}{\overline{\mathbf{D}_{tr}}} \cdot (NI_{size} - B) \right\rceil + 1$, for $i = B$.

Given the number of input neurons allocated to each bin, we can obtain the center value μ_j of each input neuron $n_j \in \text{NI}$. The center values μ_j of input neurons are directly used to calculate firing order of input neurons. The center values are calculated according to Proposition 2. For each Bin_i , let

$$Bin_i.\Delta = Bins_{width} / Bin_i.\overline{Neurons}$$

denote the width between center values of input neurons allocated to Bin_i .

Proposition 2. For each bin $i \in \{1, \dots, B\}$, the center value of each input neuron $n_j \in Bin_i.Neurons, j \in \{1, \dots, Bin_i.Neurons\}$ is calculated as follows

$$\mu_j = Min^{(F)} + (i - 1) \cdot Bins_{width} + (j - 0.5) \cdot Bin_i \cdot \Delta$$

Finally, given the center values of input neurons (please note, that it is enough to calculate the center values μ_j one time after D_{tr} is load by an eSNN), we can calculate firing order $order_{n_j}$ of spikes that are propagated into the network. Let assume that $x^{(F)}$ is the value of a feature F to be encoded by the proposed method. Proposition 3, shows how to obtain the center value closest to an input value $x^{(F)}$.

Proposition 3. Let μ_k be the center value closest to input value $x^{(F)}$. Index k is calculated as follows:

$$k = \begin{cases} j \mid |x^{(F)} - \mu_j| \text{ is smallest,} & \text{if } x^{(F)} \in [Min^{(F)}, Max^{(F)}] \\ 1, & \text{if } x^{(F)} < Min^{(F)}, \\ NI_{size}, & \text{if } x^{(F)} > Max^{(F)}. \end{cases}$$

Given the k index, the firing order of all input neurons $n_j \in NI$ is obtained as given in Algorithm 1. We illustrated the example coding using the proposed method in Fig. 2.

Algorithm 1 Calculate firing order of input neurons

Input: $x^{(F)}$ - input value to be encoded, NI_{size} - number of input neurons.

Ensure precalculated: Bin_i - the structure containing parameters of i -th bin of a feature F (i.e. $Bin_i.Neurons, Bin_i.\Delta, Bin_i.Values$), μ_j - center values of input neurons $n_j \in \{1, \dots, NI_{size}\}$, k - index of a center value μ closest to $x^{(F)}$.

Output: Firing order of input neurons $n_j \in \{1, \dots, NI_{size}\}$.

```

1:  $order_{n_k} \leftarrow 0, ord \leftarrow 0$ 
2:  $l \leftarrow k - 1; r \leftarrow k + 1$ .
3: while  $l \geq 1$  OR  $r \leq NI_{size}$  do
4:   if  $l \geq 1$  then  $dist_l \leftarrow |\mu_l - x^{(F)}|$  end if
5:   if  $r \leq NI_{size}$  then  $dist_r \leftarrow |\mu_r - x^{(F)}|$  end if
6:   if  $l < 1$  AND  $r \leq NI_{size}$  then
7:      $order_{n_r} \leftarrow ord, ord \leftarrow ord + 1, r \leftarrow r + 1$ 
8:   else if  $l \geq 1$  AND  $r > NI_{size}$  then
9:      $order_{n_l} \leftarrow ord, ord \leftarrow ord + 1, l \leftarrow l - 1$ 
10:  else if  $l \geq 1$  AND  $r \leq NI_{size}$  then
11:    if  $dist_l < dist_r$  then
12:       $order_{n_l} \leftarrow ord, ord \leftarrow ord + 1, l \leftarrow l - 1$ 
13:    else
14:       $order_{n_r} \leftarrow ord, ord \leftarrow ord + 1, r \leftarrow r + 1$ 
15:    end if
16:  end if
17: end while

```

Algorithm 1 calculates firing order of input neurons as follows. As a first fires the input neuron n_k , whose center value μ_k is closest to the input value $x^{(F)}$ (the firing order function $order_{n_k}$ of the input neuron n_k is set to 0). Subsequently,

Algorithm 1 calculates firing order of the rest input neurons, whose center values are located to the left and to the right of the center value of the first firing input neuron n_k . The firing order of these neurons is calculated in a single scan using the distances between their center values and the input value $x^{(F)}$. To this end, the algorithm uses three counters: l and r which point to the neurons whose center values are located to the left and to the right of the center value μ_k , respectively, as well as ord counter which stores the current firing counter (initially set to 0). Initially, l and r are set to $k - 1$ and $k + 1$, respectively. In each iteration of the main while loop, the algorithm calculates firing order of one input neuron pointed either by l or r counters. If the distance between center value of an input neuron n_l and $x^{(F)}$ is smaller than the distance between center value of an input neuron n_r and $x^{(F)}$, then $order_{n_l}$ is set to the current value of the ord counter, ord is incremented and l is decremented. Otherwise, $order_{n_r}$ is set to ord , ord is incremented and r is incremented. The computational complexity of Algorithm 1 is linear in the number of input neurons NI_{size} , similarly to the encoding algorithms presented in [5] or [13].

Fig. 2. The proposed encoding method - the NI_{size} input neurons are redistributed to code the values of each bin of a histogram; the encoded value is 1.75.

2) *Network's Learning and Classification:* The firing orders of input neurons are calculated separately for each text in either training or testing dataset. The firing orders obtained for texts of the training dataset are used in the network's learning phase, while the firing orders calculated for texts of the testing dataset are used to classify these texts.

In the eSNN learning process, for each training text T in dataset D_{tr} , there is created a candidate output neuron n_c

which is assigned a single decision class of text T . We denote a decision class assigned to n_c as: $Class(n_c)$.

The candidate output neuron is connected through synapses to all input neurons \mathbf{NI} . The vector of weights of such synapses is denoted as $\mathbf{w}_{n_c} = [w_{n_1, n_c}^{(A_1)}, \dots, w_{n_{|\mathbf{NI}(F_1)|}, n_c}^{(F_1)}, \dots, w_{n_1, n_c}^{(F_m)}, \dots, w_{n_{|\mathbf{NI}(F_m)|}, n_c}^{(F_m)}]$, where m is the number of features \mathcal{F} . To initialize the weights of synapses we apply the rank-order rule [24]. Each weight of a vector \mathbf{w}_{n_c} is initialized according to Eq. (1).

$$w_{n_j n_c}^{(A)} = mod^{order_{n_j}}, n_j \in \mathbf{NI}, \quad (1)$$

where mod is a modulation factor whose value is specified by the user and should be in the range $(0, 1)$.

Each output neuron (either candidate n_c or the output neuron n_i already present in \mathbf{NO}) has also an update counter M . The value of such update counter is first set to 1 when a candidate is created, and subsequently is incremented when an output neuron present in \mathbf{NO} is updated using a candidate output neuron.

After the candidate neuron n_c is created and its synapses' weights are initialized, it is either added to the repository of output neurons \mathbf{NO} or merged with one of the output neurons already existing in $\mathbf{NO}(Class(n_c))$, that is in the group of output neurons of class $Class(n_c)$ in \mathbf{NO} . To this end, Euclidean distances $Dist_{n_c, n_i}$ between the vector of synapses' weights \mathbf{w}_{n_c} and the vectors of synapses weights \mathbf{w}_{n_i} of each output neuron $n_i \in \mathbf{NO}(class_{n_c})$ are calculated. If there exists such an output neuron n_s for which $Dist_{n_c, n_s}$ is minimal and below the value $simTr \cdot \overline{Dist}$, then the vector \mathbf{w}_{n_s} and counter M_{n_s} are updated according to Eq. (2) and n_c is discarded. Otherwise, n_c is simply inserted into $\mathbf{NO}(class_{n_c})$. $simTr$ is a user-specified similarity threshold, whose value is in the range $[0, 1]$ ⁶.

$$\mathbf{w}_{n_s} = \frac{\mathbf{w}_{n_s} \cdot M_{n_s} + \mathbf{w}_{n_c}}{M_{n_s} + 1}, M_{n_s} = M_{n_s} + 1. \quad (2)$$

\overline{Dist} is the tight upper bound on the Euclidean distances between any possible candidate output neuron and any output neuron in \mathbf{NO} and, as presented in [5], can be calculated using Eq. (3).

$$\overline{Dist} = \left[\sum_{F \in \mathcal{F}} \sum_{j=1}^{NI_{size}} \left(mod^{j-1} - mod^{NI_{size}-j-1} \right)^2 \right]^{\frac{1}{2}} \quad (3)$$

After eSNN is taught using the training dataset \mathbf{D}_{tr} , each testing text $T \in \mathbf{D}_{ts}$ is assigned one decision classes of all decision classes of output neurons in \mathbf{NO} . To this end, the value of Post-Synaptic Potential PSP_{n_i} of a membrane of each output neuron n_i in \mathbf{NO} is calculated according to Eq. (4).

$$PSP_{n_i} = \sum_{F \in \mathcal{F}} \sum_{n_j \in \mathbf{NI}^{(F)}} w_{n_j n_i}^{(F)} \cdot mod^{order_{n_j}}. \quad (4)$$

⁶Please note, that the greater values of $simTr$ increase the chance that a candidate output neuron will be merged with one of the neurons already existing in the repository \mathbf{NO}

In Eq. (4), $w_{n_j n_i}$ is weight of a synapse connecting the input neuron n_j to the output neuron n_i that is calculated in the network's learning phase. $order_{n_j}$ is a firing order value of input neuron $n_j \in \mathbf{NI}^{(A)}$ given the encoding of a value of feature F in a testing text T . Finally, the testing text T is assigned a decision class of an output neuron $n_{max} \in \mathbf{NO}$, whose membrane PSP value $PSP_{n_{max}}$ is maximal. One can find the pseudocode of described learning and classification procedures of eSNNs, for example, in [5], [9], [24]. We posted our implementation that was used in the experiments along with the used dataset at the GitHub repository⁷.

B. The NeuCube Implementation of Spiking Neural Networks

As the second implementation of SNNs that is selected by us for the experiments we used the NeuCube implementation [10]⁸. Unlike the eSNNs implementation presented in subsection III-A, NeuCube implements an SNN network that consists of three layers of neurons: input, internal and output. The aim of the input layer of NeuCube is to convert values of features of a text representation into a sequence of spikes that is propagated into the network.

Since NeuCube implements four temporal coding algorithms, it requires each text (either from the training \mathbf{D}_{tr} or testing \mathbf{D}_{ts} datasets) to be represented as a time series. In our approach, each text is represented as a single time series TS containing all values of features (F_1, \dots, F_m) . Thus, given a text representation having m features \mathcal{F} , the time series of each text consists of a series of m values. The temporal encoding algorithms implemented in NeuCube are: Threshold-based Representation (TR), Moving Window (MV), Step Forward (SF), and Bens Spiker Algorithm. The results presented in [25] suggests that the most effective is the TR algorithm, which was used by us in the experiments. Given time series representation TS of a text, the TR algorithm generates spikes by first calculating $ATB = \mu SR \cdot \sigma$ value (where μ and σ are mean and standard deviation of values of TS , respectively). Next, a positive spike is generated if the difference between two consecutive values of TS is positive and greater than ATB . If the difference is negative and smaller than ATB , then a negative spike is generated. The generated example of TR encoding of the time series values of the first document of the 20-newsgroup dataset is given in Fig. 3.

The internal layer of NeuCube consists of a cube of Leaky-Integrate-and-Fire (LIF) neurons [26]–[28] that are interconnected using both excitatory and inhibitory synapses. The number of such neurons in the cube and their topological locations can be defined by the user. The initial synapses and their weights are generated using the *small-world* principle (according to which the neurons located in a topological proximity have a grater chance to be connected). In the cube's learning process, the weights of synapses are calculated according to the Spike-Time Dependent Plasticity (STDP)

⁷<https://github.com/piotrMaciag32/eSNN-short-text-classifier>

⁸NeuCube is a an application with a graphical user interface implemented in Matlab and is free for download form <https://kedri.aut.ac.nz/R-and-D-Systems/neucube>

Fig. 3. The NeuCube TR encoding of the time series values of the first document of the 20-newsgroup dataset (the upper plot presents an input time series of TF-IDF values, the lower plot shows the obtained encoding).

rules. Let us consider two neurons: n_j and n_i presented in the internal layer of NeuCube and let us assume that there is a synapse from neuron n_j to neuron n_i . Given emission of spikes from neurons n_j and n_i at times t_j and t_i , respectively, the change of the weight value of the synapse from n_j to n_i is calculated according to Eq. (5).

$$w_{j,i}(t) = \begin{cases} w_{j,i}(t-1) + \eta/\Delta t, & \text{if } t_i > t_j, \\ w_{j,i}(t-1), & \text{if } t_i = t_j, \\ w_{j,i}(t-1) - \eta/\Delta t, & \text{otherwise,} \end{cases} \quad (5)$$

where η is the STDP rate learning parameter specified by the user.

Finally, the third layer of NeuCube consists of output neurons whose aim is to represent decision classes present in the training dataset \mathbf{D}_{tr} . Each output neuron in the output layer of NeuCube is connected to all neurons in the internal layer. The output neurons in NeuCube are grouped according to decision classes similarly to the output neurons **NO** of eSNNs. As in eSNNs, for each training text there is created one candidate output neuron that is always added to the set of output neurons of NeuCube (unlike in eSNNs, in which candidate output neurons can be merged with the output neurons already existing in the output layer).

The membrane Post-Synaptic Potentials (PSP) values of both internal and output neurons are calculated according to Eq. (4). Both internal and output neurons emit a spike when their PSP values exceed a certain firing threshold C , which is specified by the user. Specifically, a neuron n_i emits a spike according to Eq. 6.

$$\text{Emit a spike by } n_i \text{ at time } t = \begin{cases} True & \text{if } PSP_{n_i} \geq C, \\ False & \text{if } PSP_{n_i} < C, \end{cases} \quad (6)$$

In Fig. 4, we present the architecture of NeuCube along with the selected representation of each text. In Table I, we

show the learning parameters of NeuCube along with their description.

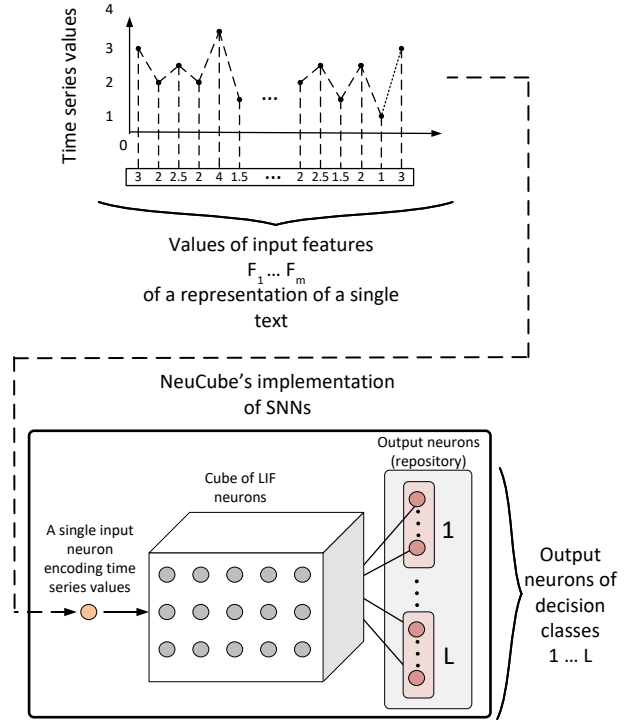

Fig. 4. The NeuCube's architecture and the applied representation of a text as a series of TF-IDF values.

C. The SNN Torch Implementation

The third implementation of SNNs selected for the experiments is the SNN Torch implementation, recently developed as the Python language package [12]. To the advantages of the SNN Torch implementation belongs the fact that it is built on the basis of the well known deep-learning Python framework *Pytorch*. SNN Torch allows us to combine SNNs with such types of neural networks as Multilayer Perceptron neural network or CNN network. Currently, SNN Torch offers eight types of spiking models of neurons: Alpha, Lapique, Leaky (LIF), RLeaky, RSynaptic, SConv2dLSTM, SLSTM and Synaptic. In our experiments, we applied the LIF neuronal model. Our applied architecture of neurons in SNN Torch consists of four layers as presented in Fig. 5. The number of input neurons equals the number of features in the input data, while the number of output neurons is the same as the number of decision classes present in the training part of the dataset.

IV. CHARACTERISTIC OF SELECTED DATASETS AND THEIR PREPROCESSING

In the experiments, we used three publicly available datasets that are widely used as benchmarks in the evaluation of text classifiers. In the experiments, we applied the TF-IDF representation of all texts. As previous experiments with text

TABLE I
THE MAIN PARAMETERS OF SNN USED IN NEUCUBE.

Parameter	Description
SR	TR algorithm threshold.
η (STDP Rate)	STDP rate for weights modification in the internal layer.
Refractory time	A period in which an input is inactive to incoming spikes after emission of a spike by itself.
Mod	Modulation parameter as given in Eq. 5.
Training iters.	Number of its. of the unsupervised learning stage.
Firing treshold	Firing threshold for spike emission by neurons.

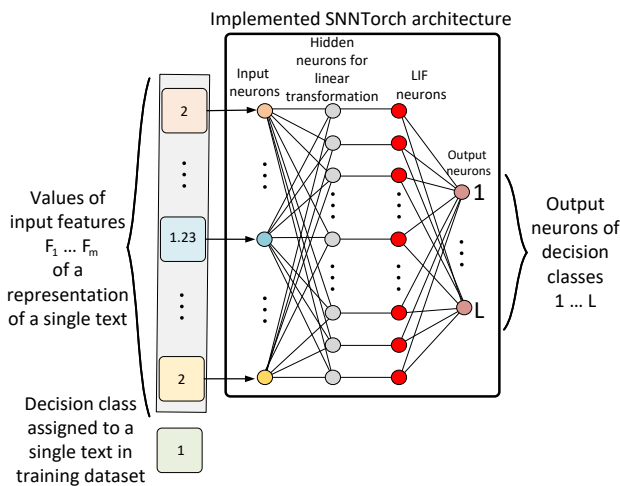

Fig. 5. The SNN architecture that was constructed using SNN Torch package for the purpose of experiments.

data and SNN networks suggest (see, for example, [20]), TF-IDF is a suitable representation for these type of neural networks. In order to obtain the TF-IDF representation, first, for each dataset we calculated the Document-Term Matrices (DTMs). DTM is a matrix that contains as many rows as the number of documents in either training or testing part of the dataset, and as many columns as the size of vocabulary (the set of all terms present in the entire dataset). Each cell of a DTM matrix can contain, for example, a number of occurrences of a given word of vocabulary (defined by a column of DTM) in a document (defined by a row of DTM)⁹.

For all selected datasets, the DTM matrices are obtained as follows. First, the vocabulary is calculated. In order to obtain the vocabulary of each dataset, we applied the *text-mining* package of the R language [29] (for the 20-newsgroup dataset) and *Gensim* package of the Python language [30] (for the PubMed Mesh dataset). The vocabulary is obtained by applying the following steps to the set of texts of each dataset:

- 1) Removing all numbers from a text.
- 2) Removing punctuation.

⁹Obviously, such a representation usually leads to a significant size of a DTM, whose cells mostly contain 0 (which indicates the situation when a word is not present in a document).

- 3) Removing English stopwords and articles.
- 4) Transforming all upper-case letters to lower-case letters.
- 5) Applying texts' stemming.

After the execution of the above steps, we calculated the DTM matrices for the training and testing parts of datasets separately as follows.

A. The Preprocessed 20-newsgroup Dataset

The 20-newsgroup dataset contains 18 846 texts that are grouped into 20 news categories. To the distinguishing characteristic of the 20-newsgroup dataset belongs the fact that 20 categories often belong to very different domains. For example: politics, sociology, religion or computer devices. The texts are split into training and testing parts in the proportion 6:4 by the author of the dataset. Thus, the training part consists of 11 307 training texts and 7538 testing texts. Most of the texts in the datasets consists of several hundreds of words. Thus, we have shorten each text by selecting only its 100 first words as text used for classification. The vocabulary calculated using such preprocessed shorten texts contains 132 370 terms. The short texts are used to obtain the Document Term Matrices (DTMs) for training and testing parts separately. Since the obtained vocabulary contains 132 370 terms, each DTM matrix would also contain 132 370 columns - far too many for most of classifiers. Thus, we decided to remove sparse words from DTMs as follows:

- For the NeuCube implementation we remove from the vocabulary these terms which are not present in at least 95% of text (this reduces the number of columns of DTM to 341) - such a reduction was forced by the memory constraint of NeuCube, which prevents loading too large datasets.
- For all other tested classifiers we remove from the vocabulary these terms which are not present in at least 99% of text (this reduces the number of columns of DTM to 751).

B. The Preprocessed Imbalanced and Balanced PubMed Dataset

The PubMed dataset contains several millions of medical publications that are categorized according to the Medical Subject Headings (MeSH). MeSH is a set of classes organized into a hierarchical structure with 16 main branches (in overall, MeSH consists of nearly 30 000 categories). Each PubMed

document is usually indexed (either by the authors of a document/publication or by a publisher) using several MeSH categories. The obtained by us metadata of PubMed documents is posted as a part of the BioASQ competition [31].

For the purpose of our experiments, we randomly selected metadata of 10 000 PubMed documents, each of which is assigned one of the 16 main categories of the MeSH classification. Since the documents in these main categories are unevenly distributed, the resultant dataset is *imbalanced* (for example, majority of publications belong to the category *Chemicals and Drugs*, while there are few publications belonging to the category *Information Sciences*). Since we are focused on classification of short texts, we decided that input data provided to classifiers will contain only a title of a publication. The selected 10 000 publications are split into a training and testing parts in the ratio 9:1.

We applied the TF-IDF encoding to obtain the DTM matrices of the training and testing parts according to the steps given at the beginning of this section. The vocabulary consists of 14553 terms from which we selected 1670 terms that occur in at least 99.9% of texts to represent input features of datasets.

In a similar way, we obtained the *balanced* PubMed dataset, which differs from the imbalanced in that it contains the 10 000 documents that are evenly distributed in the 16 main categories.

V. EXPERIMENTS

In this section, we first describe the applied input parameters of the selected classifiers. Next, we present the results of experiments on the selected datasets. The results were obtained for the three above-described implementations of SNNs as well as for the other four classification methods: Binomial logistic regression, a single Decision tree, the MLP neural network as well as Support Vector Classifier (SVC). In the second part of the experiments, we focus specifically on the presentation of the classification accuracy for the eSNN encoding method that is offered by us in Section III.

A. Parameters of Selected Classifiers

The parameters of the selected SNNs implementations that were ran on the datasets are given in Table II. The parameters were selected using the grid search procedure on a suitable set of parameters of each implementation.

The parameters of the other classifiers selected for experiments were as follows:

- Decision tree - split criterion = Gini index, maximal depth = none.
- Logistic regression - maximal no. of training iterations = 100.
- Multilayer Perceptron neural network (MLP) - no. of hidden neurons = 1000, sigmoid activation function, learning rate for weights modification in thw error backpropagation phase 0.0001, training iterations = 8, the ADAM optimization method for error backpropagation.
- Support Vector Classifier - radial kernel, misclassification cost coefficient = 1.

Fig. 6. Comparison of the classification accuracy for the selected input methods. *IJCNN2020* refers to the method offered in [5]. The method given in this work was ran with $Bins = 3$.

B. Results of Short Text Classification

The results of classification accuracy for the classifiers are given in Table III. As it can be noted, in the case of short texts of the 20-newsgroup dataset, the most effective classifier is SVC. For both balanced and imbalanced PubMed datasets, two best performing classifiers are SNN Torch and logistic regression. Among the selected SNNs implementations, the eSNN implementation provides slightly better results than NeuCube for 20-newsgroup dataset, while NeuCube is slightly superior to eSNNs in the cases of PubMed datasets. The best performing implementation of SNNs is SNN Torch. This can be explained by the fact that it contains not only spiking LIF neurons, but also incorporates learning mechanisms of traditional feedforward neural networks, such as the error backpropagation phase that applies ADAM optimizer.

C. Comparison of the Classification Accuracy for the Proposed Encoding Method of eSNNs

Our method is compared with the encoding method offered in [5] that directly calculates firing order of input neurons as well as with the widely-used GRFs method used with spiking neural networks [13]. Both the method of [5] as well as the GRFs uniformly allocate the NI_{size} input neurons to encode input values of each feature $F \in \mathcal{F}$. In this experiments we use 20-newsgroup dataset, however to better illustrate the results of encoding we selected full texts of this dataset.

In Fig. 6, we present the obtained classification accuracy of the selected methods for varying number of input neurons NI_{size} . For the proposed method, we used the $B = 3$ bins parameter to create the histogram of values of each feature in our encoding method. As it can be noticed from the figure, the offered method can significantly improve the classification accuracy comparing to the other two tested methods. For example, for $NI_{size} = 20$ the proposed method gives accuracy 0.52, while the method of [5] and GRFs method give 0.2 and 0.21 accuracy values, respectively.

TABLE II
THE APPLIED PARAMETERS OF THE SELECTED SNN CLASSIFIERS.

Classifier	20 newsgroup dataset	Imbalanced PubMed dataset	Balanced PubMed dataset
eSNN	$N_{Isize} = 25, Bins = 3,$ $mod = 0.95, simTr = 0.05,$	$N_{Isize} = 15, Bins = 3,$ $mod = 0.95, simTr = 0.05$	$N_{Isize} = 15, Bins = 3,$ $mod = 0.95, simTr = 0.05$
NeuCube	$\eta = 0.01, Firing\ thr. = 0.5,$ $mod = 0.95, Refractory\ time = 3,$ Training its. = 1	$\eta = 0.01, Firing\ thr. = 0.5,$ $mod = 0.4, Refractory\ time = 8,$ Training its. = 1	$\eta = 0.01, Firing\ thr. = 0.5,$ $mod = 0.4, Refractory\ time = 8,$ Training its. = 1
SNNTorch	Hidden neu. = 1000, Firing thr. = 1, Decay rate = 0.92, Learn. rate = 0.0001, Training its. = 8	Hidden neu. = 1000, Firing thr. = 1, Decay rate = 0.92, Learn. rate = 0.0001, Training its. = 8	Hidden neu. = 1000, Firing thr. = 1, Decay rate = 0.92, Learn. rate = 0.0001, Training its. = 8

TABLE III
THE OBTAINED CLASSIFICATION ACCURACY RESULTS.

Classifier	20 newsgroup	Imbalanced PubMed	Balanced PubMed
eSNN	0.19	0.15	0.16
NeuCube	0.10	0.17	0.29
SNNTorch	0.24	0.39	0.39
Decision tree	0.43	0.25	0.26
Logistic regression	0.55	0.36	0.32
MLP network	0.01	0.32	0.31
SVC	0.61	0.37	0.37

VI. DISCUSSION AND CONCLUSIONS

In this work, we presented the results of short text classification using three different implementations of SNNs networks, namely: evolving Spiking Neural Networks, the NeuCube implementation of SNNs and the SNNTorch implementation. In order to test the selected classifiers, we selected and preprocessed three publicly available datasets: 20-newsgroup dataset as well as imbalanced and balanced PubMed datasets of medical publications. The preprocessed 20-newsgroup dataset consists of the first 100 words of each text, while for the classification of PubMed datasets we used only a title of each publication. As a text representation of documents, we applied the TF-IDF encoding. In this work, we also offered a new encoding method for eSNN networks, that can effectively encode unevenly distributed values of each input feature. The designed method works especially effectively with the TF-IDF encoding.

The presented results of experiments indicate, that SNNs implementations that solely use the neuronal models tradi-

tionally applied in SNNs, such as the LIF model, as well as apply unsupervised learning rules like STDP, may not perform as effectively as the implementations that combine SNNs with the learning methods present in traditional neural networks, such as the MLP networks. Specifically, in the conducted experiments, the SNNTorch implementation performed better than the eSNN and NeuCube implementations. Furthermore, the computational and memory complexity of SNN networks (as in the case of NeuCube) can be a bottleneck in processing large sets of texts. In the experiments, SNNTorch was able to slightly outperform the results obtained by other selected classifiers in the case of two PubMed datasets.

Abstract—The need to understand the decision bases of artificial intelligence methods is becoming widespread. One method to obtain explanations of machine learning models and their decisions is the approximation of a complex model treated as a black box by an interpretable rule-based model. Such an approach allows detailed and understandable explanations to be generated from the elementary conditions contained in the rule premises. However, there is a lack of research on the evaluation of such an approximation and the influence of the parameters of the rule-based approximator. In this work, a rule-based approximation of complex classifier for tabular data is evaluated. Moreover, it was investigated how selected measures of rule quality affect the approximation. The obtained results show what quality of approximation can be expected and indicate which measure of rule quality is worth using in such application.

I. INTRODUCTION

IN RECENT years, eXplainable Artificial Intelligence (XAI) [1], [2], [3], [4] has become an increasingly important field of artificial intelligence (AI). The explanations generated by XAI methods allow people to understand how artificial intelligence methods work and are useful for many types of users involved in different ways with AI applications.

This work focuses on XAI derived from rule induction [5]. Rule-based models represent knowledge embedded in data in the form of IF-THEN rules. The premise of a rule is a conjunction of elementary conditions $w_i \equiv a_i \odot x_i$, with x_i , being an element of the attribute a_i domain and \odot representing a relation ($=$ for symbolic attributes; $<$, \leq , $>$, \geq for ordinal and numerical ones). The conclusion of the rule contains a decision, which can be either symbolic or numeric.

Rules and decision trees (which can be easily transformed into mutually disjoint rules) are used to generate global explanations because of their interpretability [4]. Such global explanations are obtained by generating a rule-based interpretable

This work was partially supported by: Computer Networks and Systems Department at Silesian University of Technology within the statutory research project and the Łukasiewicz Research Network (ROLAP-ML, R&D grant)

model that approximates the non-interpretable (complex) base model. The use of rule-based approximation is justified for tabular data where attributes are interpretable and the generated rules can be understood by humans.

There are recent examples in the literature of the use of rule-based systems to obtain model agnostic explanations. Rule-based models approximating the complex base model locally were considered in [6]. The works [7], [8] considered rules as interpretable expressions used to present explanations within a proposed local-to-global approach for black-box explanations.

The parameters of the rule-based model induction method affect the quality of the base model approximation. Furthermore, they affect the explanations generated from the set of input rules. To the best of the authors' knowledge, there is no published analysis showing how well a rule-based model can approximate the complex base model being explained. Therefore, the aim of this paper is to present and evaluate the rule-based, model-agnostic approach to explaining machine learning models. The rule-based approximation of a black-box model may be evaluated in terms of its accuracy and number of the generated rules. Therefore, three measures of rule quality used in the induction process are verified in this work: Correlation, C2 and Precision [9]. These measures, in the above order, generate more and more specific rules and thus build probably more and more accurate approximators but composed of an increasing number of rules. Verification of these parameters should provide clues that are useful in the development of rule-based approximators used to create explanations.

The contribution of this paper includes: (i) analysis and evaluation of the approach that generates global and local explanations from a rule-based approximation of a black-box model, (ii) verification of how the application of different measures of rule quality assessment (Correlation, C2 and Precision), which enable variation in the approximation accuracy of a machine learning model, affects the explanations obtained.

II. THE IDEA OF RULE-BASED EXPLANATIONS

The proposed approach to generating machine learning model explanations involves approximating the base model treated as a black-box using a rule-based model. Base model approximation means that the rule-based model learns the decisions of the base model. Such a learning process requires transformed training data in which the existing decision variable is replaced by the decision of the base model. In the extreme case (which may mean over-fitting the base model), the transformed training data may be identical to the original.

The generated rule-based model, although interpretable in theory, is not always clear, e.g. due to the number of rules. However, once the rule-based model is generated, the elementary conditions of the rules and their importance can be extracted. On their basis, it is possible to generate the explanations showing which attributes, and which attribute value ranges, are most important for decision making by the base model. Importance based rankings of elementary conditions are generated using the Shapley index [10] and details on the assessment of the importance of rule elementary conditions are presented in the work [11].

Using the above method to explain the black-box classifier, global and local explanations can be obtained. The global explanation of the classifier is in the form of a ranking of elementary rule conditions indicating which ones have the highest importance in the decision of the base model about the selected class. The local explanation, on the other hand, consists of a set of rules covering the data instance and an analogous ranking indicating the importance of the elementary conditions in the classifier's decision.

III. EVALUATION OF RULE-BASED APPROXIMATION

The first step in the presented concept of generating rule-based explanations of the base machine learning model is to approximate this model with a rule-based model. The base model approximation should be of high accuracy to generate reliable explanations. The rule induction algorithm can be controlled by a number of parameters. This study focuses on the rule quality measure used and verifies impact of three such measures: Correlation, C2 and Precision.

The approach presented in this paper was implemented in Python. The scikit-learn package [12] was used to generate base models and the coverage algorithm implementation available in the RuleKit package [13] via a Python wrapper¹ was used to generate the rule-based models. Four different algorithms were selected to generate complex, non-interpretable classifiers used as base models. The selected algorithms are: Artificial Neural Network (NN), Random Forest (RF), Support Vector Machine (SVM) and Extreme Gradient Boosting (XGBoost). The base models and the approximating rule-based models were evaluated in 10-fold cross validation process. Experiments were conducted on a set of 29 data sets available in the OpenML² and UCI³ repositories. These data sets consist

of tabular data and relate to the task of classification.

In the experiments, the quality of the implemented approximation with the rule-based model was evaluated in two ways. Firstly, the classification quality measures, such as Accuracy (Acc) and Balanced Accuracy (BAcc), were calculated. The quality of the approximator was determined for the transformed data in which the decision attribute represents the decision of the base model. Table I presents mean values calculated for all the data sets that were divided into train and test data. In the experiment, four base models were approximated and three rule quality measures were verified as values of the approximator parameter. Additionally, Table I presents the average number of rules that were generated by the induction algorithm.

TABLE I
QUALITY OF RULE-BASED APPROXIMATIONS ON TRANSFORMED TRAINING AND TEST DATA, FOR WHICH THE DECISION ATTRIBUTE IS THE DECISION OF THE BASE MODEL

Base model	Approx. param.	#Rules	Train data		Test data	
			Acc	BAcc	Acc	BAcc
NN	Correlation	19.9	0.938	0.932	0.894	0.878
	C2	34.2	0.968	0.965	0.916	0.902
	Precision	75.3	0.988	0.986	0.912	0.892
RF	Correlation	21.1	0.924	0.92	0.873	0.858
	C2	38.3	0.958	0.953	0.899	0.884
	Precision	82.5	0.979	0.976	0.894	0.877
SVM	Correlation	18.7	0.952	0.949	0.915	0.905
	C2	30.4	0.978	0.976	0.935	0.922
	Precision	67.1	0.989	0.986	0.938	0.922
XGB	Correlation	21.1	0.924	0.921	0.877	0.863
	C2	38.4	0.958	0.953	0.9	0.886
	Precision	81.1	0.98	0.977	0.893	0.877

Based on the results in Table I, it can be concluded that the rule-based models approximate complex models well. Furthermore, the results show that the accuracy of this approximation decreases significantly on the test data compared to the training data. This is an expected result, as rule-based models were generated to obtain the best possible approximation on the training data.

Besides, the results in Table I show that the selected measures - in order: Correlation, C2 and Precision - enable to obtain increasingly fit rule-based models. The increase in quality results from the increase in the number of rules. In other words, the more general the rules are the less accurate the approximation becomes. On test data, however, the best quality results are obtained by models generated using the C2 measure.

The generated base models and their approximators can be further evaluated on the original data sets. Fig. 1 presents the difference in Balanced Accuracy (BAcc) between the generated approximations and base models. The BAcc values were calculated on test data for each of the data sets. XGBoost was used as a base model and the C2 measure was used in rule-based approximation generation.

³<https://archive.ics.uci.edu/ml/datasets.php>

Fig. 1. Approximation quality illustrated as the difference of the Balanced Accuracy values for rule-based approximation (BACC_{AP}) and base model (BACC_{MB}) - comparison on test data

The results illustrated in Figure 1 show that an approximator operating on the original data is never better than the base model. These results provide a negative answer to the question of whether creating a rule-based model that cannot distinguish between examples that even complex models cannot correctly classify will produce rule sets with good classification quality. Moreover, it is again apparent that over-fitting to the train data results in lower accuracy on test data.

Within the second approach to rule-based approximation evaluation the generated explanations were compared. Therefore, using the SHAP method, attribute rankings were generated for the base models and their approximations. If the size of the data set exceeded 100 instances a subset of that size was selected to determine the Shapley values. Next, the top three features from both rankings were compared to verify if these three most important attributes were the same for both models. The results of the comparison are illustrated in Fig. 2. It presents for each data set the average number of identical features selected as the top three. This average is calculated as four base models (NN, Random Forest, SVM and XGBoost) were generated again for each data set. The rule-based approximation was performed using the C2 measure, which proved to be the most reasonable choice in earlier experiments. The comparison was performed on 31 data sets.

The results presented in Fig. 2 show that in most cases at least two out of three most important features are the same for the base model and its approximator.

IV. EXEMPLARY USE CASES

Having the rule-based approximator of sufficient accuracy induced it is possible to generate explanations. The example global and local explanations presented below were generated

from the rule-based model using RuleXAI package⁴. This package generates explanations by analysing the importance of the rules' elementary conditions [11]. The C2 measure was used for rule quality evaluation. The rule-based model approximated the XGBoost classifier.

The base model was trained on the wine⁵ data set representing a three-class problem and consisting of the following attributes: Alcohol, Malic_acid, Ash, Alkalinity_of_ash, Magnesium, Total_phenols, Flavanoids, Non-flavanoid_phenols, Proanthocyanins, Color_intensity, Hue, OD280_OD315_of_diluted_wines, Proline, Class.

The generated global explanations are presented in Table II. They consist of rankings built separately for each class. The rankings were built on the basis of feature importance, or more precisely on the basis of the importance of the elementary conditions of the rules.

Local explanations are generated for a specific data instance. The analysed data instance takes the following values for the above list of attributes {0.213157895, 0.029644269, 0.652406417, 0.381443299, 0.260869565, 0.420689655, 0.394514768, 0.169811321, 0.611987382, 0.151023891, 0.25203252, 0.663003663, 0.172610556, 1}. This data instance was covered by the following two rules from the approximating model:

```
IF Color_intensity = (-inf, 0.19) THEN
ref_prediction = 1.0
IF Alcohol = (-inf, 0.39) AND Flavanoids =
<0.13, inf) THEN ref_prediction = 1.0
```

In addition to the explanation in the form of rules, RuleXAI generated a ranking presented in Fig. 3. It shows which ranges of attribute values were most important for a given decision.

⁵<https://archive.ics.uci.edu/ml/datasets/wine>

Fig. 2. Number of the same features in the first three positions of the rankings generated by the SHAP method for the base model and its approximator

TABLE II
RULE-BASED GLOBAL EXPLANATION GENERATED BY RULEXAI - THE EXPLANATION OF THE XGBOOST MODEL GENERATED ON WINE DATA SET

Class 0		Class 1		Class 2	
Condition	Importance	Condition	Importance	Condition	Importance
Proline ≥ 0.51	0.872	Color_intensity < 0.19	0.906	Flavanoids < 0.13	0.841
Proline ≥ 0.4	0.609	Alcohol < 0.39	0.728	OD280_OD315_of_diluted_wines < 0.2	0.825
Alcohol ≥ 0.52	0.352	Flavanoids ≥ 0.13	0.147	Ash ≥ 0.37	0.05
				Malic_acid ≥ 0.074	0.034

Fig. 3. Rule-based local explanation showing which attributes and which ranges of attribute values were most important for a given decision

V. CONCLUSIONS

The method generating global and local explanations using rule-based approximation of the black-box model was analysed within the presented research. In addition, global and local explanations generated from the rule-based approximation were presented. The explanations generated from the rules provide a detailed understanding of which features in which value ranges are important to the classifier's decisions.

Application of the rule-based model to approximation of the complex classifier generated on tabular data was positively evaluated. The approximation obtained with the rule-based models was consistent with the approximated base models both from the point of view of classification quality measures and from the perspective of consistency in the most important features indicated by the generated explanations.

Abstract—Customer acquisition is an issue that continues to receive attention from companies worldwide. Various marketing campaigns using psychological methodologies have been designed to address this issue. However, once a campaign is launched, it is highly complicated to detect which sets of customers are most likely to purchase an offered product. This fact is key since it allows companies to focus their efforts on specific clients and discard others. Several selection techniques have been implemented, but most of them are usually very demanding in terms of time and human resources for the companies. Artificial Intelligence techniques appear to help to simplify the process. Thus, companies have started to use Machine Learning (ML) models trained to efficiently detect those clients with certain proneness to purchase. Toward this goal, this paper presents a novel purchase propensity detection ML system based on Sentiment Analysis techniques able to consider customer comments regarding the offered products. The tourist domain was selected for the case study, where the obtained product was successfully embedded in an initial prototype.

I. INTRODUCTION

CUSTOMER acquisition is one of the most important tasks companies undertake to promote their products and services. It allows expanding the business, enhancing their potential in the markets and producing benefits over time. However, companies need a clear a solid plan of action to be successful in custom acquisition. Creating such a plan in turn requires first-hand knowledge of customers' needs and tastes [1].

Several studies have been conducted to detect these customers' needs, producing behavioral profiles and other different psychological approaches. These proposals work acceptably when companies have specific employees or departments dedicated to making evaluations of the customers. In the case of small or medium enterprises with few resources, or those with high amounts of customers to evaluate, this task is difficult to achieve, becoming a very demanding process.

This work was supported by Madox Viajes Travel Agency

On the other hand, the Internet makes it easy to access collected information about customers' opinions on purchases. Thus, these data can be analyzed to detect patterns that indicate a certain propensity to buy some specific products offered by a company [2]. Specifically, customers whose search is more alternative-based are found to have a higher propensity to purchase than customers whose search is more attribute-based. The main rationale is that customers using alternative based search are evaluating products one at a time, and they are more able to judge whether the product meets their purchasing criteria or it is suitable for them with lesser distraction from other products or services.

In the case of the tourism domain, it is very difficult to build client loyalty due to the wide amount of offers and the fluctuations in the market. Moreover, the recent COVID-19 outbreak has provoked more complications for tourist companies due to the restrictions and measures imposed by governments of countries all over the world. As a result, the acquisition of customers (whose numbers reduced drastically during the period) and the detection of those who are prone to purchase has become a fundamental issue, especially for small or medium-sized companies. Due to this situation, this process is also more demanding and time-consuming, so it is important to develop specific software to support the decision-making step and provide recommendations automatically.

This paper presents a Machine Learning (ML) module able to automatize the detection of potential customers. It has been successfully embedded into an initial prototype of a tourist management framework. The fusion of both elements (i.e., the tourist domain and ML) has produced a novel and complete system based on expert knowledge to manage tourist events and provide recommendations from the perspective of the customer and the travel agency. This enhancement allows the tour companies to reduce efforts and focus their resources on specific individuals and tourist offers.

Regarding the ML module, it analyzes the opinions in texts written by potential customers for different tourist offers, being able to detect the real interest of the individuals. This allows discarding those customers with less predicted interest. Intelligent agents following a Multi-Agent System (MAS) architecture have been included to establish communication and knowledge interchange. This MAS promotes the distribution of the workload and eases the evaluation of multiple texts. This issue is relevant because companies usually need real-time analysis and responses to satisfy the requests made by customers.

Several experiments in real environments have been implemented to show the viability of the proposal. *Madox Viajes* is a tour company that has put in production the developed software, including the ML module with very successful and promising results.

The rest of the paper is organized as follows. Section II situates the approach in the domain and makes some comparisons with similar ideas. Section III details the architectures of the ML module and the prototype. Section IV illustrates a battery of experiments achieved in a real environment. Finally, Section V concludes by making a detailed analysis and provides future guidelines.

II. BACKGROUND

This section introduces the foundations of the ML module specifically designed to evaluate the opinions of customers. Opinion Mining techniques are put into the spotlight for the case of evaluating opinions. Then, intelligent agents and MAS are detailed focusing on the distribution of the workload. Finally, a first analysis addresses the problematic in tourism related to the detection of prone to purchase customers (see Section II-C).

A. Sentiment Analysis for the evaluating opinions

Sentiment Analysis (also called Opinion Mining) is one of the most relevant areas in the Natural Language Processing (NLP) domain. Its main objective is to gather the subjectivity expressed by humans in texts [3]. Thus, it measures the influence of a written text over the reader regarding the type of feelings risen and the level of affection.

There are two main perspectives in NLP to address the Sentiment Analysis issue: dictionary-based approaches and ML approaches.

Dictionary-based approaches (also called lexicons) consist of a collection of predefined words which usually appear associated with a sentiment score or a polarity (positive, negative or neutral). They are used to calculate the sentiment polarity of a sentence detecting words included in the dictionary and averaging the polarity of these words. It can be also extrapolated to paragraph or complete texts. However, it has to be considered the noise generated by the set of relevant words (e.g., substantives, verbs or adjectives) that are not detected, and the changes in the discourse made by the creator of the textual content. Well-known examples of these dictionaries are SenticNet [4] and SentiWordNet [5].

ML approaches predict the sentiment values of the words by using statistical models based on distributional semantics (e.g., word embeddings and transformers). These models are built through a training phase on which a collection of words with their corresponding polarity is used. This collection is a corpus that contains the ground truth (i.e., the reality that ML models must try to simulate adapting their parameters to learn). Subsequently, two more steps are usually included: the validation and the test phases. Both allow measuring the quality of the model regarding the ground truth (i.e., the learning capability).

Delving into the ML solutions, there exist several types of approaches to address the Sentiment Analysis task [6]. For instance, there are simple solutions that only use a basic ML discarding the processing step [7]. Other approaches use NLP techniques at the beginning of the pipeline and different embedded ML models later to produce a more complex model [8]. In the first ones, Deep Learning approaches are usually the most typical ones. They do not consider rendering the textual context as they are focused on detecting the syntax and semantics patterns of the text. Common instances of these models are word embedding-based approaches [9] as Word2Vec and LSTM neural networks. However, their performance cannot be compared to the quality provided by the most recent models implemented by bidirectional transformers and attention methods (e.g., BERT [10] and their related approaches). These ML models usually include two attention methods to estimate the value of their parameters: intra-attention and global attention [11]. The first estimates the similarity between words in a sentence, while the second follows a global perspective taking into account the whole textual content.

In the case of the Sentiment Analysis focused on opinions and reviews, the approaches are usually ML solutions adapted to the specific context. However, these proposals are usually limited to only make an estimation and later their results are complemented by the knowledge of human experts. Typical instances of this perspective are: course evaluations [12], online purchase evaluations [13] and movie reviews [14].

The proposed ML module achieves the Sentiment Analysis task, and later gathering conclusions from the results through the distributed intelligence provided by the intelligent agents. Thus, the tourism domain prototype where it is embedded is able to predict which individuals are prone to purchase tourist offers and events.

B. Intelligent agents to distribute the workload

Intelligent agents are software abstractions able to simulate interactions (with an environment or with other agents) and behaviors from the real world. These elements are proactive, autonomous, and independent, addressing different problems according to the set of predefined rules and knowledge. Their ability to interact can be exploited to solve complex problems or to distribute the workload with certain coordination. Thus, MAS appear as a possible solution. These MAS are usually designed following a level of abstraction. Agent-Based Modeling (ABM) [15] and Agent-Oriented Software Engineering

Concept	Meaning	Icon
Agent	An active element with explicit goals that is able to initiate some actions involving other elements of the simulation.	
Role	A specific collection of tasks performed by agents when pursuing a goal or offering some service to the other members of the society. It has as a result a specific behavior.	
Environment Application	An element of the environment. Agents can act on the environment using its actions and perceive information through its events.	
Goal	An objective of a role/agent. Roles/agents try to satisfy their goals executing tasks. A goal is achieved or fails if some elements (i.e. frame facts and events) are present or absent in the agent groups or the environment.	
Task	A capability of a role/agent. To execute a task, certain elements (i.e. frame facts and events) must be available. The execution produces/consumes some elements as result.	
Frame Fact	An element produced by a task, and therefore by the roles/agents.	
Mental State	Part of the internal state of a role/agent. It groups goals, frame facts and events, and specify conditions on them.	
Belief	Part of the mental state. It contains the knowledge (specific, role-based or general) that an agent possesses. This knowledge can be used to interact with its surrounded environment.	
Conversation	Communication between two or more agents to exchange information. One of these agents plays the role of initiator of the conversation, while the others are the receptors.	
Plan	Representation of the means by which a goal can be satisfied. It is usually structured to provide a deterministic meaning to the operations.	
Mental State Manager	Part of the internal state of a role/agent. It provides for operations to create, destroy and modify mental entities.	
Mental State Processor	Part of the internal state of a role/agent. It determines how a mental state evolves, described in terms of rules or planning.	

Fig. 1. Main concepts of INGENIAS for developing MAS.

(AOSE) [16] provide the elements and entities to tackle this issue.

Intelligent agents present a life-cycle focused on satisfying a collection of goals through several associated concepts (see Fig. 1). These goals are structured in a hierarchical way, having sets of sub-goals that accomplish other goals at higher levels. Goals are associated with a set of tasks that are executed by the agents. Both goals and tasks are part of the mental state of the agents. This mental state plays the role of the brain, containing rules and specific knowledge from the environment that support the execution of the tasks and the satisfaction of the goals.

Agents can take advantage of their ability to interact with the environment to solve complex problems having partial or reduced knowledge about a problem. The organization in MAS opens the collaboration, the competition and also the negotiation. Well-known approaches that use MAS to solve complex problems or simulate real environments are road traffic simulations [17], distributed decision support systems [18], bio-inspired ML-based systems [19], and computer games

[20].

MAS are usually modeled using specific artifacts and entities to tackle the development steps of complex systems. It allows generating graphically relationships and interactions between agents and later transforming them to source code automatically. INGENIAS, GAIA, Prometheus, and Tropos are well-known agent modeling methodologies in charge of providing support through specific languages [21].

Regarding the implementation of MAS, agent platforms are the typical solution. These proposals include features to ease the distribution of the agents and manage their communication channels. Standing out approaches in this area are JADE [22] and MESA [23].

In the presented approach, the selected agent methodology has been INGENIAS, adapting the agent model to the MESA framework. It uses a bio-inspired distribution model based on the behavior of ant colonies that produce a MAS organized in several cumuli of agents (anthills) working together to achieve the Sentiment Analysis task and the evaluation of customers to detect who are prone to purchase.

C. Customers in tourism

Tourism is one of the most important economic activities all over the world. Everyday, million people are traveling to different destinations in a wide bunch of means of transport: airplanes, trains, cars, etc. This movement of people is usually related to work activities and tourist events. In the first case, individuals manage their travels by themselves (e.g., commuters), while in the second, it is usually addressed by tour companies (e.g., holidays and honeymoons). These companies provide counseling and support to the customers, being responsible of managing and coordinating the different steps during the travel and their stay [24].

Tourism is a volatile active, where several changes in the prices and in the market affect the benefits of the companies, as well as the configurations of travels and its features. World events like the COVID-19 outbreak or the Ukrainian war are recent situations that have produced hard modifications in the tourist sector. For this reason, the identification and capture of new customers, and the detection of those ones that are prone to purchase is basic for companies to optimize their workload.

Delving into the proneness of customers to purchase a tourist activity, a wide range of variables motivates and make some particular purchase decisions [25]. Instances of the most typical variables are: the particular culture, the emotional and physical state, and personal issues (e.g., visit a friend or a relate). These variables are called as motivators and can be classified into six main categories: primary motives, secondary motives, rational motives, emotional motives, conscious motives, and dormant motives [26].

Primary motives are those situations that force a person to purchase a tourist offer (e.g., a health problem with a relative who is in another country), and secondary motives consists of situations that modify the choice of the customers (e.g., the price of a flight according to different companies). In the case of the rational and emotional motives, the first is

related to an objective evaluation of the customer (e.g., a group of several members rents a minibus instead of some particular vehicles), while the second is the opposite, the customers are moved by their feelings (e.g., a person is prone to purchase a flight with a company instead of another one due to only personal preferences). Conscious motives encompass those ones where customers are aware of their personal needs (e.g., customers have to travel to a place where there is not a train station, therefore renting a car could be a better option). Finally, dormant motives are those ones that are unconscious and usually related to the influence of the society over the customers (e.g., customers have to travel to a place where individuals living there usually have high incomes, then the customers prefer to rent a car instead of traveling by bus).

To address and detect these motivations, the knowledge of psychological experts and the experience provided by travel agents become very relevant. However, when a company has to evaluate hundreds of proposals each day, the human evaluation is almost impossible. Thus, different systems and models to mitigate the problem has been developed. Some of them are very specific in the tourist domain and consider only behavioral features [27]. Other approaches are focused on the impact of the current technologies in tourism and how to adapt the offers to the high connectivity world nowadays [28]. And finally, there are others that evaluate the obtained results of the companies avoiding to consider the opinion and the level of satisfaction of customers [29].

In the case of the presented approach, customers are put into the spotlight, evaluating their opinions before their purchase, knowing their proneness and preferences for the different offers proposed. It allows developing a recommendation process for customers, and it eases the work of the travel agencies being able to discard and focus on specific customers in a smart way.

III. PROPOSED FRAMEWORK

This section details the novel ML module specially designed to evaluate the opinions of potential customers regarding a set of possible tourist offers, and the initial prototype of the tourist framework where it is embedded.

The ML module allows companies to reduce the effort in time and human resources, as employees can focus only on the customers that are more prone to purchase a product. This functionality works by analyzing the textual comments provided by the customers through Sentiment Analysis techniques and MAS to distribute the workload of the system.

In the case of the tourism domain, the prototype consists of a system focused on the two main perspectives related to the tourism market: customers and travel agents. It provides some features to manage the roles independently covering all the processes from the customers' perspective and the travel agents' perspective. Moreover, it can organize the different interactions between users with both roles (e.g., a tourist offer managed by a travel agent and a customer both using the system). From the customers (i.e., the tourists), the system can make recommendations according to specific preferences

through similarity comparisons based on their profile, as well as modifications through filtering processes. On the other hand, from the travel agents, the system includes the tourist services and offers available during the day, the ratings, the feedback of former customers about the services, and a novel functionality to indicate the most prone to purchase customers.

Next section provides further details about the architecture of the ML module. Next, the design of the prototype is tackle focusing on the different modules of the system and highlighting how the ML module is included in the release.

A. Propensity to purchase detection ML module

The ML module is organized into two main components: the *module administrator* and the *Sentiment Analysis administrator*. Both components work together internally (see Fig. 2).

The first component is the manager of the complete module, being in charge of obtaining the stored opinions of customers, managing the *Sentiment Analysis administrator* component, and producing the final results from the outcome of the former component. It comprehends three different entities: the *texts gatherer*, the *workload manager* and the *result processor*.

The *texts gatherer* collects the opinion to be processed by the module. They are loaded from the *Services information* database. This element cleans the text and applies corrections to misspelled words.

The *workload manager* organizes the texts using a Kafka queue and checks if the independent anthills are busy. It can create new MAS on-demand automatically or implement load balancing politics. The configuration of the ML module consists of 4 anthills by default.

The *result processor* obtains the outcomes from the anthills and organizes them to be stored in the database. Thus, the opinion of the customers regarding a tourist offer or service is labeled as positive or negative. Then, the system can select those customers prone to purchase.

The second component is the container of the anthills. These latter are bio-inspired hierarchical structures organized to distribute the workload between several agents. Therefore, the system is ready for processing the information provided by a big amount of potential customers. These anthills are MAS formed by a queen and sets of soldiers and workers, organized in a similar way to a real ant family structure. The number of agents playing the roles of the soldiers and workers can be modified by the system, though they are prefixed to 5 and 10 respectively. The queen agent is fixed by default to one per anthill, and that fact cannot be modified in the present release of the framework. The component is completed with the previously trained ML model that encompasses techniques to achieve the Sentiment Analysis task.

Delving into the Sentiment Analysis model, initially, the Universal Sentence Encoder (USE) was used for generating embeddings from the customer comments. Then, a Convolutional Neural Network (CNN) with the next sequential model pipeline is used: an input 256 dense layer by using ReLU activation, a dropout layer with a rate of 0.5, a 128 dense

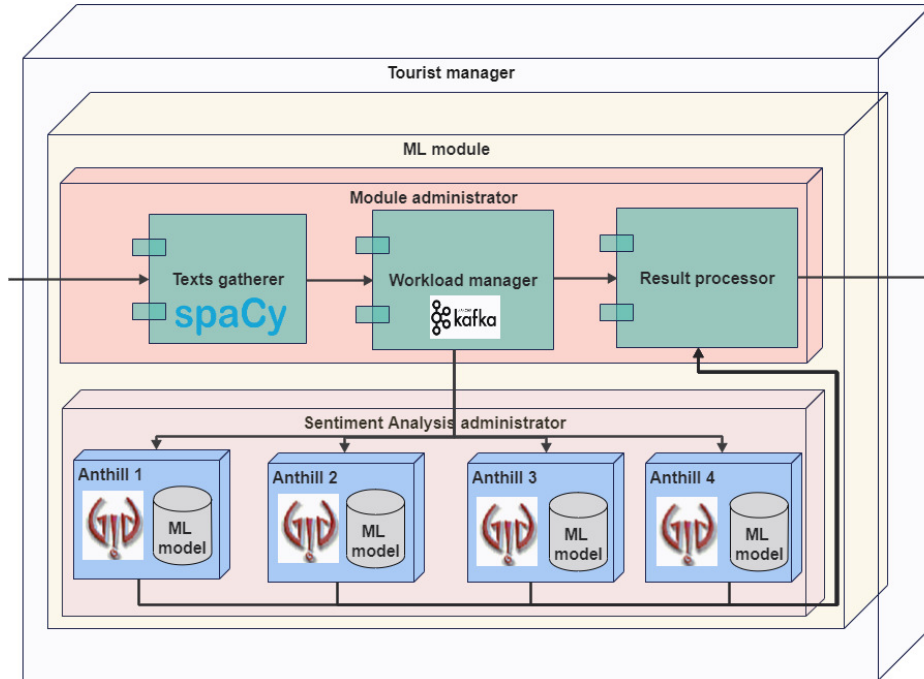

Fig. 2. Architecture of the ML module inside the *tourist manager* with the default configuration.

TABLE I
SUMMARY OF THE CNN CONFIGURATION.

Layer pipeline	Configuration
ReLU dense layer	256
Dropout	0.5
ReLU dense layer	128
Dropout	0.5
Softmax dense layer	2

layer by using also ReLU activation, another dropout layer with rate 0.5 and the end layer with a 2 dense layer by using a Softmax activation (see Table I).

Regarding the intelligent agents, they are the independent entities that process the texts through cooperative activities. A MAS consists of an anthill that encompasses three types of roles for the agents: queen, soldiers, and workers (see Fig. 3). Therefore, it is organized following bio-inspired ant social structure. The queen (i.e., the manager agent) is responsible for the anthill, receiving the texts to analyze directly from the *workload manager*. Notice that several texts can be sent to this agent. Then, the queen agent assigns the activity of evaluating the text to one soldier agent (i.e., the evaluator agent). This agent is in charge of assigning pieces of text to promote the distribution (usually paragraphs) or complete texts to the worker agents. These latter process the text through the Sentiment Analysis model provided to the anthill (each anthill has a copy of the ML model). Once worker agents have concluded their task, the soldiers join the texts if necessary (protecting and supervising the result obtained by a worker or a set of them) and they return the result to the queen agent.

This process follows the Belief-Desire-Intention (BDI) model [30] where each agent present a goal or a set of them to satisfy to complete its life-cycle. In this sense, the queen has the *assignedtask* goal, the soldiers have the *evaluatedopinion* goal and the workers have the *processedtext* goal. All the goals usually include associated tasks that are actions to achieve. Notice that the agents present at least one task that solves their corresponding goals. These tasks are applied in the environment that agents share. In this case, the environment is the current opinion or set of them of the possible customers. Each agent incorporates a mental state and a set of beliefs (motivations). The queen has in them simple rules to manage the texts, while soldiers present similar rules to distribute the text between the workers. However, workers include the ML model in their mental states to achieve the evaluation of the texts and some simple rules to organize the process in the beliefs. Finally, interactions between the individuals follow the hierarchical structure. They are completed through direct conversations. Notice that in this case, workers do not need to establish conversations with other workers since they tackle their commitment individually according to the orders of the soldier.

The design of the anthill model has been addressed through the INGENIAS agent methodology. Then, the resulting composition has been transformed to be compliant with the MESA framework. The conversations and interactions of the agents have been implemented following the Foundation for Intelligent Physical Agents (FIPA) standards [31].

Fig. 3. Excerpt of the main entities involved in the anthill MAS.

Fig. 4. Overview of the main architecture of the prototype.

B. Architecture of the prototype

The architecture of the prototype comprehends two databases and four main modules. These elements are related between them interacting automatically to recover information or responding the requests made by users through the graphical interface (see Fig. 4).

Regarding the databases, they are: *services information* and *providers information*. The first stores the information of the tourist services managed by the company. Both final users (i.e., independent customers and travel agents) produce relevant data that is stored here. It also contains a historic to generate different visual forms for the business. Note that information about customers and their opinions are also placed in that database. Therefore, it is used by the novel ML module to obtain textual content and store the obtained results. On the other hand, the second conserves the knowledge about the providers (i.e., the different companies that daily offer tourist services). That information is updated every day through an

automatic process but it needs the support of an expert in the domain to accomplish some specific and complex tasks related to the several offers and modes. The visual interface of the system provides specific graphical assistants and the architecture presents some modules to properly interact with both databases.

In the case of the main modules, they are: *information gatherer*, *tourist manager*, *travel agent manager* and *customer manager*. Notice that the first two modules are generic to every operation in the system, while the other two are specific for travel agents and customers respectively.

The *tourist manager* module is the core of the framework. It contains information about the opportunities and the profiles and preferences of the final users. With this information, it can produce recommendations to provide the best tourist resources for a trip. It is the module of the system that embeds the proposed ML module. It allows the system to select the most interesting customers according to the evaluation made through the analysis of their opinion.

The *information gatherer* module recapitulates and processes the information from the virtual tourism market. This market reflects the exchanges of information between the providers and tour companies. This module collects static and dynamic information. The first is information that is not frequently updated (e.g., the name of a hotel and its description). The second is volatile information that fluctuates several times during the day (e.g., occupancy levels or rates). Notice that some of this information cannot be stored in the system due to legal issues, so it is always consulted directly from web information sources.

The *customer manager* module is in charge of processing the events and interactions made by the customers. It provides information to the *tourist manager* module to collect information about a specific individual or tourist services and adequate offers depending on the preferences of the customers. Notice that the operations made by individuals with that role must be approved by a travel agent at some point in the pipeline before formalizing a possible trip.

The *travel agent* module provides assistance to travel agents to consult, modify and also create tourist offers. It also supports the selection of specific tourist resources to configure a trip. To achieve that task, this module makes use of the *tourist manager* module. Moreover, the filtering process of prone to purchase customers is also used here to show that knowledge to the different travel agents on demand.

IV. EXPERIMENTS

This section details the experiments achieved with the prototype of the framework in a real environment. This environment has been provided by *Madox Viajes*, a tour company that has implanted the current version of the system.

The experiment starts training the ML model used by the system. In this sense, a dataset provided by the company has been used. It consists of a set of 11,840 labeled observations being divided into 90% for training and 10% for testing purposes. These data is unbalanced since the most of opinions are from opportunities that were not bought by customers. Thus, the range of the texts in the dataset is 60% (not bought) and 40% (bought). The decision of using an unbalanced dataset is related to the idea of reducing the false positive predictions as in real environments as the customers are more likely not to purchase.

The output of the ML model is the probability of a tourist opportunity offered by the company of being purchased. Therefore, the company's employees could use this insight when working on opportunities. It should be noted that the focus on employees is important, as it requires really explaining to them what it means to "purchase" a tourist opportunity. In this case, it was necessary to make them understand that it is a probability that can guide them to focus on the best opportunities and discard or defer the rest. Thus, this probability was binarized to simplify this information to the company's employees. Several thresholds for the probability have been tested. The performance results are presented in Table II. In

this case, the optimal threshold was 0.1, corresponding to a F_2 -score equals to 0.8037, Precision 0.8488 and Recall 0.7932, respectively. That is, the ML model is right almost in the 85% of times when the prediction given by the model is "purchase". On the other hand, the ML model is able to recover more than the 79% of all the sold opportunities. Notice that the selection of the F_2 -score is motivated by the fact that for the company it is more relevant higher values of Recall to reduce efforts and increment the benefits.

After deploying the model in production, the ML module were embedded in the system with a default configuration of four anthills of intelligent agents. Then, the team of the company was trained in the use of the scoring produced by the ML model.

The system has been working during several months in the company. It was planned to measure the effect of scoring on the sales pipeline 8 months later (i.e., it was deployed on September 1st, 2021). Thus, the results were shown in the yearly harvest report for opportunities on April 1st, 2022 (see Table III). It is necessary to highlight that the 2021 sales were aligned with the 2020. It implies a normal behavior, as the company continued operating under pandemic circumstances. In this case, percentages over the total number of opportunities are used to avoid confidential data of the company that could provide insights to competitors. The most relevant information in order to evaluate the performance of the proposed ML module is the percentage of opportunities created in 2021 and sold in 2022: 2,78%. Notice that this is the highest percentage of opportunities sold in one year and were created in the previous year. This means that the scoring is really impacting positively on the travel agents. In fact, Table IV shows the percentages of opportunities created in a year and sold in the same year or in the next year. For instance, given the total amount of opportunities created in 2017 that were sold, the 89.2% were sold in the same year and the remaining ones (9.8%) were sold in 2018. In 2022, the effect of the ML model can be visualized. Thus, almost half of the tourist opportunities created in 2021 have been sold during the first four months of 2022 (41.9% which is almost more than 10 times increase compared to the previous year's value), being this number the highest in the history of the corresponding tourist company.

In conclusion, the incorporation of the proposed ML model in the framework has increased the detection of opportunities of interest for new customers. This fact has been translated into better business statistics, reducing the effort of the company in the creation of new packages, and the reduction of time demand for the employees.

V. CONCLUSIONS

This paper has presented a ML module created to evaluate the comments about different tourist offers and services, and to measure the propensity of potential customers to purchase them. It allows classifying the customers according to their proneness of completing a booking (i.e., it detects the most interesting customers). The module has been embedded in a prototype of a framework specifically designed for tourist

Opportunities created in the previous year and sold in the current year	9.8%	2.3%	2.2%	4.4%	41.9%

management from both perspectives: the customer and the travel agent.

The ML module analyzes the opinion of the possible customers through Sentiment Analysis techniques based on neural networks. Moreover, it includes a bio-inspired architecture design of MAS to distribute the workload of the system. The complete system has been deployed in a real environment, showing its ability to manage a real tour company. The obtained results have been highly satisfying; the system has increased the ability of the company to find new potential customers. These results have translated into more economical benefits, simplification of the creation of new tourist opportunities, and less time spent by the human resources.

In the future, the MAS organization will be stressed with a test battery to find possible weaknesses of the architecture. Regarding the ML module in general, it will be improved by incorporating other techniques like Weight of Evidence (WoE). This fact will produce a novel and complete release of the system for the tourist domain. The architecture of the framework will be also improved and later adapted to be used through micro-services. All these upgrades will lead to a complete deployment where travel agents and customers will have access in real-time to the provided functionalities.

ACKNOWLEDGMENT

Abstract—This paper introduces a new algorithm that utilises images from the Fruits-360 dataset, superimposes them of various backgrounds and creates associated annotation files with the coordinates of the bounding boxes surrounding the fruits. The main challenge of this task was accounting for the variations in lighting and occlusion associated with outdoor locations. The utility and application of such an algorithm is to reduce the need to collect real world data for training, accelerating the speed at which new models are developed. Using 3000 images generated by this algorithm we train a single shot multibox detector (SSD) to study the feasibility of using generated data during training. We then test the trained model on 70 real world images of apples (65 images of apples on trees and 5 images of apples in bunches) and obtain a mean average precision of 0.750 and we compare our results with those obtained by other state of the art models.

I. INTRODUCTION

THE most frequently mentioned challenge across papers that study the application of artificial intelligence in agriculture [1], [2], [3] was data scarcity [4], [5]. As such, authors have to collect images from orchards/plantations or obtain images from the Internet however, both methods have downsides. Collecting images from an orchard/plantation requires visiting the location during a certain time frame when the fruits are ripe [6]. Data collection from the Internet via scraping cannot guarantee image quality. Reference [7] suggests that multiple visits to the same or to different orchards during different periods of time are required for an ideal dataset. Both methods also require manual annotations, which is time consuming and is susceptible to human error [8]. One way to address the data scarcity problem is the creation of a data generating algorithm that can produce images that simulate real world conditions. We aimed to study the feasibility of using such generated data for training an apple detector.

The Fruits-360 dataset [9], which provides 90483 images of 131 fruits and vegetables, was introduced in 2017. The images in this dataset contain one fruit or vegetable per image with a white background. This makes the set very good for training classifiers, however it cannot be easily used to create detectors capable of locating/counting the number of fruits in an image. In order to extend the usability of the dataset for such tasks

as well, we have created an algorithm that generates artificial training images by superimposing fruits taken from the Fruits-360 dataset [10] on various backgrounds containing tree leaves, branches and other fruit. Alongside these artificial images, the software generates one annotation file per image containing all the coordinates of the bounding boxes that surround the fruits as well as the fruit class. Using a training and validation dataset of apple images generated with our algorithm we trained a SSD [11] and tested it on 70 real world images, obtaining an average precision of 0.750.

II. RELATED WORK

In paper [8], the authors proposed a novel approach based on convolutional neural networks for tomato fruit counting rather than area calculation. They used a modified version of the Inception-ResNet [12] network for this task. The authors noted that in order to obtain good performance with a deep learning algorithm, a dataset that captures all the variance in the conditions under which the model is expected to operate. Such datasets with annotated images were not available and the authors observe that they are difficult and time consuming to build. One factor that contributes to this is the limited time frame in which fruits are in the desired development stage for image taking. Another factor is human error, to which manual labelling is susceptible to. Thus, the authors created their own synthetic images by filling an image with green and brown circles to simulate background and then red circles to simulate tomatoes. Afterwards, a Gaussian blur filter was applied on the images. Training the model on a dataset consisting of exclusively synthetic images and then testing it on 100 real world images produced a 91% accuracy in estimating the fruit count.

In [13] several models for fruit detection were reviewed, such as multilayered perceptrons, LedNet [4] and InceptionV3 [14]. One issue that was present in all analysed papers was data scarcity. The authors of papers [5], [6] state that building an annotated dataset is a costly process from the perspectives of both time and material resources. For state of the art performance such a dataset should contain images of fruits in multiple

lighting and weather conditions, at different distances and at different levels of occlusions, according to the intended practical application of the model. Kang and Chen, in [4], used a multi-scale pyramid and clustering classifier to assist data labelling. Steven Chen et al. in [15] utilised a custom crowd-sourcing platform for quick data labelling to address this issue. As seen in [16], using transfer learning and a MobileNetV2 [17] model the authors achieved a good compromise between accuracy and inference speed. Similarly, Raheelin Siddiqi shows in paper [18] the effectiveness of transfer learning on classification accuracy of fruit images.

To the extent of our knowledge, outside of [8], no other projects have attempted to create a data generating algorithm that creates images of fruits on various background as well as the associated annotations.

III. METHODOLOGY

A. Data Generation

The goal of this algorithm is to allow a user to create the entirety or the majority of their training dataset without the need of seeking an orchard, collecting images and manually annotating them. This would reduce dependence on obtaining access to an orchard/plantation and on manual labelling. Furthermore, such an algorithm would allow experiments to be executed even when real world data cannot be collected. The idea behind this algorithm was inspired by paper [8], in which the authors created a dataset of synthetic images (green background with red dots) in order to simulate images of tomato plants. Using this dataset alone for training and then testing on real world images of tomato plants, the model trained by the authors achieved 91% accuracy.

The process relies on images from the Fruits-360 dataset [10] and on real images that will be used as backgrounds for the generated images. The image output size, class and maximum number of fruits contained in each such image can be customised to fit the scope of the project for which they are used.

The main steps of the algorithm that creates the dataset are:

- Randomly select a background image:
 - A folder of RGB background images (JPEG/PNG) of any resolution must be specified.
- Resize the selected background to the specified output width and height. We will refer to this image as a canvas.
 - The output width and height can be customized according to the purpose of the trained model. Similarly, random stretch can be applied to the image. This is done by specifying two intervals of floating point numbers (one for width, the other for height). From these intervals, a random float is selected and the respective dimen-

sion is multiplied by it. This simulates images taken using cameras with different aspect ratios (4:3, 16:9, etc.)

- Select fruit image from given labels.
 - Once the canvas is selected and resized, the algorithm randomly chooses a fruit image from the Fruits-360 dataset from one of the classes specified by the user.
 - The fruit image is resized to a randomly generated size within a given interval.
- Create mask and crop image to be centered on the fruit.
 - The images from the Fruits-360 dataset have a simple white background however, some fruits with a shiny texture, such as red apples, reflected the ambient light and contain white spots.
 - To ensure that, when isolating the fruit pixels, we do not remove the aforementioned white spots we apply the following operations:
 - 1) Firstly we create a mask by converting the fruit image to grayscale, then applying a threshold function such that the white pixels are transformed to black and the non-white pixels become white.
 - 2) Secondly, the mask is copied and a flood fill algorithm is applied starting from the corners.
 - 3) The flood filled mask copy is then inverted and a bitwise or is applied between it and the initial mask.
 - 4) Finally, the mask is eroded with a 3×3 kernel to eliminate border pixels between the fruit and the white background (Fig. 1).
- Augment fruit image.
 - The operations used to augment the fruit image are 90, 180, 270 degree rotations, brightness and contrast alteration and partial cropping.
 - Partial cropping simulates fruit occlusion by removing rows or columns of fruit pixels from the image. Both the probability of applying this

Fig. 1: Example of the bright spot issue caused by a granny smith apple and the solution to the problem.

TABLE I: PARAMETERS USED FOR GENERATING THE TRAINING AND VALIDATION DATA.

Max fruits per image	Min fruit size (px)	Max fruit size (px)	Training images	Validation images
50	30×30	250×250	500	100
30	150×150	400×400	1000	200
10	250×250	300×300	1000	200
25	50×50	500×500	500	100

Fig. 2: An example of the mask-creating algorithm that selects only the fruit pixels while dropping the white background

operation and the maximum amount of pixel rows or columns that can be removed can be customized.

- Attempt to add the fruit image to the canvas.
 - The algorithm keeps a set of coordinates for each fruit added onto the canvas.
 - When a new fruit image can be added to the canvas, its coordinates are randomly generated. This is done to allow a more uniform distribution of fruits on a canvas, as well as to speed up the adding phase.
 - If a set of generated coordinates allows the image to be placed with an acceptable level of overlap, then the image is added onto the canvas. This is done by copying the fruit pixels from the fruit image with the help of the generated mask.
 - If, after a number of attempts, the image was not added, then the algorithm retries by resizing the image to 80% of its initial size, but not smaller than the user defined minimum size.
 - If the image is not successfully added even after resizing, then it is discarded and a new fruit image is selected.
- Once the fruits have been added, the canvas is saved in the PNG format with an index number as a name. The bounding boxes associated with the fruits in the image are stored in a separate file, either an xml or csv.
- The process is repeated until the requested number of images have been generated.

For the experiments done in this paper we generated a dataset of 3000 training images and 600 validation

images of size 768×1024 using all the apple classes from the Fruits-360 dataset and 30 background images. The background images were scraped from the Internet and contained foliage and trees. The images were generated according to the parameters presented in Table I. This distribution was chosen to simulate both a scenario in which fruits are close to the camera, which would produce an image with a few large fruits as well as the scenario in which a photo is taken from further away, in which case there would be numerous small fruits in the image.

B. Model Evaluation

In order to evaluate the feasibility of using a synthetic dataset to train a model that can then be used in real world scenarios, we selected the SSD512 model [11] as it has shown promising results in the area of intelligent agriculture, such as fruit detection [5] and leaf disease detection [19]. The SSD network was implemented in Keras [20] and was adapted for images of size 768×1024 . Training was done on the 3000 training images using an Adam optimizer with a learning rate of 0.0001 for the first 5 epochs and with a learning rate of 0.00005 for 5 more epochs. At the end of each epoch the model was evaluated on the 600 validation images and it was saved if it improved from the previous evaluation. The experiment was repeated 3 times, each time with a new set of generated images. The machine on which the training was done was equipped with an nVidia 2070 RTX GPU, 16 GB RAM and an Intel i7-8750H CPU. The implementation was done using TensorFlow 2.4 [21] and Python 3.7.7.

IV. RESULTS

For testing the model, a set of 70 real world images was created by scraping freely reusable images from the Internet and by taking photos of apples on trees or in bunches. The images contain multiple species of apples at medium to close distance, with some fruits being partially occluded by foliage or by other apples. The quality and resolution of the test images was varied, containing even some blurred apples, further increasing the difficulty of detecting them. The images were manually annotated using the **labelme** tool [22]. In order for an apple to be included in the annotations, at least half of it had to be visible in the image and had to be larger than 30×30 if the image is resized to 768×1024 .

Following, we will present the results of the trained SSD model on the 70 test images and compare them to

Fig. 3: Precision-Recall curve at 50% IoU.

existing fruit detectors. Table II shows the results of the three experiments conducted.

In Fig. 3 the precision-recall curve is presented for model number 2. It can be noted that the high precision value of this model means that the network produces very few false positives. However, the recall value does not exceed 80% for any of the three models. This indicates that the model fails to detect all apples from the test images, producing false negatives.

After visually inspecting the predictions on the test images, we identified several reasons behind the false negatives. Fig. 4 captures several examples:

- a large difference in lighting between a fruit and the others; as an example, Fig. 4d shows an apple that is underneath a cluster of leaves such that it does not receive the same amount of light as the other fruits in the image
- blurry images can impact the detection of fruits, as seen in Fig. 4a where a fruit located in the background is blurred compared to the apples in the foreground
- fruits that have a similar or identical colour with the background (green apples in this case) paired with partial occlusion produces situations where the fruits are not detected, shown in Fig. 4b and Fig. 4c

Table III presents the results of the models studied in paper [4], in which the authors tested two augmentation pipelines aiming to improve apple detection. The models from [4] were trained on real world images exclusively while our proposed model was trained on 3000 gener-

TABLE II: THE RESULTS OF THE THREE TRAINED MODELS.

Model	AP ₅₀	F1 Score	Recall	Precision
SSD#1	0.748	0.770	0.740	0.802
SSD#2	0.750	0.816	0.769	0.869
SSD#3	0.751	0.778	0.795	0.761

ated images. It can be noted that the performance of our proposed model is in the same vicinity, indicating the viability of training a model on generated data.

In paper [5] a Faster R-CNN and an SSD model were used for counting fruits from five classes: apple, orange, mandarin, lemon and tomato. Compared to our SSD model, the one proposed in [5] performs slightly better on fruit counting on the apple subset, achieving 81% accuracy, while ours achieved 76%. As mentioned previously, the model produces false negatives, explained by partially occluded fruits of the same color as the background or by blurred fruits, which can explain the difference between the predicted count and the actual count.

V. CONCLUSION AND FUTURE WORK

In this paper we have studied the feasibility of using a dataset of generated images as training data for an object detector and then applying it on real world images. We introduced an algorithm that uses the fruit images from the Fruits-360 dataset and custom background images to create new images alongside annotation files. We trained a SSD on an apple dataset of 3000 images generated with this algorithm and tested it using 70 real world apple images. Then we compared our results with other state of the art works and concluded that using generated images for training produces a model capable of handling real world data.

In the future, we plan to study if using generated data for training and using real world images for fine tuning leads to improved detection performance. Another development direction is the addition of more augmentation operations to the data generating algorithm to account for more data variance. A better way to simulate fruit occlusion, for example overlapping images of potential obstructions (eg. leaves, branches) over the fruit image could improve a model's capacity of detecting such fruits.

Overall, the presented study shows potential in using generated images instead of images collected from orchards or plantations as the principal source of training data for a fruit detector. We think that this paper serves as a starting point for other, more complex approaches.

Abstract—Autoencoder, an hourly glass-shaped deep neural network capable of learning data representation in a lower dimension, has performed well in various applications. However, developing a high-quality AE system for a specific task heavily relies on human expertise, limiting its widespread application. On the other hand, there has been a gradual increase in automated machine learning for developing deep learning systems without human intervention. However, there is a shortage of automatically designing particular deep neural networks such as AE. This study presents the NiaNet method and corresponding software framework for designing AE topology and hyper-parameter settings. Our findings show that it is possible to discover the optimal AE architecture for a specific dataset without the requirement for human expert assistance. The future potential of the proposed method is also discussed in this paper.

Index Terms—AutoML, autoencoder, deep learning, nature-inspired algorithms, optimization

I. INTRODUCTION

DEEP neural networks (DNN)s have seen a surge in popularity in recent years, with applications in various domains. Their potential began with better-than-human performance in tasks including image recognition, natural language processing, and product recommendation [1]–[3] and progressed to sophisticated tasks such as protein-folding, self-driving cars, and weather forecasting [4]–[6]. Even if DNN-based systems are not yet intelligent, we may employ them wisely to tackle complex problems. It is projected that with the current and future rise of computational resources and the large availability of data, DNN will benefit. Greater computer capabilities enable us to build more sophisticated and complex DNN topologies, while larger datasets will improve training performance.

Despite all the outstanding achievements and expectations of employing DNNs, data scientists and researchers are still dealing with DNN construction. The DNN construction phase can be a resourcefully expensive process and contributes to the global carbon footprint [7]. The construction phase specifies DNN topology, which includes defining layers, neurons, and connections. After the DNN topology has been designed,

the optimum hyper-parameters must be chosen. Variables such as topology and hyper-parameters influence the final performance of DNN, and those variables are often limited by the researcher’s prior knowledge and experience. The most significant disadvantage is the time spent by a human expert manually attempting to determine relevant variables for a specific search space.

In the literature, we can find many studies tackling the previously mentioned problem. The techniques presented in the studies attempt to automatically optimize certain aspects of the entire DNN creation process for a given search space [8]. One efficient method is to use a technique that employs population-based nature-inspired algorithms (NIA)s [9], [10]. Mostly because such a method is good at optimizing highly computationally expensive problems. When comparing the scale of studies, we can see that they are focusing on either the topology construction (without the weights) or topology with the weights simultaneously [11]. This is to keep the search space as small as possible. More details on the related work will follow in the following sections.

Motivated by these methods, we propose NiaNet (Nature-Inspired Algorithms for Deep Neural Network creaTion), a method capable of auto-designing the novel autoencoder (AE) model with only the dataset as input. The NiaNet is simultaneously constructing the AE topology and setting the optimal hyper-parameters. This process aims to optimally explore the search space by utilizing nature-inspired algorithms. The success of our proposed method, NiaNet, is determined by evaluating the best performing AE model with the fitness function, where reconstruction error, training duration, and topological simplicity are calculated. We find an advantage in our proposed method’s ease of use and adaptation to varied datasets while achieving promising results.

Altogether, the main contributions of this paper can be summarized as follows:

- We propose a method NiaNet for constructing the autoencoder topology and hyper-parameter setting.
- We present the automated machine learning (AutoML) framework capable of applying the NiaNet method on a given dataset.

This research was funded by the Slovenian Research Agency (research core funding No. P2-0057)

- We test the NiaNet method on a well-known diabetes dataset.

The remaining structure of this paper is as follows. Section II briefly describes the related work. Section III and Section IV presents the used framework and proposed method NiaNet. Obtained results of the experiment are presented in Section V. The last Section VI contains the conclusion.

II. RELATED WORK

In this section, we review relevant strategies for building DNN models without the need for human intervention. Since the construction of DNN is a highly complex problem that can also be represented as an optimization problem, scientists are looking for the potential of applying nature-inspired algorithms to cope with this problem. These algorithms are highly efficient in finding the solutions to multi-dimensional problems such as DNN construction. This section looks at target optimization problems that have received considerable attention in the literature. All of these strategies aim to discover the DNN topology efficiently in multiple dimensions. They vary in that they may either search simply the DNN topology (neurons and connections) or DNN topology and weights. The time axis or computational resources can represent efficiency before converging to the optimal solution.

A. Neuroevolution (NE)

A population of genetic encoding of artificial neural networks (ANN)s is evolved in neuroevolution to identify a network that solves a given task. Each encoding in the population (a genotype) is chosen one at a time and decoded into the neural network corresponding to it (a phenotype). The performance of this network in the task is then measured over time, yielding a fitness value for the relevant genotype. As a result, the process resembles an intelligent parallel search for superior genotypes, and it continues until a specific fitness threshold value is found or evolution reaches a specific generation limit [12]. Neuroevolution methods differ by type of encoding genotype to phenotype:

- A direct encoding will explicitly specify the direct connection between phenotype and genotype.
- An indirect encoding specifies the rules or parameters on how the phenotype is built from the genotype.

The following evolutionary algorithms, i.e., genetic algorithm (GA) [13], memetic algorithm (MA) [14], and particle swarm optimization (PSO) [15], showed promising results when tackling this problem.

Readers are invited to read a recent comprehensive study that presents current trends and future challenges in neuroevolution, as well as various types of neuroevolution and their strengths, and limitations [16].

B. Evolutionary neural architecture search

Neural Architecture Search (NAS) is a technique that automatically designs artificial neural networks. One of the many modifications of this technique is Evolutionary NAS (ENAS). It is a bio-inspired automated neural network architecture

design technique that follows the core principles of biological evolution [17]. Its goal is to identify a network topology that will give the best result on a given task. The three main components of the NAS method are as follows [18]:

a) Search space: It defines the boundaries inside which the search is allowed. This can be a set of rules for topology, layer number, layer type, and optimizers. Its size represents the set of all possibilities.

b) Search strategy: It defines the method for exploring the search space. The majority of the work on the NAS approach was focused on addressing this aspect. Since it is always challenging to determine which optimization methods work best and how to adapt or change them to yield better results. ENAS technique is using evolving ANN (EANN) as a search strategy. The EANN strategy is used to evolve ANN's connection weights, topology, and learning rules [19].

c) Evaluation strategy: Alternatively, sometimes called performance estimation strategy, evaluates the ANN offspring. Such evaluation is done prior to construction and training phase. This method primarily depends on many factors, such as search space size, datasets size, depth of topology, and others. To accurately measure the ANN offspring performance [18] many new methods have been proposed to reduce the time, and computation resources [20].

C. Structure learning

The method of utilizing data to train the linkages of a Bayesian network is known as structural learning. The method's goal is to represent the data in a graph format, providing a good balance of expressive power and querying performance. Bayesian networks are a type of structured knowledge representation in which domain variables are represented as nodes in a graph whose structure encodes their relationships [21]. However, these techniques need a lot of computing power, making the solution unsuitable for most applications with limited computing power and time.

III. AUTOMATED MACHINE LEARNING

As mentioned in the introduction, deep learning has been applied in various fields to solve challenging artificial intelligence (AI) tasks in recent years. Such diversification often leads to specific cases where even field experts operate on trial-and-error. This substantially increases the resources and time needed to create well-performing DNN models [22]. To reduce the development cost and automate the entire machine learning pipeline, an AutoML methodology was introduced. Its pipeline consists of data processing, feature engineering, model generation, and model evaluation. The goal is to be able to automate the complicated process of selecting pipeline components so that a user only needs to specify a dataset and an appropriate pipeline will be built automatically [23]. This frees up a human specialist to concentrate on other areas of the process.

This section introduces the AutoML framework, which utilizes our proposed method, NiaNet, in a model generation stage. In symbiosis, both the framework and method construct

a deep autoencoder topology and their hyper-parameters to discover the best possible ML pipeline for an input dataset. The framework (see. Fig. 1) is built using a layer-style layout architecture with multiple components.

A. Data Ingestion

Collecting and importing data into the ML pipeline is known as data ingestion. Acquiring data can be a complex component and one of the most challenging tasks because we need to have solid business and data understanding abilities [24]. The ML pipeline components will be influenced by the dataset used. The user performs this operation before the pipeline begins.

B. Dataset processing

Data processing is the first stage in the AutoML pipeline. There are numerous approaches for processing data to be used to build models. Real-world data is commonly skewed; there is missing data, which is often noisy. As a result, processing the data is required to make it clean and processed so that it may be run through the ML algorithms. The yellow section in Fig. 1 illustrates the data processing process. As authors in paper [22] explained, it may be divided into three processes: data collecting, data cleaning, and data augmentation. Data collection is an important stage in creating a new dataset or expanding an old one. The data cleaning process filters noisy data so that subsequent model training is not affected. Data augmentation is critical for increasing model robustness and improving model performance. The three aspects will be discussed in further depth in the following subsections. This stage is not yet automated in our framework.

C. Feature engineering

Feature engineering is the next stage in our AutoML pipeline. It usually consists of feature extraction, feature selection, and feature construction. In our ML pipeline, only the process feature selection is utilized. This process builds a feature subset based on the original set by reducing irrelevant or redundant features. This simplifies the model, preventing over-fitting and boosting model performance [22]. There are many manuals or automated ways of selecting the optimal feature set for a given dataset [10].

D. Model generation

Model generation is divided into two components, search space and optimization method, as shown in the 3rd section in Fig. 1. Where search space defines the AE topology and hyper-parameters. The AE architecture refers to a complete blueprint of DNN components such as:

- Topology shape (symmetrical, asymmetrical)
- Size of input, hidden and output layers
- Number of hidden layers
- Number of neurons in hidden layers

On the other side, in our AutoML framework, the following hyper-parameters are available in the search space:

- Activation function
- Number of epochs

- Learning rate
- Optimizer

Another component in the model generation stage is the optimization method. This component is responsible for finding the optimal solution within the edges of search space - parameter values to construct and train a given AE model. The solution is a one-dimensional array of elements from the above search space dimensions, each representing one of the parameters we are trying to optimize. The task of choosing the optimum solution is an iterative process. In this process, we are using the micro-framework NiaPy [25], which is an excellent tool for using the collection of nature-inspired algorithms for optimizing a given problem, such as ours. Each returned solution array from NiaPy framework is mapped according to equations [2-8]. More details are presented in section Proposed method. The AE model is created and trained in PyTorch using mapping rules that are controlled by the proposed method.

E. Model evaluation

The performance of an AE model must be evaluated after it has been constructed. The first process in the model evaluation phase is to use the DNN training and testing technique to evaluate each solution produced by the proposed method. However, this process requires a significant amount of time and computation resources. Once the AE model has been trained, the reconstruction loss and model complexity are evaluated based on the equations 10 and 11. In addition, the fitness function 11 is calculated, and the fitness value is passed back to the optimizer algorithm, which generates a new solution. Sections 3 and 4 of Fig. 1 show the communication flow between model generation and model evaluation.

F. Fittest AE model

After our iterative AutoML pipeline is completed, the fittest AE model is returned. To put it simply, the proposed model is optimal in terms of reconstruction loss and model complexity.

IV. PROPOSED METHOD

In the following section, we present in detail our proposed method, NiaNet ¹. This research will study whether an AE neural network with topology and hyper-parameters set by our proposed method will provide better encoding performance than AE designed manually. We believe that a nature-inspired search can discover a novel solution that may be hidden by human experts who are limited by their previous experience and knowledge. Our proposed method leans to be very straightforward and utilized on different datasets. This allows users to automatically perform some ML steps when using our AutoML framework, without manually searching for the right AE building blocks.

The method is based on applying the nature-inspired optimizer (we use a collection of algorithms in the NiaPy framework) to the problem of constructing AE typed neural networks. The solution is a one-dimensional array of seven

¹<https://github.com/SasoPavlic/NiaNet>

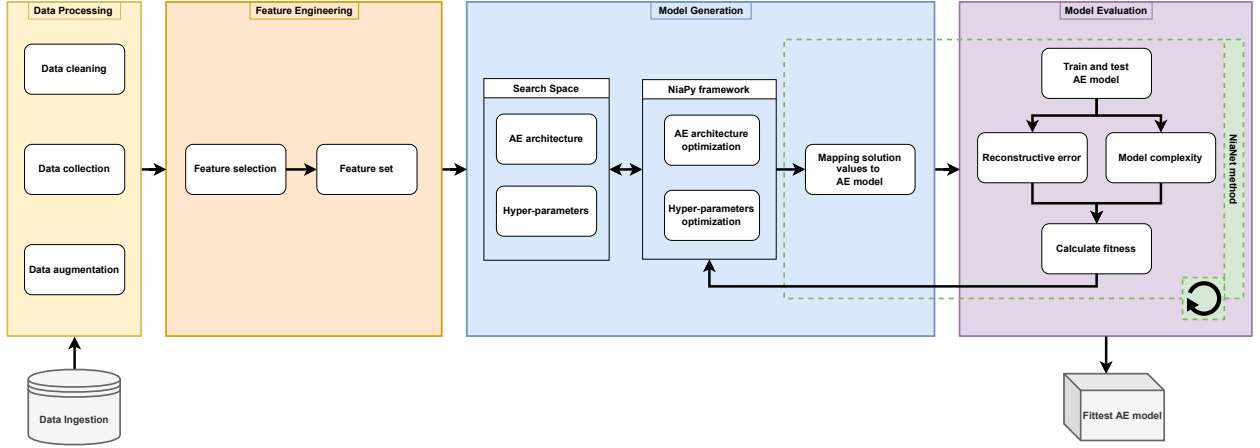

Fig. 1: A high-level overview of our AutoML pipeline, including data preparation (Section 1), feature engineering (Section 2), model generation (Section 3), and model evaluation (Section 4).

elements; each one represents one of the parameters we are attempting to optimize. The first three represent AE topology, and the last four represent hyper-parameters. The solution produced by the optimizer method is then mapped into the AE model using those representations. After the AE model has been built, it is evaluated using a fitness function that measures its performance. The fitness value represents the quality of the discovered solution. The fitness value is then reported back to the optimizer algorithm in the last step, allowing the search for the best optimal solution to continue. The algorithm is presented in Alg. 1.

A. Representation of individuals

Individuals in NiaNet are presented as real-valued vectors:

$$\chi_i^{(j)} = \{x_{i,0}^{(j)}, \dots, x_{i,n}^{(j)}\}, \text{ for } i = 0, \dots, \text{Np} - 1 \quad (1)$$

where each element of the solution is in the interval $\chi_{i,1}^{(j)} \in [0, 1]$. Real values in interval are then mapped according to equations [2-8], where y_1 stands for topology shape, y_2 for number of neurons per layer, y_3 for number of layers, y_4 for activation function, y_5 for number of epochs, y_6 for learning rate, y_7 for optimizer algorithm.

$$y_1 = \lfloor x[i] \rfloor; y_1 \in [0, 1] \quad (2)$$

$$y_2 = \lfloor \frac{x[i]}{\text{features}} \rfloor; y_2 \in [0, \text{features}] \quad (3)$$

$$y_3 = \lfloor \frac{x[i]}{\text{maxLayers}} \rfloor; y_{33} \in [0, \text{maxLayers}] \quad (4)$$

$$y_4 = \lfloor x[i] \rfloor; y_4 \in [0, 1] \quad (5)$$

$$y_5 = \lfloor x[i] * 10 + 100 \rfloor; y_5 \in [100, 200] \quad (6)$$

$$y_6 = \lfloor \frac{x[i]}{1000} \rfloor; y_6 \in [10^{-3}, 10^{-0}] \quad (7)$$

$$y_7 = \lfloor x[i] \rfloor; y_7 \in [0, 1] \quad (8)$$

The solution array is separated into two groups of indices, as shown in Fig. 2. The first three indices are used for topology mapping, while the fourth is utilized for hyper-parameter mapping. Together they form a complete solution that is subsequently used to build an AE model, as demonstrated in

Fig. 2: An illustration of how indices in a solution array are allocated to variables $[y_1-y_7]$.

the algorithm 1. Each of these solutions is retrieved from the NiaPy library during the iterations of the NiaNet algorithm, with the goal of finding the most optimal solution. The fitness function determines the most optimal solution on a given dataset.

Topology representation: As we can see in Fig. 2 the first three elements in solution array are used for constructing the AE topology based on an element value. The first element y_1 is used to determinate the topology shape, which can be symmetrical or asymmetrical. This defines the shape relationship between the encoder and decoder parts. The number of neurons per layer is calculated using the second element y_2 . This is dependent on the number of features in dataset. Once we have the number of neurons y_2 we can calculate the number of layers y_3 in AE model. In the case of an asymmetrical AE model, the element value y_3 is used to set a random number of encoder layers before setting the remaining decoder layer number.

Hyper-parameters representation: Second part of solution array as seen in Fig. 2 is used for determining the hyper-parameters values which are utilized throughout the model training. The fourth y_4 and seventh y_7 elements are used for determining the activation function and optimizer algorithm based on a list of possible values. The fifth y_5 and sixth y_6 elements are used for number of epochs and learning rate depending on a defined range.

B. Encoding strategy

Once the real-valued solution array is proposed by the NiaPy framework, the real values are then mapped into the AE model according to the equations [2-8]. The element mapping value of solution array is determined with the binning process for all variables $[y_1-y_7]$. The bins are created in interval $\in [0, 1]$. Where each bin represents the possible mapping value. For example when mapping the AE's shape y_1 , the encoding algorithm takes the element's real value from solution array and map it to corresponding bin (symmetrical or asymmetrical). This can be seen in equation 9.

$$y_1 = \begin{cases} \text{symmetrical} & \text{if } x[i] \leq 0.5 \\ \text{asymmetrical} & \text{otherwise} \end{cases} \quad (9)$$

C. Fitness function

We defined the fitness function, which measures the individual solution by calculating its reconstruction error and

DNN complexity using equations 10 and 11. This enables us to analyze the encoding effectiveness and complexity of its topology.

$$E = \left(\sum_{i=1}^D (x_i - \hat{x}_i)^2 * 1000 \right) \quad (10)$$

$$C = \frac{(y_5)^2 + (y_3 * 100) + (\text{bottleneck_dim} * 10)}{100} \quad (11)$$

$$f(\chi_i^{(j)}) = \min E + C \quad (12)$$

Where E represents the reconstruction error, C topology complexity and $f(\chi_i^{(j)})$ represents the fitness value of an individual in evolution. Since equation 12 is designed to seek the global minimum, the fittest individual will be the one with the lowest fitness value. Furthermore, with the variable C , we address the issue of over-fitting. Less complex models are less likely to over-fit during the training process [26].

D. Training conditions

Due to research limitations, some parameters of the constructed AE model were static during the training phase. One of them is batch size, which is always set to 1, and another is the activation function, which remains the same once selected, across all encoder and decoder layers.

E. Data conditions

The data structure that the NiaNet method can process is limited to tabular data with only numerical values. As a result, any other type of data must be transformed first. We plan to expand our research in the near future to include time-series data as well.

V. EXPERIMENTS AND RESULTS

A. Introduction to dataset

In our experiments, we used a dataset that includes physiological data about the patients which are identified to have diabetes. The dataset is publicly available for everyone [27]. For each of the 442 diabetic patients, ten baseline characteristics, including age, gender, BMI, average blood pressure, and six blood serum measures, as well as the response of interest, a quantitative measure of disease progression one year after baseline, were collected. The eleventh feature is measuring the diabetes level. The dataset's feature values are represented solely by numerical values, with no missing values and a weak correlation (mean is 0.2). We standardized the data for each feature before using it, so that the distribution has a mean of 0 and a standard deviation of 1. This enables the DNN to be generated later with weights that are more similar across the features, resulting in more uniform topologies. Furthermore, the dataset was divided into the training and testing subset in a ratio 3:1.

B. Enviromental setup

The environment must be properly set up before running our AutoML framework with proposed method NiaNet [28]. In this section, we list the software components and configuration parameters that are utilized in a configuration file. All experiments were carried out using the Python programming language together with the libraries: NiaPy [25] for nature-inspired algorithms, Scikit-learn [29] for evaluating DNN models with metrics, NumPy [30] for working with arrays, PyTorch for DNN initialization [31]. Following computational resources were used for development and training environment: Razer Blade 15 Advanced (Early 2021 model - RZ09-036) with Intel i7-10875H CPU, Nvidia GeForce RTX 3080 with 8 GB GDDR6 memory and 6144 CUDA cores GPU, and 32 GB DDR4 RAM. Running on Windows 11 / Ubuntu 20.04.2 LTS.

C. Experimental settings

We utilized the values in Table I for NiaPy algorithm initialization settings. With parameters supplied, specified methods are utilized to search for optimal values in the encoded solution, which is expressed in equations [2-8]. The algorithms used in our experiment are: PSO [32], Differential Evolution (DE) [33], Firefly Algorithm (FA) [34], Self-adaptive Differential Evolution (jDE) [35], GA [36].

TABLE I: Used parameter values for NiaPy algorithms.

Parameter	Value
Dimensionality problem	7
Population size	default
Max evaluations	100
Runs	2
Lower bound	0.0
Upper bound	1.0

The following is an explanation for selected parameter values in table I: *Dimensionality problem* is set to 7 based on the solution array length, *Population size* is set to default, allowing NiaPy algorithms to have their own default value, *Max evaluations* is specifying number of evaluations on each algorithm separately, *Runs* is specifying number of repetitions (low number due to limited computational resources), *Lower bound* and *Upper bound* are borders within the real value number that can be represented in solution array.

Next we set the list of available activation functions and optimizers, which can be selected based on the mapping rules of y_4 and y_7 variables. Table II shows the activation functions, whereas table III shows the optimizers used in our experiment. All of the listed activation functions and optimizers, are available in PyTorch library, therefore any other ones that are not in the list can be easily added or removed.

TABLE II: List of activation functions in NiaNet method.

Activation function name

Rprop

D. Fittest Autoencoder architecture

We present the fittest AE model in this section, which was built and trained using the proposed NiaNet method in the AutoML framework. The experiment was carried out with the diabetes dataset with the above experimental parameter values. Produced solutions by the NiaNet method were evaluated by the fitness function in equation 12, where PSO produced the fittest solution.

Topology: The proposed solution array was mapped into the AE model based on the encoding strategy. The proposed model was a symmetrical AE, having a single-layer encoder and decoder. The encoder was built to take a 10-D input vector and compress it into an 8-D latent vector. The decoder was a mirrored encoder that took an 8-D latent vector as input and decompressed it back to a 10-D output vector. This indicates that the initial 10-D vector was compressed by the 20%. Another good indication can be seen in a simplicity of a model in terms of AE deepness (see. Fig. 3).

Hyper-parameters: When mapping up the elements in solution, we got the hyper-parameters for the previously mentioned topology. Where an activation function = *RRELU*, number of epochs = 110, learning rate = 0.11 and optimization algorithm = *RAdam*.

Achieved performance: On the testing dataset, we applied the root mean squared error (RMSE) to objectively quantify the fittest AE model's performance. It allows us to examine how close the reconstructed data examples (output) are from the ground truth (input) on average. The closest the result of RMSE metric is to zero, the smaller the difference between input and output. In our case, the fittest AE model reached the value of 0.11, which can be the starting point for future research.

E. Results by optimization algorithm

The following are the findings of our more in-depth analysis. Each of the fittest solutions produced by algorithms PSO, DE, FA, jDE, and GA is listed in table IV. The PSO algorithm

Algorithm	Fitness value	RMSE	Bottleneck size	Topology shape	number of neurons per layer	Layers in AE	Activation function	Epochs	Learning rate	Optimizer algorithm
PSO	231	0.11	8	symmetrical	En[8], De[10]	2	RRELU	110	0.11	RAdam
FA	353	0.15	8	symmetrical	En[8], De[10]	2	SELU	140	0.26	Adagrad
jDE	523	0.40	5	symmetrical	En[5], De[10]	2	RRELU	110	0.38	Adagrad
GA	553	0.40	9	symmetrical	En[9], De[10]	2	TANH	120	0.04	ASGD
DE	556	0.26	9	symmetrical	En[9], De[10]	2	CELU	170	0.06	RAdam

TABLE IV: The NiaNet fittest solutions found by selected algorithms

achieved a significantly higher fitness value, closely followed by the FA algorithm. Whereas all other algorithms ended up with very comparable fitness values, despite arriving at different solutions in AE model building blocks. This can be explained by looking at the formulation of our fitness function, equation 12. When looking at the proposed bottleneck sizes, we see the values span from 5 to 9. Since the input shape is 10 for the selected dataset, this is relatively considerable variability between algorithms. While the variables such as topology shape, epochs, and number of layers are nearly identical. All the algorithms found the optimal solution in those variables for this problem. The number of neurons in each layer varies between algorithms, since it is related to the size of the bottleneck. Multiple solutions for activation function, learning rate and optimizers were also proposed.

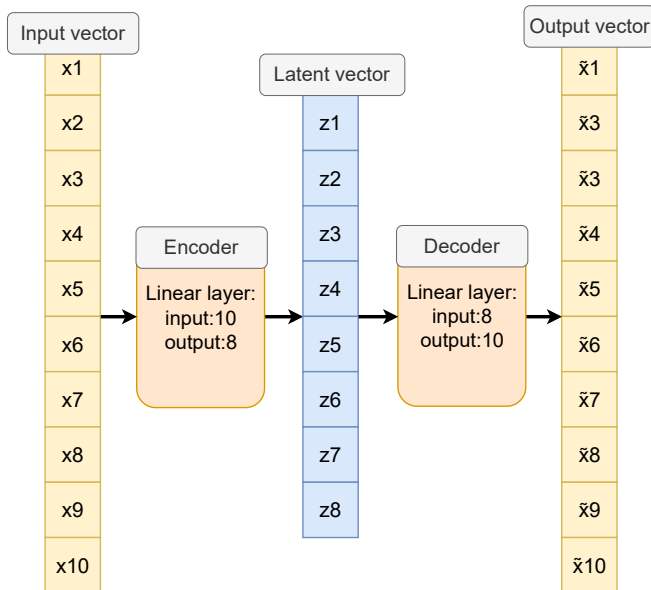

Fig. 3: Fittest autoencoder topology, designed by PSO algorithm.

VI. CONCLUSION

This paper presented NiaNet, a novel method for building AE models based on the AutoML methodology. The method sets up the topology and the hyper-parameters based on the solutions designed by nature-inspired algorithms. The results gathered in experiments are indicating a promising avenue that has to be further explored. This could help reduce the human resources needed in the model generation stage of AutoML.

Based on these exciting findings, we plan to expand our research toward finding an optimal solution for a broader

range of training parameters and AE topologies with various depth, width, and layer types. The objective for the future is to compare our proposed method to existing AutoML methodologies in a more extensive performance comparison using a variety of datasets. Having numerous solutions for various datasets could provide us with insights into how to build optimal AE models in the future.

□

Abstract— The article describes the training process and experiments regarding autonomous movement by the autonomous car Waveshare JetRacer AI. The central unit responsible for controlling the vehicle's systems, i.e. the steering servo and the DC motors used for the drive, is the NVIDIA Jetson Nano embedded device. The application of the IMX219 camera module for data acquisition and training of a neural network models on microcomputer and their use for the implementation of autonomous driving are described.

I. INTRODUCTION

THE autonomous movement of vehicles is a task that requires a careful analysis of the environment. For this purpose, vision or sensory systems are used. They play the role of a source of data about the environment in specific assistance systems, e.g., active cruise control, emergency braking, environment mapping, digital side and rear view mirrors, parking assist and lane assist [1]-[3]. Due to the advancement of such systems and their continuous development, it is possible that they will soon allow the achievement of higher levels of driving automation, ultimately leading to the mass production of fully autonomous vehicles.

There are six levels of vehicle driving autonomy defined by SAE International in the SAE J3016 standard, which are numbered from 0 to 5 [4]:

- Level 0: No Automation
- Level 1: Driver Assistance
- Level 2: Partial Automation
- Level 3: Conditional Automation
- Level 4: High Automation
- Level 5: Full Automation.

At level 0 there is no automatic vehicle control, but the system may issue warnings. In the next stage, it is defined that the driver must be ready to take control of the vehicle at any time. The automated system may be equipped with features such as Adaptive Cruise Control (ACC), Parking Assistance with automated steering, and Lane Keeping Assistance (LKA) Type II in any combination. The second level of partial automation obliges the driver to detect objects and events and to be ready for response if automated system fails to react properly. A computer executes accelerating, braking, and

steering, but can be immediately deactivated while driver takes over the control. Level 3 allows the driver to safely turn attention from driving tasks within known, limited environments (e.g. freeways). But if any warning or alert occurs, the driver must intervene. In the 4th level the vehicle is controlled by an automated system but only when the conditions in the environment allow the enabling system by the driver. When running, there is no need to pay attention to the driver while driving. The last level requires only to set the destination and press the start button. The automatic system will drive to any location where it is legal to drive [5].

Real-time processing of data received from vision modules or sensors and sending feedback control signals requires the use of computers with high computing power. Due to the dynamic development of embedded devices and increasing their efficiency, it is possible to use them for tasks that require real-time calculations [6]. Examples of such modules are microcomputers from the NVIDIA Jetson family. They are equipped with powerful GPUs that allow performing complex calculations using models of neural networks.

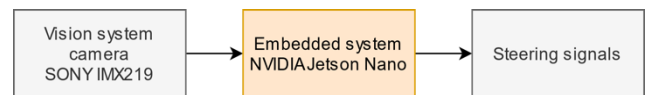

Fig. 1 Block diagram of the tested system

Fig. 2 Waveshare JetRacer AI with NVIDIA Jetson Nano microcomputer and Waveshare IMX219 camera

The purpose of processing the captured video sequences is to obtain parameters that allow precise control of the steering system of the vehicle (Fig. 1). The implementation of algorithms for autonomous driving in the model environment was carried out with the use of a four-wheeled Waveshare JetRacer AI mobile vehicle with a NVIDIA Jetson Nano

□ This research was funded partly by the 2022 subvention and partly with the SMART4ALL EU Horizon 2020 project, Grant Agreement No 872614.

minicomputer and a Waveshare IMX219 camera (Fig. 2). Various models of neural networks were trained and tested for the autonomous driving of a vehicle along a designated route. The software allows to stream the image from the car's on-board camera and enables the user to communicate with the environment by controlling the displayed widgets with the use of a mouse or an external controller.

II. WAVESHARE JETRACER AI HARDWARE BASED ON NVIDIA JETSON MICROCOMPUTER

Waveshare JetRacer AI is a platform that allows to independently construct a four-wheeled mobile vehicle. The kit consists of mechanical elements of the chassis, bumpers, camera arm, and wheels. The steering system is controlled by the MG996R servo with a torque of 9 kg/cm. The drive is provided by two 37-520 DC motors with a reduction rate of 1:10 and idle speed of 740 RPM. The 12.6V power supply is provided by the use of 3 Li-Ion 18650 batteries connected in series. Wireless communication, which allows remote programming and car control, is carried out using the AC8265 WiFi module with two antennas. The main PCB is equipped with a 0.91" OLED display with a resolution of 128×32 pixels. It shows the parameters for the use of computer resources and the IP address used to establish wireless communication. The manufacturer also includes a universal gamepad that can be used to control the car [7].

The central unit responsible for controlling the steering and drive systems as well as processing data from the camera is the NVIDIA Jetson Nano B01 microcomputer. Its most important technical specifications [8] are presented in Table I. This microcomputer was designed mainly for use in tasks related to artificial intelligence. It allows running many neural networks, which can perform processes such as image classification or object detection. Their simultaneous operation while maintaining appropriate performance is ensured by the CUDA architecture, which allows for the performance of complex and computationally expensive operations, such as matrix calculations or 3D rendering using the potential of the CPU and GPU [9].

TABLE I.
NVIDIA JETSON NANO B01 SPECIFICATION

GPU	128-core Maxwell
CPU	Quad-core ARM A57 1.43 GHz
RAM	4 GB 64-bit LPDDR4
Camera	2×MIPI CSI-2 DPHY lanes
Connectivity	M.2 Key e.g. for network card
Operating System	Linux for Tegra – JetCard 4.5.1

Image recording is possible by equipping the vehicle with a Waveshare IMX219 camera module 160 degree FoV [10]. Its resolution is 8 megapixels and the lens is wide-angle 160 degrees. This shows the significant extension of the perspective in comparison to 62.2 degrees in the commonly used Raspberry Pi Camera v2. The Waveshare IMX219 camera is also characterized by an aperture of f2.35 and a

focal length of 3.15mm. It allows to take pictures with a maximum resolution of 3280×2464 pixels and video recording with a resolution of 1080p and frequency of 30 frames per second. The camera module itself (without dedicated PCB) is compatible with both the Raspberry Pi Camera v2 PCB and the NVIDIA Jetson Nano minicomputer used by connecting via the CSI connector.

Waveshare JetRacer AI car programming can be performed through a wireless connection to the NVIDIA Jetson Nano microcomputer. For this purpose, the JupyterLab environment is used, which is installed by default in the software package provided by the manufacturer. The system also has implemented libraries necessary to support neural networks and video sequence processing operations, such as: OpenCV, Tensorflow, NumPy, PyTorch, or NVIDIA TensorRT [11].

III. DATA COLLECTION FOR NEURAL NETWORK TRAINING

The task for the Waveshare JetRacer AI vehicle is to follow an oval track, on which the edges are marked with yellow lines and the central axis with a white dotted line [12]. Based on the image from the camera, which is sent to the car's main computer, the neural network algorithm decides to correct the direction of the vehicle's movement by changing the position of the steering servo. In the presented study, movement at variable speed is not assumed. Its value is manually controlled by the program widget, but it is possible to extend the algorithm functionality of its autonomous selection in the future.

The implementation of the Waveshare JetRacer AI car autonomous movement algorithm consists of several stages. The first one is the hardware configuration of the device, i.e. the appropriate mechanical setting of the steering system and empirical determination of its correction coefficients and the parameters of the drive system. They depend on the design of a specific car. After establishing communication with the computer via the wireless network, it is possible to adjust them through the widgets included in the program. Then, in the next step, for convenience of use, it is worth connecting the wireless controller to the computer to be able to remotely control the vehicle. For this purpose, can be used the gamepad provided by the manufacturer or any other controller such as the Xbox 360 Controller.

In the next stage, the camera widget is initialized to show a preview on one screen and on the second one to precisely define the coordinates of the direction vector, according to which the car should move autonomously. These values can be set using the widget sliders, or after appropriate code modification with a wireless controller. The user interface and the actual vehicle position are shown in Figs. 3 and 4.

Fig. 3 User interface camera view in JupyterLab widget for training data collection

Fig. 4 Actual car position on track during data collection

Having prepared all the described tools and the vehicle on the track in the target environment, the neural network model training can be started. This process should begin with collecting training and validation data. It involves the car going over the track several times, but not continuously and recording the video sequence, but by stopping, changing the position, and taking pictures.

The key information, apart from the camera frame itself, is also the coordinates of the vector of the direction in which the car should move. They are saved in the file name along with a unique identifier for the image. Setting the vector position is a task that must be performed manually using the interface sliders and preview on the widget, or with the use of a controller.

It is required to prepare the dataset in such a way that it contains data allowing to choose the optimal path for the vehicle, but also boundary conditions, e.g. car on the edge of the track for the case to return to the correct trajectory. The larger the dataset that defines how a car behaves, the greater the chance of more precise autonomous driving.

IV. IMPLEMENTATION OF A NEURAL NETWORK FOR AUTONOMOUS VEHICLE MOVEMENT

The key element of the software that allows the implementation of the task of autonomous vehicle movement is the appropriate selection of the neural network model. The concept of the structure of the implemented solution is presented in Fig. 5.

The algorithm for autonomous driving of the Waveshare JetRacer AI car was based on the ResNet18 neural network. This architecture was chosen for its effectiveness at the level of other solutions such as VGG. The advantage of ResNet solutions, however, is the small size of the model at the level of 22.7 MB [13]. The architecture of this convolutional neural

network is 18 layers deep (17 convolutional and one connected) [14]. The shape of its last layer has been changed by the Linear function from the PyTorch library, and finally it has the same number of results as the number of classes in the dataset. The Linear PyTorch function creates a single-layer unidirectional feedforward network in which data only flows from input to output. An important aspect of this type of solution is backpropagation, which consists of improving at each step of the training process due to the correction of weights based on the estimation of the error made by neurons during training. The Adam algorithm was responsible for optimizing the network model with such a structure. The set of collected data (600 frames) was divided as follows: 80% of the training images and 20% of the validation data. To optimize the performance of the software, it was decided to convert the PyTorch model to the TensorRT model, which enables more than three times the increase in the number of processed frames per second, from 29.4 to 90.2 FPS [15].

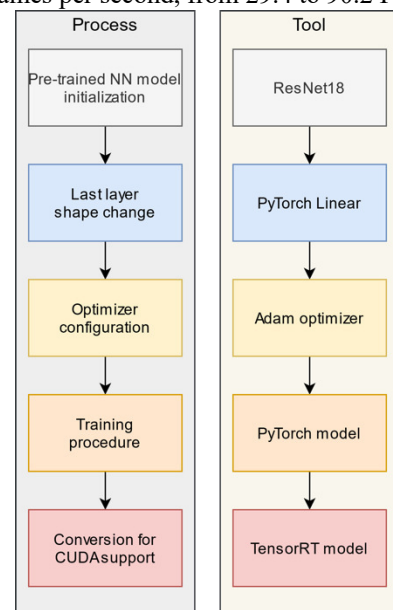

Fig. 5 Block diagram of neural network model for autonomous driving During the training of the neural network, an experiment

TABLE II.
MEAN LOSS FUNCTION VALUE FOR DIFFERENT EPOCHS NUMBER

Epochs number	Training data	Validation data	Training time [s]
30	0.042	0.035	754.7
50	0.024	0.018	1229.6
100	0.014	0.008	2459.1

was carried out to check the impact of the number of epochs on the loss function and the behavior of the vehicle in autonomous driving mode. The epoch is the one-time use of all the cases included in the training set during the whole teaching process. These repetitions are intended to perform many steps of the training algorithms until the error in the output is acceptably small. The following values of the number of epochs were checked during the experiments: 30,

50 and 100. The mean values of the loss function and training times are summarized in Table II.

The average values obtained for the loss function show the high efficiency of the neural network model training process. As expected, the dependence of the decrease in the function value with the increase in the number of epochs can be noticed. The results for the validation data are slightly lower than for the training images, but these are average values, so there is no risk of overfitting phenomenon. The analysis of the complete input data confirmed that the structure of the network, the ratio of the number of training and validation images, as well as the selection of network parameters made it possible to achieve results that allow testing under real conditions.

Due to the use of the neural network model, when the vehicle is moving, an image is taken from the camera, which, after analysis, returns the value of the function responsible for steering the torsion of the front axle of the platform, depending on the model's prediction. In addition, parameters such as steering gain and steering bias have also been implemented, which have to be set manually because they are the result of the physical imperfections of the vehicle's design and the servo used for the steering system.

Depending on the number of epochs implemented during the neural network training process, the following observations were made during real tests. The car, using a model trained for 30 epochs, tended to cross the orange lines at the exit of the curve and cut them off. This problem was regular and repetitive, since crossings of the track limits occurred more or less at the same points on the route. This phenomenon was eliminated for the model with 50 epochs. The vehicle was already moving inside the orange lines, in accordance with the planned trajectory, but on straight sections its path deviated from the central axis marked by a white dotted line. This effect was completely eliminated for a model trained with 100 epochs. The car was driven without problems along the set trajectory, not exceeding the limits of the track and keeping its position in the axis of the route.

V. CONCLUSIONS

The tested model of the Waveshare JetRacer AI vehicle allowed for the implementation of an algorithm for the task of autonomous driving along a designated route. Due to the use of the NVIDIA Jetson Nano B01 microcomputer supporting the GPU-based CUDA architecture, it was possible to run a complex model of the neural network. It processes the data obtained from the Waveshare IMX219 160 degree FoV camera, and then sends the control signals to the servo responsible for the steering system.

Preparation of training data for a dataset that reflects the test environment, selection of appropriate parameters of the neural network, and optimization of its performance allow for obtaining a reliable algorithm for autonomous driving. It should be noted that it does not require powerful computing power from efficient graphics cards dedicated to PC devices, but can also be successfully used on embedded devices [16].

The conducted experiments confirm the correct operation of both the hardware and the software part. After an appropriate selection of the number of epochs during the neural network model training process, it is possible to eliminate undesirable behavior of the vehicle, such as going beyond the boundaries of the route or deviation from the set movement trajectory. The trajectory of the movement of Waveshare JetRacer AI model based on the algorithm analyzed is stable.

Further research will allow the system to be expanded with additional sensor modules for more precise environment monitoring (including obstacles detection) using data fusion techniques [17].

Abstract—Language models are typically trained on solely text data, not utilizing document timestamps, which are available in most internet corpora. In this paper, we examine the impact of incorporating timestamp into transformer language model in terms of downstream classification task and masked language modeling on 2 short texts corpora. We examine different timestamp components: day of the month, month, year, weekday. We test different methods of incorporating date into the model: prefixing date components into text input and adding trained date embeddings. Our study shows, that such a temporal language model performs better than a regular language model for both documents from training data time span and unseen time span. That holds true for classification and language modeling. Prefixing date components into text performs no worse than training special date components embeddings.

I. INTRODUCTION

MOST language models are trained solely on text data. Leveraging text domain, such as language [12] or style [10] into a language model may have a positive effect on it. Time of text authorship may be also considered as an input feature, but this poses specific challenges (and opportunities) as:

- time is continuous, whereas language is discrete, at any time moment, an event might change a language irreversibly and not trivial to combine time and language units both from the mathematical and practical standpoint;
- texts might reflect natural and social cycles (days, weeks, years, cyclical sport and political events);
- text content might be correlated with extralinguistic features, themselves correlating with time (e.g. air temperature).

Recently, the NLP community has started to use time as a feature in training and/or fine-tuning large neural models ([1], [16], [19]). Here, we analyze temporal language modeling in the context of two classification tasks in different timescales: Ireland News Headlines and Twitter Sentiment Analysis. We also incorporate date components other than year. We focus on examining different approaches to date incorporation (learnable embeddings, prefixing text) using periodic and non-periodic time features under a downstream classification task.

The contributions of this paper are as follows:

- two classification datasets were redefined in a common setup in which three time-related tasks are introduced: classification (possibly) using temporal metadata, predicting temporal metadata (as a regression task) and temporal language-modeling task (as a cloze task).
- we compared three methods for introducing temporal information into neural language models;
- we considered not only linear time, but also cycles such as years, weeks, and months;
- we measured the performance of RoBERTa [14] models in several setups on the two datasets (using different parts of the temporal information, and both fine-tuning and training from scratch);
- the relations between the temporal metadata, the texts and the results obtained were analyzed.

The datasets and source of our code are publicly available.

Generally, utilizing a date does not cost much effort, because many internet documents are available with a timestamp and it is possible to adapt existing models to new domain. Such temporal language models may contribute to:

- e-commerce search engines, e.g. users intention with short phrase "umbrella" may refer to umbrella protecting from a rain in the autumn or sun umbrella in the summer;
- other types of search engines, e.g. historical newspapers;
- OCR for historical documents.

II. DATASETS

Usually, text classification tasks do not incorporate time and other metadata. We suppose its impact is stronger for short texts due to shorter texts carrying less information. The time impact may be stronger for text, which may depend on people's mood or different interests. We carried out experiments with two large short-text classification datasets, where every sample is assigned a time stamp. One is spread over more than 20 years, the other ones — only 80 days. Both datasets are in English.

A. Ireland News

The dataset is available at Kaggle¹, its creator is Rohit Kulkarni. It consists of article headlines posted by the Irish

¹<https://www.kaggle.com/therohk/ireland-historical-news>

TABLE I: Categories count in datasets.

category	item			
	train	dev	test	test 20/21
news	603996	75963	75783	30278
business	162550	20330	20034	14477
sport	195384	24543	24346	13447
opinion	91697	11572	11528	8086
culture	67260	8525	8424	5643
life&style	65120	8093	8084	7188

Times newspaper. Each headline is accompanied by a timestamp and article category (text of an article is not included). There are six main categories: news, sport, opinion, business, culture, life&style. The datasets statistics are described in Table I. There are more fine-grained subcategories provided in the original dataset, but they vary over time, so we didn't make use of them in our experiments.

Timestamps range from 1996-01-01 to 2021-06-30. There are 1,611,495 such headlines in total.

We employed the date range from 1996-01-01 to 2019-12-31 for most of our experiments and created an additional test set, which consists of 2020-2021 years, which dates are non-overlapping with the rest of the dataset. We refer to this test set as **Ireland News 2020-2021**. The test set **Ireland News**, without year annotation, refers to time span from training data (1996-2019). Since train/dev/test split is not determined at the original dataset site, we assign each sample randomly to train/dev/test using the 80%/10%/10% split. This resulted in the 1,186,898 / 149,134 / 148,308 train/dev/test split. The average number of words in the dataset is 7.1 per headline.

B. Sentiment140

This sentiment analysis dataset is obtained and described in [2]. Since in the original dataset the train set contains 1,600,000 items (positive and negative tweets) and test set only 498 (positive, negative, and neutral tweets), we made significant modifications: neutral tweets were deleted from the test set, 100,000 random items were added to the test set, also a dev set was created by randomly selecting 100,000 samples from the train set. This resulted in the 1,400,000 / 100,000 / 100,359 train/dev/test split. Timestamps range from 2009-04-06 to 2009-06-25. The datasets set are balanced (~50% positive and ~50% negative tweets). The average number of words is 13.8 per item. Tweets are from users in different time zones. We take time local to the author of a tweet.

III. DATASETS ANALYSIS

The number of items per category differs in time. The distribution over days of month, months, years, weekdays in train datasets are presented in Figures 1 and 2 for, respectively, Sentiment140 and Ireland News. For the Sentiment140 dataset distribution over a year is not presented, since all items are from 2009. Mutual Information between presented factors and the class is given in Table V. In Ireland News, mutual information related to days of month and months is much lower than those of years and weekdays. In Sentiment140

mutual information is similar for days of month, months, and weekdays.

In both datasets, there are dependencies, which may be helpful for model performance. E.g. in Ireland News there are more sports texts on Friday and in Sentiment140 there are more negative texts on Wednesdays and Thursdays.

IV. TASKS

We created three tasks for each dataset: classification, 'fractional' year prediction, word gap prediction. Our main objective was to examine the impact of incorporating timestamps on text classification tasks. Fractional year prediction and word gap prediction tasks are mainly for analysis of the results in classification tasks.

We added timestamps in fractional-year form, which can be described by the following code:

```
days_in_year =
366 if year_is_leap_year else 365

fractional_year =
(year + (day_in_year-1+day) /
days_in_year )
```

Each item in our tasks is associated with a text, timestamp (day precision), fractional year, and category. Sample data is described in Table IV.

Each challenge for a given dataset uses the same train/dev/test split. The challenges are publicly available, courtesy of the site's owners, via the Gonito evaluation platform [3]. Source code of the challenge is available via the platform as well.

A. Classification

The task objective is to predict the headline category given text, date, and fractional year. The evaluation metric is simple accuracy. The challenges are available at: <https://gonito.net/challenge/ireland-news-headlines> (Ireland News) and <https://gonito.net/challenge/sentiment140> (Sentiment140). Dataset download and submission instructions are under the "How To" tab, source code is under the "All Entries" → catalog icon in each submission row.

B. Year prediction

The objective is to predict the year given the text. The metric is Root Mean Square Error (RMSE). The challenges are available at: <https://gonito.net/challenge/ireland-news-headlines-year-prediction> (Ireland News) and <https://gonito.net/challenge/sentiment140-year-prediction> (Sentiment140).

C. Word gap filling

The task objective is to predict a masked word, like in Masked Language Modeling, given text, date, fractional year. Word is defined by characters split by spaces. There is always exactly one masked word in each sample to

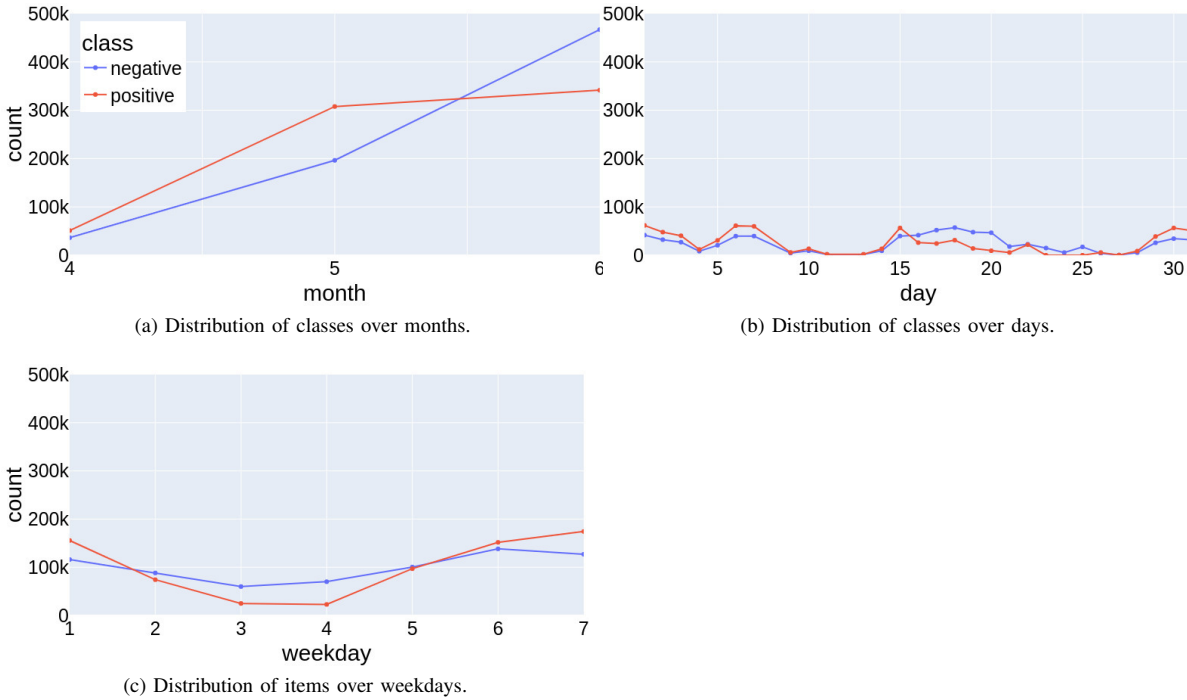

Fig. 1: Distribution of classes over date factors in Sentiment140 dataset. Distribution over year is not presented, since all items come from one year.

TABLE II: Samples from the Ireland News dataset. To check article-id visit www.irishtimes.com/article-id The article ID is not provided in the challenge.

fractional year	timestamp	text	category	article ID
2004.5082	20040705	Sudan claims it is disarming militias	news	1.1147721
2008.4426	20080611	Bluffer's guide to Euro 2008	sport	1.1218069
2017.1068	20170209	Gannon offers homes in Longview near Swords	life&style	1.2966726

predict. The metric is PerplexityHashed implemented in the GEval evaluation tool [4], which is a modified version of LogLossHashed as described by [5]. This metric ensures fair assessment disregarding model vocabulary. The challenges are available at: <https://gonito.net/challenge/ireland-news-headlines-word-gap> (Ireland News) and <https://gonito.net/challenge/sentiment140-word-gap> (Sentiment140).

V. METHODS

We used the RoBERTa model in the base version [14]. All models are described in this section. All code is publicly available via git commit hashes given in result tables.²

A. Regular Transformer as a baseline

The baseline is a regular RoBERTa with no temporal information. We refer to this method as noDate in result tables.

²Reference codes to repositories stored at Gonito.net [3] are given in curly brackets. Such a repository may be also accessed by going to <http://gonito.net/q> and entering the code there.

B. Temporal Transformer

We selected the following temporal information: year, month, day of the month (day), weekday. All of them are incorporated in our temporal models. We experimented with 3 ways of including temporal information into RoBERTa models. The first two involve slight RoBERTa model architecture changes and training new embeddings during RoBERTa training. The third one is only input data modification. They are described below.

1) *Date as embeddings added to every input token:* Temporal embeddings are added to every input token as: $embedding = token_emb + pos_emb + year_emb + month_emb + monthday_emb + weekday_emb$ for each $token_pos$. We refer to this method as addedEmbDate in result tables.

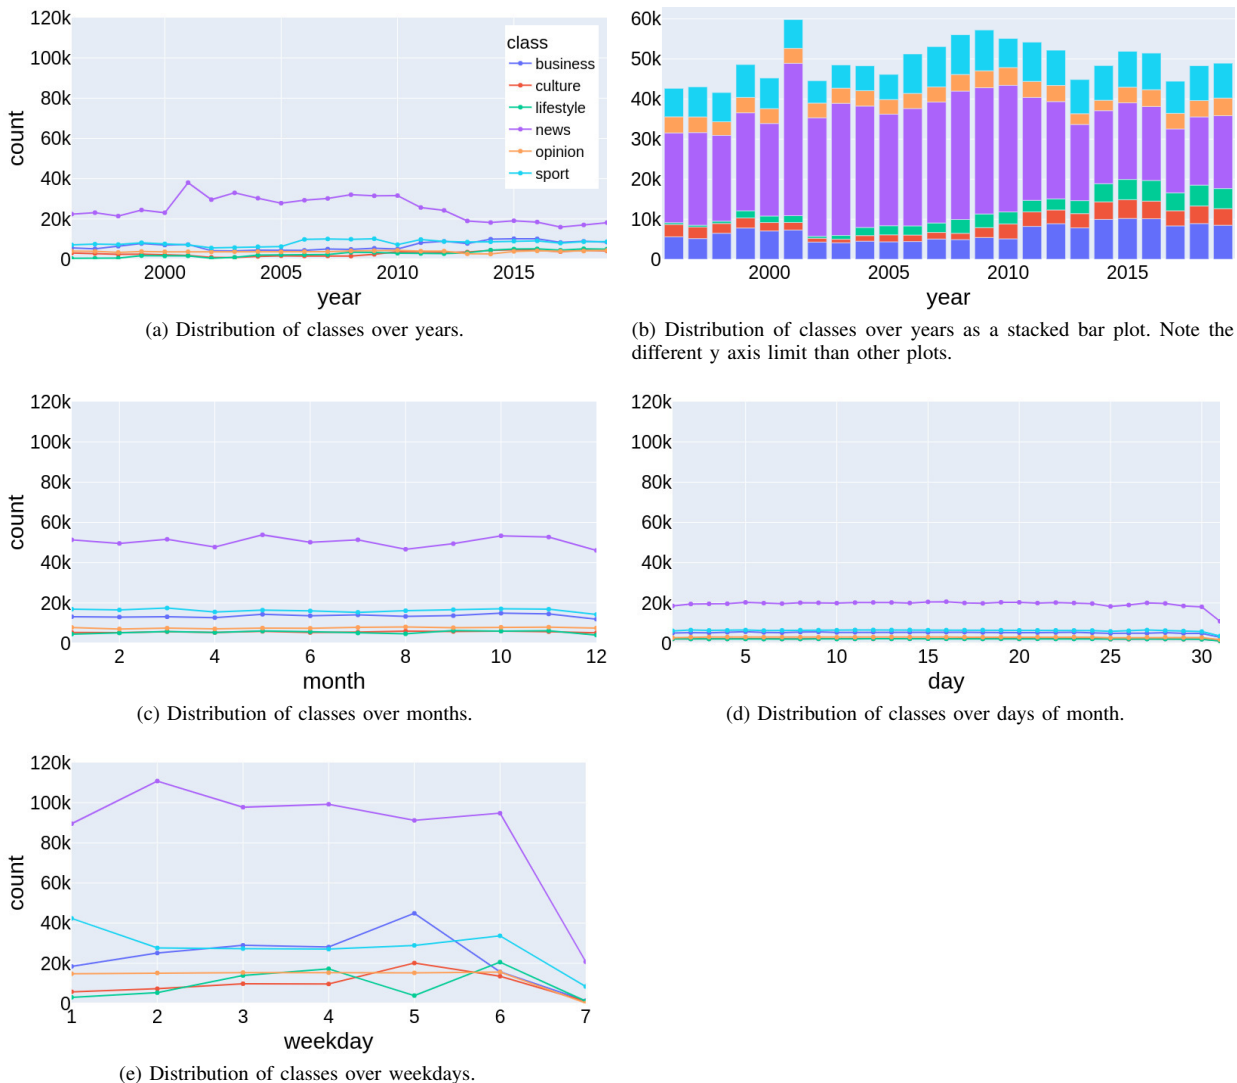

Fig. 2: Distribution of items over date factors in Ireland News dataset.

2) *Date as stacked embeddings*: Temporal embeddings are stacked at the beginning of the input sequence, as:

$$emb = \begin{cases} year_emb & \text{if } token_pos = 1 \\ month_emb & \text{if } token_pos = 2 \\ month_emb & \text{if } token_pos = 3 \\ weekday_emb & \text{if } token_pos = 4 \\ token_emb+ & \\ pos_emb & \text{otherwise} \end{cases}$$

Where all tokens are shifted 4 positions to the right, so first text token is on $token_pos = 5$. We refer to this method as `stackedEmbDate` in result tables.

3) *Date as regular text*: We only modify text input of model by adding temporal information with prefixes, so item with date `20040705` and text `Sudan claims it is disarming militias` is combined to text `year: 2004`

`month: 7 day: 5 weekday: 1 Sudan claims it is disarming militias.`

VI. EXPERIMENTS

A. Classification

We carried out experiments with text classification using all presented models. RoBERTa was finetuned and trained from pretrained checkpoints (which we refer to as `pretrained`) and with randomly initialized weights (which we refer to as `from scratch`). The only training objective is the classification task. We report the results in Table IV.

We examined the impact on classification by each date factor. Since all temporal data incorporation methods yield similar results, we chose the regular text date incorporation method due to ease of its use (only text modification with no architecture changes). The results are presented in Table V. To examine this model conditioned by different prefixes we

TABLE III: Model roberta-pretrained-textDate predictions depending on a given date in a development dataset. If a date is represented by a dash, it is not prefixed to the model, bolded dates are as they occur actually in the dataset, not bolded are random. The examples are cherry-picked. To check article-id visit www.irishtimes.com/article-id The article ID is not provided in the challenge.

TABLE VI: Roberta-pretrained-textDate classification on development set result. All results comes from the same model, the only difference is the prefix construction. Prefix is a standard model mode, no-prefix is a mode where no date is prefixed, and random-prefixed stands for a mode, where the date prefix comes from random date 1996-01-01 to 2021-06-30.

model	dev acc
prefix	87.97
no-prefix	78.38
random-prefix	73.97

checked its performance with no prefix and random prefix settings. Results are in Table VI and Table VII. The samples

from different prefix settings are provided in Table IV.

To check model degradation, we made an inference on Ireland News test set from years 2020-2021. This is a time span later than training data, which comes from 1996-2019. The results are in Table VIII.

The impact of train dataset size is presented in Figure 3.

B. Year prediction

We choose two methods for year prediction. The first is a baseline using term frequency-inverse document frequency (TF-IDF) with logistic regression. The second is averaging all output embeddings of RoBERTa and feeding to linear regression (LR) layer. Both RoBERTa and linear regression weights are tuned during training. In both methods, the minimum (maximum) output is limited to the minimum (maximum)

TABLE VII: Classification improvement due to prefixing on roberta-pretrained-textDate model. All results comes from the same model, naming convention comes from Table VI.

dev set percentage	
accurate on both prefix and no-prefix	75.14
accurate on prefix, but not on no-prefix	12.83
accurate on no-prefix, but not on prefix	3.19
not accurate on prefix, nor on no-prefix	9.84

TABLE VIII: Classification accuracy results. Test set (years 2020-2021) comes from other time span than training set (years 1996-2019).

method	Ireland News (2020/21)	
	acc	gonito
most frequent	38.27	{953311}
roberta-pretr.-noDate	85.99	{e684b3}
roberta-pretr.-textDate	87.79	{5fba22}
roberta-pretr.-textYear	87.49	{8d5ad4}

fractional year found in the datasets. The results are presented in Table IX, along with a null-model baseline using the mean fractional year from the training set as the prediction for each data point.

C. Word gap filling

RoBERTa was finetuned and trained from a pretrained checkpoint and with randomly initialized weights. The training objective is Masked Language Modeling. Only prepending data to the input was considered as a method for introducing the data. See Table X.

VII. DISCUSSION

For both datasets including dates into RoBERTa models raises the accuracy score. This stands true for pretrained and randomly initialized models. Stacked embedding and date incorporation as a text give a similar result and both are slightly better than the method of adding embeddings to every input token. It's easier to modify input text than modify model architecture, hence we recommend embedding date by prefixing input texts. The greater mutual information is between each factor and class factor, the more the model gains in accuracy score. The model trained with a date prefix performs well, only when the prefix is provided. There is no gain from date prefixing for a 1k documents train dataset and the gain is constant over 100k documents train dataset. Predicting fractional year is difficult in both datasets because all models perform not much better than baseline. We hypothesize this is a reason why classification benefits from date metadata, since adding strongly correlated factors (like a date to text in this case) would not bring information gain.

The temporal models perform better also for test sets from unseen years. To our surprise, day of the month, month, weekday, year incorporation into model performs only marginally better than incorporation only year for Ireland News 2020-2021 dataset.

In pretrained models, date incorporation slightly lowers perplexity. Models with randomly initialized weights benefit hugely from date incorporation.

VIII. RELATED WORK

There are several studies concerning language model degradation over time and adaptation to newer data [13], [17], [6]. [7] focused especially on text classification. They considered years as well as cyclical intervals (e.g., January-March). Their method was to train separate models for different time spans. [8] proposed method based on using discrete multiple temporal word embeddings based on time domains for document classification using recurrent neural networks. [9] developed model-agnostic timed dependent embedding representation for time and evaluated on recurrent neural networks across various tasks. [1] introduced temporal T5 language model, where a year was prefixed into text input and finetuned on temporal data. The experiments focused on knowledge extraction from language models and showed their method performs better in terms of language modeling and question answering than T5 language model with no prefixed year. [19] incorporated both geographical and time data into a transformer model for a QA task employing year as well as month and day. [16] prefixed year for semantic change detection. Additionally, the authors proposed the training objective of masking year information during model training. However, both [1], [16] use only year metadata, in contrast to our study, where we also days of month, months, weekdays are taken into consideration. [18] trained an SVM model to predict the date of text as a classification problem and [11] use approach of neologism based approach. Very recently [15] released temporal NLP challenges based on a large corpus of historic texts but didn't include downstream tasks, such as classification. The corpus consists of texts covering over 100 years. They trained from scratch and fine-tuned temporal RoBERTa models based on day of month, months, weekdays, and year as a prefixed text. They proved that temporal language models perform better than standard language models.

IX. CONCLUSION

Transformer models benefit from temporal information data in classification tasks for short texts. We have proved that it's not only true for a year, but also other date factors, such as weekday, day of the month, and month. The greater the mutual information between a factor and a class, the greater the benefit. The result is important, because day of the month, month, weekday factors don't outdate after model training

Abstract—Electronic Commerce (E-Commerce) has become one of the most significant consumer-facing tech industries in recent years. This industry has considerably enhanced people’s lives by allowing them to shop online from the comfort of their own homes. Despite the fact that many people are accustomed to online shopping, e-commerce merchants are facing a significant problem, a high percentage of checkout abandonment. In this study, we have proposed an end-to-end Machine Learning (ML) system that will assist the merchant to minimize the rate of checkout abandonment with proper decision making and strategy. As a part of the system, we developed a robust ML model that predicts if someone will checkout the products added to the cart based on the customer’s activity. Our system also provides the merchants with the opportunity to explore the underlying reasons for each single prediction output. This will indisputably help the online merchants in business growth and effective stock management.

I. INTRODUCTION

AS we are living in an era where digitalization and technology are evolving day by day, our dependency on the internet has noticeably increased. E-commerce has made shopping easy and safe for all internet users all over the world. People nowadays prefer exploring websites to find their daily needs rather than walking around shopping malls, supermarkets, and shops. They do not have to take the hassle of finding a product and waiting for a long billing queue, which makes purchasing simple and quick. On the contrary, e-commerce also makes it easier for companies to reach out to new customers all over the world. A report from Statista [1] shows that global sales have jumped from 1,336 billion to 5,542 billion USD in the last 6 years in the e-commerce industry. In the near future, undoubtedly the dependency on online shopping will increase significantly.

Recently, the online retailers are encountering numerous business challenges such as the lack of trust, customer churn, product return and so on. With the rapid technological advancement in the data science domain, researchers have already started to solve these type of problems by utilizing data science approaches. Some of the existing research works

are related to the product review classification such as the authors in [2] proposed DNN networks to train a classifier for identifying the product quality from product reviews. One of the major problems in e-commerce industry is the return of the product. In [3] and [4], the researchers tried to address this issue by using different predictive modeling techniques.

Apart from these, one of the most common business challenges in the e-commerce industry is high checkout abandonment rate. According to the study of Baymard Institute, a research institute in Denmark, the average checkout abandonment rate is 69.82% [5]. Also during the COVID-19 pandemic, online shopping behaviors have been significantly changed. When individuals browse an online store for a particular product, as a natural consequence, they often add many additional items to their cart. Among the added items in the cart, some are in need and the others may be their favorite but are not in great demand, and most of the time the majority of them are never checked out which results in high checkout abandonment rate. However, very few researchers have contributed to solve the issues related to online shopping carts. Jian et al [6] proposed a framework to predict buyers’ repurchases intention from the cart information. In another study [7], the author built a recommendation system using the shopping cart information.

In this research, we have tried to address the aforementioned business problem of the e-commerce industry and proposed an end-to-end ML system that will automatically perform all the steps such as data collection, transformation, preprocessing, statistical analysis, and predictive analytics. In the case of predictive analytics, we have conducted an extensive experiment and found CatBoost as the outperforming approach that predicts the checkout possibility of users with the highest accuracy ($=0.76$) and precision ($=0.694$). Moreover, we have applied a model agnostic local explanation approach for the explainability that will help the e-commerce merchants to analyze how every single customer gets influenced by different factors.

Our contribution to this study can be considered from two perspectives: one from a research standpoint, and the other from a commercial standpoint. The research perspective is that

no previous study attempted to solve this particular problem and proposed any end-to-end ML based solution. On the other hand, if business people conduct targeted marketing or apply other business strategies to consumers who are most likely to purchase the products in the cart, then the sales will be increased. Apart from that, the prediction will assist the merchant in maintaining effective stock management as well. Indisputably, the combination of statistical insights, predictive output, and local explanation aid the seller in developing proper strategies for business growth.

II. PROPOSED SOLUTION

As a solution to the checkout abandonment issue in e-commerce business, in this phase, we have proposed an end-to-end system shown in Fig. 1.

Fig. 1. System diagram

From Fig. 1 it can be observed that our proposed system takes raw data from the database and outputs analytical and predictive insights to a dashboard. Development of this system is composed of several steps: data understanding, preprocessing, exploratory data analysis, data modeling, and a model-agnostic approach.

To conduct the experiment, a large real dataset has been collected from a prominent SaaS platform that integrates with online stores to track behavior in real-time. Our dataset contains 27 features in total, where 21 features are numerical and the other 6 features are categorical. Table I and Table II shows the description of all the numeric and categorical features respectively. Among all the instances(=28410), 55% instances belong to class 0 ('not checked out') and the other 45% belongs to class 1 ('checked out') which indicates that the dataset is almost balanced.

After collecting the data, in the preprocessing phase, we have applied the James-Stein encoder to convert the categorical features into informative numerical representations. The mathematical expression of the James-Stein encoder is as follows:

$$JS_i = (1 - B) \times mean(y_i) + B \times mean(y) \quad (1)$$

Where

$$B = \frac{var(y_i)}{var(y_i) + var(y)} \quad (2)$$

The idea of the James-Stein encoder is to shrink the category's mean target towards a more median average.

As most of the features do not fall into a Gaussian distribution, in this experiment, we have applied min-max scaling to scale the features from 0 to 1.

TABLE I
DATA DESCRIPTION OF NUMERICAL FEATURES

Feature Name	Description
visited_cart	How many times did the user visit the "Cart" page so far in the current visit.
total_add_cart	How many products did the user add to the shopping cart.
total_clicked_products	How many times did the user click on products or visit the "Product Page" of products.
session_length_steps	Length of the visit in steps/events.
session_length_sec	Length of the visit in seconds.
mean_viewed_price	Mean price of clicked products.
max_viewed_price	Max price of clicked products.
min_viewed_price	Min price of clicked products.
sum_viewed_price	Sum price of clicked products.
total_orders	Total orders the user checked out so far.
total_purchased_sum	Total sum of orders the user checked out so far.
total_visits	Total previous visits of the users.
returning_visitor	Is it a new or returning user.
customer_since_days	Total minutes since user's first visit.
cart_sum	The sum of the shopping cart the user has/sees it right now.
cart_total_prd	Total products the user has in the shopping cart.
cart_total_sale_prd	Total discounted products the user has in the shopping cart.
cart_total_prd_in_sale	The ratio of discounted products vs non discounted products in the cart.
cart_total_saved	The amount of money the user is saving due to the presence of sale products in the cart.
cart_sum_without_discount	Total sum of the cart on original price of the products.
cart_total_saved_%	Total percentage of saved money in the cart.

TABLE II
DATA DESCRIPTION OF CATEGORICAL VARIABLES

Feature Name	Description
landing_page	The page where the user started the visit.
week_day	Day of the week
origin	From which origin did the user land on the store.
utm_source	From which source did the user land on the store.
utm_medium	From which medium did the user land on the store.
device	The user's device type.

Then, during the data modeling phase, we have followed a proper and systematic workflow that has been illustrated in Fig. 2. This workflow has been started just the completion of the data preprocessing steps. At first, we have segregated the entire processed dataset into training (=80%) and validation (=20%) data to eliminate biases during the model evaluation phase. Then, in the second stage, we have chosen the ML algorithms based on the objectives as well as the characteristics of the data. In this study, we have applied 5 SOTA algorithms such as XGBoost [9], LightGBM [10], CatBoost [11], mGBDTs [13], and TabNet [12] not only targeting the best prediction output but also with a special focus on interpreting the models. To create a baseline performance, we have also included a DNN model.

Then in the evaluation phase, we have applied 5 evaluation metrics namely Accuracy, Precision, Recall, $f_{0.5}$ -score, and ROC-AUC. The fourth and most important step is to tune the hyperparameters of the model very attentively to obtain the best prediction output without over-fitting or under-fitting. For

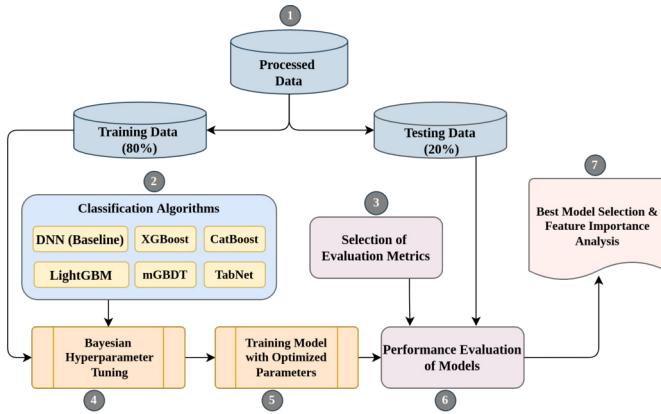

Fig. 2. Flow-diagram of Data Modeling

MODEL PERFORMANCE ON TRAINING AND TESTING DATA.

		ROC -AUC	Precision	Recall	$f_{0.5}$ Score	Accu- racy
DNN	Train	0.565	0.586	0.972	0.858	0.606
	Test	0.565	0.585	0.971	0.636	0.606
XGBoost	Train	0.798	0.742	0.778	0.771	0.802
	Test	0.753	0.689	0.729	0.720	0.758
CatBoost	Train	0.804	0.755	0.779	0.774	0.809
	Test	0.755	0.694	0.725	0.719	0.760
LightGBM	Train	0.782	0.724	0.759	0.752	0.786
	Test	0.746	0.680	0.723	0.714	0.751
TabNet	Train	0.757	0.688	0.746	0.733	0.739
	Test	0.730	0.655	0.722	0.702	0.723
mGBDT	Train	0.793	0.743	0.764	0.760	0.798
	Test	0.733	0.673	0.694	0.690	0.741

tuning the hyperparameters, the Bayesian approach has been chosen in this experiment since it takes less time compared to others to find the best set of parameters and improves generalization performance on the test data. After getting the optimized hyperparameters for all of the models, in the fifth stage, we have trained our models using the training dataset. With the completion of the training phase, we went on to the sixth stage, in which we have utilized the trained models to make predictions on the unseen validation dataset and track their performance against each evaluation metric. Then, in the following step, we have compared the performance among the models to figure out the best model for this particular business problem.

III. BEST MODEL AND FEATURES SELECTION

In this phase, we have divided our analysis into two parts. We have started the analysis by explaining the performance of each model and selecting the best model from their comparison. Finally, we have explored the top features of our best model to find insight that can help to make important business decisions.

Table III shows both of the training and testing results for each of the models of our experiment. From the Table III, it can be observed that our obtained test results are very close to the training results, which indicates that the model has learned

the underlying patterns well from the data without over-fitting. By considering the business problem we were trying to solve, we have mainly focused on Precision, $f_{0.5}$ -score, and Accuracy. Significantly, it has been appeared that all the models have been performed better than our baseline DNN model in terms of Precision, $f_{0.5}$ -score, and Accuracy. Although TabNet pretrained model performs well for tabular data, in our case it fails to outperform the tree-based models. Similarly, the mGBDT fails to outperform the other non-differentiable boosting algorithms. All of the tree-based boosting algorithms: XGBoost, Catboost, and LightGBM have yielded the results close to each other. Comparing the results of each models, it can be seen that CatBoost has consistently outperformed all other models with accuracy (=0.76) and precision (= 0.694). As the conclusion of all comparisons, we chose CatBoost as the best performing model for checkout prediction.

Furthermore, we have extracted the most effective 5 features from the CatBoost classifier. Table IV shows the best features in descending order based on the feature importance.

TABLE IV
FEATURE IMPORTANCE (TOP 5) OF CATBOOST CLASSIFIER

Rank	Features	Importance(%)
1	total visits	14.09
2	customer since days	13.56
3	total purchased sum	6.46
4	max viewed price	5.90
5	min viewed price	5.75

TABLE V
EXAMPLES FROM VALIDATION DATA FOR LOCAL EXPLANATIONS.

Features	Instance 1	Instance 2

checkout_status	not-checkout	checkout

IV. MODEL EXPLANATION AND DECISION SUPPORT

To make our model's decision more transparent, in this study, we have built a support system using the model agnostic local explanation technique, LIME [14]. This method will assist us in comprehending the factors that influence a complex black-box model around a single instance of interest.

In the following Table V, we have taken two instances from the unseen validation data for local explanations. Instance 1 has a checkout-abandonment status, and Instance 2 has a checkout status. The prediction and explanations for these examples can be found in Fig. 3 and 4.

Fig 3 illustrates the decision rules and feature significance based on which the CatBoost model made the decision for instance 1, which was actually abandoning the checkout after adding items to the cart. We can observe that the model predicts with a 95% probability that this person will abandon the checkout. Also, the aforementioned 3 most important features: "total visits", "customer since days", and "total purchased sum" significantly influenced the model to decide in favor of checkout abandonment.

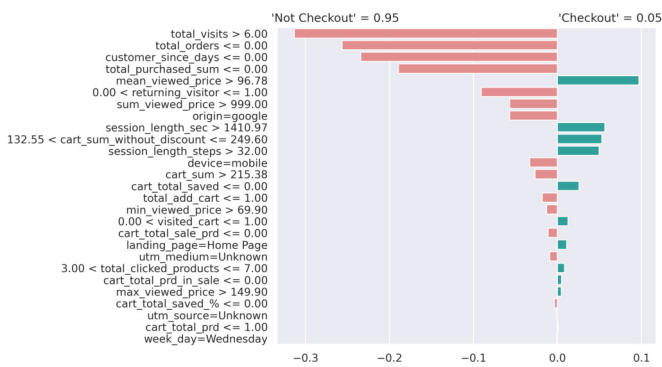

Fig. 3. Explanation of instance 1.

In Fig 4, we can observe that the model predicts with 99% probability that instance 2 will checkout the added item which is actually correct. From the value of "customer since days" feature, it is obvious that being the old customer gave the model confidence that instance 2 will checkout the products.

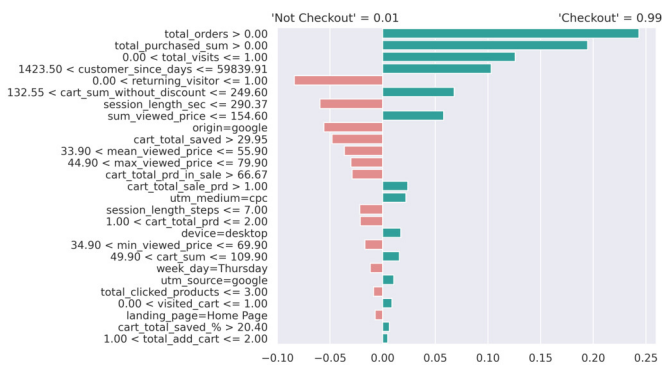

Fig. 4. Explanation of instance 2.

The aforementioned illustrations of local explanations of predictions for individual examples can immensely assist business analysts or decision-makers in making meaningful and unbiased decisions. Especially, this explanation technique can especially assist in making decisions in confusing situations where it is difficult to decide whether a person will checkout the items from the cart or not.

V. CONCLUSION

In this study, we have aimed to minimize the checkout abandonment rate, which is a key concern in modern e-commerce business, by proposing an end-to-end system. One of the most important components of the system is the ML model that predicts the probability of checkout abandonment for each of the customer. Also, it provides the explanation of the decision taken by the model for further business support. In case of predictive analytics, the CatBoost was found as the best performer with 0.694 (Precision), 0.719 ($f_{0.5}$ -score), and 0.76 (Accuracy). For reliable decision making with additional support, we have integrated the LIME, that interprets the model's output as well as extract the decision rules.

{grzegorz.rypec.stud, lukasz.lepak.dokt, pawel.wawrzynski}@pw.edu.pl

Abstract—In simultaneous machine translation (SMT), an output sequence should be produced as soon as possible, without reading the whole input sequence. This requirement creates a trade-off between translation delay and quality because less context may be known during translation. In most SMT methods, this trade-off is controlled with parameters whose values need to be tuned. In this paper, we introduce an SMT system that learns with reinforcement and is able to find the optimal delay in training. We conduct experiments on Tatoeba and IWSLT2014 datasets against state-of-the-art translation architectures. Our method achieves comparable results on the former dataset, with better results on long sentences and worse but comparable results on the latter dataset.

I. INTRODUCTION

SIMULTANEOUS machine translation (SMT) can be defined as producing output sequence tokens while reading input sequence tokens in an on-line fashion. These tokens may represent words in given languages, chunks of audio streams, or any other sequential data. The main difference between SMT and more general neural machine translation (NMT) is how the input and output sequences are processed. Most NMT methods read all input tokens and then generate the output sequence. Because of this, even though efficient state-of-the-art NMT methods exist, they cannot be used in SMT applications. Also, SMT methods need to consider the trade-off between delay and quality, as faster translation implies less context from the input. In most cases, this trade-off has to be optimized by checking various parameter settings, which is resource- and time-consuming.

SMT can be decomposed into a sequence of readings of the input tokens and writings of the output tokens. Reinforcement learning (RL) [1] is often applied to train SMT systems that sequentially choose between these actions and/or choose the written token. In this paper, we present an RL-based method with self-learning delay. Unlike in other approaches, we apply bootstrapping in training, which means that the sequences translated can be in principle infinite. We conduct experiments on Tatoeba and IWSLT2014 datasets against state-of-the-art translation architectures. Our method achieves comparable results on the former dataset, with better results on long sentences and worse but comparable results on the latter dataset.

The paper is organized as follows. Section II overviews literature related to neural machine translation, reinforcement learning, and simultaneous machine translation. Section III formally defines the problem considered in this paper. Section IV presents our method. Section V describes simulations

evaluating the presented architecture. Section VI discusses the experimental results and limitations of our approach. Section VII concludes the paper.

II. RELATED WORK

a) Neural machine translation (NMT): A basic architecture for neural machine translation includes an encoder that is fed with the input sequence; its final state becomes the initial state of a decoder that produces the output sequence [2]. In order to produce the right output, attention must be paid to significant input tokens. Attention was introduced to the encoder-decoder architecture in [3] and [4]. An architecture for NMT that is based solely on attention is Transformer [5]. Recurrent neural networks (RNN) were applied to capture short-term dependencies in input sequences and combined with multilayer attention in R-Transformer [6]. However, all these architectures only produce output when given the whole input sequence and hence are not applicable to on-line translation.

b) Reinforcement learning (RL): RL is a general framework for adaptation in the context of sequential decision making under uncertainty [1]. In this framework, an agent operates in discrete time, at each instant observing the state of its environment and taking action. Subsequently, the environment state changes, and the agent receives a numeric reward. Both the next state and the reward result from the previous state and action. By repeatedly facing the sequential decision problem in the same environment, the agent learns to designate actions in current environment states to be able to expect the highest future rewards.

In the context of this paper, especially interesting is the case where the agent cannot observe its state but only the value of a certain function of the state. This case is modeled as the Partially Observable Markov Decision Process (POMDP) [7]. In this model, the agent needs to collect subsequent observations to be able to recognize its current situation at any specific time. This can be done effectively with an RNN. Deep Recurrent Q-Learning [8] is an RL method for POMDP, which applies an RNN for that purpose.

RL has been applied to neural machine translation to optimize a policy, which, given an input sentence, assigned maximum probability to the corresponding output sentence. RL was applied this way to optimize the translation quality expressed in BLEU [9] which is not directly differentiable. RL has also been applied to train a random generator of sentences in

a generative adversarial architecture [10]. A similar architecture has been applied for the sequential generation of graphs [11].

c) *Simultaneous Machine Translation (SMT)*: A number of SMT methods use reinforcement learning. One of the first examples of using RL for SMT was presented in [12]. It uses imitation learning from the optimal sequence of actions to learn a policy for the system. In [13], a two-action framework was introduced, where the agent can read an input token, named READ, or write a new output token, named WRITE. This framework serves as a baseline for many new SMT methods, with authors extending and modifying it to achieve better results. The proposed reward function is based on the achieved BLEU score [14] and the translation delay metrics proposed by the authors, with the trade-off between delay and translation quality controlled by setting appropriate parameter values. In [15], a third action was added, named PREDICT, which works similarly to READ, but instead of reading an input token, it predicts this token. The reward function was also changed to include predictions' quality, with delay-quality trade-off still controlled by parameters. In [16], a commonly used NMT encoder-decoder structure was modified to work with SMT by making encoder, and attention dynamically change after every READ and adding an incremental decoder, which outputs a token from them after every WRITE. In [17], a method was proposed for extracting action sequences from NMT architectures, which were later used with sentence pairs in imitation learning to learn an optimal policy. Recently, reinforcement learning was used in multimodal translation [18], utilizing text and visual data to improve the quality of translations.

Not every SMT method uses reinforcement learning. In [19], the "wait- k " strategy was proposed, which produces a new output token with a fixed delay equal to k . It can be easily implemented in commonly used NMT architectures, shown by modifying the original Transformer. In [20], the "wait- k " strategy was used in speech-to-text task, showing it is efficient in applications other than machine translation.

III. PROBLEM DEFINITION

We consider input sequences, $x = (x_i)_{i=0}^{|x|-1}$, that contain tokens, $x_i \in \mathbb{R}^d$, $d \in \mathbb{N}$. The input sequences correspond to target sequences, $y = (y_j)_{j=0}^{|y|-1}$, $y_j \in \mathbb{R}^{d'}$, $d' \in \mathbb{N}$. The sequences are of variable lengths presented by the $|\cdot|$ function. An *interpreter agent* is fed with subsequent tokens from x and produces tokens of an output sequence, $(z_j)_{j=0}^{|z|-1}$, $z_j \in \mathbb{R}^{d'}$ on the basis of x .

Three special tokens playing various roles exist in both the input and the output space. They are:

- NULL — a missing element,
- EOS — denotes the last element of each sequence,
- PAD — an element concatenated to sequences after EOS for technical reasons.

For brevity, we will assume $x_i = \text{PAD}$, $y_j = \text{PAD}$, $z_j = \text{PAD}$ for, respectively, $i \geq |x|$, $j \geq |y|$, $j \geq |z|$.

Given x , the agent should produce z that minimizes the quality index in the form

$$J(y, z) = \sum_{j=0}^{K-1} L(y_j, z_j). \quad (1)$$

The loss L penalizes mistranslation; $L(\text{PAD}, \text{PAD}) = 0$; K is a number larger than any $|y|$. The sequence z that minimizes (1) is of length $|y|$, contains tokens equal to those in y , and ends with EOS.

We also require the interpreter agent to be of limited capacity but handle sequences of arbitrarily large lengths. In other words, we require the agent to operate on-line, i.e., it is fed with subsequent tokens of the input sequence and simultaneously produces subsequent tokens of the output sequence.

IV. METHOD

A. Reinforcement learning to transform sequences

We formalize the transformation of one sequence into another as an iterative decision process. At each of its instants, an agent reads a subsequent token from the input sequence or writes a subsequent token of the output sequence, similarly to [13]. That is, at each instant, the agent executes one of two actions:

- READ — another input token is read. This action is useful when it is (still) unclear what output token should be produced.
- WRITE — a subsequent output token is produced. This action is useful when a certain comprehensive portion of input tokens have been read, and a subsequent part of its interpretation can be presented.

A *policy* is a method of selecting actions and producing output tokens based on tokens read and those produced so far.

After execution of some of the actions, the agent receives numerical *rewards*. Let the rewards received during the process be denoted by $r = (r_k)_{k=0}^{|r|-1}$. A reward, r_k , is emitted at the following times:

- An output token, z_j , has just been written. Then r_k is the negative cost of mistranslation, i.e.

$$r_k = -L(y_j, z_j). \quad (2)$$

- A whole input sequence has been read, and the READ action is taken. This action does not make sense at this time. Therefore, for a certain constant $M > 0$, we have

$$r_k = -M. \quad (3)$$

Let $n(t)$ be the number of rewards emitted before the t -th action. The quality criterion for the policy is maximization of future discounted rewards. That is, at each time t the expected value of the *return*

$$R_t = \sum_{k=n(t)}^{|r|-1} \gamma^{k-n(t)} r_k \quad (4)$$

should be maximized, where $\gamma \in (0, 1)$ is a discount factor. In one episode of its operation, the agent transforms a single

Fig. 1: Proposed architecture for on-line sequence transformation. The black squares represent passing/delaying x_i and outputting/skipping N_t^p depending on the action a_t .

sequence. It stops producing additional output tokens when it has outputted EOS.

In training, the agent, not having learned how to finish sequences, must be prevented from producing them infinitely long. Here we assume that an episode of training is terminated when the agent has produced as many tokens as in the target sequence y . The last target token is EOS, which is enough for the agent to learn to finish the output sequences.

Usually, in reinforcement learning [1] a reward comes after each action. However, here we want the agent to be rewarded only for the tokens it produces, bearing in mind that it does not produce them with READ actions. Rewards equal to zero for such actions do not make sense here because they could encourage the agent to maximize the sum of discounted rewards by postponing the production of output. Therefore, here we admit actions that are not immediately followed by rewards. Those emitted rewards have their own indices and are discounted according to them.

At each instant of its operation, a *state* of the agent's environment consists of the tokens the agent has read so far and the tokens it has written so far. However, before taking another action, it is only fed with the next input token and with the last written token. Therefore, the agent's environment is partially observable.

B. Architecture

We propose an architecture that learns to make the actions discussed above. The policy has the form of a recurrent neural network. Its input size is $d + d'$. In an instant of its operation it is fed with a subsequent input token concatenated with a preceding output token. Specifically, the first input to the network is the pair (x_0, NULL) . Let us assume that the agent has already read i input tokens and produced j output tokens. Thus, after the READ action, the network input is (x_i, NULL) . After the WRITE action, the network input is (NULL, z_{j-1}) .

In training *teacher forcing* can also be applied: The agent is fed not with the tokens it has already outputted but with target tokens.

Output of the network is of size $d' + 2$. The network produces a d' -dimensional *potential output token* and 2 scalar *return*

estimates that approximate returns (4) expected if actions WRITE and READ, respectively, were taken.

Let N_t be the $d' + 2$ -dimensional output of the network at t -th instant. It is composed as

$$N_t = [N_t^p, N_t^W, N_t^R],$$

where $N_t^p \in \mathbb{R}^{d'}$ is the potential output token, and $N_t^W, N_t^R \in \mathbb{R}$ are the return estimates for the WRITE and READ actions, respectively. The architecture is depicted in Fig. 1.

The network output that estimates the return corresponding to the just taken action a_t is trained to approximate the conditional expected value

$$Q_t(a_t) = E(R_t | C_t), \quad (5)$$

where the condition C_t includes the following:

- 1) The action just taken is a_t .
- 2) Subsequently, those actions are selected, which correspond to the network return estimates with maximum values.
- 3) Input tokens read so far, and output tokens produced so far. At the time t , the rest of the tokens are unknown, thereby remaining random vectors.

The actions actually taken are usually selected as those maximizing the return estimates given by the network. However, with a small probability, the agent chooses the other action since it needs to explore different actions to learn their consequences. Therefore, we will not estimate $Q_t(a_t)$ based on the actual return, but on a recursion instead. Specifically, let us denote by j the number of output tokens produced before the analyzed action is taken. A simple analysis reveals that $Q_t(a_t)$ (5) satisfies the following recursive equation:

$$Q_t(a_t) = E \left\{ \begin{array}{l} -M + \gamma \max_b Q_{t+1}(b) \\ \quad \text{if } a_t = \text{READ}, \text{fin}(x) \\ \max_b Q_{t+1}(b) \\ \quad \text{if } a_t = \text{READ}, \neg \text{fin}(x) \\ -L(y_j, z_j) + \gamma \max_b Q_{t+1}(b) \\ \quad \text{if } a_t = \text{WRITE}, j < |y| - 1 \\ -L(y_j, z_j) \\ \quad \text{if } a_t = \text{WRITE}, j = |y| - 1 \end{array} \middle| a_t \right\} \quad (6)$$

where $\text{fin}(x)$ means that all x tokens have been read. The condition for the above expectation is that the action actually taken is a_t .

Target values for the network will be based on the above recursive equation and the fact that $Q_{t+1}(\text{READ})$ and $Q_{t+1}(\text{WRITE})$ are estimated by N_{t+1}^R and N_{t+1}^W , respectively. Therefore, the network outputs at time t are trained as follows.¹ After the READ action, when x is not finished yet, N_t^R is adjusted:

$$N_t^R \leftarrow \max\{N_{t+1}^R, N_{t+1}^W\}. \quad (7)$$

¹We apply the notation:

$$[\text{predicate}] = \begin{cases} 1 & \text{if } \text{predicate} \text{ is true} \\ 0 & \text{otherwise.} \end{cases}$$

After the READ action, when x is already finished:

$$N_t^R \leftarrow -M + \gamma \max\{N_{t+1}^R, N_{t+1}^W\}. \quad (8)$$

After a WRITE action, the return estimate for the WRITE action is adjusted as

$$N_t^W \leftarrow -L(N^p, z_j) + [j < |y| - 1] \gamma \max\{N_{t+1}^R, N_{t+1}^W\}, \quad (9)$$

Also, the potential output is adjusted

$$N_t^p \leftarrow y_j. \quad (10)$$

C. Weighting losses due to mistranslation and return estimation

The network produces outputs of two qualitatively different kinds: the potential output tokens and the return estimates. The network training requires minimization of an aggregated loss that combines a loss due to mistranslation and a loss due to return estimation. We propose to normalize these losses with their averages defined below.

Let $n = 1, 2, \dots$ be a training minibatch index. We average original mistranslation losses, L_n^M , and original estimation losses, L_n^E , according to

$$\bar{L}_n^M = w_n \bar{L}_{n-1}^M + (1 - w_n) L_n^M, \quad (11)$$

$$\bar{L}_n^E = w_n \bar{L}_{n-1}^E + (1 - w_n) L_n^E \quad (12)$$

where $\bar{L}_0^M = \bar{L}_0^E = 0$, and

$$w_n = \rho(1 - \rho^{n-1}) / (1 - \rho^n), \quad (13)$$

where $\rho \in (0, 1)$ is the decay factor, e.g. $\rho = 0.99$. The terms (11,12) approximate arithmetic means for small n , and exponential moving average for larger n .

Training the network aims at minimizing the aggregated loss in the form

$$L_n = L_n^M / \bar{L}_n^M + \eta(n, n_0) L_n^E / \bar{L}_n^E. \quad (14)$$

The term $\eta(n, n_0)$ is a relative weight of the estimation loss for the current minibatch/epoch index n and the (expected) total number n_0 of minibatches/epochs in the whole training. For small n this weight should be small: $\eta(n, n_0) \approx \eta_{min}$, since high accuracy of future rewards is pointless when quality of outputted tokens is poor. $\eta(n, n_0)$ is gradually growing with n to a certain asymptote, η_{max} . η_{min} and η_{max} are hyperparameters of the training process, e.g. 1/50 and 1/5, respectively. The η function may have the form

$$\eta(n, n_0) = \eta_{max} - (\eta_{max} - \eta_{min}) \exp(-3n/n_0). \quad (15)$$

V. EXPERIMENTAL STUDY

In this section, we demonstrate the effectiveness of our proposed architecture, henceforth called RLST (Reinforcement Learning for on-line Sequence Transformation). We perform experiments with seven machine translation tasks. They are based on datasets taken from Tatoeba [21] and dataset taken from IWSLT2014 [22].

In our machine translation tasks, the input sequence consists of tokens representing words of a sentence in a source language. The aim is to generate a sequence of tokens with

the same sentence meaning as the source sequence. We conduct experiments on datasets presented in Table I which contains basic statistics on the source and target languages datasets, sizes of source and target dictionaries, and numbers of sentences in each data split. For Tatoeba datasets, we also separate long test splits, where source sentences have more than 22 tokens. The long test split allows us to compare how models deal with longer input sentences. For all datasets, we compare our proposed RLST architecture with state-of-the-art machine translation architectures, namely encoder-decoder with attention [3] and Transformer [5]. For both encoder-decoder and Transformer, the minimized loss is cross-entropy. For RLST, we quantify L_n^M and L_n^E in (14) as cross-entropy and mean square error, respectively.

In our experiments, we employed the following procedure to optimize hyperparameters of the compared architectures. For Tatoeba datasets, we optimized the hyperparameters manually for all three architectures to obtain their best BLEU score [14] on the En-Es language pair and applied these values to all language pairs. For IWSLT2014 datasets, we optimized the hyperparameters of RLST manually and took the hyperparameters for the Transformer from [5] and for the encoder-decoder with attention from [23].

Our simulation experiments have been performed on a PC equipped with AMD Ryzen™ Threadripper™ 1920X, 64GB RAM, 4xNVIDIA™ GeForce™ RTX 2070 Super™.

A. Tatoeba

Tatoeba datasets [21] contain various, mostly unrelated, sentences and their translations provided by the community. We preprocess them using spaCy tokenizer [24] and replace tokens that appear in training corpora less than three times with a unique token representing an unknown word. We also remove duplicated source sentences.

Experiments on Tatoeba for all architectures are run for 50 epochs, with a batch size of 128 and gradient clipping norm set to 10.0. Encoder-decoder and RLST have weight decay set to 10^{-5} , while Transformer has weight decay set to 10^{-4} . Source and target tokens are converted to trainable vectors of length 256 initialized with $\mathcal{N}(0, 1)$. There is a dropout applied to them with a probability of 0.2. We use Adam optimizer with default parameters and a constant learning rate equal to 0.0003. The reference encoder-decoder is presented in [3]. Its encoder is a bidirectional GRU recurrent layer with 256 hidden neurons followed by a linear attention layer with 64 neurons. The decoder is a GRU recurrent layer with 256 hidden neurons followed by a dropout with 0.5 probability and a linear output layer with a number of neurons equal to the target's vocabulary size. The teacher forcing ratio for encoder-decoder during training is set to 1.0. For the Transformer, we use the following parameters: the number of expected features in the encoder and decoder inputs is 256, the number of heads in multiattention is 8, the number of encoder and decoder layers is 6, the dimension of feedforward layers is 512, the dropout probability is 0.25 and the teacher forcing ratio to 1.0. For RLST, we use the following approximator. Input and

Dataset	Abbr	Src. dict.	Trg. dict.	Train set	Valid. set	Test set	Long test

TABLE I: Basic statistics of machine translation datasets.

previous output embeddings with a dimension of 256 are passed to a dense layer with 512 neurons, Leaky ReLU activation with negative slope set to 0.01 and dropout probability of 0.2. Its output is processed by four GRU layers with the hidden dimension of 512 and residual connections between them. The output of the last recurrent layer is passed to a dense layer with 512 neurons, Leaky ReLU activation with a negative slope set to 0.01, and a dropout probability of 0.5. The output of the last dense layer is passed to the output linear layer with number of neurons equal to the target’s vocabulary size and additional 2 neurons representing Q-values of actions. We also set $\gamma = 0.9$, $\varepsilon = 0.3$, $M = 3$, $N = 50000$, $\eta_{min} = 0.02$, $\eta_{max} = 0.2$, $\rho = 0.99$ and teacher forcing ratio to 1.0.

B. IWSLT2014

We conduct experiments on IWSLT2014 German-English and English-German datasets using the *fairseq* framework [22]. Data is preprocessed using the script provided by the benchmark, which utilizes byte-pair encoding (BPE) [25]. For every architecture, the training lasts for 100 epochs with varying batch sizes to ensure that the maximum number of tokens in a batch equals 4096 and the gradient clipping norm is set to 10.0. The encoder-decoder and RLST architectures are trained using Adam optimizer with default parameters and constant learning rate scheduling with weight decay of 10^{-5} . The Transformer is also trained using Adam optimizer, with parameters and a learning rate scheduler described in [5]. For the encoder-decoder and the Transformer, we use the *lstm_wiseman_iwslt_de_en* architecture (based on [23]) and *transformer_iwslt_de_en* (based on [5] with some changes), respectively. The encoder-decoder model has trainable source and target embeddings dimensions of 256 without dropout. Its encoder is an LSTM layer with 256 hidden neurons, and its decoder was also an LSTM layer with 256 hidden neurons followed by an output layer with the number of neurons equal to the target’s vocabulary size. The decoder uses the attention mechanism. The encoder and decoder layers have a dropout probability of 0.1. The Transformer has the following parameters: The trainable source and target embeddings dimensions are 512 without dropout, the number of neurons in feedforward layers is 1024, the number of multiattention heads is 4, the number of encoder and decoder layers is 6 and a dropout probability of 0.1. For RLST, we set trainable source and target embedding dimensions to 256 with a dropout of 0.2 probability. In the case of IWSLT-En-De, we

use the same approximator as in Tatoeba. For IWSLT-De-En, we changed the dimensions of dense and GRU layers from 512 to 768. We also set $\gamma = 0.9$, $\varepsilon = 0.30$, $M = 7$, $N = 100000$, $\rho = 0.99$, $\eta_{min} = 0.02$, $\eta_{max} = 0.2$ and teacher forcing ratio to 1.0. For encoder-decoder and Transformer, we set beam search width to 1 and teacher forcing ratio to 1.0.

C. Results

The results are presented in Table II. For each dataset and architecture, we show BLEU values computed on a test split from checkpoints for which the BLEU value on a validation split was the highest. We also show the number of parameters for each model. The highest values of BLEU for each dataset are bolded. On the Tatoeba test confined to sentences of length up to 22 words, all three architectures achieved similar BLEU. However, in the test confined to longer sentences, RLST outperforms the other architectures in 4 language pairs out of 5, usually by a large margin. The architecture to achieve the best results on fairseq datasets is the Transformer. RLST and the encoder-decoder with attention achieve similar BLEU on this benchmark.

In order to gain an additional insight into the operation of the RLST interpreter agent we present in Figure 2 the timing of taking the READ and WRITE actions. As one may expect, initially, the agent is mostly reading, then reading and writing ratios are roughly equal, and finally, the agent is mostly writing. It appears that the agent has read about five more words than it has written for most of the time. That seems to correspond to a common intuition: A human interpreter also needs to be delayed a few words in producing an accurate translation of a speech.

VI. DISCUSSION

Our proposed interpreter agent RLST is designed to transform arbitrarily long sequences on-line. In each cycle of its operation, it performs the same number of computations in which it reads an input token or writes an output token. The agent has only limited memory space to store information about recently read tokens, a context of these tokens defined by previous ones, and recently written tokens. Therefore, the agent is not a method of choice for translating sentences of moderate length without any context.

The RLST architecture outperformed others in the test on long sentences (longer than 22 words) taken from Tatoeba. The memory state of the interpreter agent preserved the context

Architecture → Dataset ↓	Encoder-decoder		Transformer		RLST

of the outputted words better than the attention mechanism managed to do in the reference architectures. We hypothesize that the sequential nature of human language makes it possible to translate properly separate parts of a speech, but in order to do that, the end of each part must be identified. It appears that RLST manages to do it better in long sentences than the reference architectures.

The goal of a large fraction of algorithms developed in computer science is to transform input data into output data whose size is unknown in advance. For some data types, it is natural to process them sequentially. These types include natural language, sound, video, and bioinformatic data, e.g., genetic. The experiments in Section V confirm that our introduced RLST architecture is very well adapted to such data.

VII. CONCLUSIONS

In this paper, we have presented the RLST architecture that transforms on-line sequences of arbitrary length without the need to define the trade-off between delay and quality. In the transformation process, it makes sequential decisions about

whether to read an input token or write an output token. The architecture learns to make these decisions with reinforcement. The experimental study compared the architecture with state-of-the-art machine translation methods, namely the Transformer and the encoder-decoder with attention. Benchmark datasets taken from Tatoeba and IWSLT with seven language pairs were employed in the experiments. The RLST architecture solved a more complex problem of on-line transformation than the reference methods, which produced output tokens knowing the entire source sequence. Even so, RLST produced translations of comparable quality. It also outperformed reference architectures in tests with long sentences (longer than 22 words) taken from Tatoeba. That confirms that it is particularly well suited to applications in which transformation of sequences of arbitrary lengths and/or on-line is required.

Abstract—We introduce a new loss function based on cross entropy and SoftTriple loss, TripleEntropy, to improve classification performance for fine-tuning general knowledge pre-trained language models. This loss function can improve the robust RoBERTa baseline model fine-tuned with cross-entropy loss by about 0.02–2.29 percentage points. Thorough tests on popular datasets using our loss function indicate a steady gain. The fewer samples in the training dataset, the higher gain—thus, for small-sized dataset, it is about 0.71 percentage points, for medium-sized—0.86 percentage points, for large—0.20 percentage points, and for extra-large 0.04 percentage points.

I. INTRODUCTION

NATURAL language processing (NLP) is a rapidly growing area of machine learning with applications wherever a computer needs to operate on a text that involves capturing its semantics. It may include text classification, translation, text summarization, question answering, and dialogues. All these tasks are downstream and depend on the quality of the text representation [1]. Many models can produce such text representations, from Bag-of-Word (BoW) or Word2Vec word embedding to the state-of-the-art language representation model BERT with variations in most NLP tasks.

The best performance on text classification tasks is obtained when the model is first trained on a general knowledge corpus to capture semantic relationships between words and then fine-tuned with an additional dense layer on a domain corpus with cross-entropy loss [2].

We introduce a new loss function – TripleEntropy – to improve classification performance for fine-tuning general knowledge pre-trained language models based on cross-entropy loss and SoftTriple loss [3], [4]. Triplet Loss transforms the embedding space so that vector representations from the same class can form separable subspaces, stabilizing and generalizing the language model fine-tuning process. TripleEntropy can improve the fine-tuning process of the RoBERTa based models, so the performance on downstream tasks increases by about 0.02 - 2.29 percentage points.

In the following sections, we review relevant work on state-of-the-art in distance metric learning (Section II); describe our approach for training and our metric SoftTriple loss and outline the experimental setup (Section III); discuss the results

(Section IV); conclude and offer directions for further research (Section V).

II. RELATED WORK

A. Building Sentence Embeddings

Building embeddings that represent sentences is challenging because the natural language can be very diverse. The meaning can change drastically depending on the context of a word. It is also an important issue because the quality of sentence embeddings substantially impacts the performance of all downstream tasks like text classification and question answering. Because of that, so far, considerable research effort has been put into building sentence embeddings.

One of the first vector representations (embeddings), BoW, is an intriguing approach in which the text is represented as a bag (multiset) of its words, with each word represented by its occurrence in the text [5]. The disadvantage of this strategy was that the BoW embeddings fail to capture hidden meaning of words and sentences, unlike the Word2Vec approach, which used a machine learning process to predict word embeddings [6] and is able to represent the latent meaning of the word. In Word2Vec, each word embedding is selected based on its overall context in the training corpus and can express the latent semantics of words. Unfortunately, this method does not express the semantics of the whole sentence, so several approaches have been proposed to solve this problem. The most popular approaches build the sentence embedding as a weighted average of the sentence's word vectors. Since in Word2Vec every word embedding is static, regardless of its meaning in the whole sentence, this approach is not adapted to changes in sentence and context semantics.

Bidirectional Encoder Representations from Transformers (BERT) is a well-known technique for constructing high-quality sentence embeddings that can express the dynamic and latent meaning of the whole sentences better than any previous approach. Its sentence embeddings can accurately reflect the meaning of the input text, making a significant difference in the quality of the downstream tasks performed. An even better variant of the BERT-based architecture, RoBERTa, has

emerged and has lately become unquestionably state-of-the-art in terms of sentence embedding construction [7], [8].

B. Distance Metric Learning

Embedding learning that exploits the fact that instances from the same class are closer than instances from other classes is known as Distance Metric Learning (DML) [4]. DML recently has drawn much attention due to its wide applications, especially in image processing. It can be used in the classification tasks together with the k-nearest neighbour algorithm [9], clustering along with K-means algorithm [10] and semi-supervised learning [11]. DML's objective is to create embeddings similar to examples from the same class but different from observations from other classes. [12]. In contrast to the cross-entropy loss, which only takes care of intra-class distances to make them linearly separable, the DML approach maximizes inter-class and minimizes the intra-class distances [13]. Aside from that, a typical classifier based solely on cross-entropy loss concentrates on class-specific characteristics rather than generic features of the dataset, as it is only concerned with distinguishing between classes rather than learning their representations. DML focuses on learning class representations, making the model more generalizable to new observations and more robust to outliers. There are various DML methods in use today, of which the following are the most important.

1) *Contrastive Loss*: Contrastive Loss (CL) is one of the earliest methods in DML [14]. It concentrates on pairs of similar and dissimilar observations¹, whose distances are attempted to be minimized if they belong to the same class and maximized if they belong to different classes. The CL method is given in Equation 1.

$$\ell = \sum_{i=1}^N \left[(1 - y_i) \frac{1}{2} (d(z_i^1, z_i^2))^2 + (y_i) \frac{1}{2} \left\{ \max(0, m - d(z_i^1, z_i^2)) \right\}^2 \right] \quad (1)$$

where i denotes the index of a pair of representations z_i^1, z_i^2 of the sample pair x_i^1, x_i^2 from the set of all pairs \mathcal{P} in the training set with the cardinality N . y_i denotes label assigned to the i th pair. It has a value of 0 if the associated samples x_i^1 and x_i^2 belong to the same class, otherwise it has a value of 1. $d()$ is the Euclidean distance functions between a pair of representations z_i^1, z_i^2 . $m > 0$ is the margin beyond which dissimilar points have no effect on the loss.

2) *Triplet Loss*: Triplet Loss, as another solution to the DML problem, is similar to Contrastive Loss but works with triplets instead of pairs [15]. Each triplet comprises an anchor, a positive, and a negative observation. Positive examples are members of the same class as an anchor, but negative instances belong to a separate class. Because it considers more observations simultaneously, it optimizes the embedding space

¹In this paper we use: observations, samples, examples as synonyms. We even refer to sentences as observations because most datasets contain one sentence as an observation, i.e., the input to the ML model

better than Contrastive Loss. The actual formula for Triplet Loss is in Equation 2.

$$\ell = \sum_{i=1}^N \left[\|z_i^a - z_i^p\|_2^2 - \|z_i^a - z_i^n\|_2^2 + m \right]_+ \quad (2)$$

where i is the index of a triplet of representations z_i^a, z_i^p, z_i^n of the samples x_i^a, x_i^p, x_i^n from the set of all triplets \mathcal{T} in the training set with the cardinality N . x_i^a denotes an *anchor*, x_i^p (*positive*) is the observation from the same class as the anchor, x_i^n (*negative*) denotes an observation belonging to a different than the anchor class, m is a margin imposed between positive and negative pairs margin.

The most typical issue with triplets and contrastive learning is that as the number of observations in a batch grows, the number of pairs and triplets grows squarely or cubically. Another point is that using training pairs and triples, which are relatively easy to distinguish, leads to poor generalization of the model. Semi-solutions of the above problems are as introducing τ a temperature parameter that controls the separation of classes [16], or hard triples, which samples such triplets that the anchor and the positive are not close together, and the anchor and the negative are close together [17].

Triplet Loss has previously been used with the BERT language model to detect whether new claims are similar to a set of claims that were previously fast-checked online [18]. Another interesting work uses self-supervised triplet training to learn similarities for recommendations [19]. The triplet network was also used with the BERT encoder in the domain of protein modelling to solve several regression tasks with limited data such as peak absorption wavelength or enantioselectivity [20].

3) *ProxyNCA Loss*: It is a more general approach to solving a problem with high resource consumption [12]. It employs proxies – artificial data points in the representation space that represent the entire dataset. One proxy approximates one class; therefore, there are as many proxies as classes. This technique drastically reduces the number of triplets while simultaneously raising the convergence rate since each proxy makes the triplet more resistant to outliers. The proxies are integrated into the model as trainable parameters since the synthetic data points are represented as embeddings. Equation 3 depicts a ProxyNCA loss formula.

$$\ell = -\frac{1}{N} \sum_{i=1}^N \log \left(\frac{\exp(-d(z_i, p(y_i)))}{\sum_{p(ne) \in p(Ne_i)} \exp(-d(z_i, p(ne)))} \right) \quad (3)$$

where i denotes the index of the representation z_i of the observation x_i , N indicates the number of observations in the training set, $p(y_i)$ denotes the anchor's proxy, $p(Ne_i)$ denotes proxies representing the different classes that x_i belongs, d is the Euclidean distance between the anchor and the given proxy.

4) *SoftTriple Loss*: A single proxy per class may not be enough to represent the class's inherent structure in real-world data. Another DML loss function introduces multiple

proxies per class - SoftTriple Loss [4]. It can produce better embeddings while maintaining a smaller number of triplets than Triplet Loss or Contrastive Loss. The SoftTriple Loss is defined by the Equations 4, 5 and 6.

$$\ell_{SoftTriple} = -\frac{1}{N} \sum_{i=1}^N \ell_{ST_i} \quad (4)$$

$$\ell_{ST_i} = -\log \frac{\exp(\lambda(S'_{i,y_i} - \delta))}{\exp(\lambda(S'_{i,y_i} - \delta)) + \sum_{j \neq y_i} \exp(\lambda S'_{i,j})} \quad (5)$$

$$S'_{i,c} = \sum_k \frac{\exp\left(\frac{1}{\gamma} z_i^\top w_c^k\right)}{\sum_k \exp\left(\frac{1}{\gamma} z_i^\top w_c^k\right)} z_i^\top w_c^k \quad (6)$$

where N denotes the number of observations in the training set, $c \in C$ indicates the class index, C indicates number of classes, k is the number of proxies per class, δ defines a margin between the example and class centres from different classes, λ reduces the influence from outliers and makes the loss more robust, γ is the scaling factor for the entropy regularizer, z_i defines the representation of the observation x_i , w_c^k denotes proxy embeddings of the class c (there are k of them).

III. OUR APPROACH

For fine-tuning pre-trained language models, we offer a novel objective function TripleEntropy. It is based on the supervised cross-entropy loss and the SoftTriple Loss [4]. The latter component is a loss from the Distance Metric Learning (DML) family of losses, which learns an embedding by capturing similarities between embeddings from the same class and distinguishing them from embeddings from different classes [4].

For the classification problem, let us denote (as in the previous section):

- N – the number of observations,
- $c \in C$ the class index, where C indicates the number of classes,
- y_{ic} – the objective probability of the class c for the i th observation,
- β – the scaling factor that tunes influence of both parts of the loss.

The TripleEntropy is given by the Equation 7:

$$\mathcal{L} = (\beta)\ell_{MCE} + (1 - \beta)\ell_{SoftTriple} \quad (7)$$

where

$$\ell_{MCE} = -\frac{1}{N} \sum_i \sum_c y_{ic} \log(p_{ic}) \quad (8)$$

It can be applied for different encoders $E(\cdot) \in \mathbf{R}^d$ from natural language processing domain such as BERT [3], RoBERTa [7] or others models that create text representations (embedding).

A. Model

In our work, we use the objective function from Equation 7 to fine-tune the pre-trained BERT-based language models provided by the *huggingface* library as RoBERTa-base and RoBERTa-large as depicted in the figure 1. In the standard settings, the single input text is first tokenized with Byte-Pair Encoding (BPE) tokenizer [2], which produces a vector of tokens x_i with a maximum length of 512, with $[CLS]$ at the beginning of an array, $[EOS]$ at the end and $[SEP]$ between tokens representing different sentences. The output of RoBERTa model $E(x_i) \in \mathbf{R}^d$ is an array of embeddings, where each input token has its corresponding embedding.

1) *Multinomial Cross-Entropy Loss*: In our experiments, we used the multinomial cross-entropy (MCE) loss calculated in the same way as it was proposed by the authors of the BERT language model [3]. The sentence representation is obtained by pooling the output of the model $E(x_i) \in \mathbf{R}^d$ and passing it to the C dimensional single fully connected layer. Its output is passed to the softmax function generating probabilities p_{ic} , which are, along with objective probabilities y_{ic} , directly feeding the multinomial cross-entropy loss.

2) *SoftTriple Loss*: The second component of the TripleEntropy loss Equation 7 is SoftTriple Loss Equation 4, responsible for a more robust and better generalization of the model during tuning. It is fed by the direct output of the model $E(x_i) \in \mathbf{R}^d$, even before pooling. It means that if the batch size is B , then the total number of embeddings that feed SoftTriple Loss during one training iteration is $B * |x_i|$. This implementation ensures that the proxies representing each class will be well approximated so that the quality of fine-tuning increases.

Our implementation is a development of the earlier work [21], where Contrastive Loss was applied only to the embedding corresponding to the first $[CLS]$ token of the input vector x_i . We apply SoftTriple Loss to the embeddings corresponding to all tokens from the input vector x_i , which ensures the better generalization of the fine-tuning process but requires more computing power. Fortunately, the SoftTriple Loss is significantly more efficient than the Contrastive Loss since it generates triplets not from all observations but from its approximated proxies.

B. Training and testing

During our experiments, each result (average accuracy) was obtained as based on 4 seed runs (2, 16, 128, 2048), where each run was 5-fold cross-validated. It means that each accuracy result is an averaged of 20 different results. Apart from that, each result was based on the best parameter combination obtained by grid search which included parameters $k \in \{10, 100, 1000, 2000\}$, $\gamma \in \{0.01, 0.03, 0.05, 0.07, 0.1\}$, $\lambda \in \{1, 3, 3.3, 4, 6, 8, 10\}$, $\delta \in \{0.01, 0.1, 0.3, 0.5, 0.7, 0.9, 1\}$ and $\beta \in \{0.1, 0.3, 0.5, 0.7, 0.9\}$. We noticed that for most experiments, the best hyperparameter set is following $k = 2,000$, $\gamma = 0.1$, $\lambda = 3.3$, $\delta = 0.3$ and $\beta = 0.9$.

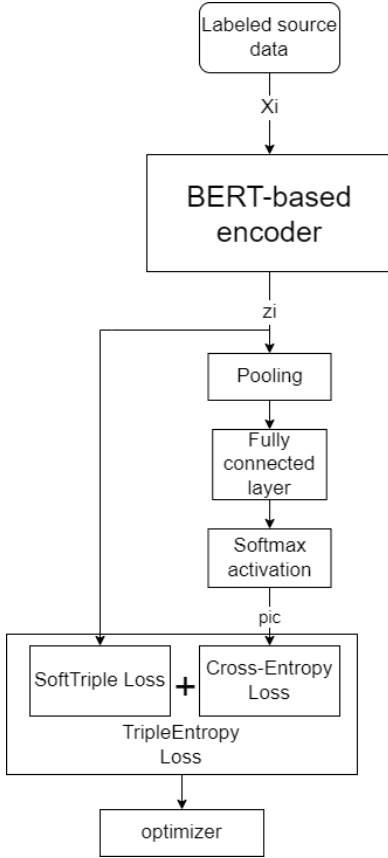

Fig. 1. BERT-based model fine-tuning architecture using TripleEntropy loss as the sum of SoftTriple Loss and Cross-Entropy Loss

C. Datasets

We conducted experiments to assess the usefulness of our TripleEntropy loss. To do so, we employed a variety of well-known datasets from SentEval [22] along with the IMDb [23]. These datasets cover both text classification and textual entailment as two important natural language tasks. Additionally, we have examined the performance of our method when the number of training examples is limited to 1,000 and 10,000 observations on sampled datasets. Table I shows the description of the datasets and their sampled versions.

IV. RESULTS

Our results are presented in the form of a comparison between the performance of the RoBERTa-base (RB) and the RoBERTa-large (RL) models as baselines, followed by the RoBERTa-base with TripleEntropy Loss (RB TripleEntropy) as well as RoBERTa-large with TripleEntropy Loss (RL TripleEntropy). All results shown below are expressed as a weighted F1 score. Moreover, we have created 4 experimental groups depending on the size of the dataset. In the first group, we present results regarding the small-sized datasets with a number of sentences of 1,000. In the second group, we explore results for the medium-sized datasets in which the number of sentences is about 4,000. In the third group, we present

results belonging to the large-sized datasets with a number of sentences of about 10,000. The extra-large-sized group consists of elements where the number of observations is larger than 50,000.

The RB baseline models were trained with the use of AdamW optimizer [30], beginning learning rate $1e-5$, L2 regularization, learning rate scheduler and linear warmup from 0 to $1e-5$ for the first 6% of steps and batch size of 64. The RB TripleEntropy models were trained on the same set of hyperparameters as the baseline models they refer to and additional parameters specific to TripleEntropy Loss, as it is described in Section III-B.

A. RB TripleEntropy for small datasets

Table II presents the results for the datasets containing 1,000 sentences. We observe that models trained using TripleEntropy have a higher performance than the baselines by about 0.71 percentage points. It is worth noting that the gain in performance is observed in each dataset, especially for the TREC-1k and MRPC-1k, where it amounts to 2.29 and 1.11 percentage points, respectively.

B. RB TripleEntropy for medium datasets

Table III shows the results based on the datasets containing about 4,000 sentences. Here, we can observe that models trained using TripleEntropy have higher performance than the baselines by about 0.86 percentage points. The highest gain in performance is observed in the case of TREC and MRPC datasets by 1.00 and 1.28 percentage points, respectively.

C. RB TripleEntropy for large datasets

Table IV shows the results based on the datasets containing about 10,000 sentences. The gain in the performance amounts to 0.20 percentage points.

D. RB TripleEntropy for extra-large datasets

Table V shows the results based on the datasets containing more than 50,000 sentences. The gain in the performance is not as high as in the case of the medium and small-sized datasets, and it is 0.04 percentage points on average, which is not significant.

E. RL TripleEntropy for small datasets

We have compared our results to the related work [21] where the authors claim the performance gains over baseline RoBERTa-large by applying loss function consisted of cross-entropy loss and Supervised Contrastive Learning loss. The work shows the improvement over baseline in the few-shot learning, defined as fine-tuning based on the training dataset consisting of 20, 100 and 1,000 observations. In order to compare our new loss function with the results from the related work, we conducted experiments where the baseline was RoBERTa-large (RL) with cross-entropy loss and compared it to the RoBERTa-large with TripleEntropy loss (RL TripleEntropy) on the dataset consisted of 1,000 observations. Our method yields a gain over baseline of 0.48 percentage points, which is higher than the performance improvement

TABLE I
SENTEVAL AND IMDB DATASETS, AND THEIR SAMPLED SUBSETS, USED IN OUR EVALUATION.

Dataset	# Sentences	# Classes	Sampled sub-sets	Task
SST2	67k	2	10k, 1k	Sentiment (movie reviews)[24]
IMDb	50k	2	10k, 1k	Sentiment (movie reviews) [23]

Model	SST2-XL	IMDb-XL	avg
RB	94.89	87.10	91.00
RB TripleEntropy	94.95	87.12	91.04

over baseline for a dataset of the same size from the related work, in which improvement over baseline is 0.27 percentage points. The results are presented in Table VI.

F. Discussion

Our method improves the performance most significantly for the small-sized dataset by 0.87 percentage points in the case of the RoBERTa-base baseline and 0.48 percentage points in the case of the RoBERTa-large baseline and the medium-sized dataset, where the increase amounts to 0.86 percentage points. For the large-sized dataset, the rise over baseline is 0.20%, while for the extra-large-sized dataset, the gain over baseline amounts to 0.04 percentage points. Our experiments show consistent performance improvement over baseline when using TripleEntropy loss, which is highest for the small and medium-sized datasets and decreases for the large and extra-large sized datasets. It is an improvement over previous related

work, where the performance improvement for the supervised classification tasks was achieved only for the few-shot learning settings [21].

We also conclude that the smaller the dataset is, the higher our new goal function’s performance gain over baseline. This observation is consistent with the conclusions of previous work [21]. The increase is negligible when the dataset is larger than about 10k observations. In addition, our work focuses on datasets of no less than 1k observations, so we do not know how it behaves in the case of few-shot learning, which in contrast, has been well documented in the case of work [21]. The performance comparison between baseline and our method throughout dataset size is depicted in Figure 2.

V. CONCLUSIONS

We proposed a supervised Distance Learning Metric objective that increases the performance of the RoBERTa-base

TABLE VI
WEIGHTED F1 SCORE OF ROBERTA-LARGE (RL) VS ROBERTA-LARGE WITH TRIPLEENTROPY LOSS (RL TRIPLEENTROPY) FOR SMALL DATASETS CONTAINING 1,000 OBSERVATIONS

RL	91.96	90.18	76.09	83.75	93.43	89.69	87.52
RL TripleEntropy	92.14	90.59	77.16	84.59	93.62	89.89	88.00

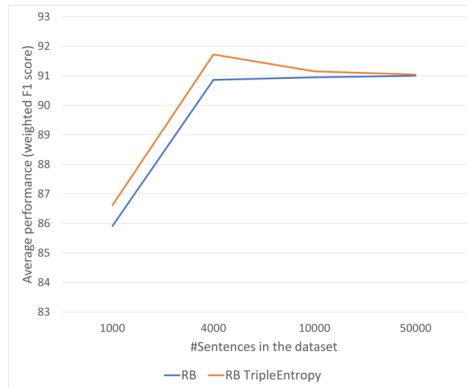

Fig. 2. Performance comparison between RB and RB TripleEntropy

models, which are strong baselines in the Natural Language Processing tasks. The performance is improved over multiple tasks from the single sentence classification and pair sentence classification to be higher by about 0.02-2.29 percentage points depending on the training dataset size. In addition, each result has been confirmed through tests with 5-fold cross-validation on 4 different seeds to increase its reliability.

In the future, we plan to investigate the effect of other DML methods on the performance of language models in a manner similar to the SoftTriple Loss method. We also want to extend the applicability of TripleEntropy by comparing the results with language models from different architectures, such as BERT, DistilBERT, or XLNet, to investigate its overall usefulness. Furthermore, given that our new loss function performs better the smaller the dataset, we plan to test how TripleEntropy behaves under few-shot learning settings.

Abstract—In this work, we propose a new parameter to study the effectiveness of classifiers - the AUC (area under curve) of the balanced accuracy curve (BAC) on data with different balance degrees - we compare its effectiveness with the popular AUC parameters for the ROC and PR curve. We use a global kNN classifier with typical metrics to verify the utility of the new parameter. BAC, ROC and PR curves generate similar results, the advantage of BAC is its simplicity of implementation and ease of interpretation of results.

I. INTRODUCTION

CLASSIFICATION accuracy is the most natural parameter for assessing classification quality. Total accuracy fails when test data are unbalanced in terms of class sizes. With help comes a balanced version of accuracy, which is simply the efficiency of the average across all test classes. Thanks to this parameter, even small test classes are equally taken into account in the classification. In this work, we present a preliminary verification of whether the AUC of a balanced accuracy curve applied on training data balanced in different levels can create a valuable competitive parameter for PR and ROC curve. Let us turn to a brief review of the literature on the topic under discussion. First of all, the parameters that we discuss in this paper concern the evaluation of binary classifiers. Let us introduce the basic notation. The following symbols shall be used: $T = True$, $P = Positive$, $F = False$, $N = Negative$. TP is the number of test objects from the positive class that were correctly classified. FP is the number of test objects from the negative class that were classified into the positive class. FN is the number of objects in the positive class that have been classified in the negative class. A receiver operating characteristic curve (ROC) is a chart that shows the predictive capability of a binary classifier as its threshold of discrimination evolves. The method was initially designed for military radar receiver operators in 1941, resulting in its name [1], [2]. The ROC curve shows the ratio of TP to FP values through the prism of thresholds determining membership to a positive class. The best value of the ROC curve is closest to the upper left corner of the plot. A Precision Recall curve (PR) [4], [3] is basically a chart with the Precision values on the y axis and the Recall on the x axis. $precision = \frac{TP}{TP+FP}$

Precision is understood as the accuracy of the classification of a positive class - the percentage of correctly classified objects in that class out of those classified. $recall = \frac{TP}{TP+FN}$ The Recall parameter tells us about the relevance to the positive class - it specifies the percentage of correctly classified objects in the positive class in relation to all classified objects to the positive class. The best value of the PR curve is closest to the top right corner of the plot. An extensive introduction of the relationship of ROC and PR curves can be seen in papers [5] and [6]. In paper [7], the author leads a discussion on the imbalance of decision classes vs PR curve. The literature review related to classification quality assessment is enormous, we will not even attempt to review it in this paper, for further reading the reader is directed to e.g. paper [12].

In the following sections we have the following content. In Section II we present the research methodology. In section III we present the results of the experiments. In section IV we summarise the work and indicate further research plans. Let us move on to discuss the methodology used in this thesis.

II. METHODOLOGY

In this section we discuss how we implemented the ROC, PR, BAC curves and introduce information about the classifier used.

A. Basic classifier

In testing the effectiveness of AUC values for BAC, ROC and PR curve, we used the kNN classifier. Which does not mean that there is any restriction on the use of other classifiers. The one chosen is an initial reference point. The procedure used is as follows.

Step 1. We input a training decision system (U^{trn}, A, d) and a test decision system (U_{tst}, A, d) , where A is a set of conditional attributes, d a decision attribute.

Step 2. The classification of test objects using training objects is carried out as follows.

Across all conditional attributes $a \in A$, training objects $v \in U^{trn}$ and test objects $u \in U_{tst}$, we calculate the importance weights $w(u, v)$ using selected metric.

In the version used, the obvious limitation k is the size of the training system.

The test object u is classified using the weights computed for all training objects v . The weights are ordered in ascending order as,

$$w_1(u, v_1) \leq w_2(u, v_2) \leq \dots \leq w_{|U_{trn}|}(u, v|_{U_{trn}})$$

Using the calculated and sorted weights, the training decision classes vote with the following parameter, where c is over the decision classes in the training set,

$$Class_{weight_c}(u) = \sum_{i=1}^k w_i^c(u, v_i^c).$$

Eventually, the test object u is categorized into the class c with the smallest value $Class_{weight_c}(u)$.

Assume that the positive class is denoted by 1 and the negative class by 0. Once all test objects u have been classified, the quality parameter accuracy, acc is calculated, according to the equation

$$acc_{balanced} = \frac{acc_{class_1} + acc_{class_0}}{2}$$

$$acc_{class_c} = \frac{|correctly\ classified\ objects\ in\ class_c|}{|classified\ objects\ in\ class_c|}$$

B. BAC curve

We propose the AUC of the balanced accuracy curve as a new factor for cross-sectional assessment of classification quality. The curve is constructed from balanced accuracy values using training systems with varying levels of class balance. We divide the analyzed data into test and training datasets and determine which of the two possible classes is a positive class and which is a negative class. After classifying each decision class, we create a test set containing 30% of the total number of objects. From the remaining 70% (excluding the data contained in the test set), we create a training set. The splitting and classification procedure is carried out a hundred times - we include the average accuracy value as the final result. In the case of BAC, we use a 0.5 threshold for classification. The class balance levels (of training decision system) we use are: (10 : 90, 20 : 80, 30 : 70...90 : 10). The use of BAC is possible when the decision classes are adequately represented in terms of size, since we require the creation of subsets with different levels of balance used data should have access to the same number of objects in the classes. In other words, in the case of data that is highly unbalanced, where one of the important classes is small the use of BAC can be difficult.

Fig. 1. An exemplary detailed result for Australian Credit decision system. From the top, BAC, ROC, and PR curves. The metric used is Canberra defined as follows: $d(x, y) = \sum_{i=1}^n \frac{|x_i - y_i|}{|x_i| + |y_i|}$

C. ROC and PR curve

We chose the AUC of the ROC and PR curves as reference parameters. We divide the analyzed data into test and training datasets and determine which of the two possible classes is the positive class and which is the negative class. After determining each decision class, we select 50 random objects from each class and combine the objects into one test set containing 100 objects. Then using the remaining objects from the entire dataset, we create a training set. We use the classification probabilities obtained after applying the kNN classifier to obtain the optimal threshold visualized by ROC curve and PR curve. We compare the probabilities with thresholds in the range from 0 to 1 with a step=0.001. If the probability is greater than or equal to the threshold, then we classify the object into the positive class, otherwise into the negative class. For each threshold, we calculate the coefficients of true positives (sensitivity), false positives and the accuracy

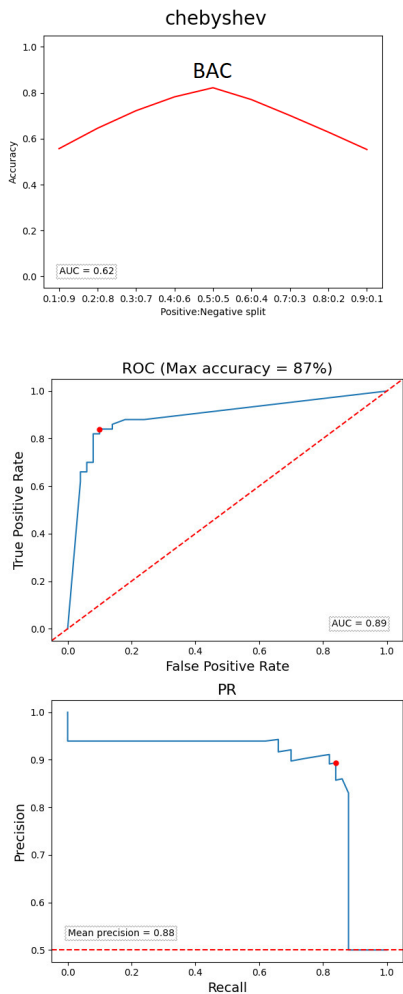

Fig. 2. An exemplary detailed result for Australian Credit decision system. From the top, BAC, ROC, and PR curves. The metric used is Chebyshev distance defined as follows: $d(x, y) = \max_i |x_i - y_i|$

Fig. 3. An exemplary detailed result for Australian Credit decision system. From the top, BAC, ROC, and PR curves. The metric used is Chi-squared distance defined as follows: $d(x, y) = \sum_{i=1}^n \left(\frac{|x_i - y_i|}{|x_i| + |y_i|} \right)^2$

(precision) of classifying objects. The example detailed results for the ROC and PR curves, due to the difficulty of showing the mean result are from single classifications. The results summarising the performance of the curves are the average of a hundred times of the experiment.

III. EXPERIMENTAL SESSION

In the experimental part we use the kNN method (See description in section II-A) with metrics: manhattan, euclidean, manhattan-maxmin, cosine, minkowski, chebyshev, canberra, chi-square, jaccard, epsilonHamming, sørensen. Definitions of each metric are provided in the headings of Figures 1 to 11. For the selected classifier, custom implementations for creating BAC, ROC and PR curves were written. We verify parameter performance on three decision systems selected from the UCI repository [15] - Australian Credit, Pima Indians Diabetes and Heart Disease datasets. Detailed results showing all three

curves are presented for the Australian Credit decision system only - see figures from 1 to 11. A summary of metrics ranking generation based on AUC of BAC, ROC and PR curves for Australian Credit, Pima Indians Diabetes and Heart Disease systems can be seen in figures 12, 13 and 14.

A. Result summary

In Figures 12, 13 and 14 we have the rankings of the kNN method metrics based on the AUC of the BAC, ROC and PR curves - for Australian Credit, Heart Disease and Pima Indians Diabetes datasets respectively.

Results for Australian Credit decision system : AUC range of three positions for BAC and ROC curve agree for the metrics: canberra, euclidean, manhattan, minkowski, sørensen and epsilonHamming. AUC range of three positions for BAC and PR curve agree for the metrics: canberra, euclidean, minkowski, sørensen, epsilonHamming.

Fig. 4. An exemplary detailed result for Australian Credit decision system. From the top, BAC, ROC, and PR curves. The metric used is Cosine distance

defined as follows:
$$d(x, y) = \frac{\sum_{i=1}^n x_i y_i}{\sqrt{\sum_{i=1}^n x_i^2} \sqrt{\sum_{i=1}^n y_i^2}}$$

Results for Heart Disease decision system: AUC range of three positions for BAC and ROC curve agree for the metrics: canberra, cosine, chisquared, manhattan, maxmin, euclidean, minkowski, chebyshev, epsilonHamming and sorenson. AUC range of three positions for BAC and PR curve agree for the metrics: jaccard, canberra, manhattan, maxmin, chisquared, minkowski, epsilonHamming, sorenson.

Results for Pima Indians Diabetes decision system: AUC range of three positions for BAC and ROC curve agree for the metrics: jaccard, cosine, chisquared, maxmin, sorenson and epsilonHamming. AUC range of three positions for BAC and PR curve agree for the metrics: jaccard, manhattan, chisquared, maxmin, minkowski, sorenson and epsilonHamming. The overall shape of the ranking indicates that the BAC, ROC and PR curves are comparable tools for assessing classification quality.

Fig. 5. An exemplary detailed result for Australian Credit decision system. From the top, BAC, ROC, and PR curves. The metric used is epsilonHamming distance

defined as follows:
$$d(x, y) = |\{a \in A : \text{dist}(a(x_i), a(y_i)) \geq \varepsilon\}|, \varepsilon = 0.01$$

When analyzing the results for the three selected decision systems (Australian Credit, Heart Disease, and Pima Indians Diabetes), we see that the area under the balanced accuracy curve for the entire training system balance spectrum can be a competitive factor for determining the quality of classifiers to ROC and PR curve. The ranking results are similar to each other. Some metrics are mixed among themselves because the data are randomly selected, but there are clear common features to these rankings. The shape of the curve showing the ranking of metrics is similar. The main advantage of using the field under the accuracy curve is the simplicity of implementation and the ease of understanding the resulting factor. Which is simply the cross-sectional stability of the classifier for training knowledge balanced in different levels.

Fig. 6. An exemplary detailed result for Australian Credit decision system. From the top, BAC, ROC, and PR curves. The metric used is euclidean distance defined as follows: $d(x, y) = \sqrt{\sum_{i=1}^n (x_i - y_i)^2}$

IV. CONCLUSION

This paper examines the applicability of the field under the accuracy curve-defined as the set of classification accuracies using training systems with different levels of decision class balancing-to the cross-sectional evaluation of the kNN classifier. We used the global method (k is selected from the entire system at once) with different metrics as reference kNN variants. By seeing the results, we can summarise that the specified factor is competitive with the ROC and PR curve, with its implementation and interpretation being much simpler and more understandable. Preliminary results show a similar gradation of methods, the difference in the performance of the metrics is due to the fact that the data were randomly selected, but the overall ranking looks similar. We consider our results as an initial step to open a discussion on the potential applicability of BAC to assess the stability of classifiers. We plan to extend our research to the entire spectrum of

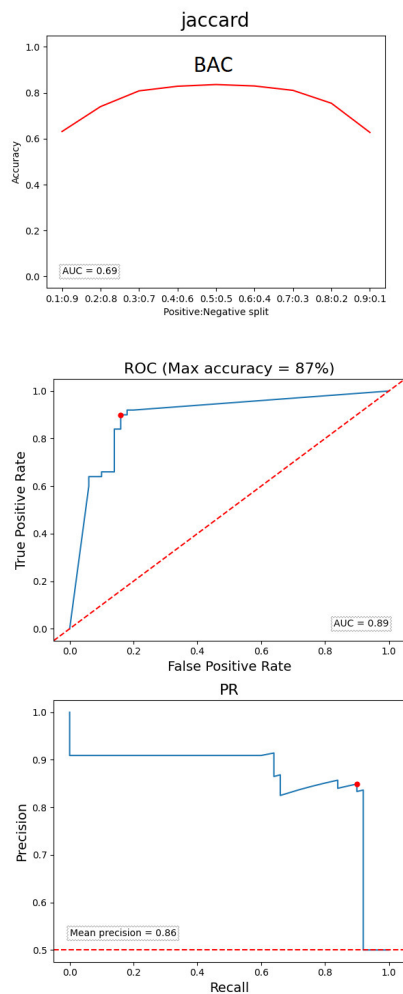

Fig. 7. An exemplary detailed result for Australian Credit decision system. From the top, BAC, ROC, and PR curves. The metric used is jaccard distance defined as follows: $d(x, y) = 1 - \left| \frac{\sum_{i=1}^n (x_i * y_i)}{\sum_{i=1}^n x_i^2 + \sum_{i=1}^n y_i^2 - \sum_{i=1}^n (x_i * y_i)} \right|$

classification methods in the future.

Extending Word2Vec with Domain-Specific Labels

Abstract—Choosing a proper representation of textual data is an important part of natural language processing. One option is using Word2Vec embeddings, i.e., dense vectors whose properties can to a degree capture the "meaning" of each word. One of the main disadvantages of Word2Vec is its inability to distinguish between antonyms. Motivated by this deficiency, this paper presents a Word2Vec extension for incorporating domain-specific labels. The goal is to improve the ability to differentiate between embeddings of words associated with different document labels or classes. This improvement is demonstrated on word embeddings derived from tweets related to a publicly traded company. Each tweet is given a label depending on whether its publication coincides with a stock price increase or decrease. The extended Word2Vec model then takes this label into account. The user can also set the weight of this label in the embedding creation process. Experiment results show that increasing this weight leads to a gradual decrease in cosine similarity between embeddings of words associated with different labels. This decrease in similarity can be interpreted as an improvement of the ability to distinguish between these words.

I. INTRODUCTION

TRANSFORMATION of text into a numerical representation is an important part of any natural language processing (NLP) problem. Considering the level of words, one can choose between alternatives ranging from simple one-hot encoding to complex language models such as ELMo [9], BERT [3], or GPT-3 [2]. Word2Vec embeddings lie in-between these two extremes in terms of level of complexity.

Word embeddings are dense vectors usually of several hundred dimensions with the ability to at least partly capture the meaning of each word. This meaning is based on each word's context, i.e., words that co-occur with a given target word. It is captured by the relative position of different words in the embedding vector space. Words with similar meaning should be represented by vectors close to each other, while dissimilar words should be more distant. Moreover, basic operations such as addition or subtraction enable the derivation of representations for new words. A common example is the subtraction of the embedding for the word *man* from of the word *king*, followed by the addition of the embedding of *woman*. the result should be close to the embedding of the word *queen*.

Originally proposed by [6], Word2Vec is an algorithm for creating word embeddings. It is based on a simple idea: words with similar meaning occur in similar contexts. This context is usually defined by surrounding words. One issue with this line of thinking is that although Word2Vec works well for detecting

synonyms, hyponyms or hypernyms [5, 14], it can't easily distinguish between two antonyms [11, 1]. Hence, words such as *good* and *bad* are often represented by relatively similar embeddings.

Several authors, including [8] or [4], addressed this issue by extending the basic Word2Vec algorithm to consider not only the context of words, but also thesauri information. In cited papers, several well known public datasets such as WordNet or Roget are used. [10] claim that the information about antonyms can be extracted from the geometry of the embedding space with a method called *contrasting maps*.

This paper describes a simple modification of the Word2Vec algorithm for considering domain specific document labels data during embedding creation. In contrast with the aforementioned work, presented approach is more flexible and can be adopted to many domains of interest.

In the paper, the modification is applied in the domain of finance. The problem can be stated as follows: We have set of tweets related to a specific publicly traded company. It is assumed that certain words occur more frequently when the stock price of a company drops, while others are used more when the stock price rises. In many financial analysis tasks it would be useful to represent words with occurrences associated with these opposite situations with vectors that are distant from each other. Can we improve on the basic Word2Vec algorithm by considering the information about stock price increase or decrease in the time of tweet publication?

Incorporating this information directly into word embeddings could be helpful in risk or return prediction. Some researchers, e.g. [12] or [13] are already using the basic Word2Vec model for similar tasks and this work could improve the prediction power of their models.

The remainder of this paper is organized as follows: Section II provides a basic overview of the Word2Vec algorithm, section III describes a modification for considering domain-specific labels during embedding creation, and section IV introduces the experiments performed to evaluate this modification. Results of these experiments are then presented and discussed in section V. Finally, the presented work is summarized in section VI. This section also discusses future research opportunities.

II. WORD2VEC OVERVIEW

The Word2Vec algorithm is based on a simple feed-forward neural network with a single hidden layer. The number of

neurons in this hidden layer determines the dimensionality of the embedding space. Word embeddings are found by training this neural network in one of two ways – **continuous bag of words** (CBoW) and **skip-gram**.

The extension presented in this paper is based on the skip-gram model. When using this approach, the neural network uses the one-hot encoded target word as its input and tries to predict its multi-hot encoded context. The objective of the skip-gram model can be further formulated as maximizing the log probability [7]:

$$\frac{1}{T} \sum_{t=1}^T \sum_{-c \leq j \leq c, j \neq 0} \log p(w_{t+j}|w_t) \quad (1)$$

where T is the total number of target words, and c is the context window size, i.e., the number of words before or after the target word in the text to consider as skip-gram output.

The training sets for both CBoW and skip-gram methods are practically identical and can be created easily from a corpora of text documents. After the neural network is trained, the embeddings of different words are simply the weights of connections between the input element representing a given word in one-hot encoding and all neurons of the hidden layer.

In their subsequent paper, [7] extended the Word2Vec algorithm to improve both its performance in terms of training time and its accuracy. Two modifications were proposed:

- **Frequent word subsampling:** Words that occur frequently in the text are omitted from the document with probability:

$$P(w_i) = 1 - \sqrt{\frac{t}{f(w_i)}} \quad (2)$$

where $f(w_i)$ is the frequency of the word w_i and t is a threshold usually around 10^{-5} . Most frequent words include articles such as *the*, *a* and *an* that do not carry that much information about the contextual meaning of a specific word.

- **Negative sampling:** Leads to a modified objective function:

$$\log \sigma(v'_{w_o}{}^T v_{w_t}) + \sum_{i=1}^k \mathbb{E}_{w_i \sim P_n(w)} [\log \sigma(-v'_{w_i}{}^T v_{w_t})] \quad (3)$$

which in practical terms causes only k words that are missing in a given context to update their embeddings during training.

Experimental results show that these extensions lead to both more efficient training, and to better quality of final embeddings. Proposed extension implements word subsampling, but not negative sampling.

III. PROPOSED EXTENSION

As discussed in introduction, one of Word2Vec's disadvantages is antonym representation. Antonyms such as *good*

and *bad* are often surrounded by similar words, hence their Word2Vec embeddings are relatively similar.

I propose an extension of the Word2Vec model that allows for consideration of domain specific document labels to better distinguish between words related to different classes. In contrast to previous work presented in section I, it does not rely on general purpose thesauri.

The extension is based on the idea of modifying the output to be predicted by the neural network. In addition to context (surrounding words) for a certain input word, the neural network also has to predict the document class.

This extension further lets the user set the weight of this class label prediction relative to word context prediction. Modified objective function can then be formulated as:

$$\frac{1}{T} \sum_{t=1}^T \sum_{-c \leq j \leq c, j \neq 0} (\log p(w_{t+j}|w_t) + u \log p(d_t|w_t)) \quad (4)$$

where u is the label prediction weight and d_t is the document label associated with word w_t . This weight is implemented as replication of the output neurons for label prediction u times.

IV. EXPERIMENT DESIGN

To verify that the extension helps the Word2Vec algorithm better consider domain specific labels, an experiment with the goal of creating embeddings from tweets related to a publicly traded company was performed. Each tweet was labeled with a label "1" if the stock price increased one day after tweet publication. If the stock price decreases, the tweet was labeled with "0". Difference of 2 subsequent daily close prices was used to determine the label. The basic skip-gram model was then extended to predict not only the context of a word but also the label representing the stock price increase or decrease.

The hypothesis to test can be stated as follows: When the price change label is considered during embedding creation, the distance between embeddings of words occurring more frequently on price decrease and embeddings of words occurring more frequently on price increase will be greater as compared to the embeddings created with the standard Word2Vec skip-gram model. Moreover, this distance should grow with the weight of this price change label represented by u in equation 4.

A. Data and Preprocessing

The experiment utilized tweets related to the Walt Disney Company, which is publicly traded on the New York Stock Exchange under the *DIS* symbol. Tweets published between January 1, 2017 and December 31, 2020 were used to train the Word2Vec model. The *\$DIS* "cashtag" was used to find tweets related to the company. 45 000 tweets containing 401 000 words were further randomly selected in order to reduce both the training time and memory use.

These tweets were preprocessed before they were used as input for the skip-gram model. Following steps were performed:

- the text was transformed to lower-case,
- cashtag symbols \$, hashtag symbols # and the user mention symbols @ were removed,

- all other non-alphanumeric symbols were removed,
- all HTML tags were removed,
- all URLs were replaced by a "__URL__" placeholder,
- and all numbers were replaced by a "__NUMBER__" placeholder.

B. Hypothesis Evaluation

To evaluate the aforementioned hypothesis, the polarity of each word was calculated as the difference between the number of occurrences of a given word in tweets associated with a price increase (positive occurrences) and in tweets associated with a price decrease (negative occurrences).

Since the dataset contains a different number of positive and negative tweets, the polarity of negative tweets was further modified using the following equation:

$$pol_m(w) = \frac{N_{pos}}{N_{neg}} pol(w) \quad (5)$$

where $pol_m(w)$ is the modified polarity of word w , $pol(w)$ is the basic polarity of the same word calculated as the difference between positive and negative occurrences, and N_{pos} and N_{neg} is the total number of tweets related to price increase and price decrease respectively.

Top 75 positive words were then paired with top 75 negative words (most negative word was paired with the most positive word, 2nd most positive word was paired with 2nd most negative word and so on). Then the distances between the embeddings of paired words were examined.

Furthermore, a list of 10 specific antonym pairs was constructed. This list was then verified to make sure that one word in the pair has indeed negative polarity, while the other word's polarity is positive. These antonym pairs are listed in table IV-B. Distances between the embeddings were again examined.

To consider different vector norms, cosine similarity was used as a measure of distance. According to Agudo [1], cosine similarity is also preferred for synonym or antonym detection tasks.

All experiments were implemented in Python 3.9 using well-known libraries including *numpy*, *pandas* and *Keras*.

Positive word	Negative word

upgraded	downgraded
raised	lowered
strength	weakness
ahead	delayed
bullish	bearish
up	down
above	below
high	low
positive	negative

TABLE I
PAIRS OF ANTONYMS WHOSE DISTANCES WERE EXAMINED DURING EXPERIMENTS

V. EXPERIMENT RESULTS

Table II shows the cosine similarity measure for the antonym pairs listed above. These results include three different levels of label weight, as well as similarity derived from

the embeddings trained by the well-known Gensim¹ Word2Vec implementation. With label weight set to 1, the average cosine similarity is very close to the similarity exhibited by Gensim embeddings. This small difference can be attributed to the random nature of the neural network training process. However, as the label weight increases the similarity between embeddings starts to drop significantly. When the label weight is set to 100 the embeddings become almost orthogonal.

These results are confirmed by the second test examining 75 pairs of top positive and top negative words. Noteworthy negative words include "down", "coronavirus", "below", "downgraded" or "risk". Interesting positive words include "higher", "nice", "streaming", "up" or "nflx". Using the same label weight values as in table II, mean cosine similarities across all word pairs were 0.36 ($u = 1$), 0.315 ($u = 10$) and 0.046 ($u = 100$). The cosine similarity mean for Gensim embeddings was 0.346. These results manifest the same behavior as the results for 10 selected antonym pairs.

Both experiments support the hypothesis stated in section IV. Given a specific minimum weight, domain-specific labels can indeed help increase the distance between relevant word embeddings. Moreover, this distance increment grows with the label weight.

VI. CONCLUSION

This paper explored the possible utilization of domain-specific labels during word embedding creation with the Word2Vec algorithm. An extension to the skip-gram model was proposed and evaluated in an experiment where word embeddings were created from a dataset of tweets related to the Walt Disney company. Results of this experiment show that the extension helps distinguish between words whose occurrence is correlated with different labels (in this case stock price increase and decrease). Furthermore, the cosine similarity between such words decreases as the label weight increases.

Presented experiments were performed on a relatively small dataset of 45000 tweets related to a single company. The proposed extension should therefore be examined on significantly larger amounts of data in the future. Moreover, the extension implementation used during experiments is not ready to be deployed to production. Further performance improvements are needed. Combining the extension with negative sampling should also be examined.

The extension was compared with a standard Word2Vec implementation provided by the Gensim library. Additional comparison to the models proposed by [8] or [4] would be beneficial. One of the potential benefits of the presented extension is its ability to consider any domain-specific labels instead of relying on a specific thesaurus.

The work presented in this paper is a part of a larger project with the aim of examining if sentiment and other information

1st Workshop on Artificial Intelligence for Next-Generation Diagnostic Imaging

THE application of artificial intelligence (AI) becomes nowadays one of the most promising areas of health innovation. Among the most promising clinical applications of AI is diagnostic imaging, where AI algorithms can boost processing power of huge, heterogeneous medical image resources and therefore uncover disease characteristics that fail to be found by the naked eyes. AI can optimize radiologists' workflows and facilitate quantitative assessments of radiographic characteristics using radiomics approach. Nowadays refinement of AI imaging studies is required by consistent selection of clinically meaningful and patient-related endpoints.

The workshop on Artificial Intelligence for Next-Generation Health and Medical Applications – AI4NextGenHMA'22— provides an interdisciplinary forum for researchers, developers, radiologist and clinicians to present and discuss latest advances in research work related to theoretical and practical applications of AI in diagnostic imaging and related areas. The workshop aims to bring together specialists for exchanging ideas and promote fruitful discussions.

TOPICS

The list of topics includes, but is not limited to:

- AI for diagnostic imaging and digital pathology
- DL models and architectures for medical image analysis

- Explainable AI (XAI) for diagnostic imaging
- Radiomics and quantitative image analysis
- Structured reporting in radiology
- Standardization of data annotation for AI
- Clinical decision support systems, especially integrating results of image analysis
- Clinical pathways based on image analysis and integration of clinical data
- Biomedical ontologies, terminologies, standards and clinical guidelines
- Data mining and knowledge discovery in radiology
- Domain knowledge representation and integration into DL/ML models in medical tasks
- Precision medicine and personalized medicine based on diagnostic imaging
- Natural language processing for radiological report analysis
- Medical signal processing and analysis
- Social and ethical aspects of AI in radiology

Abstract—Hearing loss is one of the most significant sensory disabilities. It can have various negative effects on a person’s quality of life, ranging from impeded school and academic performance to total social isolation in severe cases. It is therefore vital that early symptoms of hearing loss are diagnosed quickly and accurately. Audiology tests are commonly performed with the use of tonal audiometry, which measures a patient’s hearing threshold both in air and bone conduction at different frequencies. The graphic result of this test is represented on an audiogram, which is a diagram depicting the values of the patient’s measured hearing thresholds. In the course of the presented work several different artificial neural network models, including MLP, CNN and RNN, have been developed and tested for classification of audiograms into two classes - normal and pathological represented hearing loss. The networks have been trained on a set of 2400 audiograms analysed and classified by professional audiologists. The best classification performance was achieved by the RNN architecture (represented by simple RNN, GRU and LSTM), with the highest out-of-training accuracy being 98% for LSTM. In clinical application, the developed classifier can significantly reduce the workload of audiology specialists by enabling the transfer of tasks related to analysis of hearing test results towards general practitioners. The proposed solution should also noticeably reduce the patient’s average wait time between taking the hearing test and receiving a diagnosis. Further work will concentrate on automating the process of audiogram interpretation for the purpose of diagnosing different types of hearing loss.

I. INTRODUCTION

HEARING IS one of the most important senses and is crucial for a human to maintain full connectivity to the world. Early on in life, hearing helps one to establish language skills which lays the groundwork for quick development during school years. In daily tasks, hearing is used in communicating with other people as well as for listening to music, television and radio, and going to the cinema or theatre.

According to World Health Organization (WHO), currently, around 430 million people globally require rehabilitation services for their hearing loss [1]. Estimations show that by 2050 nearly 2.5 billion people will be living with some degree of hearing loss, at least 700 million of whom will require rehabilitation services [1]. Overall, hearing impairment has devastating consequences for interpersonal communication, psychosocial well-being, quality of life and economic inde-

pendence [2]. The consequences of hearing loss are frequently underestimated and ignoring the initial symptoms usually leads to further degradation. Once diagnosed, early intervention is the key to successful treatment. Medical and surgical treatment can cure most ear diseases, potentially reversing the associated hearing loss. Research has shown that, particularly in children, almost 60% of hearing loss is due to causes that can be prevented [1], [6], [7].

The standard hearing test is carried out using pure tone audiometry, which determines the hearing thresholds at different frequencies. As a rule, a frequency range of the hearing test varies within 125 – 8000 Hz. The sound level of pure tones is given in dBHL, and the subject is tested in both air and bone conduction. The test results in two data series containing discrete hearing thresholds in the function of frequency, separately for both conductions. This data series is usually presented in the form of an inverted graph called audiogram. An audiogram helps to determine the degree of hearing loss, but also the type of pathology: sensorineural, conductive or mixed [3], [4].

According to projections, the demand for professional audiologists will burgeon in near future [1]. Nowadays, around 78% of low-income countries have less than one otorhinolaryngologist per million inhabitants and about 93% have less than one audiologist per million inhabitants [1], [5]. In this context, introduction of expert systems based on artificial intelligence for preliminary audiogram interpretation could significantly reduce the workload of specialists, while at the same time shortening the patient’s wait for a diagnosis.

Over the last decade, a comparison of several approaches to hearing loss determination, including Decision Tree, Naive Bayes and Neural Network Multilayer Perceptron (NN) model, has been prepared by Elbaşı & Obalı [10]. The tests have been carried out using a set of numerical values representing Decibels corresponding to fixed frequency levels (750Hz, 1kHz, 1.5kHz, 2kHz, 3kHz, 4kHz, 6kHz, 8kHz). The achieved accuracy was 95.5% in Decision Tree, 86.5 % in Naive Bayes and 93.5 % in NN.

A different approach was presented by Noma & Ghani [11], who developed a classification system based on the relationship between pure-tone audiometry thresholds and inner ear

disorders symptoms such as Tinnitus, Vertigo, Giddiness etc. The classifier, based on the multivariate Bernoulli model with feature transformation, has shown to provide 98% accuracy of predicting hearing loss symptoms based on audiometry results.

Recently, Charih et al. [12] presented their Data-Driven Annotation Engine, a decision tree based audiogram classifier which considers the configuration, severity, and symmetry of participant's hearing losses and compared it to AMCLASS [13], which fulfils the same purpose using a set of general rules. Both classifiers have achieved similar accuracy of around 90% across 270 different audiometric configurations by three licensed audiologists.

More recently, Crowson et al. [14] adopted the ResNet-101 model to classify audiogram images into three types of hearing loss (sensorineural, conductive or mixed) as well as normal hearing using a set of training and testing images consisting of 1007 audiograms. This approach resulted in 97.5% classification accuracy, however it is limited to processing images.

In summary, the combination of neural networks and increased computing resources of new hardware architectures has the potential to deliver faster overall tests results and more detailed assessments[15]. This being said, however, the currently proposed solutions deliver classification accuracy in the 90-95% range, which, although very high, still leaves considerable room for error. Clinical standards suggest that the margin of error should be kept under 5%[16] and optimally should be close to 3% [17]. These requirements are met only by two of the discussed classifiers. The method proposed by Noma & Ghani achieves 98% accuracy, however it has been designed to predict significant symptoms of inner ear disorder, and thus it cannot be used for general purposes such as early detection of hearing degradation. The best audiogram classifier to date has been presented by Crowson et al., who used transfer learning to adapt an established image classifier network to analysis of audiogram images. While this approach resulted in a 97% classification accuracy, it exhibits serious limitations. Because it is an image classifier, it cannot be used with the original data series produced by tonal audiometry. This means that the data series first need to be converted into audiogram images, which may result in data loss. Moreover, although the structure of audiograms generally is similar, there can still be significant differences between audiograms generated by different hardware and software configurations. Aside from differences such as background and line colours, audiograms can also differ in the amount of presented information (eg. they may contain data for a single ear or both). A sample comparison of significant differences between audiograms obtained from different sources is presented in Figures 1 and 2. In consequence, a universal solution for classifying results of tonal audiometry cannot be based on an image classifier.

This study presents the development of a neural network for classification of discrete tonal audiometry data series. In the course of this study, several different neural network architectures have been trained and tested with the use of 2400 audiogram data series analysed and classified by professional audiologists. The goal of the presented study was to achieve a

Fig. 1. A pure tone audiogram showing air and bone conduction thresholds for **both left and right ear** [8]. The "X" and "O" symbols are used to mark left-sided air and bone conduction, respectively. The "O" indicate air conduction, whereas the "<" denote bone conduction, both in the right ear.

Fig. 2. A pure tone audiogram showing air and bone conduction thresholds **only for the right ear**. The "O" and "<" indicate left-sided air and bone conduction, respectively.

high enough classification accuracy for the developed network to be applicable for use in a clinical environment.

II. MATERIALS & METHODS

A. Data

The study has been conducted with the use of 2400 data series containing results of pure tone audiometry tests performed from 2020 to 2021 by clinicians working at the Otolaryngology Clinic of the University Clinical Centre in Gdansk, Poland. The data contains 650 examples of normal hearing and 1750 examples of pathological hearing loss. The tests had been performed in a soundproof booth, according to ISO 8253 and ISO 8253 standards. Air conduction tests employed TDH-39P headphones, while bone conduction testing involved a Radioear B-71 bone-conduction vibrator. The data series have been analysed and labelled by expert audiologists from the

Medical University of Gdansk Department of Otolaryngology according to established methodology [9]. In consequence, the dataset has been classified into two subsets: hearing pathology and normal hearing.

B. Preprocessing

The input data series contained numerical information about tonal points, defined as loudness (dB) for a given frequency (Hz), in XML format. The dataset included the following range of frequencies:

125Hz, 250Hz, 375Hz, 500Hz, 750Hz, 1000Hz, 1500Hz, 2000Hz, 3000Hz, 4000Hz, 6000Hz, 8000Hz.

Every tested frequency has been assigned a loudness level in the range from -10dB to 120dB. If certain frequencies had not been registered during the hearing test, they have not been included in the corresponding data series.

C. Testing methodology

Using the prepared dataset, three different neural network architectures have been trained to interpret tonal audiometry data and in order to differentiate normal hearing (N) from pathological hearing loss (P). The tested architectures included Multilayer Perceptron (MLP), Convolutional (CNN) and Recurrent (RNN) neural networks, all of which have been previously applied to data classification problems [18], [19], [20]. The general workflow of the presented study is shown in Fig. 3. Each model has been assessed using k-fold cross-validation, which consists of dividing the data into k subsets and training the model k-times with k-1 subsets, with a different subset being used for testing in every iteration. The presented research used $k = 5$, which resulted in train to test dataset proportions of 80% to 20%, respectively.

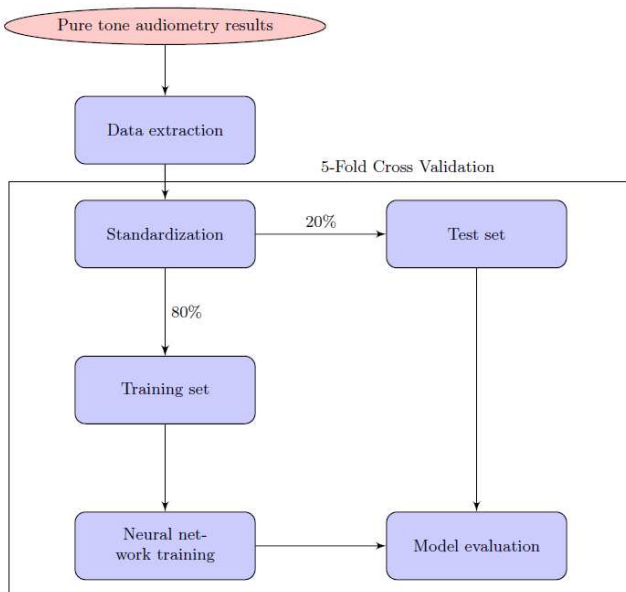

Fig. 3. Workflow of processes leading to model evaluation.

After revealing the best performing architecture, further tests and optimizations would be carried out in order to improve classification accuracy.

III. RESULTS

The purpose of the initial tests was to reveal the best neural network architecture model for classification of pure tone audiometry data. The tested neural network architectures included MLP, CNN and RNN. The results of those tests are presented in Table I.

TABLE I
COMPARISON OF PERFORMANCE RESULTS OF PRELIMINARY MODELS.

Parameters	MLP	CNN	RNN
Accuracy	0.9458	0.9563	0.9604
Loss	0.6429	0.1185	0.1346
Precision	0.8255	0.8984	0.9062
Recall	1.0	0.9349	0.9430
F1	0.9044	0.9163	0.9243

As it can be seen, initial research revealed that the best classification performance has been produced by the RNN architecture model. Once the most promising neural network architecture has been identified, three of its variants have been trained and optimized in terms of hyper parameters, including number of nodes and hidden layers, dropout layers, learning and decay rate. The first model consisted of a simple RNN, second one was based on Gated Recurrent Units (GRU) [22] and the last one used Long Short-Term Memory (LSTM) [21]. The results of these tests are shown in Table II.

Receiver Operating Characteristics (ROC) curves with corresponding Area Under the Curve (AUC) parameters for these models are presented in Fig. 4.

TABLE II
COMPARISON OF PERFORMANCE RESULTS OF RNN MODELS.

Parameters	Simple RNN	GRU	LSTM
Accuracy	0.9646	0.9771	0.9812
Loss	0.0836	0.0530	0.0540
Precision	0.9030	0.9453	0.9394
Recall	0.9680	0.9680	0.9920
F1	0.9344	0.9565	0.9650

The cross validation scores for $k = 5$ with LSTM classifier are given in Table III. The average accuracy was 98.08% (+/- 0.17%).

TABLE III
K-FOLD VALIDATION SCORE OF LSTM MODEL ($k = 5$).

Iteration	1	2	3	4	5
Accuracy	97.96	98.33	97.96	97.91	98.22

A detailed analysis of classification performance achieved by the tested RNN models can be made using a confusion matrix, which visualizes the number of True Positives (TP

Fig. 4. ROC curve with AUC parameter of RNN models.

- patients who have been properly classified with hearing loss), True Negatives (TN - patients who have been properly classified with good hearing), False Positives (FP - patients who have been improperly classified as hearing loss) and False Negatives (FN - patients who have been improperly classified with good hearing). The confusion matrix for the tested RNN models is presented in Figures 5, 6 and 7.

Fig. 5. Confusion matrix of simple RNN.

Fig. 6. Confusion matrix of GRU.

IV. DISCUSSION

Initial tests have shown that the simple RNN architecture model delivers noticeably better pure tone audiometry classification results in comparison to MLP and CNN models, achieving accuracy of 96.04% versus 94.58% and 95.63% respectively (Tab. I). The chosen network architecture appears to have the largest impact on classification accuracy, as further tests and optimizations resulted in minor improvements. Optimization of parameters such as the number of nodes and hidden layers, dropout layers as well as learning and decay rate improved the accuracy of simple RNN from 96.04% to 96.46%. In comparison, applying the same optimization process to MLP and CNN models did not result in markedly improved evaluation parameters. A possible explanation for this could be the fact that RNN have been designed to process time series data, and structurally pure tone audiometry results could be interpreted as a special case of time series. This could be further explored by testing the effectiveness of more advanced RNN models such as GRU and LSTM. As it can be seen in Tab. II, both of these models obtained more than 97% accuracy, with the highest out-of-training set accuracy being achieved by LSTM at 98.12%. While these results, which have been cross-validated using the 5-fold method, would seem to indicate a general prevalence of the RNN architecture in processing audiometry data, establishing an effectiveness hierarchy of RNN models is a more complex matter. Although LSTM has shown the best classification accuracy, when analysed in terms of confusion matrix, the lowest number of False Positives (FP) was obtained by GRU (Figures 6 and 7), with LSTM taking second place. In comparison, the simple RNN produced over 62% more False Positives than LSTM and 85% more than GRU.

Overall, simple RNN and GRU performed equally well in terms of False Negatives (FN), producing them only in 0.8% of cases, whereas LSTM significantly outperformed the other models with only one case of error occurring. It can be argued that when classifying results of pure tone audiometry tests, the FN number is more important than FP because it shows that a patient does not have hearing loss when they actually do. In this case the patient may not receive treatment and

get worse because their disease was undetected. On the other hand, a false positive would only result in the patient being unnecessarily referred to an audiologist, who would properly interpret the test results and inform the patient that their level of hearing is normal.

Summing up, it can be said that the 98.12% classification accuracy achieved by LSTM fulfills the established margin of error criteria and is significantly better than the 97.5% classification accuracy offered by the best existing algorithm for audiogram data classification, proposed by Crowson et al. [14]. While some of the difference could be attributed to the rival method providing a larger set of classes, the presented method provides an additional advantage in the type of processed data: it works with original tonal audiometry data series instead of audiogram images and therefore is more universal. The only rival method also designed for processing tonal audiometry data series, presented by Elbaşı & Obali [10], provides an even lower 95.5% classification accuracy.

In terms of classifying pure tone audiometry data, the only existing solution with a similar classification accuracy level (98%, proposed by Noma & Ghani [11]), has been designed to predict significant symptoms of inner ear disorder and thus cannot be used for general classification of tonal audiometry test results.

V. CONCLUSIONS

The presented work aimed to develop a neural network for classification of discrete tonal audiometry data series with accuracy high enough for medical application. In the course of this study, several different neural network architectures, including MLP, CNN and RNN, have been trained and tested with the use of 2400 audiogram data series analysed and classified by professional audiologists. The highest classification accuracy was achieved with an optimized LSTM RNN at 98.12%. The high accuracy of the obtained neural network, particularly the low number of False Negatives (0.2%), allows for its application at the Otolaryngology Clinic of the University Clinical Centre in Gdansk, Poland. Results of pure tone audiometry tests, which thus far needed to be examined by professional audiologists, can now be classified with the developed neural network under the supervision of general practitioners. This change may result in a significant reduction of the workload of audiology specialists, as they will no longer need to deal with patients whose symptoms are not caused by hearing loss (which may amount to over 10% of all patients subjected to pure tone audiometry tests) [23], [24]. After it has been further tested in practice, the developed solution could be introduced directly in the audiometry laboratory, ensuring that the patient receives a first interpretation of the performed tests as soon as they have been completed. Further work will concentrate on expanding the classifier for the purpose of diagnosing different types of hearing loss.

ACKNOWLEDGEMENT

The authors would like to thank M. Grono, K. Koźmiński, P. Mierzwińska and A. Romanowicz who helped to create the

pure tone audiometry test dataset used in this study.

Abstract—The main goal of this work was to implement a reliable machine learning algorithm that can classify a dog’s age given only a photograph of its face. The problem, which seems simple for humans, presents itself as very difficult for the machine learning algorithms due to differences in facial features among the dog population. As convolutional neural networks (CNNs) performed poorly in this problem, the authors took another approach of creating novel architecture consisting of a combination of CNN and vision transformer (ViT) and examining the age of the dogs separately for every breed. Authors achieved better results than those in initial works covering the problem.

I. INTRODUCTION

DELAYING the aging and preventing diseases associated with it is becoming increasingly prevalent in state-of-the-art medicine. Biological and chronological age comparison is one of the primary assessment tools to estimate the health status of a given subject. The trend is also prevalent in veterinary medicine as animals, especially domesticated ones such as dogs, play an essential role in modern societies.

Machine learning and its growing effectiveness and versatility provide valuable tools that can be used in medicine and anti-aging research to create simple and easy-to-use methods for assessing biological age.

The age assessment can help approximate an animal’s health status, allowing the animal owner to take preventive actions before a health condition is developed. The authors hope this work’s findings will also be useful for further research in human and animal preventive medicine.

The main goal of this work was to create a tool to assess a dog’s age, given only its picture. The age groups of the dogs were classified as follows:

- Young dogs, aged from 0 to 2 years,
- Adult dogs, aged from 2 to 6 years,
- Senior dogs, aged from 6 years and more.

The tool will be a part of the larger project aiming to detect animals’ health conditions and belongs to a realm of preventive medicine solutions. The system’s overall architecture is presented in Fig. 1.

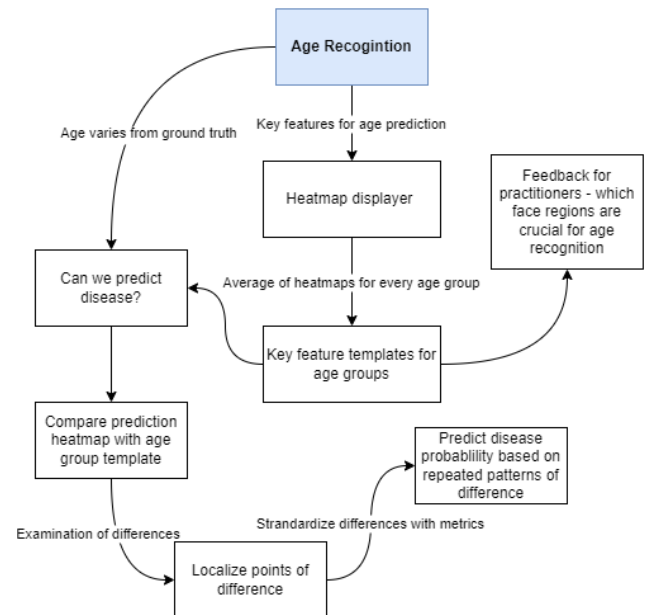

Fig. 1. A block diagram of the CyfroVet system for early disease diagnostics (a part of it presented in [11])

This work is part of CyfroVet, a research project run by ACC Cyfronet to utilize technology, especially AI, in veterinary medicine. The anti-aging and presented system is one of the topics covered by the project, alongside cancer cell detection and segmentation.

The summary of this paper’s contributions is as follows:

- new architecture for addressing the difficult task of dogs classification, which outperforms available state-of-the-art models,
- new dataset which enables effective training of the classification models,
- conceptualization of using age assessment in animals for disease prevention and their early diagnosis.

We make our code and the dataset publicly available.

II. MATERIALS AND METHODS

There are multiple methods for assessing canines age. Most of them involve a certain kind of precise examination. The few most popular are:

- Ocular lens examination [1]
- Teeth examination [2]
- Bone examination [3]

Authors have noticed an opportunity to use computer vision in this field, as it can recognize image features and patterns sometimes impossible to notice for humans with a bare eye examination. As mentioned before, a reliable age assessment based on appearance can be a straightforward tool to use for veterinary medicine practitioners and pet owners. Facial appearance differing vastly from the typical one for a given age group can be a sign of accelerated biological aging, which may be an indicator of the overall health status of an individual. Having preliminary warning signs, practitioners can take preventive steps and make a detailed diagnosis to detect early signs of disease before more severe symptoms develop. This early warning can be beneficial in treating potentially terminal conditions in their early stage. Quick detection and treatment of medical conditions such as cancer can significantly increase an individual's chances of survival.

A. Datasets

In this experiment, the authors initially decided to use the DogAge dataset containing dogs of various age groups created by the Tech4Animals research group [5]. This dataset was used in the Dog Age Challenge competition organized by the group mentioned earlier, which required participants to create a neural network algorithm that could assess the dog's age. It took place in 2019.

The expert dataset consisted of photographs classified into age groups by animal scientists. The photographs were high-quality, and the dog was directly facing the camera.

The Petfinder dataset consisted of photographs downloaded from *Petfinder.com*, a website for pet adoption [4]. Experts did not verify the classification of each age group. The images were often of poor quality, with dogs at various angles and distances.

Several preprocessing techniques were used for those datasets, such as cropping and data augmentation. They will be described in detail in the next section. The Petfinder dataset was cleared of irrelevant photos (i.e., dog's face not clearly visible, other dogs appearing).

After the initial experiments, the authors sought to expand the datasets, as the performance was not reaching satisfying results. The data was collected from the *Petfinder.com* [4], as the website provided the divisions of the dogs by age and breed. The photographs were downloaded and cleared, as many repeating adoption offers were on the website. Two approaches were taken, with the first dividing the problem into examining only one breed at a time and the second by expanding the mixed breeds datasets. Obtained photos were similar to those described in the previous case of the

Petfinder dataset. The datasets are described in Tab. I. *Expert dataset* and *Petfinder dataset* refer to datasets presented in DogAge Challenge. *Big dataset* refers to a dataset created by downloading new photos. Two datasets consisting only of dogs of single breeds are also presented in Tab. I. The dataset name describes the breeds. Given breeds were selected based on data availability - the number of photos and class balance.

III. EXPERIMENTS

The initial datasets presented many challenges. Firstly, they were greatly imbalanced, with the adult category containing more images than the other two combined. Secondly, the data quality was also an obstacle - the *Petfinder* set contained many invalid photos (i.e., dog's face not visible, humans present in the image) for the network training. Those problems were also present within the new datasets. The experiments were run on the Prometheus cluster, using one node with 2 Nvidia Tesla v100 GPUs and 36 CPU cores.

A. Image cropping algorithm

A two-way approach was introduced to address the problem of low image quality. Firstly, the *Petfinder* dataset was manually cleared, removing the inadequate pictures (e.g., a dog looking back or to the side, two dogs in the picture, dog with toys in its mouth). Secondly, two cropping algorithms were tested: YOLO (You Only Look Once)[6] and FaceDetector. After the evaluation, the latter was chosen. Both algorithms could correctly detect the dogs. However, FaceDetector focused only on the dog's face. Therefore, it presented itself not only as a cropping mechanism but also as a tool to clear the new datasets of irrelevant photos, as manual clearing is time inefficient. Results of both cropping algorithms are visible in Fig. 2. for FaceDetector and Fig. 3. for YOLO.

Fig. 2. An image cropped with FaceDetector

Fig. 3. An image cropped with YOLO

B. Metrics

Categorical accuracy (CA), F1-score (F1), and recall (RA) metrics were used to examine the performance of tested models. In the DogAgeChallenge announcement, [10] a modified version of mean average error (MAE), average accuracy (ACA), and average recall (aRA) is used. In this paper, the authors decided not to use mMAE since it was concluded that this metric would provide no meaningful information.

TABLE I
SUMMARY OF THE DATASETS

Dataset name	Total number of photos	Number of adult group photos	Number of senior group photos	Number of young group photos
Expert dataset	1088	370	495	223
Petfinder dataset	22573	13016	1898	7659
Big dataset	49010	26021	5523	17464
Big dataset (balanced)	16964	5999	5517	5448
Chihuahua	3933	1898	875	1160
Pitbull terrier (balanced)	3195	1128	996	1071

C. Augmentation, class weights and data balancing

To cope with a class imbalance within the datasets, the authors tried to introduce data augmentation via random flip, rotation, brightness, and contrast changes. However, augmentation harmed models' performances, lowering CA on validation sets on average by 5% when augmenting by flip and rotation and 10% when augmenting via contrast and brightness changes. Those tests were run on a balanced Pitbull Terrier dataset, excluding the influences of class imbalance being magnified by augmentation. Authors suspect that augmentation via brightness and contrast shifts may negatively influence the results by skewing some features crucial for age assessment (for example, fur color). Data augmentation failed to solve the class imbalance problem, so the authors used class weights during training. Weights were chosen as 1, 5, and 2 for Adult, Senior and Young classes. Only the Expert dataset, showing different data distribution, was assigned weights 2, 1, and 2 for the same class order. Also, class balancing via removal of the photos from most numerous classes was tested. The number of removed photos was chosen so that all classes had roughly the same number of photos as the least numerous ones. In the case of balanced datasets, no class weights were applied in the final experiments, as this approach did not perform well for balanced datasets (once again reducing CA and F1).

D. Initial network architecture and experiments

Initial trials were conducted using the transfer learning protocol. The backbone of the model consisted of CNN pre-trained on ImageNet dataset with a classifier consisting of fully connected layers. During the experiments, the EfficientNetB7 [7] was chosen as the final backbone for the model, as the results of different commonly used CNN architectures were performing on a very similar level. The architecture of the initial model is based on the EfficientNetB7 backbone, followed by global average pooling and two fully connected layers.

The initial model was tested on the available datasets. During the experiments, the random data splits were as follows:

- training split - 80% of the dataset
- validation split - 10% of the dataset
- test split - 10% of the dataset

The network was tested on both single and mixed-breed datasets. It was trained using AdamW [8] optimizer with a learning rate parameter equal to 0.0001 and the weight decay

TABLE II
ARCHITECTURE OF THE NETWORK WITH ViT AS CLASSIFIER

Layer number	Layer name	Parameters
1	EfficientNetB7	Weights from pretraining on Imagenet
2	Patch Encoding 2D	Embedding dimension of 64
3	Layer normalization	-
4	Multi-Head Attention	6 attention heads
5	Skip connection	Adding outputs from layers 2 and 4
6	MLP layer	-
7	Skip connection	Adding outputs from layer 5 and 6
8	Layer normalization	-
9	Flattening layer	-
10	Dropout layer	50% dropout
11	MLP layer	dropout increased to 50%
12	Dense layer	Softmax activation

parameter of the same value. Different configurations of the classifier with the usage of regularization, dropout layers, more dense layers, and different values of units within dense layers did not significantly influence the model's performance. The results of experiments with the initial network are visible in Tab. III and Tab. IV.

E. Transformer-based classifier as a method to improve the classification results

During the experiments, the CNN model obtained better results than those found in the literature [10]. However, they still were not satisfying, so the authors decided to modify the architecture, adding a small version of ViT as a classifier after the backbone CNN block. ViT implements an attention-based model known in the field of NLP. The decoder block is omitted in the computer vision version compared to the original implementation. The model uses an attention mechanism to learn relations between different parts of the input image. Dosovitskiy et al. [9] showed that ViT can outperform current state-of-the-art CNN architectures in image classification. As it requires large datasets, the authors decided to extract features from the data using pre-trained CNN. Architecture is presented in Tab. II.

The model was again trained using available datasets, with the same data split as for experiments with the initial network. Results are visible in Tab. III and Tab. IV.

TABLE III

FINAL RESULTS OF THE INITIAL AND MODIFIED NETWORKS TRAINED ON THE DESCRIBED DATASETS.

Model	Initial network		Network with ViT as classifier	
	CA	RA	CA	RA
Expert dataset	0.49	0.44	0.51	0.49
Petfinder dataset	0.49	0.23	0.55	0.50
Big dataset	0.44	0.23	0.46	0.29
Big dataset (balanced)	0.53	0.25	0.54	0.45
Chihuahua	0.45	0.35	0.48	0.45
Pitbull Terrier (balanced)	0.50	0.22	0.50	0.44

TABLE IV

FINAL F1 SCORE OF THE INITIAL AND MODIFIED NETWORKS TRAINED ON THE DESCRIBED DATASETS FOR SPECIFIC CLASSES (A - ADULT, S - SENIOR, Y - YOUNG).

Model	Initial network			Network with ViT as classifier		
	A	S	Y	A	S	Y
Expert dataset	0.47	0.57	0.35	0.33	0.64	0.41
Petfinder dataset	0.47	0.40	0.55	0.57	0.42	0.56
Big dataset	0.28	0.42	0.56	0.32	0.45	0.57
Big dataset (balanced)	0.45	0.61	0.53	0.49	0.60	0.55
Chihuahua	0.27	0.54	0.55	0.49	0.51	0.43
Pitbull Terrier (balanced)	0.43	0.60	0.48	0.55	0.40	0.50

F. Results

The results obtained during the experiments are presented in this section compared to the previous experiments. In the comparison, classification accuracy (CA) and recall (RA) were used to compare the obtained results with the ones conducted previously during the DogAge Challenge [10]. During DogAge Challenge, authors showed that using Squeezenet and Inception v3 with dense layer classifiers resulted in the CA and RA of 32% for the Squeezenet model and 34% on both metrics for Inception v3. Comparing these values with the ones seen in Tab. III, which describes the ones obtained with solutions proposed by the authors trained on available datasets, we can see that significant improvement is made. The networks can reach both higher CA and RA. The CNN + ViT architecture improved CA and RA for every dataset. The single breed approach was similarly effective compared to the mixed breed approach. Examining Tab. IV, it is visible that CNN + ViT does not necessarily improve F1 for given classes but instead results in more even per-class F1. It can also be concluded that the class balancing and weighting approach can be a helpful tool to cope with class imbalances for this problem, as balanced datasets' results are comparable to those obtained on unbalanced datasets with class weights applied during network training.

IV. DISCUSSION

Several challenges affect the experiment and results presented in this work. The most important of them are as follows:

- limited access to high-quality data,

- lack of the effective data specification methods, which makes both augmentation and preparation of the validation dataset challenging,
- it is tough to deal with multiple breeds using a single model,
- granularity of the age classification is tightly related to an ability to label images precisely.

Other research projects in this domain may also consider these remarks to reach a high performance of ML models.

V. CONCLUSIONS AND FUTURE WORK

The problem of dog age classification using neural networks turned out to be more demanding than expected in the beginning. Experiments showed that state-of-the-art CNN models provided insufficient accuracy while using datasets with multiple dog breeds. The transformer-based architecture introduced in the paper improved the performance results, but there is still much space for progress in future research.

VI. DATA AND CODE AVAILABILITY

The code and datasets as well as additional results available: github.com/SzymonMazurekAGH/Age_recognition_Cyfrovet

4th International Workshop on Artificial Intelligence in Machine Vision and Graphics

THE main objective of the 4th Workshop on Artificial Intelligence in Machine Vision and Graphics (AIMaViG'22) is to provide an interdisciplinary forum for researchers and developers to present and discuss the latest advances of artificial intelligence in the context of machine vision and computer graphics. Recent advancements in artificial intelligence resulted in the rapid growth of both methods and applications of machine learning approaches in computer vision, image processing, and analysis. The development of parallel computing capabilities in the first decade of the 21st century that boosted the development of deep neural networks became a real gamechanger in machine vision. The workshop covers the whole range of AI-based theories, methods, algorithms, technologies, and systems for diversified and heterogeneous areas related to digital images and computer graphics.

TOPICS

The topics and areas include but are not limited to:

- image processing and analysis:
 - image enhancement,
 - linear and non-linear filtering,
 - object detection and segmentation,
 - shape analysis,
 - scene analysis and modeling,
 - scene understanding,
- machine learning for vision and graphics:
 - pattern recognition,
 - deep neural models,
 - convolutional networks,
 - recurrent networks,
 - graph networks,
 - generative adversarial networks,
 - neural style transfer,
 - deep reinforcement learning,
- machine vision:
 - image acquisition,
 - stereo and multispectral imaging,
 - embedded vision,
 - robotic vision,
- image theory:
 - computational geometry,
 - image models and transforms,
 - modeling of human visual perception,
 - visual knowledge representation and reasoning,
- visualization and computer graphics:

- data-driven image synthesis,
- graphical data presentation,
- computer-aided graphic arts and animation,
- applications:
 - innovative uses of graphic and vision systems,
 - image retrieval,
 - autonomous driving systems,
 - remote sensing,
 - digital microscopy,
 - security and surveillance systems,
 - document analysis,
 - OCR systems.

TECHNICAL SESSION CHAIRS

On the Feasible Regions Delimiting Natural Human Postures in a Novel Skeletal Representation

Simon B. Hengeveld* A. Mucherino,*

*IRISA, University of Rennes 1, Rennes, France.

simon.hengeveld@irisa.fr, antonio.mucherino@irisa.fr

Abstract—The de facto standard for storing human motion data on a computer involves a representation based on Euler angles. This representation, while effective, has several shortcomings. Triplets of Euler angles are not unique, and the same posture may be expressed using different combinations of angles. Furthermore, many possible Euler angle triplets correspond to unnatural positions for human joints. This means that, in general, a large part of the representational space remains unused. In this paper, we further investigate a recently proposed representation inspired by molecular representations. It uses only two (instead of three) degrees of freedom per joint: a vector and a torsion angle. Using the two key ingredients of this new representation, we present a complete analysis of the Graphics Lab Motion Capture Database. The data found in this analysis provide us with some powerful insights about natural and unnatural human postures in human motions. These insights can potentially lead to possible constraints on human motions which may be used to more effectively solve open problems in the computer graphics community, most notably the problem of (human) motion adaptation.

I. INTRODUCTION

SEVERAL open problems in computer graphics deal with human motions [2], [3], [9], in which these motions may come from motion capture recordings. In human motions, we have a skeletal character which changes its postures over time. The anatomy of the character in these motions can be defined as a graph $G = (V, E)$, in which the vertex set V represents the *joints* and the edge set E represents the *bones* of the human skeleton. In this work, and generally in the context of human motions, these graphs G are regarded as trees, in which every joint $v \in V$ has a unique *parent* joint, assigned by a function $p : v \in V \setminus \{v_0\} \rightarrow p(v)$. Note that because G is a tree, we have that the number of bones $|E| = |V| - 1$.

In order to complete the representation of our characters, we need the function

$$\chi : v \in V \rightarrow \chi(v) \in \mathbb{R}^3,$$

which assigns a three-dimensional offset from to every joint of the character to its unique parent joint. The real value $\|\chi(v)\|$ corresponds to the length of the bone $\{u, v\} \in E$, where the symbol $\|\cdot\|$ represents the Euclidean norm. This means that this function χ together with the anatomy G lets us define the *morphology* of the skeleton (G, χ) [8]. In graph theory, the pair (G, χ) is generally referred to as “skeletal structure”.

Furthermore, if we add a fictive root joint v_0 to the tree G and fix it at position $(0, 0, 0)$, we can use the offsets between

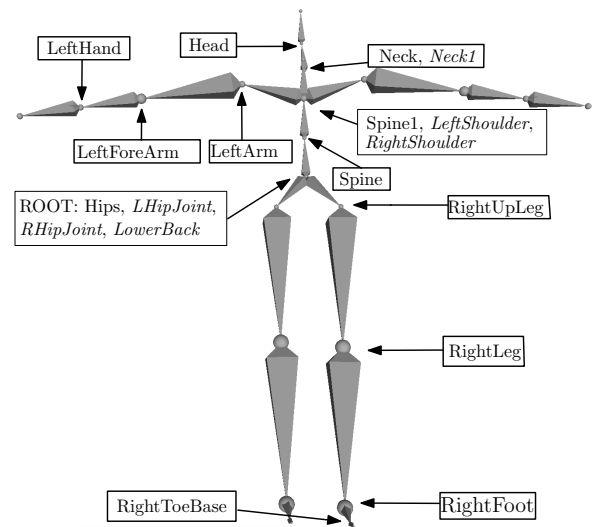

Fig. 1: An example of skeletal structure (G, χ) . This T-pose is the commonly used initial posture of the human motions, particularly in BVH files [6]. These labels we use for the joints originate from files composing the motion database we use in our analysis. Joints with $|\chi| = 0$ are shown next to their parent joint, marked in italic.

a joint v and its parent defined by χ to find a realization of the *initial posture* x_0 of the skeleton. If we let p be the function that pairs the parent to each vertex $v \in V$, we can define the realization of the initial posture as follows:

$$x_0 : v \in V \rightarrow \begin{cases} (0, 0, 0) & \text{if } v = v_0, \\ x_0(p(v)) + \chi(v) & \text{otherwise.} \end{cases}$$

Fig. 1 shows a commonly used default position for the skeletal motions considered in this paper. The motion itself is then defined by the changing positions of the n joints in V over time, where the time is generally defined as a sequence of m frames $t \in T$, with $T = \{1, 2, \dots, m\}$. A possible simple choice for representing the motion of the character would be to use Cartesian coordinates to assign a three-dimensional position to each joint changing over time:

$$x_t : v \in V \rightarrow x_t(v) \in \mathbb{R}^3. \quad (1)$$

However, this Cartesian representation does not explicitly encapsulate the information about the morphology of skeleton.

The standard way of describing human motions utilizes an Euler angle representation ρ . At every frame t , we assign a triplet of Euler angles θ (pitch), ϕ (roll) and η (yaw) to every bone of the skeletal structure representing our character. Together with the known offset between $p(v)$ and v , we can define a transformation matrix $M_t(v)$ that takes into consideration both the translation data from $\chi(v)$ and the given Euler angles. The formula capable to converting the Euler angles in absolute positions for the joints is:

$$\rho_t : v \in V \longrightarrow \begin{cases} (0, 0, 0) & \text{if } v = v_0, \\ \prod_{u \in P(v)} M_t(u) [0, 0, 0, 1]^T & \text{otherwise,} \end{cases}$$

where $P(v)$ is set of vertices u that form the unique path from v_0 to v over the tree structure of the graph. For a more detailed discussion of the transformations involved in the Euler representations (with a particular focus on the standard BVH file format), the reader is referred to [6].

In this work, we consider the vector-torsion angle representation proposed in [4] to represent our human skeletons, and present an in-depth statistical analysis, over a large database, aiming at identifying the feasible regions in the vector-torsion angle space for all joints forming a human character. This is a continuation of the work previously proposed in [4], in which we had only presented some preliminary results for this analysis. To the best of our knowledge, this is the first time an analysis of this kind on the full skeleton has been performed in the relation to human motions and motion capture in general.

The rest of the paper is organized as follows. In Section II, we recall the main definitions regarding our vector-torsion angle representation of the human skeleton. In Section III, we present our analysis on a very-well known motion capture database where the new vector-torsion angle representation is employed. This complete analysis allows us to identify constraints for each of the joints of the skeleton. As finally discussed in Section IV, the results of the presented analysis are likely to have a positive impact on computer graphics applications such as motion adaptation.

II. THE VECTOR-TORSION ANGLE REPRESENTATION

We briefly summarize in this section the main ideas behind the vector-torsion angle representation initially proposed in [4]. Recall that the graph G is a tree representing the anatomy of the human character, and that, together with the offset function χ , it defines a skeletal structure (G, χ) describing the full morphology of the character. By following the natural vertex order given by the structure of G , we can define two angles, a *vector* angle and a *torsion* angle ω_v , for every vertex $v \in V$ which has at least three ancestors.

Definition 1 Given a skeletal structure (G, χ) and one realization x , the vector angle ζ_v for the joint v in this realization is the **smallest** angle (in the range $[0, 180^\circ]$) formed by the line passing through $x((p \circ p)(v))$ and $x(p(v))$, and the line passing through $x(p(v))$ and $x(v)$.

Definition 2 Given a skeletal structure (G, χ) and one realization x , the torsion angle ω_v for the joint v in this realization is the **clockwise** angle (in the range $[0, 360^\circ]$) formed by the plane defined by $x((p \circ p \circ p)(v))$, $x((p \circ p)(v))$ and $x(p(v))$, and the plane defined by $x((p \circ p)(v))$, $x(p(v))$ and $x(v)$.

When a realization x preserves the morphology of the character, we can use this pair of angles combined with the bone lengths (defined by χ) to find the Cartesian coordinates of any joint v that has at least three ancestors. We point out that the idea of using these two angles, while novel in relation to motions, stems from work in the field of Molecular Biology. There, the angles are in fact used in the context of proteins and other molecules in order to differentiate between molecular conformations [1], [10]. The value that the vector-torsion representations has to offer to represent motions can be summarized in the following four advantages: (i) the combination of a vector angle with a torsion angle cannot lead to any representation singularities, (ii) there exists a bijective correspondence between the value of the angles and the positions in space for the joints, (iii) it exhibits only two degrees of freedom for recovering the same joints positions of the skeletal representations, as the triplets of Euler angles are capable to do with three degrees of freedom, and (iv) it allows us to empirically constrain the feasible (and mostly continuous!) regions in the vector-torsion angle space where only natural postures for the human skeleton can be found.

For more details about the vector-torsion representation, the reader is referred to our original publication [4].

III. MOTION ANALYSIS

In this section we present an analysis of the Graphics Lab Motion Capture Database¹, a large database of human motions resulting from recordings using motion capture. The database contains 2436 motion files which sum to a total of more than four million frames. In the following, we will refer to human joints with labels such as Hips, RightShoulder, LeftLeg and others, which we take from the data file forming the motion database.

Using the vector-torsion representation briefly presented in Section II, we conducted a statistical analysis of the vector angles ζ_v^t and torsion angles ω_v^t of every applicable joint v at every frame t of these four million frames. Using the resulting data from this experiment, we generated a heat-map scatter-plot for each joint v .

Even though it is not possible to define the vector and torsion angles for the joints having fewer than three ancestors, we also performed the analysis on these joints. In fact, there is no need in our analysis to build up human postures, but only to *look at* the available postures of the database. Therefore, for those joints missing a sufficient number of ancestors, we have simply defined a different set of “reference joints” in the graph G , that we subsequently use for defining the vector and torsion angles. Table I shows the complete set of joints for which we performed our analysis, together with the list of

¹<https://mocap.cs.cmu.edu>

TABLE I: The three reference joints for each joint involved in the analysis. We suppose that the reference joint with smallest numerical label is the closest; the one with largest numerical label is instead the farthest. In some cases, the reference joints are not the joint ancestors implied by the graph structure.

<i>joint</i>	<i>ref#1</i>	<i>ref#2</i>	<i>ref#3</i>

LeftToeBase	LeftFoot	LeftLeg	LeftUpLeg
RightToeBase	RightFoot	RightLeg	RightUpLeg

three reference joints used for computing the vector and the torsion angles.

Other joints are however excluded from our analysis. These are all the joints which share the same global position with some other joints, because their offset to the parent has zero length. Although this may sound like a contradiction, these joints actually have the purpose of modifying the orientation (the corresponding Euler angles are non-zero) of the entire set of subsequent bones on the current skeleton branch. Therefore, joints with $|\chi_v| = 0$ are omitted, and they are not counted as ancestors of other joints either.

We present several scatter-plots obtained in the analysis described above, starting at the head of the skeleton, working our way down to the feet. The following figures show a total of 18 plots for different joints of our human skeleton, with the vector angles on the x -axis and the torsion angles on the y -axis. In these plots, points tending to the warmer colors correspond to pairs of angles that were found more frequently.

Fig. 2 collects the first set of 12 scatter-plots. The name of joints related to the presented plots are given in the plot itself. The first joint we considered, the Head joint, is only able to perform limited movements in the space defined by the vector and torsion angle, as expected. Roughly speaking, only one third of this space is actually feasible for this joint. Moreover, the warmer part of the scatter-plot indicates that the most common posture for this joint is when the two angles are close to 180° , which is compatible with an erected posture for the upper body part.

While the Neck joint exhibits a pattern very similar to the one of the Head joint, we notice that the two joints involved in the modeling of the human spine (Spine and Spine1 joints) admit an even smaller feasible space. This is particularly true for the Spine1 joint (see Fig. 1 to identify the exact location of the joint), where a large part of the scatter-plot remained

“immaculate white”, which is, the combinations of vector and torsion angles in those white areas are completely infeasible for a human spine.

The LeftArm and RightArm joints exhibit a quite constrained pattern as well, which is similar to those found for some of the previous joints but shifted in the center of the vector angle axis (the x -axis). This corresponds to saying that the angle formed by the spine and the one of these two joints is in most of the cases close to 90° . Notice in fact that these two joints share the same global Cartesian positions with the LeftShoulder and RightShoulder joints. We can also remark that the two scatter-plots are symmetric w.r.t. the axis parallel to the x -axis and passing through the torsion angle value 180° .

The expected flexibility for the human arms is reflected in the two corresponding scatter-plots, the ones related to the LeftForeArm and RightForeArm joints. This is in fact the first pair of joints that we comment for which the “colored areas” are able to cover more than 50% of the two-dimensional space. Yet, there are still particular combinations of vector and torsion angles that correspond to unnatural postures.

Similarly, the scatter-plots related to the LeftHand and RightHand joints show a quite large range of movement possibilities. This was expected as well. Moreover, the little populated blue areas in these two scatter-plots seem to suggest the extremely high flexibility of the human hand: even if sometimes very uncommon (a few frames of the database may contain them), there exist very special (and still natural) postures that the human hand can take. Therefore, if we take into consideration in full these low-populated areas, we can state that the scatter-plots related to the human hands are the ones that almost cover the entire two-dimensional space.

When stepping down over the joints forming the human legs, we can observe similar patterns. For the LeftUpLeg and the RightUpLeg joints, we can notice that the patterns are similar to those observed for the two upper arm bones. The same applies for the LeftLeg and RightLeg joints (see Fig. 3, even if they seem to admit little larger movement possibilities w.r.t. the corresponding arm joints). The human feet (LeftFoot and RightFoot joints) also exhibit quite large movement possibilities, similarly to what we have observed for the hand joints, but the low-populated areas in the scatter-plots for the feet are much more sparse. This may be consequence of the fact that the human feet lost, during evolution, part of their movement possibilities, but the similarity to the hands seems to be still visible in our figures.

Finally, the scatter-plots of the LeftToeBase and RightToeBase joints show that they are the only joints that can actually span the entire two-dimensional space, but the region is mostly not continuous and most of the vector-torsion combinations are actually placed around the center of the plot, where $\zeta_v = 90^\circ$ and $\omega_v = 180^\circ$.

To sum up, our analysis shows that there exist large differences in flexibility between different joints, and the feasible regions tend to vary a lot on the basis of the nature of each joint. In general, the vector angle seems to be the most restrictive factor. In fact, for joints like the Head, Neck and

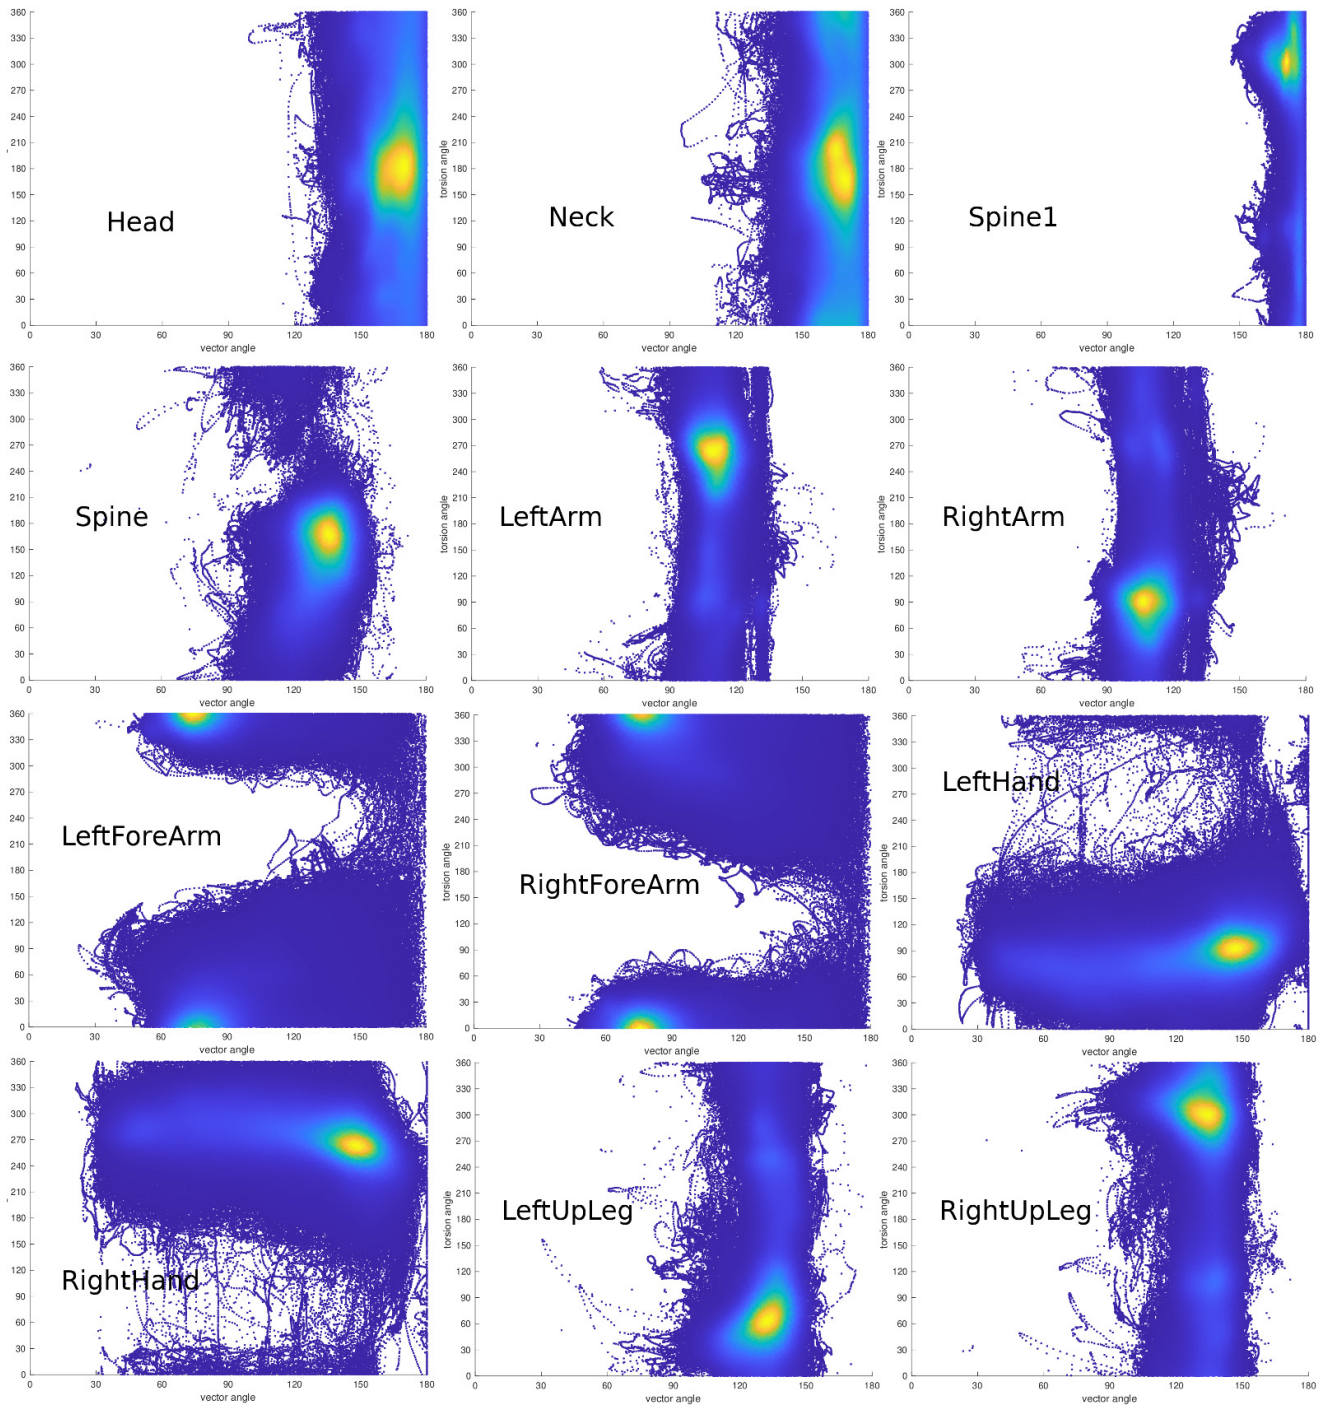

Fig. 2: The first 12 scatter-plots obtained in our analysis.

Spine joints, we see that the feasible vector angle regions are around the 180° mark and do not vary much. The plots for these joints are quite similar, and this makes sense when we look at their respective ancestor joints in the skeleton (see Fig. 1)

Joints on the right and left side of the human body appear

to have very comparable regions, except for the fact that the values of the torsion angles are generally inverted. This is a result from the fact that we use a clockwise rotation to compute the torsion angles between the two planes defined by the quadruplets of joints. This gives rise to the symmetry property mentioned above.

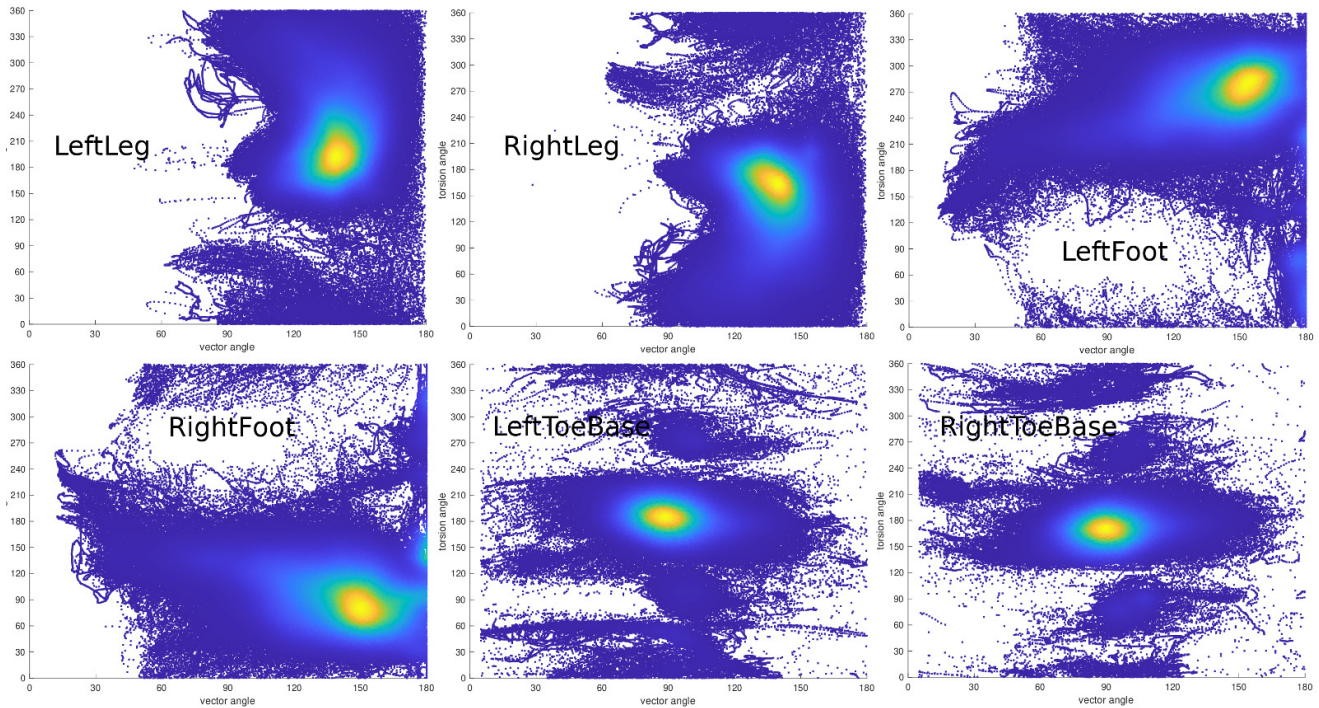

Fig. 3: The remaining 6 scatter-plots obtained in our analysis.

IV. CONCLUSIONS

We have further expanded on the recently proposed vector-torsion angle representation for human motions. Furthermore, we presented an extensive analysis using this representation, in order to find the feasible regions which delimit natural human postures during human motions.

Constraints that can be derived from this analysis are likely to play a very important rule in works on motion adaptation [2], [3]. They may allow us to avoid defining many unnatural human positions in an attempt to create motions satisfying some new constraints, related for example to a change of morphology for the character. When using our vector-torsion representation, the constraints on the values of the vector and torsion angles can directly be imposed; those related to joints with too few ancestors may instead be used for verification. Applying such constraints for motion adaptation, in the context of *dynamical distance geometry* [7], [8], [9], is one of the main directions for future work.

Abstract—A lightweight neural network-based approach to two-person interaction classification in image sequences, based on human skeletons detected in sparse video frames, is proposed. The idea is to use an ensemble of pose classifiers (“experts”), where every expert is trained on different time-indexed snapshots of an interaction. Thus, the expertise of “weak” classifiers is distributed over the time duration of an interaction. The overall classification result is a weighted combination of all the pose experts. Important element of proposed solution is the refinement of skeleton data, based on a merging-of-joints procedure. This allows the generation of reliable features being passed to the artificial neural network. This is the key to our lightweight solution, as ANN resources, needed for feature space transformation, can be significantly limited. Our network model was trained and tested on the interaction subset of the well-known NTU RGB+D dataset, although only 2D skeleton information is used, typical in video analysis. The test results show comparable performance of our method with some of the best so far reported STM- and CNN-based classifiers for this dataset, when they process sparse frame sequences, like we did. The recently proposed multi-stream Graph CNNs have shown superior results but only when processing dense frame sequences. Considering the dominating processing time and resources needed for skeleton estimation in every frame of the sequence, the key to real-time interaction recognition is to limit the number of processed frames.

I. INTRODUCTION

The aim of our work is the analysis of human interactions in specific time-related image sequences. The data can originate from decomposition of video clips onto frames or directly from snapshots of videos posted as image galleries in the Internet. Their common property is the sparsity of time-relevant information (Figure 1).

The approaches to vision-based human activity recognition can be divided into two main categories: activity recognition directly in video data [1] or skeleton-based methods [2], where the 2D or 3D human skeletons are detected first, even by specialized devices, like the Microsoft Kinect.

In early solutions, hand-designed features like edges, contours, Scale-Invariant Feature Transform (SIFT), Histogram of Oriented Gradients (HOG) have usually been used for

detection and localization of human body parts or key points in the image [3], [4].

More recently, Neural Network-based solutions were successfully proposed for solving human pose- and human activity recognition problems, e.g., solutions are based on Deep Neural Networks (DNN) [5], especially on Long-Short Term Memory (LSTM) models and Convolutional Neural Networks (CNN) [6], and more recently on Graph CNNs [7]. CNNs have the capability automatically to learn rich semantic and discriminative features from images and multi-dimensional signals. Furthermore, CNNs can learn both spatial and temporal information from signals and model scale-invariant features as well. Graph CNNs allow efficient implementations of convolution layers when structured data (i.e., graphs) are processed. Some popular solutions to human skeleton estimation (i.e., the detection and localization) in images, based on DNN and CNN models, can be mentioned: OpenPose [8], DeepPose [9] and DeeperCut [10].

Hence, nowadays human action- and interaction recognition in video is most often based on skeleton data extracted from video frames. The state-of-the-art solutions to human action encoding and classification, which process human skeleton data, typically use “heavy” deep neural networks, like 3D CNNs and LSTMs or slightly lightweight Graph CNNs [11], [12].

In this work, we focus on two-person interaction recognition in sparse frame sequences, assuming the existence of skeleton data for key video frames. We took the straightforward idea of extending two-person pose classification of still images to two-person interaction classification in image sequences, by applying an ensemble of pose classifiers [13]. Typically for a classifier ensemble, individual classifiers are “experts” in different parts of the input data domain and the extra weighting network differentiates between subdomains. In our approach, the pose-classifiers are experts at different time stages, while their input space itself (i.e., the spatial image information) is not affecting the fusion weights. By performing a simple time decomposition, we are going to distinguish four subsequent time periods of an interaction process, e.g. start, before midterm, after midterm and final. The final fusion will take the form of a weighted sum of class likelihoods of all the pose classifiers.

Fig. 1. Example of a sparse sequence of frames from a two-person interaction video

There are 4 remaining sections of this work. Section II refers some recent approaches in human pose, -action and -interaction recognition. Our solution is presented in section III. In section IV, experiments are described, to verify the approach. The classifiers are trained and tested on two datasets: an own human pose image dataset, called "humiact5", and the well-known video dataset for action and interaction, NTU RGB+D [14]. Finally, in section V, we summarize our work and contribution to the subject.

II. RELATED WORK

The recognition of human activities in video is a hot research topic in the last 15 years. Typically, human activity recognition in images and video requires first a detection of human body parts or key-points of a human skeleton. The skeleton-based methods compensate some of the drawbacks of vision-based methods, such as assuring the privacy of persons and reducing the scene lightness sensitivity.

The vast majority of research is based on the use of artificial neural networks. However, more classical approaches have also been tried, such as the SVM (e.g. [15], [16]). Yan et al. [17] used multiple features, like a "bag of interest points" and a "histogram of interest point locations", to represent human actions. They proposed a combination of classifiers in which AdaBoost and sparse representation (SR) are used as basic algorithms. In the work of Vemulapalli et al. [18] human actions are modeled as curves in a Lie group of Euclidean distances. The classification process is using a combination of dynamic time warping, Fourier temporal pyramid representation and linear SVM.

Thanks to higher quality results, artificial neural networks are replacing other methods. Thus, the most recently conducted research in the area of human activity classification differs only by the proposed network architecture. Networks based on the LSTM architecture or a modification of this architecture (a ST-LSTM network with trust gates) were proposed by Liu et al. [19] and Shahroudy et al. [14]. They introduced so called "Trust Gates" for controlling the content of an LSTM cell and designed an LSTM network capable of capturing spatial and temporal dependencies at the same time (denoted as ST-LSTM). The task performed by the gates is to assess the reliability of the obtained joint positions based on the temporal and spatial context. This context is based on the position of the examined junction in the previous moment (temporal context) and the position of the previously studied junction in

the present moment (spatial context). This behavior is intended to help network memory cells assess which locations should not be remembered and which ones should be kept in memory. The authors also drew attention to the importance of capturing default spatial dependencies already in the skeleton data. They have experimented with different mappings of the a joint's set to a sequence. Among the, they mapped the skeleton data into a tree representation, duplicating joints when necessary to keep spatial neighborhood relation, and performed a tree traversal to get a sequence of joints. Such an enhancement of the input data allowed an increase of the classification accuracy by several percent.

The work [20] introduced the idea of applying convolutional filters to pseudo-images in the context of action classification. A pseudo-image is a map (a 2D matrix) of feature vectors from successive time points, aligned along the time axis. Thanks to these two dimensions, the convolutional filters find local relationships of a combined time-space nature. Liang et al. [21] extended this idea to a multi-stream network with three stages. They use 3 types of features, extracted from the skeleton data: positions of joints, motions of joints and orientations of line segments between joints. Every feature type is processed independently in an own stream but after every stage the results are exchanged between streams.

Graph convolutional networks are currently considered as a natural approach to the action (and interaction) recognition problem. They are able to achieve high quality results with only modest requirements of computational resources. "Spatial Temporal Graph Convolutional Networks" [22] and "Actional-Structural Graph Convolutional Networks" [23] are examples of such an solution.

Another recent development is the pre-processing of the skeleton data in order to extract different type of information (e.g., information on joints and bones, and their relations in space and time). Such data streams are first separately processed by so called multi-stream neural networks and later fused to a final result. Examples of such solutions are the "Two-Stream Adaptive Graph Convolutional Network" (2S-AGCN) and the "Multistream Adaptive Graph Convolutional Network" (AAGCN), proposed by Shi et al. [24], [25].

One of the best performances on the NTU RGB+D interaction dataset is reported in the work of Perez et al. [26]. Its main contribution is a powerful two-stream network with three-stages, called "Interaction Relational Network" (IRN).

The network input are basic relations between joints of two interacting persons tracked over the length of image sequence. An important step is the initial extraction of relations between pairs of joints - both distances between joints and their motion are obtained. The neural network makes further encoding and decoding of these relations and a final classification. The first stream means the processing of within-a-person relations, while the second one - between-person relations. The use of a final LSTM with 256 units is a high-quality version of the IRN network, called IRN-LSTM. It allows to reason over the interactions during the whole video sequence - even all frames of the video clip are expected to be processed. In the basic IRN, a simple densely-connected classifier is used instead of the LSTM and a sparse sequence of frames is processed.

The currently best results are reported by Zhu et al. [27], where two new modules are proposed for a baseline 2S-AGCN network. The first module extends the idea of modelling relational links between two skeletons by a spatio-temporal graph to a "Relational Adjacency Matrix (RAM)". The second novelty is a processing module, called "Dyadic Relational Graph Convolution Block", which combines the RAM with spatial graph convolution and temporal convolution to generate new spatial-temporal features.

From the analysis of the recent most successful solutions, we can draw three main conclusions:

- 1) using an analytic preprocessing of skeleton-data to extract meaningful information and cancel noisy data, either by employing classic functions or learnable function approximations (e.g. relational networks);
- 2) preferring light-weight solutions by employing background (problem-specific) knowledge, i.e. using graph CNNs instead of CNN, CNNs with 2-D kernels instead of 3-D CNN;
- 3) a video clip containing a specific human action or interaction can be processed alternatively as a sparse or dense frame sequence, where sparse sequence is chosen to achieve real-time processing under limited computational resources, while the processing of a dense sequence leads to better performance.

III. THE APPROACH

A. Structure

The input data for our interaction classifier is a sequence of sparse video frames. Assuming, a video clip is given the start and end of an interaction should be detected first. Then, the video clip is split into some number M of consecutive time intervals (e.g. $M = 16$). From each interval one frame is selected for classification. Assume, that $M = N \cdot m$, where N is a period of time, while m the number of frames in one period. We may distinguish $N = 4$ periods: start, 1-st intermediate, 2-nd intermediate and final. To the classification of frames from a single period, a separate pose classifier (the "expert") is dedicated. As shown in Figure 2, the proposed solution consists of several processing stages:

- 1) *Skeleton estimation*: the OpenPose net [28] is applied to detect human skeletons with their 2D joints in an RGB image (a video frame);
- 2) *Feature engineering*: a *keypoint enhancement algorithm* is proposed in order to get more reliable two sets of skeleton joints from the OpenPose results; next, *feature vectors* are extracted from the refined joints.
- 3) *Pose classifier training*: several lightweight, densely-connected MLP networks are trained - every one is a "weak" classifier.
- 4) *Model evaluation*: alternative network models are evaluated, to find the optimal model configuration and training parameter. A *Keras-tuner* [29] - the *RandomSearch* algorithm [30] is applied to find optimal hyper-parameter settings.
- 5) *Ensemble classifier*: a dense gain network is also trained to learn the weights for results of individual pose classifiers. Two versions of the final classifier are implemented - one with fixed weights and one with learned weights.
- 6) *Model testing*: after accumulating the pose class likelihoods over the frame sequence the final most likely interaction class is selected as the winner. Two datasets - an own *humiact5* and the RGB subset of the NTU RGB+D dataset, are used to evaluate the created models.

B. Skeleton estimation

In the paper [8], a multi-person 2D pose estimation architecture was proposed based on part affinity fields (PAFs). The work introduced an explicit nonparametric representation of the keypoint association which encodes both position and orientation of the human limbs. The designed architecture can learn both human keypoint detection and association using heatmaps of human key-points and part affinity fields respectively. It iteratively predicts part affinity fields and part detection confidence maps. The part affinity fields encode part-to-part association including part locations and orientations. In the iterative architecture, both PAFs and confidence maps will be iteratively refined over successive stages with intermediate supervision at each stage. Subsequently, a greedy parsing algorithm is employed to effectively parse human poses. The work ended up releasing the OpenPose library, the first real-time system for multi-person 2D pose estimation [28]. In our research, we use the core block of OpenPose, the "body_25 model", to extract 25 human key-points in images. The result is an 25-elementary array, providing 2D image coordinates and confidence score for every keypoint.

C. Feature engineering

From the (eventually more than two) sets of skeleton joints, detected in the image by OpenPose, the two main actors are selected based on size measure. A total variability of skeleton keypoint locations is calculated for every skeleton and the two with the highest variability are chosen for feature engineering.

1) *Skeleton enhancement*: There are cases where OpenPose wrongly splits one human region into different regions due to

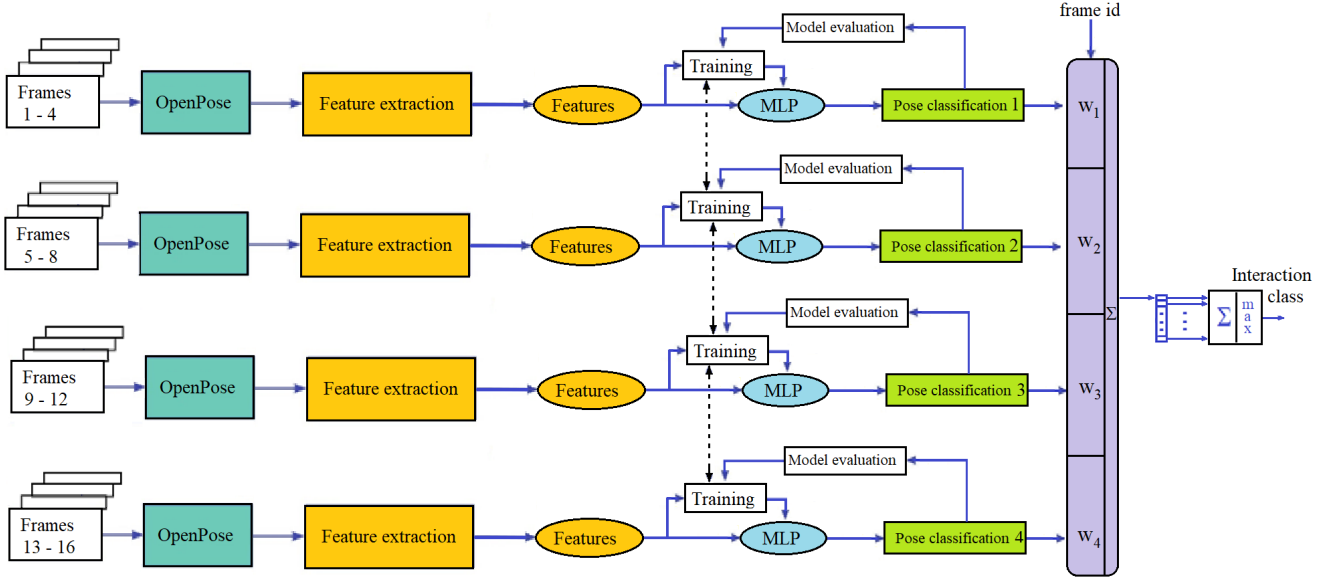

Fig. 2. General structure of our approach

occlusion, low resolution, or complex visual context. Therefore, we developed a keypoint (i.e., skeleton joints) merging and replacement algorithm. In the first step, we try to merge sets of joints, where applicable, to produce finer skeleton joints (see Figure 3).

Two calculations are made for each pair of sets including the number of intersection points of the two sets and the distance between them. The intersection indicator value is scaled by the number of points of the smaller set. The distance calculation takes their two mean points and two standard deviation values into account. These calculated values then will be compared with corresponding thresholds to decide whether the two sets are going to be merged or not. In case merging conditions are met, the intersection points of the two sets will be treated in the following way: the data points with higher probability will be kept and the lower ones will be ignored.

For the sake of clarity, Figure 4 illustrates the merging procedure of two specific sets, A and B , based on the assumption that they come from the same person in the image. The bigger set A is missing key-points for the left leg, while the smaller set B includes these key-points. The mean points (center of gravity) of A and B are m_A and m_B , respectively, the standard deviations of joints locations for A and B are $[std_{A,x}, std_{A,y}]$ and $[std_{B,x}, std_{B,y}]$, respectively.

The conditions for a merging action are as follows:

$$\frac{|A \cap B|}{|B|} \leq \theta_1 \quad (1)$$

$$\frac{|m_{A,x} - m_{B,x}|}{std_{A,x} + std_{B,x}} + \frac{|m_{A,y} - m_{B,y}|}{std_{A,y} + std_{B,y}} \leq \theta_2 \quad (2)$$

where θ_1, θ_2 are intersection threshold and distance threshold, respectively.

After a merging action has been performed, the remaining joints in the smaller set (call it S) can eventually replace low-confident, corresponding joints in a subset B_s of the big set B . To decide about this, the following values are considered: the normalized Euclidean distance between the smaller set joints and the corresponding candidate joints of the subset B_s , the average confidence of all candidate joints in the small set S and the average confidence of the corresponding joints in the bigger set (Figure 5).

Let N -elementary sets S and B_s of corresponding joints are given, considered for possible replacement. Standard deviation coefficients of the smaller set joints locations are $[std_{S,x}, std_{S,y}]$. Let the confidence value of a joint j be denoted as $P(j)$. The conditions for a joints replacement are as follows:

$$\frac{1}{std_{S,x} + std_{S,y}} \sum_{i=1}^N \sqrt{(x_{S_i} - x_{B_{s_i}})^2 + (y_{S_i} - y_{B_{s_i}})^2} \leq \theta_3 \quad (3)$$

$$\frac{1}{N} \sum_{i=1}^N P(S_i) \geq \theta_4 \quad (4)$$

$$\frac{1}{N} \sum_{i=1}^N P(B_{s_i}) \leq \theta_5 \quad (5)$$

where θ_3 is the normalized Euclidean distance threshold, θ_4 - the confidence threshold for S and θ_5 - the confidence threshold for B_s .

The skeletons, which remain after the merging and replacement steps, will be ordered by their bounding box size in descending order. With (w, h) representing width and height of a bounding box, the $score = w \cdot h$. The two sets with highest score will be kept and used further in the feature extraction step.

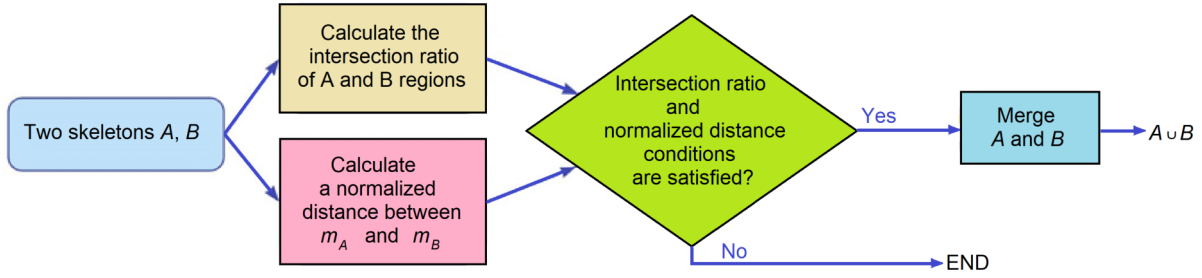

Fig. 3. The skeleton merging step.

Fig. 4. Illustration of a skeleton merging situation.

2) *Feature extraction*: Feature extraction means the calculation of normalized distances between pairs of joints from two skeletons, tracked in the frame sequence of a video clip. First, the distance between two middle-of-spine points of two human skeletons is calculated and normalized by the length of the spine I_1 of the first person, giving the distance feature (Figure 6). Then, every set of joints is independently normalized by: translating the local coordinate system to the middle-of-spine point O_1 or O_2 , rotating the points so that the spine segment (connecting joint 1 with joint 8) is parallel to the Y axis of local system, and finally, scaling the point coordinates by the spine length I_i .

Denote by $\mathbf{H}_1, \mathbf{H}_2$ the skeletons of the first and the second human; O_1, O_2 - the centers of spine segments of the first and second human, respectively; l_1 - the length of the spine segment of the first human; α_1, α_2 - the rotation angles to make corresponding spine segments parallel to the Y axes of local Cartesian coordinate systems. The *distance* feature is calculated as the distance between local system origins, O_1, O_2 , normalized by the length l_1 :

$$d = \frac{\text{distance}}{l_1} \quad (6)$$

The normalization of joints coordinates (translation to local system, rotation, scaling) is performed independently for every set $\mathbf{H}_1, \mathbf{H}_2$. Let $\mathbf{p}_i = (p_{i,x}, p_{i,y})$ denotes the image

coordinates of a joint from skeleton $\mathbf{H}_i, (i = 1, 2)$. The normalization of this joint is given as follows:

$$\mathbf{p}'_i = (p'_{i,x}, p'_{i,y}) = (p_{i,x} - O_{i,x}; p_{i,y} - O_{i,y}), \quad i = 1, 2 \quad (7)$$

$$\begin{pmatrix} p''_{i,x} \\ p''_{i,y} \end{pmatrix} = \begin{bmatrix} \cos(\alpha_i) & -\sin(\alpha_i) \\ \sin(\alpha_i) & \cos(\alpha_i) \end{bmatrix} \begin{pmatrix} p'_{i,x} \\ p'_{i,y} \end{pmatrix}, \quad i = 1, 2 \quad (8)$$

$$(p'''_{i,x}, p'''_{i,y}) = \left(\frac{p''_{i,x}}{w_i}, \frac{p''_{i,y}}{h_i} \right), \quad i = 1, 2 \quad (9)$$

3) *Feature vector*: Both the OpenPose (applied for our RGB dataset) and the built-in skeleton detector from Kinect v2 (generating the skeleton data in the NTU RGB+D dataset) deliver person skeletons of 25 joints. By analysing a small skeleton data subset, we found that the data for joints numbered from 15 to 24, corresponding to "small" parts, like fingers, are very often missing. Thus, we use only joints numbered from 0 to 14. The feature vector obtained from skeleton data of a single frame has 61 dimensions as there are $15 \text{ joints} \times 2 \text{ coordinates} \times 2 \text{ sets}$ and one distance feature. Assuming that we have selected m frames for analysis, we get a map of $m \times 61$ features.

D. Pose classifier training and evaluation

The feature data is fed to several MLP-based pose classifiers. We use fully-connected MLP architecture with variants of several hyper-parameters: the number of hidden layers of the network can vary from 1 to 3, different activation functions (ReLU and/or sigmoid) may be chosen, as well as the number of neurons in hidden layers and the learning rate can vary. The ANN is implemented using Keras [29].

Automated hyper-parameter tuning [31] is a crucial step during ANN model training to increase the model's performance. We perform a hyper-parameter search during training using the *Random Search* algorithm, offered in Keras [30]. For both datasets the hyper-parameter search space is defined as:

$$S_{\text{search}} = [a_{\text{fun}}, l_{\text{rate}}, n_{\text{layer}}, n_{\text{neur}}], \quad (10)$$

where the entries are: activation function, $a_{\text{fun}} \in \{\text{relu}, \text{sigmoid}\}$, learning rate, $l_{\text{rate}} \in [10^{-5}, 10^{-2}]$, number of hidden layers, $n_{\text{layer}} \in \{1, 2, 3\}$, number of neurons in hidden layer, $n_{\text{neur}} \in \{100, 200, \dots, 1000\}$.

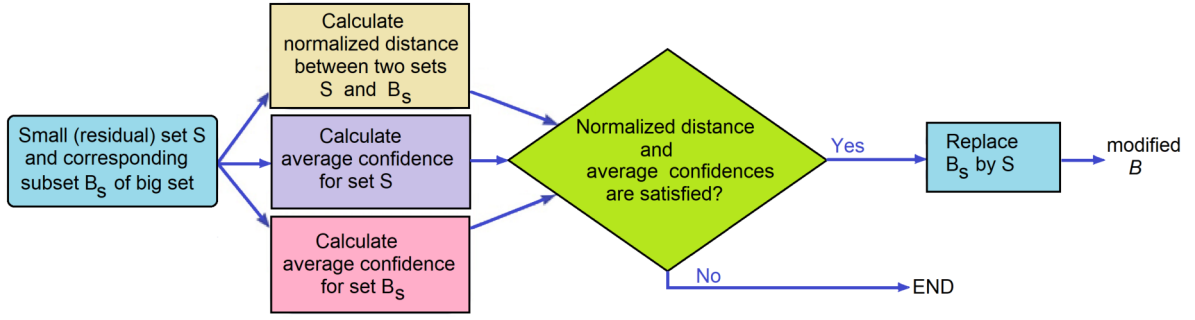

Fig. 5. The joints replacement step

Fig. 6. The normalization elements for two sets of joints

E. Ensemble classifier

As mentioned earlier, every pose classifier is an "expert" to recognize snapshots taken during different time period of an interaction. In practice, the training of such an assembly is performed at the same time, but 3 out of 4 "expert" networks are always in a dropout mode. The actually updated network depends on the time period the current input frame belongs to.

In the testing process, the interaction class is known after the entire frame sequence - from a single video clip - has been classified and the results of individual pose classifiers were accumulated. The likelihood of every interaction class comes from an aggregation of pose class likelihoods, as a weighted sum of pose likelihoods, for frames indexed from $t=0$ to $t=T$.

1) *Fixed gains*: In a hand-crafted form we define the aggregation of likelihoods, obtained by particular pose classifiers ($i = 1, 2, 3, 4$) for frames ($t = 1, 2, \dots, N$), the $\Pr_{pose_i}(t) - s$, as follows:

$$\begin{aligned} \mathbf{S} = \sum_{t=0}^T & [\Pr_{pose_1}(t) \cdot \max(0, (T/2 - t)/T) + \\ & + \Pr_{pose_2}(t) \cdot \min(0.5, t/T) + \\ & + \Pr_{pose_3}(t) \cdot \min(0.5, (T - t)/T) + \\ & + \Pr_{pose_4}(t) \cdot \min(0, (t - T/2)/T)] \end{aligned} \quad (11)$$

2) *The gain network*: In the trained case, the gain network provides gain coefficients $w_i(t)$ for the four pose classifiers depending on the frame index (t):

$$\mathbf{S} = \sum_{t=0}^T [\Pr_{pose_1}(t) \cdot w_1(t) + \Pr_{pose_2}(t) \cdot w_2(t) + \Pr_{pose_3}(t) \cdot w_3(t) + \Pr_{pose_4}(t) \cdot w_4(t)] \quad (12)$$

IV. RESULTS

A. Datasets

In order to evaluate and test the trained classifiers, two datasets were used. The search after best hyper-parameters of a single pose classifier will be performed by training and validating them on our **humiact5** dataset. Its consists of images of 5 two-person poses - snapshots of interactions: boxing, facing, hand holding, hand shaking and hugging/kissing. There are 1695 images in total, in which 1154 images are in the training set and remaining 541 images are in the evaluation set (Figure 7). In this series of experiments, the OpenPose library has been applied for skeleton detection in RGB images.

The best configuration of the pose experts and the final, time-accumulating network will be trained and tested on the interaction subset of the **NTU RGB+D** dataset. It includes 11 two-person interactions of 40 actors: A50: punch/slap, A51: kicking, A52: pushing, A53: pat on back, A54: point finger, A55: hugging, A56: giving object, A57: touch pocket, A58: shaking hands, A59: walking towards, A60: walking apart. In our experiments, already the skeleton data of the NTU RGB+D dataset is considered. There are 10420 video clips in total, in which ca. 70% are in the training set and remaining 30% are in the test set. No distinct validation subset is distinguished.

The NTU RGB+D dataset allows to perform a cross-subject (person) (short: CS) or a cross-view (CV) evaluation. In the cross-subject setting, samples used for training show actions performed by half of the actors, while test samples show actions of remaining actors. In the cross-view setting, samples recorded by two cameras are used for training, while samples recorded by the remaining camera - for testing. We apply the cross-subject (CS) evaluation mode, i.e., videos of 20 persons are used for training and videos of remaining 20 persons - for testing. The training set contains video clips of users identified as: 1, 2, 4, 5, 8, 9, 13, 14, 15, 16, 17, 18, 19, 25, 27, 28, 31,

Fig. 7. Samples from our *humiact5* dataset: RGB images with skeleton data

Fig. 8. Samples from the NTU RGB+D interaction dataset: RGB video frames with skeleton data [14]

34, 35 and 38. The number of samples in the training set is 7649, while in the test set - 2771.

Each skeleton instance consists of 25 joints of 3D skeletons that apparently represent a single person (Figure 8). As our research objective is to analyse video data and to focus on only reliably detected joints, we use only the 2D information of only first 15 joints.

From a video sample a set of frames is chosen as follows: the video clip is uniformly split into $N = 4$ time intervals ("periods"), from every interval some number of frames m is selected (we tested $m = 2, 4, 8$). The number of frames in the training set grows from 61192 to 244768 and the number of frames in the test set grows from 22168 to 88672, accordingly to the value of m from 2 to 8.

B. Pose classifier optimization

The hyper-parameter optimization of a pose classifier is performed on the small *humiact5* dataset. In order to run the *RandomSearch* function of Keras, a *NNHyperModel* is created, which implements the *HyperModel* class from the Keras-tuner. The hyper-parameters of the search space are declared in *NNHyperModel* as class parameters. Using the *RandomSearch* function, we identified three ANN configurations, each one being optimal for given number of hidden layers (1, 2 or 3).

The performances of the three selected models after 100 epochs of training are shown in Table I. The best test accuracy (i.e., the **recall** averaged over all classes) of 84% was achieved by the second model, whereas the other two have shown an accuracy of 82%. Consequently, we have chosen an ANN

TABLE I
THE MEAN ACCURACY ON THE *humiact5* DATASET OF THREE OPTIMAL ANN CONFIGURATIONS WITH 1, 2 AND 3 HIDDEN LAYERS.

Training/test	1 hidden	2 hidden	3 hidden
ANN - mean training accuracy	95%	96%	99%
ANN - mean test accuracy	82%	84%	82%

TABLE II
THE MEAN ACCURACY OF POSE CLASSIFIERS VERIFIED ON THE NTU RGB+D INTERACTION DATASET IN THE CS (CROSS SUBJECT) MODE

Expert	2 f/p	4 f/p	8 f/p
Pose - mean training accuracy	79.2%	82.4%	88.2%
Pose - mean test accuracy	61.2%	70.8%	76.1%

configuration of 2 hidden layers with 700 and 500 neurons in the first and second layer, respectively. The activation functions are ReLU and sigmoid, respectively. The learning rate is $5.89 \cdot 10^{-5}$.

C. Verification on the NTU RGB+D dataset

We train and test our models in the CS (*cross-subject*) verification mode proposed for the NTU RGB+D dataset, i.e. when actors in the training set are different than in the test set, but data from all the camera views are included in both sets. The frame sampling process for both training and testing will be done three times with different number of frames per time period (i.e., extracted from a single video sample): 2, 4, 8. The training set is split into learning and test subsets - two third for learning and one third for validation/testing. There are run 100 epochs of training and the best validation result will be chosen.

1) *Pose classifiers*: In the following, we apply the second version of the ANN pose classifiers, with two hidden layers, as reported earlier in Table I. We train four pose classifiers three times - every one is effectively trained on different frames according to its dedicated time period of action (i.e. $t \in [0, T/4], [T/4, 2T/4], [2T/4, 3T/4], [3T/4, T]$) of training samples with different frame sampling rates (i.e. $n = 2, 4, 8$ frames/period). The mean accuracy of these four pose experts, depending on the number of frames per period is shown on (Table II).

An immediate observation is, that all learning and test accuracies increase, when the training data size is increased. Specifically, with 8 frames per time-period (f/p), these accuracies reach to 88% and 76%, respectively. The average per class accuracies (i.e. four class poses representing the same interaction class) of the ANN experts, obtained with a 4 f/p

TABLE III
THE PER-CLASS TEST ACCURACY OF ANN POSE EXPERTS TRAINED ON THE NTU RGB+D INTERACTION DATASET, VERIFIED IN THE CS (CROSS SUBJECT) MODE, WHEN SAMPLED WITH 4 F/P

Class	A050	A051	A052	A053	A054	A055
Test accuracy	58%	52%	66%	69%	72%	83%
Class	A056	A057	A058	A059	A060	
Test accuracy	70%	64%	80%	81%	78%	

TABLE IV

THE ACCURACIES OF ANN POSE CLASSIFIER AND TWO VERSIONS OF THE ENSEMBLE CLASSIFIER (E-ANN-1, E-ANN-2), VERIFIED ON THE NTU RGB+D INTERACTION DATASET IN THE CS (CROSS SUBJECT) MODE

Classifier	Training accuracy	Test accuracy
Mean of pose classifiers	88.2%	76.1%
E-ANN-1, eq. (11)	92.4%	81.3%
E-ANN-2, eq. (12)	94.5%	83.3%

TABLE V

THE PER-CLASS TEST ACCURACY OF ANN ENSEMBLE CLASSIFIER, TRAINED ON THE NTU RGB+D INTERACTION DATASET, VERIFIED IN THE CS (CROSS SUBJECT) MODE, WHEN SAMPLED WITH 8 f/P

Class	A050	A051	A052	A053	A054	A055
Test accuracy	67%	67%	77%	87%	86%	91%
Class	A056	A057	A058	A059	A060	
Test accuracy	81%	76%	92%	93%	90%	

frame sampling on the test set, is shown on Table III. There are 3 classes (A55, A58, A59) that perform at least at 80%, other 6 classes - from 60% to 80% and two - below 60%. Compared with random choice - there are 11 classes and the random prediction (a guess) would be $1/11 = 9.09\%$. The largest accuracy is observed for the "A055 - hugging" class. The distance between two persons is here significantly smaller than of the rest and the poses are relatively stable in every time period.

2) *Ensemble of pose classifiers*: There are two variants of the final ensemble classifiers: E-ANN-1, when the final score of every interaction class is obtained by fixed weights, according to equation (11), or E-ANN-2, where the trainable gain network is used, according to equation (12). The class with highest score is selected as the winner of the interaction classifier. A notable improvement of interaction classification is observed, when accumulating over time sequence the weighted pose likelihoods. The mean accuracy of the best version of pose experts (i.e., for frame sampling of 8 f/p) was 88.2% (training) and 76.1% (testing), while the ensemble classifier has reached 92.4 % and 81.3% (version 1), or 94.5% and 83.3% (version 2), respectively (Table IV).

The per-class test accuracy of our ensemble classifier E-ANN-2 (with 8 f/p frame sampling) is shown in Table V. There are four classes (A55, A58, A59, A60) with an accuracy of 90% and higher, while the lowest performance (67%) is achieved for classes A50 (punch) and A51 (kicking). The confusion matrix for this testing case is shown in Figure 9. As the numbers of class samples in the test set are slightly unbalanced, we normalized the results, assuming 276 test instances per class, to make them easier comparable. "Punch" (A50) is most often misclassified with classes A51-A58, which all use hands to express an action, but most often is confused with "Point finger". "Kicking" (A51) is frequently confused with all other classes, slightly less with "pat on back". The main errors appear between actions "giving an object" (A56) and "shaking hands" (A58) - 18 and 9 cases, and between "pat on back" (A53) and "touch pocket" (A57) - 9 and 18 cases.

Fig. 9. The confusion matrix for the ensemble classifier E-ANN-2, verified on the NTU RGB+D interaction dataset in the CS (cross subject) mode

2S DR-AGCN [27]	94.6%	3.57M	max(all, 300)

D. Comparison

Many approaches to two-person interaction classification have been tested on the NTU RGB+D interaction dataset. We list some of the leading works in the Table VI. Our solution needs a low number of weights to be trained and it processes a sparse frame sequence. It shows a good tradeoff between competitive accuracy and low complexity when compared with other recently reported results.

Let us notice how we counted the number of parameters of the E-ANN-2 network. Remember that the pose classifiers have a common part - the feature transforming MLP with 2-hidden layers - and there are separate fully-connected output layers for every pose classifier. We can create two versions of the E-ANN network - one network with multiple feature-transforming MLPs that processes in parallel the four frame subsets, and another one that processes all frames in sequence.

As the individual results are finally aggregated over all frames, both configurations deliver the same final result. In the first configuration, there are 1 597 677 weights needed, while in the sequential version - 399 444 weights only:

- 1) The feature transforming ANN: $61 \cdot 700 + 700 + 700 \cdot 500 + 500 = 393\,900$ The FC classification layer: $500 \cdot 11 + 11 = 5\,511$ The gain network: $(11 + 11) + 11 = 33$
- 2) Four parallel pose classifiers: $4 \cdot 393\,900 + 4 \cdot 5\,511 + 33 = 1\,597\,677$
- 3) Four sequential pose classifiers: $393\,900 + 4 \cdot 5\,511 + 33 = 399\,444$

Taking into account, that the dominating processing time for a single frame is spent by the skeleton detector (on our equipment, it takes ca. 67 ms, compared to 1 ms for the pose classifier), the sequential version is preferred. Even when the skeleton detection itself will be performed in parallel, for every phase subset of frames one pose classifier will be allocated, the sequential version will take only $(N - 1)$ ms more time than when using N pose classifiers in parallel.

Typically, the performance of an interaction classifier is significantly improved when dense frame sequences are processed instead of sparse ones. But the overall processing time grows proportionally to the frame number, as the computation is dominated by the skeleton estimation step. Thus, processing a dense sequence of 100 frames (typical for the best performing solutions with accuracy $> 90\%$) takes roughly three times longer than the time needed for a sparse sequence of 32 frames (where a typical accuracy is $< 90\%$). The recently proposed multi-stream Graph CNNs have shown superior results but only when processing dense frame sequences. Considering the dominating processing time and resources needed for skeleton estimation in every frame of the sequence, the key to real-time interaction recognition is to limit the number of processed frames.

V. CONCLUSION

A light-weight approach to two-person interaction classification was proposed, that can be applied both in video- and single image-analysis. This is a skeleton-based approach, what means, that an external module for human detection and estimation in images is needed. We adopted the state-of-the-art OpenPose library for this purpose. This is a powerful deep network solution for human skeleton estimation in images. Our main contribution are algorithms for skeleton data correction and normalization and the design of an ANN classifier that has the form of an ensemble of several ANN-based pose experts. Aggregating four or more "weak" pose classifiers leads to an efficient and robust solution to human interaction classification. We also found that a comparison of classification approaches should not only consider the accuracy measure but also the amount of information received (i.e., whether a sparse or dense frame sequence is analyzed). Our future research should focus on the extraction of motion information for the skeleton joints and testing the model network on longer frame sequences.

Abstract—In this paper, we consider a challenging scenario of localising a camera with respect to a charging station for electric buses. In this application, we face a number of problems, including a substantial scale change as the bus approaches the station, and the need to detect keypoints on a weakly textured object in a wide range of lighting and weather conditions. Therefore, we use a deep convolutional neural network to detect the features, while retaining a conventional procedure for pose estimation with 2D-to-3D associations. We leverage here the backbone of HRNet, a state-of-the-art network used for detection of feature points in human pose recognition, and we further improve the solution adding constraints that stem from the known scene geometry. We incorporate the reprojection-based geometric priors in a novel loss function for HRNet training and use the object geometry to construct sanity checks in post-processing. Moreover, we demonstrate that our Geometry-Aware Keypoint Network yields feasible estimates of the geometric uncertainty of point features. The proposed architecture and solutions are tested on a large dataset of images and trajectories collected with a real city bus and charging station under varying environmental conditions.

I. INTRODUCTION

Estimation of the absolute pose of a camera from a single image is a classic problem in computer vision [1], which is being solved in a number of ways, depending on the application. Conventional, structure-based algorithms yield accurate camera pose estimates if stable, salient point features can be extracted. Unfortunately, in a number of practical scenarios, particularly outdoors, good quality point features (keypoints) are hard to extract from images, due to weak textures, difficult lighting, and motion blur.

The localisation scenario considered in this paper is part of the Advanced Driver Assistance System (ADAS) which we developed in cooperation with Solaris Bus & Coach, one of the manufacturers of electric buses [2]. The ADAS provides a bus driver with visual cues on how to operate the steering wheel in order to perform the desired manoeuvre. To perform successful docking, the driver has to put the tip of the vehicle's pantograph into the head of the charger, which is mounted on a support pylon. An important prerequisite for successfully planning such a manoeuvre is an accurate estimate of the bus position in relation to the charger head and its pylon. The use of GPS for localising while docking is considered unreliable in an urban environment. Active beacons or even large passive

Fig. 1. Accurate detection of keypoint features for vision-based localisation of an electric bus while docking to a charging station. The inset images show a charging station with the ground truth keypoints (upper), the estimated locations of these keypoints with uncertainty ellipses (lower), and a close-up of the roof-mounted sensor unit with a camera (in the circle)

markers installed at the charging station cannot be considered as well, because bus operators often do not permit deployment of any additional elements at the stations due to legal issues. For localisation, the bus has only a monocular camera mounted in the front part of the roof. The use of such a simple sensor was required by the bus manufacturer, as the ADAS equipment has to be affordable and scalable to different bus models.

The charging station is detected automatically from a long distance (typically 30 m), using the approach introduced in [3]. Once the station gets detected, the task comes down to the estimation of the camera pose with respect to certain predefined points of the charger structure. Despite its apparent simplicity, this scenario raises a number of issues in the camera pose estimation method. Firstly, the method needs to work without an initial pose guess, considering each observation of the charging station as a separate global localisation act. Secondly, the charging station is assumed to be the only known object in the environment, for which we have a 3-D model. Hence, we need to use the keypoints defined on the charging station that are observed during the entire docking manoeuvre over a large range of viewpoints, appearance, and scale change. All these difficulties make the existing simultaneous localisation

and mapping (SLAM) or visual odometry (VO) algorithms impractical in our scenario, as SLAM and VO systems need to be initialised with a known camera pose and require the salient features to be present in the environment all along the executed trajectory.

To address the specific requirements we proposed in [4] a two-step procedure, which uses a conventional, structure-based pose estimation algorithm with 2D-to-3D associations between the keypoints found in the camera image and predefined points from the three-dimensional model of the charger. Whereas this procedure using a Faster R-CNN network architecture adopted to detect the keypoints has been positively verified in docking experiments with a real bus [2], [4], we observed, that any inaccuracy in the position of the estimated keypoints significantly deteriorates the accuracy of the final position estimate. A mismatch of detected points with other features makes the pose estimate completely wrong.

Therefore, in this paper we investigate how to adapt to our application a different network architecture: the High Resolution Network (HRNet) [5], which is a leading solution for keypoint detection in human pose estimation. The detection of body points in humans is a major area of interest for researchers and commercial use, and thus it arguably sets the state-of-the-art in keypoint detection in the wild [6]. We conjecture that a network architecture achieving top scores in the COCO Keypoint Detection Task would be a good starting point for use in the considered application. However, our application offers some a priori knowledge about the geometry of the observed object, which is not present in the human pose estimation task. Thus, we investigate how to include this knowledge either in the learning process, creating an inductive bias in the neural network, or in post-processing, defining a sanity check procedure that quickly eliminates implausible predictions of the network. We also extend the neural network architecture by adding a separate branch that estimates covariance matrices describing the 2-D uncertainty of the detected keypoints. Finally, we get the new Geometry-Aware Keypoint Network that addresses the specific challenges of the bus localisation process at the charging station.

In this work, we contribute: (i) an analysis of the HRNet architecture aimed at the accuracy improvement of the keypoints locations with respect to ground truth, also considering the computation burden; (ii) a novel loss function that exploits the available geometric priors of our application; (iii) a sanity check procedure based on these geometric priors, and (iv) an extended experimental evaluation of all these components on a unique application-specific dataset, which is made publicly available.

The remainder of this paper is organised as follows. Section II reviews the most important related work in similar applications and in keypoints detection from monocular images. Section III gives a description of the proposed neural network architecture, and provides technical details pertaining to its novel components. Then, section IV describes the experimental procedure and summarises the results of the experiments, while section V draws conclusions upon these results.

II. RELATED WORK

A. Vision for automated docking

There are few works concerning vision-guided docking of larger vehicles to electric chargers [7]. Precise docking to a charging station under the control of a camera can be cast as a visual servoing problem. Unfortunately, visual servoing methods [8] require the target object or marker to appear big enough in the images, whereas the charging station detected from a distance of 30 m is too small to make a visual servoing method effective. Recent visual SLAM algorithms can estimate a camera's trajectory precisely over hundreds of metres [9]. In practice, however, a SLAM method requires a large number of features detected over several consecutive image frames [10] and has to be initialised properly, which is problematic in the monocular case and often requires several attempts with camera relocation. These problems make SLAM impractical for the specific task we consider, as neither visual odometry nor SLAM exploit the knowledge about the appearance and geometry of the charging station, which is assumed to be visible during the entire docking manoeuvre.

On the other hand, automated charging for self-driving electric cars is often implemented using devices that plug into the car's charging port [11]. This approach eases the guidance process, as only this port has to be localised with respect to the plugging arm/device. In this context, the approach we propose is of practical importance, as we do not need any active devices, nor markers/fiducials attached to the charging station, and we can localise the bus during the entire manoeuvre, starting 30 metres from the station.

B. Camera pose estimation

A wide variety of algorithms have been presented in the literature for the camera pose estimation problem. The classic way is to compute the camera pose from 2D-to-3D correspondences between 2-D features in the image and 3-D points in the model [1]. The model can be given a priori, from CAD data or via accurate laser scanning, as in our scenario, or can be obtained through 3-D structure-from-motion (SfM). Correspondences between points are established through the matching of descriptors, which can either be handcrafted [12] or learned [13]. The camera pose is then computed upon the known correspondences applying a variant of the perspective- n -point (PnP) algorithm [14] or optimised using bundle adjustment [15]. The conventional approach can estimate the camera pose accurately [16], but it struggles whenever the features are difficult to match. Our approach follows the classic pipeline with respect to pose computation using a PnP algorithm, but deploys a specialised neural network as the feature detector, thus obtaining a well-defined pattern of a few keypoints that are already associated with the model points. Owing to this concept we do not need to use RANSAC for outlier rejection.

In the last few years, learning-based approaches to camera pose estimation have been gaining attention. End-to-end methods have been pioneered by PoseNet [17], which used a trained convolutional neural network to regress a six degrees-of-freedom camera pose. A similar idea was followed by

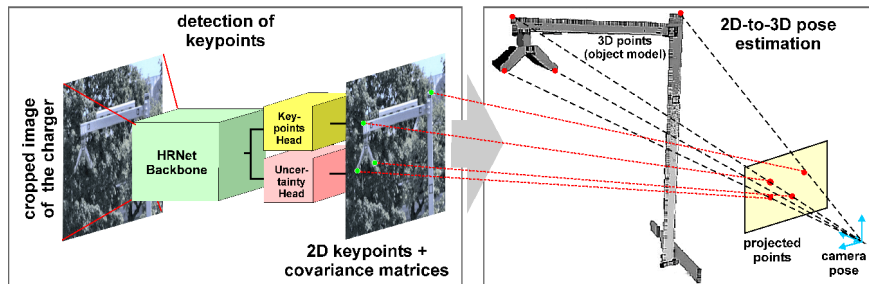

Fig. 2. Structure of the camera pose estimation system consisting of a CNN-based keypoint detection module and a conventional pose computation method

[18], demonstrating camera relocalisation in cluttered scenes. Although PoseNet can localise the camera without an initial pose guess, as we require in our scenario, the accuracy of pose estimates yielded by this neural network is inferior with respect to its conventional, structure-based counterparts using principled algorithms. As concluded in [19], the main reason for the insufficient accuracy was the use of a naive regression loss function without consideration of the scene geometry. The improved PoseNet presented in [19] uses reprojection-based loss, thus narrowing the performance gap to pose estimation using principled algorithms. The importance of using the geometric knowledge about the scene and enforcing the geometric constraints during learning was pointed out in [20], and has been demonstrated recently also by other pose estimation methods. A camera pose estimation pipeline that is applicable for fusing classical geometry and deep learning is proposed in [21], while [22] introduces an end-to-end system consisting of deep learning modules for feature extraction, matching, and outlier rejection while optimising for the camera pose objective.

C. Detection of keypoints

In conventional, structure-based pose estimation systems detectors and descriptors designed by heuristics are applied. However, in recent years, deep learning has been applied to obtain feature detectors and descriptors in visual odometry and SLAM. LIFT [23] was among the first attempts to detect features by end-to-end learning, and was trained on ground truth obtained from SIFT and SfM. The more recent SuperPoint [13] introduced a self-supervised approach to learn the detectors and descriptors of keypoints simultaneously, while DISK [24] demonstrated learning of features using policy gradient.

Independently, a number of neural network architectures for keypoint detection have been proposed in the context of human pose estimation. The architecture from [25] is based on Faster R-CNN with ResNet-101 backbone, similarly to our previous camera pose estimation system described in [4]. Whereas this approach yields accurate keypoints, and thus is included in our experiments for comparison, it is computationally heavy and hence does not allow to exploit the full resolution of the acquired images. A recent paper [26] demonstrated the use of novel self-calibrated convolutions that expand fields-of-view of each convolutional layer to detect keypoints. A leading

solution for keypoint detection in human pose estimation is the High Resolution Network [5], which was designed specifically to keep the high resolution of the feature maps through the entire processing pipeline. This approach is in line with our idea of using high-resolution images for reliable detection of keypoints from longer distances, while still keeping good accuracy of their localisation in images. Therefore, we selected the HRNet as our baseline approach and adopted its backbone network as a feature extractor in our GAKN architecture.

Uncertainty in learned feature extractors and camera pose estimation methods seems to be not yet fully exploited, despite its importance in the conventional, geometric approaches. Among the examples considering uncertainty, [27] uses Bayesian neural networks to obtain localisation uncertainty, and a recent approach [21] learns the deep neural network uncertainty guided by the geometric uncertainty. In our localisation scenario, we are interested in aleatoric uncertainty, which depends on the inputs, and may be estimated from data [28]. Whereas Bayesian deep learning is popular for this purpose, we leverage the Cholesky Estimator Network to represent the uncertainty of each keypoint as a Gaussian distribution with covariance matrix [29].

III. STRUCTURE OF THE PROPOSED SOLUTION

The main inspiration for this work was an excellent performance of state-of-the-art keypoint detectors in the top down human pose estimation methods [6]. In the top down approach to human pose estimation keypoint locations are predicted within bounding boxes obtained from a person detector. This fits our processing pipeline, where the charging station is detected by a Faster R-CNN object detector [3], and further processing for localisation is limited to the image area cropped by the object's bounding box [4] (Fig. 2).

Therefore, we adopt the keypoint detection architecture with HRNet [5] backbone implemented using the MMPose framework [30] as a baseline model during our experiments. This architecture consists of a backbone network and the keypoint head. We decided to use a pre-trained backbone, and design our own head, also adding an auxiliary branch for the estimation of spatial uncertainty of the keypoints (Fig. 3). The keypoint head contains Deconv Blocks which double the resolution of the feature maps. A single Deconv Block is built with a Transposed Convolution Layer followed by a Batch

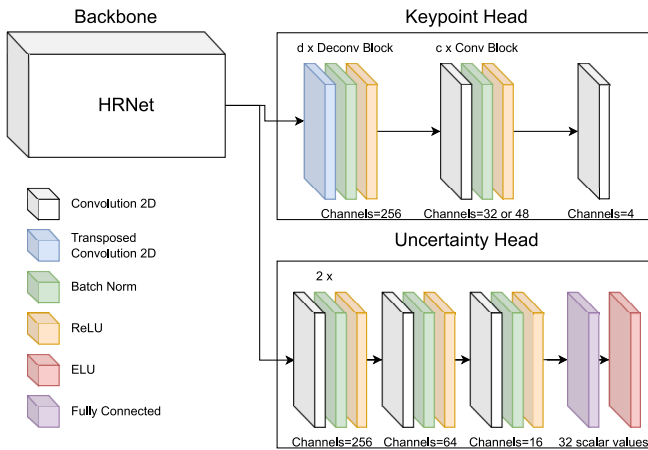

Fig. 3. Architecture of the GAKN model. Configurations with heatmap size of 128×128 , 256×256 and 512×512 contains d equal 0, 1 or 2 Deconv Blocks respectively. Architectures can be extended with c additional Conv Blocks in the keypoint head

Norm and ReLU layers. The final layer in the keypoint head is a single Convolution Layer that outputs n heatmaps, where n is the number of keypoints. For the preparation of ground truth heatmaps as training targets and the decoding of the final keypoint coordinates from the heatmaps we incorporated the UDP and DarkPose methods described in [31] and [32], respectively. These data preprocessing techniques allow us to preserve the accuracy of ground truth coordinates of the keypoints through the labelling and augmentation process. During the inference, while decoding the coordinates from predicted heatmaps, those methods allow for extracting unbiased, subpixel-accuracy keypoint locations.

Point detection in objects such as an electric bus charger is different from body point detection in humans. The human body is composed of numerous parts moving relatively to each other, therefore choosing which part of the image should be used to look for a given point is not obvious. Due to the rigid geometric configuration of the charging station, this is not a problem in our network design, thus we focused on developing methods to increase the accuracy of point localisation. We experimented with several configurations of the HRNet architecture in order to find the limits of the keypoints location accuracy, and to choose a reasonable trade-off between the accuracy and the number of computations. We selected three aspects of the HRNet model for potential improvements: the selection of a backbone network for feature extraction, the size of the returned heatmaps, and the structure of the keypoint head. Next, having a reasonable baseline design customised to our application, we investigated the best way of injecting the prior geometric knowledge to the network model.

A. Backbone network

We evaluated two backbone networks HRNet32 and HRNet48. The difference between HRNet48 and HRNet32 lies

in the width of the convolutional layers in the high-resolution stream (48 and 32 respectively). This enhances the capability of HRNet48 to extract more feature maps but at the cost of higher computational cost.

B. Keypoint head depth

We evaluated the influence of the additional convolutional layers in the keypoint head to find out whether it will improve the pose estimation accuracy. The extra layers were added after the Deconv Block and before the convolution layer which produces final heatmaps. Each extra layer consists of 256 filters of the size 3×3 and is followed by Batch Norm and ReLU.

C. Heatmap size

The default implementation of the keypoint detector based on HRNet returns heatmaps which are downsampled four times compared to the input image size, so using an image of 512×512 pixels results in 128×128 pixels heatmaps. The upsampling of the heatmaps is achieved using Transposed Convolutional layers. A single transposed convolutional layer increases the width and height of the heatmap twice.

The charging station pylon and head do not contain moving parts and their geometric configuration is constant. This makes rough estimation of the keypoints locations easier than the same task in human pose estimation because we can expect the given point in the specific area of the image. On the other hand, the accuracy of the described pose estimation method is strongly dependent on the accuracy of estimation of the keypoints. Small inaccuracies in the location of keypoints propagate to relatively large pose estimation errors, especially from larger distances. The above considerations suggest, that increasing the resolution of the output heatmaps may promote accurate subpixel estimation of the keypoint locations, which in turn will lead to a significant improvement of the camera pose estimation accuracy.

D. Reprojection loss

The key role of scene geometry in conventional pose estimation models and the fact that ground truth points can be easily identified for the charging station, together with the geometric relations between these points, were inspirations for developing the HRNet baseline model into the Geometry-Aware Keypoint Network.

This network exploits these geometric priors while training, as it uses an additional cost function based on the reprojection error. The reprojection loss penalises spatial configurations of the keypoints which are physically impossible. We define camera projection function, π , which maps the i -th 3-D point \mathbf{w}_i to the 2-D image point $(\tilde{u}, \tilde{v})^T$ leveraging the given camera intrinsics parameters \mathbf{K} :

$$\pi(\mathbf{T}, \mathbf{K}, \mathbf{w}_i) \mapsto (\tilde{u}, \tilde{v})^T, \quad (1)$$

where \mathbf{T} is a rigid transformation matrix (rotation and translation).

To calculate the reprojection loss, we minimise the difference between the projection of the real 3-D object points $(\tilde{u}, \tilde{v})^T$ and the points predicted by the network $(\hat{u}, \hat{v})^T$. The optimisation problem is solved by the Trust Region Reflective algorithm [33] which finds a transformation \mathbf{T}^* :

$$\mathbf{T}^* = \underset{\mathbf{T}}{\operatorname{argmin}} \sum_{i=1}^n (\tilde{u}_i - \hat{u}_i)^2 + (\tilde{v}_i - \hat{v}_i)^2. \quad (2)$$

Trust Region Reflective is a robust optimisation method for constrained problems that has a Python implementation in the SciPy library, which facilitates integration in a deep learning framework.

To limit the search space and keep the solution physically correct we applied constraints on the transformation \mathbf{T} to reflect only the operating area of the bus. All three values of the rotation vector are limited to $\frac{\pi}{4}$. Assuming that roll and pitch angle are close to zero, this constraint limits the yaw angle to be less than $\pm \frac{\pi}{4}$. The translation in the lateral axis is limited to ± 20 m, the longitudinal axis is limited to 50 m and the translation in the z axis is limited to 50 m (Fig. 4).

Fig. 4. The considered search space for the bus location and orientation.

Then, the reprojection loss is the value of the cost function for the optimal \mathbf{T}^* transformation:

$$\operatorname{loss}_{\text{repr}} = \sum_{i=1}^n (\pi(\mathbf{T}^*, \mathbf{K}, w_i^x) - \hat{u}_i)^2 + (\pi(\mathbf{T}^*, \mathbf{K}, w_i^y) - \hat{v}_i)^2, \quad (3)$$

where w_i^x and w_i^y are x and y coordinates of point \mathbf{w}_i .

The second loss element is a Mean Squared Error Loss:

$$\operatorname{loss}_{\text{MSE}} = \sum_{i=1}^n \left(\frac{1}{m} \sum_{j=1}^m (m_{ij} - \hat{m}_{ij})^2 \right), \quad (4)$$

where m_{ij} is the j -th pixel of the ground truth heatmap corresponding to the i -th point and \hat{m}_{ij} is the j -th pixel of the predicted heatmap corresponding to the i -th point. The final loss function is a sum of the MSE loss (4) and the reprojection loss, calculated according to the formula:

$$\operatorname{loss} = \operatorname{loss}_{\text{MSE}} + \lambda \cdot \operatorname{loss}_{\text{repr}}, \quad (5)$$

where the metaparameter λ was estimated experimentally and is set to 0.01 for our evaluation.

E. Reprojection-based refinement

Each of the four points defined on the charging station can be detected more or less accurately, depending on a number of circumstances, including the camera viewpoint and the amount of motion blur in the image. In this situation, it may happen, that some keypoints are well extracted, while some others are inaccurate or even misplaced.

To cope with this problem we define a sanity check procedure that incorporates the geometric constraints during the inference of the neural network. This procedure refines the neural network predictions, solving the same task as described by the equation (2). Having the optimal transformation \mathbf{T}^* , we project 3-D coordinates of the keypoints on the image. Then the distances between the predicted point $(\hat{u}, \hat{v})^T$ and the projected point $(\tilde{u}, \tilde{v})^T$ are calculated. Then, we compare the maximum distance d_{\max} with the mean of three remaining distances d_{res} multiplied by parameter $\gamma = 2$. If the inequality $d_{\max} > \gamma d_{\text{mean}}$ is satisfied, we use this projection as the final prediction of keypoints location. The above condition ensures that we are refining only the cases where there is only one point with inaccurate prediction.

F. Uncertainty estimation

As knowing the geometric uncertainty of extracted keypoints may be instrumental when computing the camera pose estimate and then fusing it with other localisation data in the vehicle, we extended the GAKN architecture with an uncertainty estimation branch. Our aim was to obtain a trainable model that predicts covariance matrices of the individual keypoints depending on the input images. With such a model we can judge if the extracted keypoints are accurate enough for the camera (and then vehicle) localisation task. For this purpose, we implemented the Gaussian Log-Likelihood Loss proposed in [29]. We estimate the uncertainty of all four keypoint locations as a Gaussian distribution with covariance matrix Σ , an 8×8 symmetric positive definite matrix. Σ has $(2n + 1)n$ degrees of freedom which are estimated by a lower triangular matrix \mathbf{L} such that $\Sigma = \mathbf{L}\mathbf{L}^T$ (Cholesky decomposition). The GAKN uncertainty estimation branch consists of four blocks built with a convolutional layer followed by Batch Norm and ReLU. The final layer is Fully Connected which predicts 36 values of the \mathbf{L} matrix. The loss function used during training is described by:

$$\operatorname{loss}_{\text{unc}} = \sum_{i=1}^n \log |\Sigma| + (\mathbf{p} - \hat{\mathbf{c}}) \Sigma^{-1} (\mathbf{p} - \hat{\mathbf{c}}), \quad (6)$$

where \mathbf{p} is a vector of ground truth keypoint locations and $\hat{\mathbf{c}}$ is a vector of predicted keypoint locations. The 2×2 covariance matrices of the individual keypoints are then extracted from Σ , and can be visualised as uncertainty ellipses in the image plane.

IV. EXPERIMENTS

A. Evaluation procedure

The purpose of the presented experiments was to examine the influence of the neural network architecture on the 2-D pose estimation accuracy and the computational complexity. All experiments were performed off-line using Nvidia A100 GPU on a custom dataset recorded using a real electric bus and charger with the ground truth poses obtained using Differential GPS (DGPS). In our experimental installation (cf. Fig. 1) a high-resolution camera (5472×3648 pixels) is used, as the application scenario requires to detect the charging station from a distance of at least 30 m and localise with a 2-D circular position error smaller than 0.35 m when approaching the charger’s head (this error can be compensated mechanically). The camera is mounted in a detachable unit with a laser scanner for safety monitoring (not used here), and a DGPS receiver, which was used only to obtain ground truth trajectories of the bus. Note that compared to [4] we no longer use the black rectangular markers that are visible on the charger’s pylon (cf. Fig. 1). The ground truth keypoints are defined by manual labelling directly on the training sequence images. They are two corners of the charger’s head and two other points on the extreme parts of the supporting pylon. The dataset consists of 81 image sequences gathered over five days. The diversity of data was achieved by different manoeuvre starting points, different bus trajectories, and changing lighting and weather conditions.

The final pose estimate of the camera is computed as in [4], using an iterative perspective- n -point algorithm, which minimises the reprojection error. The cost function of this optimisation problem is defined as sum of squared distances between the point localisation on the image, and the object model points projected on this image:

$$\mathbf{T}^* = \underset{\mathbf{T}}{\operatorname{argmin}} \sum_{i=1}^n \left((\hat{u}, \hat{v})_i^T, \pi(\mathbf{T}\mathbf{w}_i) \right)^T \left((\tilde{u}, \tilde{v})_i^T, \pi(\mathbf{T}\mathbf{w}_i) \right). \quad (7)$$

To consider the detection of a keypoint as accepted, the RMSE of the 3-D point projected on the image using ground truth transformation from DGPS should be less than d pixels:

$$\sqrt{\frac{1}{n} \sum_{i=1}^n \left(\sqrt{(\tilde{u} - \hat{u})^2 + (\tilde{v} - \hat{v})^2} \right)^2} < d, \quad (8)$$

with d set to 10 in our experiments.

Finally, we evaluated the performance of the different neural models applied for keypoints extraction directly for the objective of camera pose accuracy. The ground truth trajectories were provided by DGPS (2 cm of accuracy), while the camera and DGPS receiver were calibrated using an optimisation-based procedure developed specifically for this project [34]. The 3-D model of the charging station was obtained using a geodetic laser scanning system. For evaluation we use three metrics: median of the 2-D translation error, the median of the yaw angle estimation, and percentage of accepted detections. We project the 3-D camera pose into the 2-D manifold and

ignore the pitch and roll angles, as these dimensions are irrelevant to localisation of the bus on a flat area. For all experiments, the image input size was set to 512×512 pixels. Results of the main experiments are presented in Tab. I. The considered configurations of the keypoint extraction network are the Baseline (i.e. HRNet32 with 3 layers head), Refined, which is Baseline with the geometric sanity check, GAKN, and GAKN+Refined, which is GAKN equipped with the sanity check in the post-processing.

B. Comparison with the state-of-the-art

To compare the GAKN architecture with the state-of-the-art we use the HRNet configured for the considered application scenario according to the outcome of our experiments, i.e. with the HRNet32 backbone and the keypoint head with 3 layers, which we call the “Baseline” configuration. Additionally, we use for comparison the Faster R-CNN-based network described in [25]. During the inference, this network required above 32 GB of GPU memory, most of it was consumed by the extraction of the keypoint location offset values. The inference time is significantly longer and the pose estimation errors are larger than for the HRNet-based networks. In our application scenario, the weakest point of the network from [25] is a low percentage of accepted detections (40.9 %). To improve this parameter, we tested also our sanity check procedure (post-processing) with this network architecture. However, in this case, application of the reprojection-based refinement does not bring the expected results. The ratio of accepted detections increased to above 50 % but the pose estimation accuracy dropped. This case shows that the reprojection-based refinement can improve results only when the raw predictions are relatively close to ground-truth and there is usually only a single keypoint of lower accuracy.

C. Backbone network

Comparing the HRNet32 and the HRNet48 (Tab. II) we can notice that the medians of rotation and translation errors are lower for the HRNet48 network for both keypoint head variants. There is no significant influence on the percentage of accepted detections. The inference time is slightly longer for the HRNet48 version and the required operations and number of parameters are over twice as large as for the HRNet32 backbone. Using the HRNet48-based network, the whole processing pipeline requires more than 8 GB of GPU memory. The commercial application of this system requires that the cost of used hardware must be considered. Despite better pose estimation accuracy, we selected the HRNet32 backbone for the Baseline, as it provides acceptable accuracy and can be run on low-end hardware (GPU). Consequently, the GAKN architecture configurations evaluated in our experiments also use the HRNet32 backbone.

D. Keypoint head depth

Additional convolutional layers in the keypoint head decrease slightly the median of translation and rotation error (Tab. II). Applying this modification does not affect the

	HRNet32	3	41.12	28.54 M	35.60	0.43	0.97	93.89 %
	HRNet48		84.18	63.60 M	37.60	0.40	0.71	92.87 %

percentage of accepted detections and has a marginal influence on the number of operations and inference time.

E. Heatmap size

In this subsection, we compare the results of the Baseline network on three different heatmap resolutions. The default implementation of the keypoint detector based on HRNet returns heatmaps which are downsampled four times compared to the input image size, so using an image of 512×512 pixels results in 128×128 pixels heatmaps. The influence on the percentage of accepted detections is marginal, but increasing the heatmap size significantly reduces the translation and rotation error. The difference in the number of operations between a 128×128 and a 256×256 heatmap is small, compared to the 512×512 version, where the number of operations increases three times. This translates into processing time for a single image, wherein the 512×512 version is characterised by the processing time twice as large as in the 128×128 version. Increasing the size of the processed heatmap allows for increased location accuracy, but at the cost of increased processing time. However, there is only a slight increase in the number of network parameters when increasing the heatmap size. This means that all of the architectures discussed, including the largest one, should fit on a graphics card with 8 GB of memory. As the size of the heatmap increased, we achieved a reduction in errors (e.g., the translation error of a 128-sized heatmap relative to a 512-sized heatmap was 26.7%, the rotation error in the same ratio was 33.9%), which was the main research goal. When considering the errors of a 256-sized heatmap, they

were larger than 512 and smaller than a 128-sized heatmap confirming the relationship between heatmap size and location accuracy. Heatmap size does not affect the percentage of accepted detections.

F. Reprojection loss

The configuration of the GAKN network features the same number of operations, parameters, and processing times because the only modification to the baseline network was made during the training phase and does not affect these parameters during inference. There is a reduction in translation and rotation errors in all three heatmap sizes considered. When using reprojection loss for heatmap size 128, there was a 15.2 % reduction in translation error, 37 % in rotation error, for size 256, the translation error decreased by 8.4 %, and rotation error decreased by 15.5 %, whereas for heatmap size 512: there was a 2.6 % reduction in translation error and 9.5 % in rotation error. By combining both approaches - increasing the heatmap size and applying reprojection loss, we obtain the lowest median translation error among all tested models, and a median rotation error comparable to the lowest obtained with heatmap size 256. We believe that using a heatmap size of 256 is a reasonable trade-off between processing time and location accuracy. It achieved the best rotation error result, translation error comparable to the best result, and features a short inference time – similar to the one for 128×128 heatmap. Additionally, the percentage of accepted detections in the GAKN configuration with this heatmap size is higher than in the baseline.

TABLE III
PERCENTAGE OF GROUND-TRUTHS WITHIN UNCERTAINTY ELLIPSE FOR
DIFFERENT STANDARD DEVIATIONS

Standard deviation	1σ	2σ	3σ
Percentage of ground-truths within uncertainty ellipse	48.75 %	87.38 %	98.00 %

G. Reprojection-based refinement

Using reprojection-based refinement does not affect the number of operations performed by the network and the number of parameters, because it is performed at the post-processing stage. On average, this step takes 4 ms per image, which constitutes 11% of the processing time for heatmap 128×128 , and only 8 % for heatmap 512×512 , therefore adding reprojection-based refinement does not increase significantly the image processing time. No clear effect on location accuracy was observed when using reprojection-based refinement. The main goal of this method was to increase the percentage of accepted detections, which was achieved. As a result, we are able to provide a higher number of correct pose estimates, making the localisation system more reliable. By using the GAKN network together with reprojection-based refinement, we eliminate the relatively low percentage of accepted detections.

H. Uncertainty estimation

Using a hand-labeled validation dataset of about 200 images, we evaluated the geometric uncertainty prediction. We checked the percentage of ground truth keypoint locations that are within the 1, 2, and 3 σ uncertainty ellipses. The numerical values are presented in Tab. III.

Qualitative results of covariance matrices prediction are demonstrated in Fig. 5. Comparing Fig. 5A and Fig. 5B, we can notice that the uncertainty of keypoint detection decreases with the distance to the charger. Figure 5C and Fig. 5E show larger uncertainty for poor quality images. On Fig. 5D, the two leftmost points have larger uncertainty along x axis because, from that point of view, estimation of their exact location is ambiguous.

I. Analysis of cumulative distribution plots

Comparing the 3 pairs of graphs (Fig. 6, Fig. 7 and Fig. 8) corresponding to heatmap sizes, it can be seen that the benefit of reprojection loss is biggest for heatmap size 128×128 , and decreases as the heatmap size increases. It can also be seen that by using reprojection-based refinement, we increase the number of accepted detections that provide coarse location information, despite the relatively large translation and rotation error (right part of the graph). Furthermore, we are able to improve the detection accuracy for which the error is below the median (the red line in Fig. 6. is above the green line for values below 0.4 m and 0.6 deg).

J. Network attention analysis

Starting this research we conjectured that the prior geometric knowledge represented by the reprojection-based loss

Fig. 5. Visualisation of estimated keypoints locations and 3 sigma uncertainty ellipses for different observation cases. Fig. A presents detection from close distance, B - far distance, C - blurry image, D - different observation angle, E - cloudy/foggy weather

component introduces to the GAKN architecture an inductive bias that helps the network to focus on the most relevant image areas when searching for the keypoints. To verify this claim, we implemented in GAKN an attention analysis layer, based on the Score-CAM method [35]. Compared to the older, gradient-based methods Score-CAM produces results that are visually less noisy, making it easier to interpret the attention depending on the input image.

In Fig. 9 and Fig. 10, the top row (A, B, C and D) shows the activation maps for all 4 detected points in an example image from the test set. Comparing the activation maps shown, it can

Fig. 7. Cumulative distribution functions of 2D translation error (A) and orientation error (B) for the HRNet32 models with the heatmap size 256×256

Fig. 8. Cumulative distribution functions of 2D translation error (A) and orientation error (B) for the HRNet32 models with the heatmap size 512×512

be seen that the activations of individual points for the GAKN network are more concentrated and have higher intensity. In the bottom row of Fig. 9 and Fig. 10 (E, F, G, and H), the Score-CAM method marked the parts of the image that had

Fig. 9. Heatmaps (top) and the output of the Score-CAM algorithm (bottom) from the baseline HRNet32. Warmer colors mean higher activation

Fig. 10. Heatmaps (top) and the output of the Score-CAM algorithm (bottom) from the Geometric Aware Keypoint Network. Warmer colors mean higher activation

the greatest effect on selecting a specific location in the image as the searched point. The first thing you notice is that in the case of the baseline network, activation is scattered throughout the background image, indicating that the network attention is highly scattered. Furthermore, in the case of point three (G), there is very weak activation near the actual point location and large activation on a portion of the image completely unrelated to the charger structure (lower left corner). In Fig. 10, showing points from the GAKN network, the network's attention is more focused near the searched points than at the baseline.

V. CONCLUSION

This paper evaluated our experience with applying the state-of-the-art HRNet architecture for the detection of keypoints in a challenging scenario of camera pose estimation for localisation of an electric bus. The proposed GAKN model achieved better results than both the Faster R-CNN-based keypoint detector and the baseline HRNet32. Our solution takes less than 50 ms for processing a single image on Nvidia A100, which makes it possible to update the camera pose frequently and facilitates accurate bus localisation along its path to the charging station. Reliable localisation under changing viewpoint, scale, lighting, and weather conditions is achieved without any markers deployed at the charging station. The contributed modifications to the baseline HRNet, based on exploiting the available geometric priors were evaluated positively, as they improve the accuracy of keypoint locations.

Finally, we evaluated the novel elements of GAKN with respect to the localisation accuracy objective, and we have found that using the reprojection loss reduces translation and rotation errors, while using refinement (sanity check) in postprocessing increases the number of accepted detections, thus increasing the availability of the camera pose estimates. Our future research will determine if the proposed GAKN architecture can be scaled down to edge computing platforms, for better cost-efficiency. The project with datasets is available at https://github.com/ZephyrII/mmpose_charger

Abstract—The increasing rates of deadly brain tumors in humans correspondingly increase the need for highly experienced medical personnel for diagnosis and treatment. Therefore, to reduce the workload and the time from suspicion of disease to diagnosis, then plan for suitable treatment, there is a need to automate the initial part of the process by implementing a Computer-Aided-Disease-Diagnosis (CADD) system for brain tumor classification. The aim of this research is to develop and deploy all the needed components to design and implement a working Computer-Aided-Disease-Diagnosis (CADD) system for brain tumor classification. First, by understanding the brain tumors themselves and the convention of their classification. Second, the convolution neural network (CNN) structure and functionality and how to manipulate it. Third, find different CNN architectures with promising results in similar tasks. Fourth, find and evaluate the applicability of available data sources. Fifth, implement the most promising solutions and explore the applicability of using transfer learning for the given task to take advantage of previously gained knowledge. Finally, evaluate the results of the experiments, where we show that the DenseNet121 architecture, either fully trained or using transfer learning, likely is the most appropriate candidate for the CADD system in development.

Index Terms—Brain Tumor Classification, Medical Imaging, CADD, Convolutional Neural Networks, Machine Learning, Deep learning.

I. INTRODUCTION

THE CELL of origin and features found when examining the cells tissue define central nervous system tumors and predict their behavior [1]. After meningiomas, the most common primary brain tumor in adults is gliomas, with a rate of 5 to 6 persons per 100,000 annually [2].

The World Health Organization (WHO) tissue classification system categorizes gliomas, with grade 1 as the lowest and grade 4 as the highest. Thus, low-grade gliomas (LGG) consist of grade I and II tumors [3], while high-grade gliomas (HGG) consist of grade III and IV [2]. Grade I are the least malignant or benign tumors. Grade II is relatively slow-growing but may recur as a higher grade. Grade III is malignant and tends to recur as higher grades. Finally, grade IV is the most malignant, aggressive, necrosis and recurrence prone [1].

Histopathologic examination to study tissue morphology, diagnose, and grade brain tumors is the gold standard [3]. However, surgical resection for diagnosing a brain tumor is invasive and risky. Nevertheless, non-invasive diagnostic methods exist, like neuroimaging with Magnetic Resonance Imaging (MRI) [4].

Conventional MRI is the current imaging procedure of choice and identifies tumor size and associated Peritumoral Edema (PTE), one of the main features of malignant glioma [5]. To diagnose the brain tumor without surgical intervention, researchers have developed more advanced imaging methods such as texture analysis, mechanic modeling, and machine learning (ML) that form a predictive multi-parametric image-based model. The application of ML models is an emerging field in radiogenomics and represents a data-driven approach to identifying meaningful patterns and correlations from often complex data sources. ML models train by feeding the ML algorithm a substantial amount of pre-classified image data as input, such as MRI images, to learn which patterns belong to the different classes.

The convolutional neural network (CNN) is a concept introduced by [6] as the Neocognitron, as a model of the brain’s visual cortex; an improvement of [7] previous model for visual pattern recognition. Furthermore, [8] significantly improved the Neocognitron to one of the most successful pattern recognition models, dramatically influencing the field of computer vision and pattern detection in images.

In 2021 a fully automatic hybrid solution for brain tumor classification comprised of several steps was proposed [9]. First, pre-process the brain MRI images by cropping, resizing, and augmenting. Second, use pre-trained CNN models for feature extraction with better generalization. Third, select the top three performing features using fined-tuned ML classifiers and concatenate these features. Finally, use the concatenated feature as input for the ML classifiers to predict the final output for the brain tumor MRI. The proposed scheme uses a novel feature evaluation and selection mechanism, an ensemble of 13 pre-trained CNNs, to extract robust and discriminative features from brain MRI images without human supervision. The CNN ensemble, is comprised of ResNet-50, ResNet-101, DenseNet-121, DenseNet-169, VGG-16, VGG-19, AlexNet, Inception V3, ResNext-50, ResNext-101, ShuffleNet, MobileNet, and MnasNet. Since the researchers use fairly small datasets for training, they take a transfer learning-based approach by using the fixed weights on the bottleneck layers of each CNN model pre-trained on the ImageNet dataset.

II. DATA GATHERING & PRE-PROCESSING

The data-gathering part of the research starts with outlining some criteria. The data should contain non-tumorous, LGG,

and HGG samples and be well balanced between the labels. The latter is essential since too much data augmentation on medical images often does not generalize well. A well-suited candidate was found at The Cancer Imaging Archive (TCIA). The REMBRANDT (REpository for Molecular BRAin Neoplasia DaTa) Dataset [10] seemed to have all this research’s characteristics. The dataset is one of the most trusted publicly available datasets, comprised of MRI scans from 130 subjects of three classes, non-tumorous, LGG, and HGG. Furthermore, the LGG and HGG classes have subclasses that opened the opportunity to make the classification outcome more extensive. The dataset is a combination of metadata from various text and spreadsheet files and the 110,020 images in the DICOM format, which also includes a vast quantity of metadata. After preprocessing, the dataset comprises 123 patients and 105,265 slides, distributed as shown in Table I. At this point, it was discovered that one key bit of information was missing; how to separate the MRI slides that contained the tumorous cells from the ones that did not contain them. All the source data were reexamined, but the answer was not found. While searching online for how to find the needed key, one paper stood out [11]. The paper used that same dataset for a similar application. While being reduced to 4069 slides, it seemed that the authors of this paper had found a way to filter the data further. A meeting with the paper’s main author was arranged to understand how to reproduce the dataset. His research team had employed help from neurologists to go through each slide manually and label them correctly. Fortunately, the main author offered to share a smaller dataset version. After further processing, the dataset has 735 samples distributed, as shown in Table II, and is now ready for training CNN models.

III. METHODOLOGY

Finding the CNN architecture with or without transfer learning that yields the best results for the classification task is the primary goal of the current research. Therefore designing a

pipeline where the CNN architecture can easily be substituted is essential. Doing so required finding the generally most suitable division of the Test, Validation, and Train subsets, the most suitable baseline hyperparameter settings, and whether image augmentation was to be used. For this task, VGG16 [12] was selected, as it had been used for the same application with promising results [13] [14]. After training a large number of VGG16 models, a baseline for training other CNN architectures was established. A total of 60 images, 20 from the three classes, were randomly picked for the Test set. The remaining images are divided into 30% and 70% for the Validation and Training sets. The Training set is also augmented with rotation, width and height shift, shearing, zoom and brightness adjustment, and horizontal flipping. Filters with minimal adjustments to the original gave better results than fewer with more extensive adjustments. The Normal label has a little over half of the samples as LGG and HGG, and is therefore producing a higher number of augmented images. The Normal label in the Train set is increased from 103 to 309, LGG from 186 to 372, and HGG from 182 to 364. With a batch size of 24, the baseline uses 10 epochs for training with a learning rate of 0.001, Adam for optimization with categorical cross-entropy as the loss function. In addition to the VGG16 architecture, five other CNN architectures were used to train models, including AlexNet, MobileNet [15], ResNext [16], DenseNet121 [17], and a custom-designed architecture. The custom CNN architecture is designed to accept N amount of 224x224 image matrices with 3 color channels; it consists of three convolutional layers of 32, 64, and 64 filters, of filter size 3x3, with zero-padding, and ReLU as the activation function. The first convolutional layer is followed by a max-pooling layer of pool size 4x4, and the last two convolutional layers have a pool size of 2x2, each followed by a dropout layer with a dropout rate of 0.15. Next, a flattening layer is added to transform matrix output to vector inputs to be accepted by the first dense layer, which is comprised of 512 ReLU activated neurons, followed by a dropout layer with a 0.5 dropout rate. The last hidden layer is a dense layer of 256 ReLU activated neurons. The model’s final layer, its output, is a 3 neuron softmax activated dense layer for classification. The general architecture of this model is shown in Fig. 1, and the flowchart is provided in Fig. 2.

IV. RESULTS

All the CNN architectures implemented to this point show outstanding results, as shown in Table III. While multiple runs were made on each architecture to obtain the given results, and there is an indication that the Test set in particular needs expansion, the results indicate that DenseNet121 is the best candidate for the given classification task. Surprisingly enough, with the custom architecture as the runner-up.

V. RESEARCH CONTRIBUTIONS

The research conducted has been a good start for further developing a usable CADD system. A pipeline for data preprocessing that makes preparing new data samples both easy and

Fig. 1. Custom CNN Architecture.

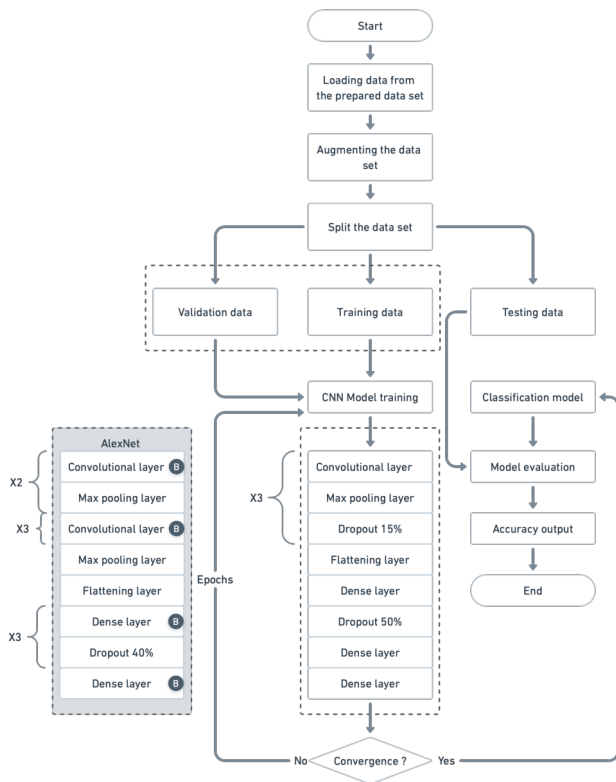

Fig. 2. Flowchart of the custom framework.

TABLE III
CNN ARCHITECTURE RESULTS

Architecture	Epochs	Initial learning rate	Loss	Accuracy & F1
VGG16	10	0.001	0.3218	0.933
ResNext	12	0.001	0.1244	0.933
MobileNet	28	0.001	0.1141	0.950
Custom	22	0.000316	0.0989	1.00
AlexNet	28	0.001	0.0582	0.983
DenseNet121	12	0.001	0.0254	1.00

fast has been developed. Similarly, a pipeline for augmenting the training data and a pipeline for defining CNNs, training them, and providing a classification model as the output has been developed successfully. Also, to demonstrate the potential of the research, a user interface has been developed and deployed to a web server where the general public can accessed at tumorclass.info. All the source code used in this project can be found in the [GitHub repository](#).

VI. DEPLOYMENT

A service called ngrok was selected for the deployment. Ngrok is a free service that allows the exposure of localhost to the internet in a secure manner. With ngrok installed, the only steps needed were to run the FastAPI in uvicorn on the local machine and then run ngrok in a separate terminal to expose the local host to the internet. To make it a little more elegant, a domain name was purchased, and the DNS was set to give access to ngrok. A monthly subscription on ngrok was also purchased to connect the autogenerated ngrok domain name to the custom domain name. In figures Fig. 3, Fig. 4, Fig. 5, and Fig. 6 the implemented user interface is shown.

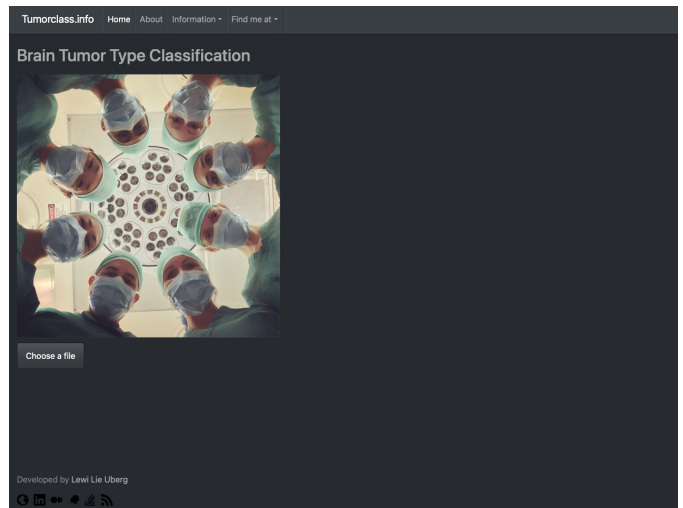

Fig. 3. Interface of our platform.

VII. CONCLUSION & FUTURE WORK

The next step after our CADD system is to expand the data set. The amount of suitable data available is limited. However, the REMBRANDT dataset has a vast number of images suitable for manual labeling performed by radiologists. Expanding the data set will make it more transparent, which architectures generalize well. As such, these architectures can be the focus of further development. These days, MRI scans provide 3D images, so further development to facilitate 3D classification is also a viable option.

Insights into Neural Architectures for Learning Numerical Concepts from Simple Visual Data

Andrzej Śluzek

 Email: andrzej_sluzek@sggw.edu.pl

Abstract—The paper reports some results on neural architectures for learning numerical concepts from visual data. We use datasets of small images with single-pixel dots (*one to six per image*) to learn the abstraction of small integers, and other numerical concepts (e.g. *even versus odd numbers*). Both fully-connected and convolutional architectures are investigated. The obtained results indicate that two categories of numerical properties apparently exist (in the context of discussed problems). In the first category, the properties can be learned without acquiring the counting skills, e.g. the notion of *small, medium and large numbers*. In the second category, explicit learning of counting is embedded into the architecture so that the concepts are learned from numbers rather than directly from visual data. In general, we find that CNN architectures (if properly crafted) are more efficient in the discussed problems and (additionally) come with more plausible explainability.

I. INTRODUCTION AND MOTIVATION

THE CONCEPTS of numbers and numerical properties develop primarily (e.g. [1], [2]) from sensory experiences, with visual inspection playing the pivotal role.

Researchers investigate the topic of learning numerical abstractions mainly (apart from actual and prospective applications) as a challenging AI/ML problem.

Initially, the works were focused on object counting rather than understanding the abstractions, with efforts on *counting-by-localizing* sub-tasks, e.g. [3]. This was an application-oriented approach, and some sources (e.g. [4]) indicate that true understanding of numbers may not be even needed to perform counting tasks in visual data.

Later, researchers expressed more interests in grasping/learning the concept of numbers and numerical abstractions. First, it was done in the context of human brain functioning (e.g. [5]) but recent works focus on machine learning aspects as well. In particular, visual data have been explicitly used as inputs to learning algorithms and architectures, e.g. [6], [7], [8]. Complexity of those visual inputs is usually limited to avoid complicated image processing sub-tasks, i.e. either binary [6], [7] or near-binary [8] low-resolution images are used.

In this paper, we follow the same approach. Using results of [6] and [8] as the starting point, we attempt to develop simple neural architectures for learning the concept of numbers (from a limited range 1 to 6) and other numerical abstractions which can exist within such a narrow range of integers. Examples of such abstract concepts are:

- *even* and *odd* numbers;
- *small* (1, 2), *medium* (3, 4) and *large* (5, 6) numbers;
- etc.

Formally, each concept is a division of integers (from 1 to 6 range) into classes. For example, enumeration from 1 to 6 corresponds to six classes (1), (2), (3), (4), (5) and (6), *even* and *odd* numbers form two classes (1, 3, 5) and (2, 4, 6), etc. Then, an input image should be assigned to the correct class based on the number of dots it contains.

In Section II, we explain the proposed methodology and overview the developed datasets. The considered neural architectures are also briefly explained. Section III presents the conducted experiments and achieved performances. Informal explanations of the trained architectures are provided there as well. The concluding Section IV highlights the most significant facts, underlines unsolved problems and proposes directions for the future work.

II. METHODOLOGY

A. Assumptions

In [6], two neural models are proposed for estimating numbers of white non-overlapping rectangles (up to 10) in small black images of 28×28 resolution.

In [7], more general (but still simple) tasks are discussed, i.e. estimating either the numbers of white isolated pixels or white connected components in 256×256 black images. The assumed numbers of counted objects are much larger (e.g. up to 3,000 isolated pixels).

In [8], the task is to count isolated pixels (up to 10) in 10×10 images. However, the images are only approximately binary with random polarity (bright pixels on dark backgrounds or another way around).

In this paper, the proposed scenario (based on the above approaches) is further simplified. Images are very small (7×7) and contain up to 6 dots. Such small numbers of dots are motivated by a well known psychological fact that humans can visually perceive (without explicit counting) at most 7 objects. The images are only approximately binary and their polarity is random.

We consider both fully-connected (FcNN) and convolutional (CNN) neural networks. This is motivated by inconclusive reports from the past papers, where *pros* and *cons* of both

Fig. 1. Exemplary dataset images.

TABLE I
FIRST CNN ARCHITECTURE (CNN1).

Layer	Parameters	Activation
input	7×7	
conv.	$16 \times 3 \times 3$, str=1	relu
maxpool	2×2 , str=1	
conv.	$16 \times 16 \times 2 \times 2$, str=1	relu
fc	10 outputs	tanh
fc	6 (or 2, or 3) outputs	softmax
output	6 (or 2, or 3)	

architectures are highlighted. Obviously, the considered architectures are rather simple to reflect small size and low complexity of input images.

B. Datasets

The developed dataset consists of 12,000 7×7 near-binary images (6,000 dark images with bright dots and 6,000 images of the opposite polarity). The numbers of dots range from 1 to 6 (each number in 2,000 images).

Near-binary images are used to alleviate overfitting, and to more realistically represent the real-world visual conditions.

Figure 1 shows a small sample of dataset images.

For the actual training and testing, the dataset is divided into two parts of 6,000 images each (with the same ratio of all types of images). Only one half is used for training and validation, while the other half is used for testing only.

C. Neural architectures

As mentioned earlier, both FcNN and CNN architectures are considered. After extensive *try-and-error* tests (and partially following the ideas from [6] and [8]) we eventually propose two CNN and two FcNN architectures shown in Tables I- IV.

It can be noticed that (CNN1, CNN2) and (FcNN1, FcNN2) pairs are very similar. Actually, 'variant 2' architectures are obtained by embedding 'variant 1' (with 6 nodes in the terminal layer) and adding an additional FC layer. In the embedded 'variant 1', its last layer is assumed to learn numbers from 1 to 6. Thus, the terminal layer of 'variant 2' architectures would infer the numerical abstractions from presumably learned concepts of enumeration. This is further explained in Section III (with some special cases separately discussed).

TABLE II
SECOND CNN ARCHITECTURE (CNN2).

Layer	Parameters	Activation
input	7×7	
conv.	$16 \times 3 \times 3$, str=1	relu
maxpool	2×2 , str=1	
conv.	$16 \times 16 \times 2 \times 2$, str=1	relu
fc	10 outputs	tanh
fc	6 outputs	softmax
fc	2 (or 3) outputs	softmax
output	2 (or 3)	

TABLE III
FIRST FCNN ARCHITECTURE (FcNN1)

Layer	Parameters	Activation
input	49	
fc	53 outputs	tanh
fc	10 outputs	tanh
fc	6 (or 2, or 3) outputs	softmax
output	6 (or 2, or 3)	

Actually, the architectures can be much slimmer than presented here. For example, the first hidden layer of FcNN architectures can be reduced from 53 nodes to, for example, 20 nodes. The current size is proposed to satisfy theoretical conditions of approximation theorems.

Similarly, the number of filters in convolutional layers of CNN architectures can be much smaller (see Section III); the proposed numbers just provide safe margins.

III. EXPERIMENTS AND RESULTS

The proposed architectures were separately trained for various concepts, including:

- learning the concept of numbers from 1 to 6;
- differentiating between *even* and *odd* numbers;
- differentiating between *medium* (3, 4) numbers and other numbers (i.e. either *small* (1, 2) or *large* (5, 6));

TABLE IV
SECOND FCNN ARCHITECTURE (FcNN2)

Fig. 4. Examples of images with incorrectly identified numbers of dots by CNN1.

- and a few other (sometimes slightly artificial) numerical concepts.

In the following subsections, we discuss how the architectures can handle the above tasks.

A. Learning numbers from 1 to 6

This task is the only one similar to the problems discussed in earlier papers (e.g. [4], [6], [7], [8], [9]).

We found that both CNN1 and FcNN1 architectures can easily learn to nearly flawlessly recognize the number of dots in test dataset images. As an example, Fig. 2 shows training performances of CNN1.

The overall accuracies (on the test dataset, see Section II-B) are almost the same, i.e. 99.68% for CNN1 and 99.17% for FcNN1. However, the confusion matrices (given in Fig. 3) indicate more plausible performances of CNN1. Errors are located within classes with larger numbers of dots, i.e. in the scenarios where humans can make mistakes more frequently.

Examples of some incorrectly identified images are given in Fig. 4. At the first glance, they may look confusing even for humans.

B. Learning even and odd numbers

In this task, classification is not directly related to magnitudes of numbers but to their specific quantifiers (which should be identified by trained networks). In [5], it is argued that in human perception knowledge of numbers makes important contributions to acquiring meanings of such quantifiers. Our observations confirm this conclusion.

We find that 2-output architectures of CNN1 and FcNN1 type (i.e. the hidden layer for learning numbers is missing) are apparently unable to learn the abstraction of *even* and *odd*

Fig. 5. Training (continuous line) and validation (circles) accuracy plots for CNN1 learning *even* and *odd* numbers.

Fig. 6. Training (continuous line) and validation (circles) accuracy plots for CNN2 learning *even* and *odd* numbers.

numbers. The most typical accuracy for CNN1 is the random-choice 50.00%. FcNN1 performs slightly better, reaching 60.48%. Thus, the architectures are unable to learn such numerical abstractions.

An exemplary plot of CNN1 performances during training is shown in Fig. 5.

When 'variant 2' architectures are used, the situation changes. Although accuracy of FcNN2 architecture deteriorates compared to FcNN1 (58.52% versus 60.48%), a significant improvement can be noticed for CNN2. Accuracy reaches 83.32% and training is very fast, as shown in Fig. 6.

In other words, if the concept of numerical values is embedded in the process (as explained in Section II-C) the convolutional architecture is able to quickly generalize the abstraction of *even* and *odd* numbers with reasonable accuracy. This can be considered a kind-of-projection of [5] observations onto machine learning domain.

C. Learning other numerical abstractions

The other exemplary numerical abstractions considered in the experiments are:

- *medium* numbers, i.e. (3, 4) versus all other numbers,
- various classes of *compact* and *disconnected* subsets of integers (see Table V).

In the first experiment, the overall conclusions are similar to Section III-B. CNN1 architecture achieves results equivalent to random choice (66.67% accuracy; a training plot shown in Fig. 7) while FcNN can reach 74.36%.

Again, a switch from CNN1 to CNN2 architecture significantly improves performances. With the concept of numbers embedded, CNN2 achieves almost perfect 99.38% accuracy, and the learning curve is very steep (see Fig. 8). For FcNN2, however, there is no real improvement.

In other experiments, various classes have been proposed within the range 1, 6; examples are shown in Table V. We

Fig. 7. Training (continuous line) and validation (circles) accuracy plots for CNN1 learning to distinguish $\{3, 4\}$ from other numbers.

Fig. 8. Training (continuous line) and validation (circles) accuracy plots for CNN2 learning to distinguish $\{3, 4\}$ from other numbers.

found that learning abilities of proposed architectures strongly depend on whether the classes consist of compact subsets of integers (e.g. *even* and *odd* numbers are disconnected classes).

For FcNN architectures (regardless the variant) the results are satisfactory only if the classes are *compact*. Table V contains a number of examples with the top accuracies obtained by FcNN architectures (either FcNN1 or FcNN2). The accuracy is always very high for *compact* classes, while for *disconnected* classes the results are unacceptable (often even below the level of random choice).

For CNN architectures the results are generally much better. For *compact* classes, almost perfect accuracies can be obtained both by CNN1 and CNN2, while for *disconnected* classes only CNN2 are able to reach very high accuracies. CNN1 architectures usually struggle to go beyond the random-choice level.

However, some interesting examples of *disconnected* classes have been identified, where even CNN1 are able to score near-perfect performances. Learning numbers divisible by 3 (i.e. $\{3, 6\}$ and $\{1, 2, 4, 5\}$ classes) is one of such examples.

As expected, FcNN architectures perform rather poorly (63.25% for FcNN1 and 64.92% for FcNN2) in this example. However, CNN architectures can almost perfectly grasp this abstraction, even in CNN1 variant (i.e. without the embedded concept of numericals). Accuracy reaches 99.97% for the test

TABLE V
ACCURACY OF FCNN ARCHITECTURES IN SELECTED OTHER PROBLEMS.

Classes	accuracy	compact?
$(1, 2)(3, 4)(5, 6)$	99.1%	YES
$(1)(2)(3, 4, 5, 6)$	99.5%	YES
$(1, 4)(2, 5)(3, 6)$	56.1%	NO
$(2, 4)(1, 3, 5, 6)$	74.7%	NO
$(3, 5)(1, 2, 4, 6)$	68.3%	NO
$(4, 5)(1, 2, 5, 6)$	74.1%	NO

Fig. 9. Training (continuous line) and validation (circles) accuracy plots for CNN1 learning numbers divisible by 3.

Fig. 10. First-layer of 3×3 filters for (from top to bottom): CNN1 for learning 1 to 6 numbers, CNN2 for learning *even* and *odd* numbers and CNN1 for learning numbers divisible by 3.

dataset, and the learning curve is very steep (see Fig. 9).

Very similar results are obtained for another (somehow artificial) case, where the first class consists of $(2, 6)$ and all other numbers form the second class.

D. Explainability issues

The complexity of proposed architectures is (deliberately) very low to correspond to low complexity of the input data. Therefore, it is possible to inspect the learned values of NN parameters, and informally explain their roles in the process.

Again, the conclusions are very different for FcNN and CNN architectures. In FcNN structures, it is hardly possible to identify any intuitive explanations for the obtained weights. The numbers look random, and even if some specific features (e.g. near-zero columns in the weight matrix of the second hidden layer) can be noticed, they do not exist in other nets trained to learn similar concepts.

For CNN structures, however, the convolutional layers of successfully trained architectures are almost identical. Fig. 10 shows visual representations of 3×3 filters of the first convolutional layer for several such cases. It looks obvious that in all of them only one filter plays an active role (others are approx. averaging filters) and its apparent role is to detect isolated pixels.

Fig. 11 presents the corresponding filters for an unsuccessfully trained CNN1 (see Fig. 5) for learning *even* and *odd* numbers. Again, only one active filter can be noticed, but its effective functionality is unclear. Thus, the failure of this architecture can be attributed to unsuccessful building of the first-layer filters.

Similarly, 2×2 filters of the second convolutional layer are virtually identical for all CNN architectures, and (again) only

Fig. 11. First-layer of 3×3 filters in CNN1 unsuccessfully trained to distinguish between *even* and *odd* numbers.

Fig. 12. Second-layer of 2×2 filters for CNN architectures. They are virtually the same for all trained CNN1 and CNN2 structures. Only one filter (in the last row) seems to perform actively.

one of the filters seems active (see Fig. 12). Apparently, its role is to accumulate large-magnitude instances of the first-layer results, i.e. to effectively count the number of dots.

Thus, the inferred explanations accurately correspond to the common-sense understanding of the investigated learning tasks.

IV. SUMMARY

The paper presents some insights into processes of learning basic numerical concepts from visual data (small near-binary images containing several single-pixel dots) by using simple FcNN and CNN architectures.

It was found that in case of concepts with classes forming *compact* subsets in the domain of integers (e.g. (1), (2) and (3, 4, 5, 6)) both FcNN's and CNN's can be trained to achieve nearly perfect accuracy on test datasets. However, for *distributed* classes (e.g. *even* and *odd* numbers) the conclusions are less straightforward.

For *distributed* classes, FcNN architectures are sometimes able to achieve accuracies above the random-choice level, but generally their performances are unsatisfactory. Typically, CNN's in CNN1 variant also do not go above the random-choice levels. However, CNN2 architectures (where learning numbers is embedded into a hidden layer of the net) can achieve very high (or almost perfect) accuracies even for *distributed* classes. There are, nevertheless, specific cases where both CNN2 and CNN1 architectures can achieve almost perfect accuracy after very short learning period (with very steep learning curve). Further experiments and analysis are needed to better understand this phenomenon.

In many aspects, the obtained results supplement conclusions from past works on similar topics (mainly [6], [7] and [8]). In particular, we can (partially) support opinions

from [7] about limited usefulness of fully connected architectures for counting tasks in visual data. The concepts of using small-scale CNN's for learning numerical abstractions (proposed in [6]) is also confirmed.

However, conclusions from our earlier work [8] about limited capabilities of CNN architectures should be significantly revised.

Additionally, we found that in the investigated problems CNN architectures can be much better explained. In particular, the weights of convolutional filters nicely correspond to the intuitive understanding of the problems. In FcNN architectures, we did not find any regularities coinciding with the nature of learned problems.

Last but not least, our investigations can be (distantly) related to works discussing learning numerical concepts from neuropsychological perspectives. For example, relations between numerical and logical quantifiers are discussed in [5], while early stages of sensory-based counting abilities and understanding numbers by animals (from insects to humans) are presented in [1], [10], [11], [12] (and many other works). We believe that similar investigations can be continued in the domain of AI agents and systems.

1st Workshop on Personalization and Recommender Systems

RECOMMENDER Systems are present in our everyday life while we reading news, logging in to social media or buying something at e-shops. Thus, it is not surprising that this domain is getting more and more attention from researchers from academia as well as from industry practitioners. However, the way in which they look at the same problem differs a lot.

Personalization is an important element in novel recommendation techniques. Nonetheless, it is a wider topic that concerns also user modelling and representation, personalized systems, adaptive educational systems or intelligent user interfaces.

The objective of PeRS is to extend the state-of-the-art in Personalization and Recommender Systems by providing a platform at which industry practitioners and academic researchers can meet and learn from each other. We are interested in high quality submissions from both industry and academia on all topics related to Personalization and Recommender Systems.

TOPICS

The list of topics includes, but is not limited to:

- Personalization
 - User Profiles
 - Ontology-based user models
 - Personalized systems
 - Intelligent user interfaces
- Recommender Systems approaches
 - Collaborative Recommender Systems
 - Semantic-based Recommender Systems
 - Context-aware Recommender Systems
 - Cross-domain Recommender Systems
- Machine Learning techniques for Recommender Systems
 - Association Rules
 - Clustering methods
 - Neural Networks
 - Deep Learning
 - Reinforcement Learning
- Applications of Recommender Systems methods
 - News recommendations
 - Tourism recommendations
 - Fashion recommendations
 - Podcasts recommendations
 - Medical recommendations
 - Other domain-specific recommenders
- Evaluation of Recommender Systems

- Metrics
- Evaluation studies
- Reproducibility of existing methods
- Case studies of real-world implementations

Abstract—User experience as a concept of human-computer interaction is crucial for the evaluation of systems and applications. Every new generation of navigational systems provides new features and extended functionality, which has additional functions that can oftentimes confuse the primary information on the system’s functionality. The conducted experiment analyses and observes available versions of navigation systems such as Garmin Drive 50 and/or TomTom Go, which are offered with certain advantages on features. The paper presents the selected aspects regarding the implementation, design, environment, recruitment, tests, and evaluation of the navigation systems, concluding from the results that there is difference between audio and visual mode.

Index Terms—navigation systems, human-computer interaction methods, user experience, multimodal usability

I. INTRODUCTION

New generation of navigational systems provide new features and extended functionality, which can sometimes be source of confusion on the primary information of the system’s functionality. This often times lead to poor usability, especially when it comes to operations of the primary functions [1], [5]. In order to design a proper environment with effect on user satisfaction, the usability aspect should be taken into account. This is to ensure successful performance on the primary operations of the system, as well as on the upgraded versions, regardless of the users’ experience and ability with it. User experience as a concept of human-computer interaction is a fundamental concept in the evaluation of systems and applications, particularly because it affects issues such as usability, cognitive load, affective experiences, mental demand, efficiency, etc.

The evaluation of usability is quite diverse. As an area, it is under uninterrupted and active development, meaning new approaches and procedures come as continuous expansion of the practice into several contexts [2]. Hence, the testing methodologies can be different based on aim, place, and moderating style. However, in general there are two evaluation methods on usability, namely qualitative and quantitative [2], [6]. The quantitative evaluation is required to generally get numerical values that represent the level of usability, whilst qualitative evaluation is required to identify and examine issues and problems. In our work, we focus mainly on the

quantitative method as a primary evaluation, namely surveys designed for specific tasks.

The concept of cognitive load, in the other hand, referring to the amount of effort required while performing an action, is an aspect taken into consideration mainly because of potential interference with the processes in the use of a system [17]. Considering that an ideal application or system ensures an interface that keeps user cognitive load to a minimum, what we have considered as an important indicator [18].

Additionally, mental workload, considered as a demand placed on the user by the system, depends on many parameters, which lead to the fact that the result of a task performed is subjective to the users’ experience and the ability [7]. For this reason, it was determined that during the recruitment process the experience, initial capacities, reaction time and fatigue will be taken into account. The conducted experiment analyses and observes available navigation systems such as Garmin Drive 50 and/or TomTom Go, which are available and with certain advantages on features, although not as widely used as the most traditional available Maps. The compactible devices used were Camper/RV 890 and/or TomTom GO 60S Automotive GPS Navigation Device. The main reasons for carrying out this experiment are to find out the satisfaction and efficiency of the applications used and how much of the aimed aspects are satisfactory. This experiment is carried out aiming to analyse and compare user experience on aspects as efficiency, usability, and cognitive load on system’s multimodal mode.

The defined null hypothesis assumes that there is slightly no difference between visual or audio mode of feedback in the user experience. Hence, it was decided on three defined dependent variables, namely efficiency, usability, and cognitive load, where the efficiency regards how fast the user finished the task, taking into account its completion time. Furthermore, usability as the second variable is defined as how easy the feedback is learned by the user. Finally, the mental and/or physical load for the tasks being taken by the user and the difference between audio and visual feedback. The independent variable is the feedback type with the given conditions on the audio and visual feedback treatments, shown in table I. The environment of the design is certainly basic, as it contains only one independent variable with two possible conditions based on the mode of the feedback. The design would be affected

by different user features, such as background, accessibility, previous experience which affects efficiency and other minor variables [5], [14], [15].

Aspects regarding the implementation, design, environment, recruitment, tests and evaluation are thoroughly discussed in the next sections. The paper is structured as follows: section 2 presents the recruitment process, selected profile and confounding variables together with the methods, tasks and setup. Section 3 deals with the result, statistics and significance of each test performed. Finally, section 4 gives an overall conclusion and discussion on final findings.

II. METHODOLOGY OF THE STUDY

The recruitment design is selected considering different factors, concentrating especially on the depended variable – the user experience, which should consider that has a wide range of variations. In the view of certain complex tasks that require information retrieval from the system, problem-solving skill of a certain level is necessary for multimodal feedback. Certainly, some individual users might have limitations, disabilities, or accessibility issues, hence within group design would be best to eliminate such differences [3], [4], [16].

Participant's profile is selected deciding in various factors in order to minimize the confounding factors:

- Users with similar experience in using such systems.
- User of similar age group.
- User with/without IT background.
- Accessibility or level of disability (visual or audio issues/impairments).

Training and overview of the proposed navigation system is given to the user and an orientation session conducted to make participants familiar with the tasks required and how to tackle it. Moderators are not allowed to interfere during any ongoing activity, only in case of error issues, to allow completion of the activity.

In this setting the dependent variable is User Experience for the following categories, i.e., Efficiency, Usability and Cognitive Load. Given it with only one independent variable which is the type of feedback for the chosen systems, taking into consideration two conditions/states: Audio and Visual feedback for the respective system.

Whereas the environment of the carried experiment consisted of several elements. The first session was conducted to assess the navigation system usability, first by being introduced to the use of the system. Secondly, specific tasks for a specific period of time and path. It was followed by a session with the test environment where participants were asked to explore the virtual landscape freely and navigate from one place to another. The participants were instructed to try all of the navigation functions provided.

A short questionnaire was handed out after the road/path completion and the participants answered the questions within d minutes. The moderator followed a set of predefined questions during the later session. Preparation required before the study starts includes the consent form, demographic question-

naire, participants coding and preparing all other questionnaires.

The tasks described in table I shall be assigned to the user walking or riding a car. This was not given, and in order to avoid any confounding variables, it could be provided.

Conditions intended are audio and visual feedback. The order of the condition to which the participant was assigned is the key to avoiding other factors or confounding variables. To avoid variables or other factors on the evaluation of dependent variable, it is very important to use randomization in order to lessen the effects. Such variables can be fatigue, or the learning curve while trying the tasks of audio than visual mode in order.

The conditions are counterbalanced among 20 participants using a simple randomization technique. The certain sequencing considering only two options of sequencing: $C1\beta C2$ or $C2\beta C1$, having in mind the counterbalance of the order effect, for $n = 20$, gives times 10 for each sequence, hence it was assigned which participant gets what sequence in order, having randomly "1" or "0" assigned and counted equal, followed by code of sequences.

After conducting the test, every participant filled in two questionnaires, one for the SUS (System Usability Scale) and second for TLX (Task Load Index). Using the adopted version of the questionnaire for system usability scale to measure the user experience for both audio and visual feedback [6], [7] as presented in the tables II and III. Similarly, some questions were adopted from user satisfaction questionnaire GUESS [9].

The questions defined in table III are required as a post questionnaire for participants who completed the tasks that had been discussed to measure the usability. For the efficiency measurement [8], the evaluation was done taking into consideration two features: the task completion time and the speed of conducting it, taken into units; time in seconds and speed per minute respectively. After the measurement of efficiency for both modes of the system, using T-Test was possible to compare the two means of speed and task completion for audio and visual feedback.

III. SYSTEM USABILITY SCALE (SUS) TESTS OF NAVIGATION SYSTEMS

Usability studies are well suited for gathering qualitative or quantitative behavioural data and for answering design-related questions. Considering that our setup is rather focused on collecting feedback on the features rather than attitudinal feedback [10], [11], [12], it is well fit for our purpose. Nevertheless, data collected through methods mentioned, was later on described and analysed with Paired Sample T-Test. System usability score was calculated based on the questionnaires filled by participants [13].

Table IV contains the results from preliminary questionnaire, calculated and elaborated accordingly to the System Usability Scale (SUS) test score. In a general view the Visual mode tends to draw higher values than the Audio one (Fig. 1). Similarly, as seen in the results from boxplot the mean SUS scores of visual values are higher than the audio values.

TABLE I
TASKS AND SETUP.

Scheduled routes	Schedule a route in advance, either by given destination, decided route according to the path and time given	≈ 45min
Specific destination	Type in an address from a location outside of the city center (e.g., Suburban area in proximity to the city) you want to travel and follow a direction on the navigation system using the feedback type assigned.	≈ 90min
Find a nearby medical center	Find closest hospital/clinic specialized in surgery and follow feedback from a navigation system	≈ 45min
Completion	Wrap-up, archiving logs and documents, collection of results.	≈ 45min

TABLE II
SYSTEM USABILITY SCALE QUESTIONS.

Sentence	Score (1-5)
1. I think that I would like to use this system frequently.	Score (1-5)
2. I found the system unnecessarily complex.	Score (1-5)
3. I thought the system was easy to use.	Score (1-5)
4. I think that I would need the support of a technical person to be able to use this system.	Score (1-5)
5. I found the various functions in this system were well integrated.	Score (1-5)
6. I thought there was too much inconsistency in this system.	Score (1-5)
7. I would imagine that most people would learn to use this system very quickly.	Score (1-5)
8. I found the system very cumbersome to use.	Score (1-5)
9. I felt very confident using the system.	Score (1-5)
10. I needed to learn a lot of things before I could get going with this system.	Score (1-5)

TABLE III
TASK LOAD INDEX QUESTIONNAIRE TO ASSESS THE WORKLOAD OF TASKS FOR GIVEN CASES.

Subject	Question	Scale elaboration
Mental Demand (MD)	How mentally demanding was the task?	Very low to Very high
Physical Demand (PD)	How physically demanding was the task?	Very low to Very high
Temporal Demand (TD)	How hurried or rushed was the pace of the task?	Very low to Very high
Performance (P)	How successful were you in accomplishing what you were asked to do?	Failure to Perfect
Effort (E)	How hard did you have to work to accomplish your level of performance?	Very low to Very high
Frustration (F)	How insecure, discouraged, irritated, stressed, and annoyed were you?	Very low to Very high

FAUD	20	9.821	5.976	1.129

(Fig. 2). Results of Paired Samples T-Test conclude that the differences between is significant which means that the population (SUS scores for different feedback systems) have intrinsic differences. The p-value of 0.012 is much smaller than 0.05, so it is possible to reject the null hypothesis of no difference between type of feedback in system usability and consider with a high degree of confidence 98.8% that visual type of feedback is giving better usability. It is shown in table VI, that Fatigue and Mental Demand have significance, results have p value smaller than 0.05, so we can say high confidence that there is difference in Mental Demand and Fatigue factor effected user experience for both Audio and Visual feedback.

The observed result were $t(27) = -3.170$ and $p = 0.004$ for the Mental Demand, whilst for the Fatigue $t(27) = -3.663$ and $p = 0.001$. So null hypothesis that there is no difference in user experience between audio and visual feedback is rejected. Due to the significance test results applied.

IV. CONCLUSIONS

The main goal of this paper was to find out whether there is a difference in user experience and system usability, in case of audio and visual feedback of navigation systems. The paper further investigated how using audio or visual mode impacts the variables user experience, usability and cognitive load in given setup. The results of the experiment show that there is a considerable difference in user experience for the System Usability and task cognitive load for the two types of audio and visual feedback for navigation systems, as shown in the results of the tests engaged. As for system usability dependent variable Visual Feedback was preferred among all participants

with 98.8% confidence, whereas the degree of freedom showed the result: $t(19) = 2.778, p = 0.012$. On the other hand, for the Task Cognitive Load as dependent variable, the results showed that only two factors have significant effect in its Task Load, namely Fatigue and Mental Demand where p resulted smaller than 0.05, what leads to confidence of 99% that Audio type feedback requires more mental demand and causes more Tiredness to the users. These data resulted on given scores: $t(27) = -3.170, p = 0.004$ for Mental Demand and $t(27) = -3.663, p = 0.001$ for Fatigue. Consequently, the results lead to the rejection of null hypothesis that there is no difference in user experience between audio and visual feedback.

Abstract—Although several approaches have been proposed throughout the last decade to build recommender systems (RS), most of them suffer from the cold-start problem. This problem occurs when a new item hits the system or a new user signs up. It is generally recognized that the ability to handle cold users and items is one of the key success factors of any new recommender algorithm. This paper introduces a frequent pattern mining framework for recommender systems (FPRS) - a novel approach to address this challenging task. FPRS is a hybrid RS that incorporates collaborative and content-based recommendation algorithms and employs a frequent pattern (FP) growth algorithm. The article proposes several strategies to combine the generated frequent itemsets with content-based methods to mitigate the cold-start problem for both new users and new items. The performed empirical evaluation confirmed its usefulness. Furthermore, the developed solution can be easily combined with any other approach to build a recommender system and can be further extended to make up a complete and standalone RS.

Index Terms—recommendation system, cold-start problem, frequent pattern mining, quality of recommendations.

I. INTRODUCTION

OVER the past few decades, alongside the explosion in the amount of data on the internet, the popularity of online streaming services, e-commerce, and social media has highlighted an important challenge to provide users with recommendations that match their preferences and interests. Therefore, the demand for finding more efficient techniques to generate recommendations has received more attention. Over the years, researchers have suggested various approaches for building recommender systems that leverage the rating history and possibly some other information, such as users' demographics and items' characteristics. The majority of these approaches can be classified into three main categories: (i) collaborative filtering (CF), (ii) content-based (CB) filtering, and (iii) hybrid filtering.

The basic idea behind collaborative filtering is that users with similar tastes or preferences tend to behave similarly in the future. This technique relies on historical transactions to compute similarities among users from which the recommendations are eventually generated. An analogous approach can be applied to create recommendations based on item similarities. On the other hand, content-based filtering tries to utilize items' characteristics, users' demographics, and

contextual information to recommend additional items similar to those preferred by the target user in the past. Finally, hybrid techniques cover the weaknesses and exploit the strengths of CF and CB models by combining them to provide more relevant results.

The aforementioned techniques are highly appreciated by practitioners and businesses. However, they also encounter significant difficulties in terms of data characteristics. One of the issues is related to the sparsity of data. The discussed methods rely on modeling the user-item interactions, and hence, the quality of such may be impacted by an insufficient number of movies rated by each user. Another challenge is related to the so-called cold-start problem. This phenomenon is particularly inconvenient and occurs whenever recommendations are generated for a new item or user that does not have any interaction or rating in the history. In fact, many state-of-the-art recommendation algorithms may generate unreliable recommendations for such cases since they cannot learn the preference embedding of these new users/items [1], [2], [3].

In this study, we presented a particular take on the challenge of devising more effective and efficient recommendation techniques. We put special attention to properly handling the new users and items. We propose several methods to overcome the cold-start problem and the sparsity nature of the datasets by utilizing the FP-growth algorithm to generate frequent patterns based on items' characteristics and users' demographics. The main contributions of this paper are as follows:

- 1) We introduce *frequent pattern mining framework for recommender systems* (FPRS) - a novel hybrid recommender system that utilizes the FP-growth algorithm to produce frequent itemsets based on the ratings in the user-item matrix.
- 2) We utilize the items' and users' features to extract particular patterns based on the features selected.
- 3) We propose several techniques to mitigate the cold-start problem by using the discovered patterns to provide recommendations for new users and involve new items into the recommendations generated for the users.
- 4) We conduct the empirical evaluation of the proposed approach on well established benchmark data (MovieLens 100K and MovieLens 1M), showing its effectiveness in the presence of new entities (users and items, i.e., movies) in test data.

Research co-funded by Polish National Science Centre (NCN) grant no. 2018/31/N/ST6/00610.

The remainder of this paper is organized as follows. Section II describes and reviews important research efforts that addressing the cold-start problem in the domain of Recommender systems. In Section III, we provide background information for collaborative filtering and frequent pattern mining. In Section IV, we present a novel frequent pattern mining model (FPRS) that utilizes the ratings in user-item rating matrix to discover the frequent itemsets associated with selected users/items features. Section V evaluates and compares the proposed model with a baseline recommender system. Finally, in Section VI, we draw conclusions and suggest possible future work.

II. RELATED WORKS

Recommender systems (RS) predict the utility of an item to a user and suggest the best items concerning the user's preferences, where the items may represent movies, books, restaurants, or any other things [4], [5]. The aforementioned capability of RSs makes those techniques especially useful, and indeed, there are many areas of their successful applications like eCommerce, online marketing, or social networks [6], [7]. The scientific literature provides several taxonomies for RS [8]. However, the most common approaches refer to content-based or collaboration-based techniques and their various hybridizations [9]. Collaborative Filtering (CF) is one of the most widely used and successful techniques, with excellent results in a wide range of applications in many fields [8], hence is particularly interesting in our research and further reviewed in detail in Section III-A. Despite the noticeable decline in their popularity in favor of collaborative systems, content-based techniques are still widely used because of handling the so-called cold-start problem [10]. Because of the significantly different characteristics of those approaches, it is advisable to construct hybridizations of both [11], as further discussed in our study.

A typical RS consists of the three main elements: a user model (established by analyzing the users' interests and preferences), an item model (based on its characteristics), and the recommendation algorithm that is a key constituent. There are many reported approaches to implementing the recommendation algorithm by the specific adoption of machine learning (ML) models like matrix factorization, deep neural networks, or factorization machines (FM) [12], [13], [14]. Building RS on top of the state-of-the-art ML models leveraged the quality of recommendation results, improving user satisfaction and profits in e-commerce [15], [6], [16]. At the same time, however, we may observe the known problems with ML related to the data sparsity, the latency of prediction returned by complex models, and foremost, the unfairness of recommendations for new users or items that is often referred to as the *cold-start* problem [17], [18].

Solving scalability issues is one of the most common tasks when deploying big-scale recommender systems. Especially as the number of users and items significantly grows over time, it is essential for RSs to handle requests without appreciable

latency. This problem is particularly challenging for memory-based methods like k-nearest neighbors. However, in the case of web-scale recommendation tasks like social media, the Internet of Things (IoT), or various e-commerce applications, it is a hot topic also for model-based techniques, especially considering more complex and deep models [1], [19]. Another aspect that is particularly noticeable for collaborative filtering is related to the sparsity of user-item interactions [20]. Here, the quality of CF-based methods may be impacted by an insufficient number of items rated by each user [21]. Some recommender systems suffer from their over-specialization (sometimes referred to as a serendipity problem). It is observed when the RS produces recommendations with minimal novelty, i.e., all of the same kind [22]. Recently, there is also an increasing interest in privacy awareness when handling user data and explainability of recommendations [23], [24].

Regardless of recent achievements in RS, the cold-start problem is still one of the most prevailing topics deserving further attention and is particularly interesting in the context of our study [3], [21]. The difficulty arises due to the deficient information about new entities. Therefore it has a particularly strong negative impact on collaborative methods, heavily impacting the fairness of recommendations for new users, often passing over new items [18]. Most of the attempts to deal with such a problem consider enhancing the collaborative-based methods with content-based approaches that leverage the intrinsic characteristics of the analyzed entities. For example, in [2], the authors propose hybrid recommender models that use content-based filtering and latent Dirichlet allocation (LDA)-based models. Whereas in [9], we may find a hybrid RS that combines the singular-value decomposition-based collaborative filtering with content-based and fuzzy expert systems.

There are many more techniques to dealing with the cold-start problem by combining collaborative filtering with a content-based methods, including using simultaneous co-clustering [25], self-organizing maps, or Siamese neural networks [3]. There are also some attempts to combine RSs with various dimensionality reduction techniques [26]. Considering the discussed problem of missing or insufficient information, it seems interesting to refer to the dimensionality reduction methods based on the granularization of the attribute space [27], and particularly on resilient techniques [28], [29] - i.e., resistant to data deficiencies. The hybridization of soft computing techniques with collaborative and content-based methods is a wide-ranging field of research and an interesting area for the further development of recommendation systems [30], particularly interesting for context-aware RSs [31], [4].

Some approaches to dealing with cold-start refer to popularity measures, e.g., on the recent trend in users' preferences or always returning the most popular items [14], [10]. However, these may be very misleading and result in so-called popularity bias since users often differ in their preferences, which may also vary between types of products and their characteristics [18]. Hence, an additional effort to deal with biases in data is required [32]. Another interesting approach to dealing with insufficient or missing historical transactions avail additional

sources of information to enhance the data representation. In particular, in [21], the authors train RSs with the Linked Open Data model based on DBpedia to find enough information about new entities. When dealing with the cold-start problem, some researchers rely on directly inquiring the users about their preferences. Such information may be collected, e.g., via survey or by asking users to select the most relevant picture related to the desired item [33]. Combining community-based knowledge with association rule mining to alleviate the cold-start problem is also bringing very promising results [31]. Referring to association rule mining (cf. [34]) and frequent pattern mining (cf. [35]) techniques to address the cold-start problem is interesting also from the perspective of speeding up the recommender systems. For this reason, frequent patterns mining is particularly interesting in our research, and we review this field in detail in Section III-B.

III. PRELIMINARIES

In this section, we briefly summarize the academic knowledge of collaborative filtering and frequent pattern mining techniques. Then, we review some of the research literature related to addressing the cold-start problem.

A. Collaborative Filtering

The basic idea behind collaborative filtering (CF) is that the users who have similar preferences in the past tend to behave similarly in the future. Basically, CF-based methods rely only on users rating history to generate recommendations, meaning that the more ratings the users provide, the more accurate the recommendation become [4]. Usually, the historical ratings or preferences can be acquired explicitly or implicitly. So, the CF-based methods are often distinguished by whether they operate over explicit ratings, where the user explicitly rate particular items, or implicit ratings, where the ratings are inferred from observable user activity, such as products bought, songs heard, visited pages, or any other types of information access patterns [4]. In the literature, collaborative filtering methods can be classified into two main categories: (i) memory-based techniques, and (ii) model-based techniques.

The memory-based technique uses directly the rating history, which is stored in memory, to predict the rating of items that the user has not seen before. However, the memory-based techniques can be grouped into two different classes: (i) user-based collaborative filtering, and (ii) item-based collaborative filtering. The user-based collaborative filtering, also known as k-NN collaborative filtering, works by finding the other users (neighbors) whose historical rating behavior is similar to that of the target user and then using their top-rated products to predict what the target user will like [36]. To mathematically formulate the problem, let us assume there is a list of users $U = \{u_1, u_2, \dots, u_m\}$ and a list of items $I = \{i_1, i_2, \dots, i_n\}$. Then, the user item rating matrix consists of a set of ratings $v_{i,j}$ corresponding to the rating for user i on item j . If I_i is

the set of items on which user i has rated in the past, then we can define the average rating for user i as follows [36]:

$$\bar{v}_i = \frac{1}{|I_i|} \sum_{j \in I_i} v_{i,j} \quad (1)$$

In user-based collaborative filtering, we estimate the rating of item j that has not yet rated by the target user a as follows [36] [37]:

$$p_{a,j} = \bar{v}_a + \frac{\sum_{i=1}^k s(a,i)(v_{i,j} - \bar{v}_i)}{\sum_{i=1}^k |s(a,i)|} \quad (2)$$

where k is the number of most similar users (nearest neighbors) to a . The weights $s(a,i)$ can reflect the degree of similarity between each neighbor i and the target user a . On the other hand, item-based collaborative filtering is just an analogous procedure to the previous method. The similarity scores can also be used to generate predictions using a weighted average, similar to the procedure used in user-based collaborative filtering. Mathematically, we can predict the rating of item j that has not yet been rated by the target user a as follows [36] [37]:

$$p_{a,j} = \frac{\sum_{i=1}^k s(j,i)(v_{a,i})}{\sum_{i=1}^k |s(j,i)|} \quad (3)$$

where k is the number of most similar items (nearest neighbors) to j that the target user a has rated in the past. However, the most popular metrics used to calculate the similarity between different users, or items, are cosine similarity and Pearson correlation. Finally, the recommendations are generated by selecting the candidate items with the highest predictions.

On the other hand, the model-based technique works by learning a predictive model using the rating history. Basically, it is based on matrix factorization which uses the rating history to learn the latent preferences of users and items. Matrix factorization is an unsupervised learning method that is used for dimensionality reduction. One of the most popular techniques applied for dimensionality reduction is Singular Value Decomposition (SVD). Mathematically, let us assume M is the user item rating matrix. The SVD of M is the factorization of M into three constituent matrices such that [37]:

$$M = U\Sigma V^T \quad (4)$$

where U is an orthogonal matrix representing left singular vectors of M . V is an orthogonal matrix representing right singular vectors of M . Σ is a diagonal matrix whose values σ_i are the singular values of M [37].

B. Frequent Pattern Mining

The basic idea of frequent pattern mining, also known as association rule mining, is to search for all relationships between elements in a given massive dataset. It helps us to discover the associations among items using every distinct transaction in large databases. The key difference between association rules mining and collaborative filtering is that in

association rules mining we aim to find global or shared preferences across all users rather than finding an individual's preference like in collaborative filtering-based techniques [38] [39] [40].

At a basic level, association rule mining analyzes the dataset searching for frequent patterns (itemsets) using machine learning models. To define the previous problem mathematically, let $I = \{i_1, i_2, \dots, i_m\}$ be an itemset and let D be a set of transactions where each transaction T is a nonempty itemset such that $T \subseteq I$. An association rule is an implication of the form $A \Rightarrow B$, where $A \subset I$, $B \subset I$, $A \neq \emptyset$, $B \neq \emptyset$, $A \cap B = \emptyset$. In the rule $A \Rightarrow B$, A is called the antecedent and B is called the consequent. Various metrics are used to identify the most important itemset and calculate their strength, such as support, confidence, and lift. Support metric [40] is the measure that gives an idea of how frequent an itemset is in all transactions. In other words, the support metric represents the number of transactions that contain the itemset. The Equation 5 shows how we calculate the support for an association rule.

$$\text{support}(A \Rightarrow B) = P(A \cup B) \quad (5)$$

On the other hand, the confidence [40] indicates how often the rule is true. It defines the percentage of transactions containing the antecedent A that also contain the consequent B . It can be taken as the conditional probability as shown in Equation 6.

$$\text{confidence}(A \Rightarrow B) = P(B|A) = \frac{\text{support}(A \cup B)}{\text{support}(A)} \quad (6)$$

Finally, the lift is a correlation measure used to discover and exclude the weak rules that have high confidence. The Equation 7 shows that the lift measure is calculated by dividing the confidence by the unconditional probability of the consequent [40] [38].

$$\text{lift}(A \Rightarrow B) = \frac{P(A \cup B)}{P(A)P(B)} = \frac{\text{support}(A \cup B)}{\text{support}(A)\text{support}(B)} \quad (7)$$

If the lift value is equal to 1, then A and B are independent and there is no correlation between them. If the lift value is greater than 1, then A and B are positively correlated. If the lift value is less than 1, then A and B are negatively correlated.

Various algorithms exist for mining frequent itemsets, such as Apriori [39] [41], AprioriTID [39] [41], Apriori Hybrid [39] [41], and FP-growth (Frequent pattern) [39] [42]. In this paper, we employ FP-growth algorithm to generate frequent itemsets. What makes FP-growth better than other algorithms is the fact that FP-growth algorithm relies on FP-tree (frequent pattern tree) data structure to store all data concisely and compactly which greatly helps to avoid the candidate generation step. Moreover, once the FP-tree is constructed, we can directly use a recursive divide-and-conquer approach to efficiently mine the frequent itemsets without any need to scan the database over and over again like in other algorithms [42].

IV. FREQUENT PATTERN MINING FRAMEWORK FOR RECOMMENDER SYSTEMS (FPRS)

The main problem we address in this paper is to alleviate the impact of new users and new items cold-start in recommender systems based on collaborative filtering techniques. In theory, collaborative filtering methods can be grouped into two general categories (i) memory-based techniques and (ii) model-based techniques. In memory-based techniques, we calculate the similarities between users/items based on the rating history and then generate recommendations based on the most similar users/items. In model-based techniques, we rely, e.g., on matrix factorization methods to learn the latent factors of users and items and then decompose the user-item interaction (rating) matrix into the product of two lower dimensionality matrices. Collaborative filtering methods are strictly relying on user ratings or user interactions. For that reason, these methods suffer from the cold-start problem whenever a new user joins the system or when a new item is added. In practice, both situations often lead to the inability to provide accurate or meaningful recommendations.

To tackle the cold-start problem, we implement the Frequent Pattern mining framework for Recommender Systems (FPRS). This framework extends the popularity-based approach by employing frequent pattern mining techniques to learn the user preferences depending on users' and items' characteristics. Fig 1 shows the high-level design which is used to develop the FPRS framework. The process of generating the recommendations consists of four stages: (i) Data Input, (ii) Data Preparation, (iii) Frequent Pattern Mining, and (iv) Recommendation Generation. In the first stage, we enrich the user-item rating matrix by users' demographics and items' characteristics. The data preparation stage consists of three steps. In the first one, we store only the favorable reviews by filtering out every review/rating below a determined threshold. In the second step, we perform attributes analysis and check the validity of using them for generating the recommendation. In the last step, we split the dataset for each selected attribute. It is important to note that we follow multiple strategies to perform the attribute selection. More details about these strategies will be provided later in this section. Then, in the third stage, we generate frequent itemsets using FP-Growth algorithm. Finally, we produce the recommendations in the last stage for user cold-start and item cold-start. However, the FPRS framework consists of two main modules: (i) user cold-start module, and (ii) item cold-start module. Each of these modules has dedicated strategies that are used to select the features and produce the recommendations.

Strategy 1 User Cold-Start Module

- 1: Use entire training set (no records splitting)
 - 2: Generate frequent 1-itemsets {support > min_support}
 - 3: Recommend all these frequent 1-itemsets to any new user
-

a) user cold-start module: In this module, we focus on generating recommendations for new users who signed

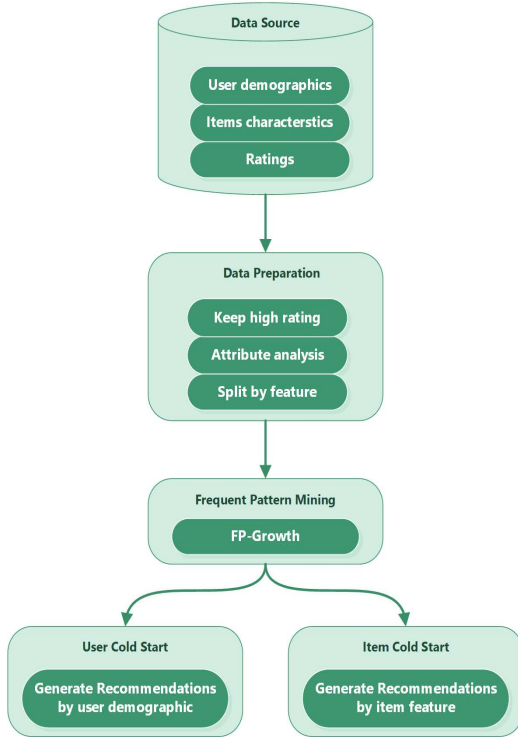

Fig. 1: Frequent Pattern Mining Framework For Recommender Systems

up recently to the system and most likely do not have, or have very few, ratings in the user-item rating matrix. We follow two strategies to generate such recommendations. These strategies differ in two main factors: (i) features selected to split the data, and (ii) the way how the frequent patterns are utilized to generate the recommendations. More details about the strategies followed in the user cold-start module are introduced in Strategy 1 and Strategy 2.

Strategy 2 User Cold-Start Module

- 1: Split the records based on users demographics (i.e. gender)
 - 2: Generate frequent 1-itemsets $\{\text{support} > \text{min_support}\}$
 - 3: Recommend to the new user all frequent 1-itemsets which are generated based on the demographics of new user
-

b) item cold-start module: In this module, we focus on generating recommendations for new items which are recently added to the system and most likely do not have, or have very few, ratings in the past. We follow multiple strategies to generate such recommendations. More details about the strategies followed in the item cold-start module are provided in Strategy 3, Strategy 4, and Strategy 5.

Finally, it is worth mentioning that the threshold values used in the above strategies are selected carefully by objectively searching for a good set of values that achieves the best performance on a given dataset. More details on how we choose these values are provided in Section V.

Strategy 3 Item Cold-Start Module

- 1: Split the records based on items characteristics (i.e. genre)
 - 2: Generate frequent itemsets $\{\text{support} > \text{min_support}\}$
 - 3: Set the participation percentage threshold
 - 4: **for each** value in genre **do**
 - 5: Find all users who involved in creating larger than the participation threshold of frequent itemsets
 - 6: **end for**
 - 7: Recommend the new item based on its genre to all users found in previous step
-

Strategy 4 Item Cold-Start Module

- 1: Split the records based on users demographics and items characteristics (i.e. gender and genre)
 - 2: Generate frequent itemsets $\{\text{support} > \text{min_support}\}$
 - 3: Set the participation percentage threshold
 - 4: **for each** value in genre **do**
 - 5: Find the dominant gender by counting how many frequent itemsets are generated by male and female
 - 6: **end for**
 - 7: Recommend the new item based on its genre to all users belong to dominant gender who involved in creating larger than the participation threshold of frequent itemsets
-

Strategy 5 Item Cold-Start Module

- 1: Split the records based on users demographics and items characteristics (i.e. gender and genre)
 - 2: Generate frequent 1-itemsets $\{\text{support} > \text{min_support}\}$
 - 3: Set the participation percentage threshold
 - 4: Assign frequent 1-itemsets created by male to one cluster, and frequent 1-itemsets created by female to another cluster
 - 5: Find the center of each cluster
 - 6: Calculate the distance between the new item and the center of each cluster
 - 7: Recommend the new item to all users who involved in creating larger than the participation threshold of frequent itemsets in the closest cluster
-

V. EVALUATION METHODOLOGY

In this section, we conduct comprehensive experiments to evaluate the performance of the FPRS recommender system.

A. Dataset and Evaluation Measures

In our experiments, we used two datasets (MovieLens 100K and MovieLens 1M)¹ which were collected by the GroupLens research project at the University of Minnesota. MovieLens 100K contains 100,000 ratings given by 943 users on 1682 movies on a scale from 1 to 5. While MovieLens 1M contains 1,000,000 ratings of approximately 3,900 movies made by 6,040 users on a scale from 1 to 5. In both datasets, we

¹<https://grouplens.org/datasets/movielens/>

combine three files (users.data, items.data, ratings.data) in order to join users' demographics, items' characteristics, and ratings in one dataset. The final/joined dataset contains userId, itemId, rating, gender, age, occupation, and genres attributes (cf. Table I). Moreover, we performed further analysis of the features we used in our experiments (gender, genre) to understand the interrelation between these features and obtained results. Figures 2 show the most popular movie genres among males and females for both datasets (MovieLens 100K and MovieLens 1M).

TABLE I: Selected data characteristics.

Attribute Name	Data Type	Value Range (MovieLens 100K)	Value Range (MovieLens 1M)
gender	Character	M-F	M-F
age	Number	Under 18-73	Under 18-56
occupation	Text	21 occupation	21 occupation
genres	Text	19 genres	19 genres

Fig. 2: Histogram of the variables (rating, genre and gender) in the MovieLens 100K and 1M datasets.

After clearing the data from invalid records, we split it into training and testing datasets according to FPRS module as follows:

- For the user cold-start module testing, the 20 users with the highest number of ratings on the 50 most popular movies were selected. The ratings given by all those 20 users (9052 records in MovieLens 100K and 25533 records in MovieLens 1M) are considered a testing set, keeping the rest of the records in the training set. This way, all the record related to the selected users were removed from the test set, which simulates the cold-start problem associated with new users.
- To properly evaluate the item cold-start module, the testing data is chosen similarly. We firstly find the 50 most active users. Then, we select the 20 most rated movies by those 50 users. The ratings of all those 20 movies by all the users in our data (7320 records in MovieLens 100K and 41105 records in MovieLens 1M) are considered as a testing set, keeping the rest of the records in the training set. Note that all the ratings for the selected movies are removed from the training data set, which corresponds to the item cold-start.

In our study, we consider a binary decision task whether a given item (i.e., movie) is appropriate for the user. To correctly model this situation for the MovieLens data, we assume that films rated by users 4 or 5 are preferred by them (belong to the positive class). In contrast, those ranked lower are poorly matched to the users. Therefore, the FPRS recommender system feedback for each new user or item is binary information: recommend or not recommend. Following that, in order to assess the quality of the prediction, the F1 measure is used [43].

$$F_1 = 2 \cdot \frac{\text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}} \quad (8)$$

where precision quantifies the number of correct positive recommendations made (see Equation 9). While recall quantifies the number of correct positive recommendations made out of all positive predictions that could have been made (see Equation 10).

$$\text{Precision} = \frac{TP}{TP + FP} \quad (9)$$

$$\text{Recall} = \frac{TP}{TP + FN} \quad (10)$$

Moreover, we use the accuracy metric to measure all the correctly identified cases. This measure is mostly used when all the classes are equally important.

$$\text{Accuracy} = \frac{TP + TN}{TP + FP + TN + FN} \quad (11)$$

B. Baseline Recommender System

To showcase the strengths of frequent pattern mining in RS, we build a baseline model in a similar way to the strategies described previously, but the FP-growth algorithm was omitted. In order to evaluate both modules of FPRS, two versions of baseline RS are developed as follows:

- New user baseline model: for each movie in the training set, the most common gender and age group of the user was found. When a new user comes, they get recommended all movies that were assigned to their age group and gender.
- New item baseline model: it works similarly. We find the most popular (watched) genre for each user. Then each new movie is recommended to all users whose favorite genre was the same as the new movie's.

C. Performance Comparison and Analysis

In order to provide a fair comparison, we use precision, recall, F1, and accuracy measures to compare the performance of FPRS against the baseline RS. After splitting the dataset into the training and testing sets and training both baseline and FPRS recommendation systems, we run two experiments to evaluate the user cold-start module and item cold-start module.

a) *User cold-start module*: In the performed experiment, we evaluated the user cold-start module in FPRS. We calculated precision, recall, F1, and accuracy measures for the results generated by the baseline RS and FPRS following the two strategies, which we have described in Section IV. The comparison results of this evaluation method are shown in Tables II and III. The results show that all developed strategies outperformed the baseline RS for precision, F1, and accuracy on both data-sets. However, the baseline solution reported higher recall, which is quite natural since the developed methods are more selective, providing more apt results with a tradeoff that some potentially relevant movies may be omitted. For the user-cold start problem, both strategies were evaluated at $min_support$ value of 0.08 and performed similarly. The second one was just slightly better.

TABLE II: Evaluation for user cold-start (MovieLens 100k).

Strategy	Precision	Recall	F1-score	Accuracy
Baseline	0.24	0.72	0.33	0.44
Strategy 1	0.58	0.56	0.57	0.80
Strategy 2	0.59	0.58	0.58	0.80

TABLE III: Evaluation for user cold-start (MovieLens 1M).

Strategy	Precision	Recall	F1-score	Accuracy
Baseline	0.33	0.82	0.44	0.47
Strategy 1	0.63	0.63	0.62	0.77
Strategy 2	0.64	0.64	0.63	0.78

b) *Item cold-start module*: In the second experiment, we evaluated the item cold-start module in FPRS. We calculated precision, recall, F1, and accuracy measures for the results generated by the baseline RS and FPRS following all the strategies described in Section IV. The comparative summary of this evaluation is shown in Tables II and III. The results show that the performance of FPRS, using all strategies, is superior to the baseline solution. However, the results differ

slightly between datasets. For MovieLens 100K, all strategies reported similar recall. Regarding precision and F1 measures, the most successful in dealing with new items in this data appeared to be strategy no. 4, which is based on both items' and users' characteristics. However, for the applications that do require high accuracy, it would be better to apply strategy no. 5, which was also superior in terms of recall, F1, and accuracy on the second data-set (MovieLens 1M). All strategies were evaluated at the participation threshold value of 30% and $min_support$ value of 0.2.

TABLE IV: Evaluation for item cold-start (MovieLens 100k).

Strategy	Precision	Recall	F1-score	Accuracy
Baseline	0.38	0.3	0.32	0.59
Strategy 3	0.69	0.64	0.66	0.75
Strategy 4	0.79	0.62	0.69	0.84
Strategy 5	0.67	0.63	0.63	0.86

TABLE V: Evaluation for item cold-start (MovieLens 1M).

Strategy	Precision	Recall	F1-score	Accuracy
Baseline	0.49	0.43	0.43	0.64
Strategy 3	0.65	0.71	0.64	0.76
Strategy 4	0.64	0.73	0.66	0.83
Strategy 5	0.6	0.79	0.66	0.86

D. Thresholds Sensitivity Analysis

In FPRS model, we use some threshold values, such as $min_support$ and participation percentage, in order to extract frequent itemsets and produce relevant recommendations for new users and new items. In this section, we conduct some experiments to show how changing those values may impact performance of FPRS. Moreover, the output of this experiment helps to find the optimal values of these thresholds, and hence to conduct fair and reliable experiments.

In the first experiment, we aim to find the optimal value of min_sup threshold by evaluating FPRS (item cold-start module) using different min_sup values. Fig 3a shows how the F1-score of FPRS is impacted by applying different values for MovieLena 100K data. Observably, the best min_sup values for all strategies used in FPRS (item cold-start module) are between 0.1 and 0.2. The similar observations, regarding MovieLens 1M data, we may find in Figure 3b.

In the second experiment, we search for the optimal value of the participation threshold in FPRS (item cold-start module). Figures 3c and 3d show how F1-score of FPRS is impacted by applying different values for both investigated datasets. Observably, the best participation threshold values for all strategies used in FPRS (item cold-start module) are between 15% and 30%. Finally, it is worth noting that when we run this experiment, we use the optimal value of min_sup we found in the previous experiment.

(a) min_supp threshold (MovieLens 100k)

(b) min_supp threshold (MovieLens 1M)

(c) participation percentage threshold (MovieLens 100k)

(d) participation percentage threshold (MovieLens 1M)

Fig. 3: Sensitivity analysis for min_supp and participation percentage thresholds for MovieLens 100k and 1M.

VI. CONCLUSIONS AND FUTURE WORKS

This article introduces FPRS, a novel recommender system, which methodically utilizes the ratings to discover frequent itemsets associated with selected users/items features and then incorporates these frequent itemsets in generating recommendations for new users and items. Our study evaluates multiple strategies for creating frequent itemsets to produce meaningful and relevant recommendations.

To evaluate FPRS, we conducted comprehensive experiments on MovieLens 100K and 1M datasets using the FP-growth algorithm to generate the frequent itemsets. The experimental results show that FPRS has outperformed the baseline recommender system in terms of the precision, recall, F1, and accuracy measures.

In the future work, we plan to incorporate additional contextual information and evaluate more advanced algorithms, such as AprioriTID and Apriori Hybrid, in the process of producing frequent patterns. Another important aspect to consider is to evaluate our method against more state-of-the-art recommender systems on various datasets. Furthermore, we plan to consider changes in users' behavior and preferences by periodically updating frequent itemsets based on recent changes in rating history. It would also be of value to extend the users' and items' data representation by applying a more advanced feature extraction to model the similarities among them more effectively [44], [45], [46].

Abstract—In this work, we propose the P3 Learning to Rank (P3LTR) model, a generalization of the RP3Beta graph-based recommendation method. In our approach, we learn the importance of user-item relations based on features that are usually available in online recommendations (such as types of user-item past interactions and timestamps). We keep the simplicity and explainability of RP3Beta predictions. We report the improvements of P3LTR over RP3Beta on the OLX Jobs Interactions dataset, which we published.

I. INTRODUCTION

GRAPH-BASED RP3Beta model [1] is a very strong baseline on multiple recommender systems datasets [2], [3], [4]. This relatively simple model outperformed other approaches on our published OLX Jobs Interactions dataset and is currently a state-of-the-art collaborative filtering recommender system at OLX. In this work, we propose P3LTR (P3 Learning to Rank) model which generalizes the RP3Beta model.

In RP3Beta each user and item is represented as a node of the user-item bipartite graph. The recommendations are generated based on the paths of length 3 starting from a given user. The scores of these paths are calculated based on the scores assigned to the edges of the graph. Scores of the edges are directly calculated based on the degrees of the connected nodes. Hence, there is no learning process in this approach.

In P3LTR, to better leverage the importance of the user-item relation, we learn the score of a given edge based on the features of this edge. As features, we not only use node degrees but also utilize the sequence of interactions between two given nodes. It enables us to incorporate the information that the user visited the item several times and that the user not only clicked but applied for a given job, or how recent the click was.

In this work, we propose a training procedure and a loss function for the P3LTR model. We tune, train, and evaluate RP3Beta and P3LTR models on the OLX Jobs Interactions dataset.

The paper consists of 6 sections. The second section presents a literature review and formulates a research gap addressed by this work. Section III proposes the P3LTR model and describes its advantages and relation to the RP3Beta model. Section IV describes the considered dataset and hyperparameter tuning procedure. The results of our model are discussed in Section V. Section VI presents the conclusions and future perspectives.

II. RELATED WORKS

A. Recommender systems

Most digital platforms provide more choices than the user can explore in a reasonable time. Even a perfect search engine can not resolve this problem, because it requires users to know what they are looking for and to spend time providing this information. For this reason, powerful recommendation systems are developed by multiple companies, such as Netflix [5] or Amazon [6].

We usually distinguish two categories of recommendation methods: *content-based* and *collaborative filtering*. In *content-based* models [7], [8] we utilize user and item features to provide recommendations. The history of interactions between users and items is considered from the perspective of a single user. In contrast, *collaborative filtering* techniques [9], [10] do not consider additional information about users or items but utilize the rating history of all users at the same time to provide recommendations. During the last few decades several collaborative filtering recommendation techniques have been proposed: neighborhood-based (e.g., [11], [12]), matrix factorization-based (e.g., [13], [14]), graph-based (e.g., [1], [15] or Word2Vec-based (e.g., [16], [17])).

Another category of recommendation systems, *context-aware recommendation systems* (CARS) [18], [19], utilize contextual information of user-item interactions such as time or location. We can distinguish an important subcategory of these methods, *sequence-aware recommendation systems* [20], which utilizes sequentially-ordered user-item interaction logs.

In this work, we extend a graph-based collaborative-filtering approach that does not utilize additional contextual information. Our approach is a sequence-aware recommendation method that utilizes timestamps and types of interactions.

B. Graph-based recommendations

Many graph-based recommender systems are focused on producing the item and/or user embeddings. Some of them utilize the graph structure to produce random walks which are used as an input for the model which produces embeddings. For instance, Node2vec [21], or DeepWalk [22] utilize a SkipGram model [23]. In recent years, several collaborative filtering methods based on graph convolutional neural networks have been proposed [15], [24], [25], [26].

Another type of graph-based recommendation systems directly utilizes the graph structure to calculate the scores of items, usually by utilizing a user-item bipartite graph. Cooper *et al.* [27] proposed simple and efficient P3 and P3alpha methods which outperformed more complex and computationally demanding techniques [28], [29], [30]. Paudel *et al.* [1] extended this work by proposing the RP3Beta model, an extension of P3alpha which recommends popular items less often. These methods were recently used as a benchmark by Dacrema *et al.* [2], [3] and Anelli *et al.* [4] who compared them with several state-of-the-art neural recommendation methods. P3Alpha and RP3Beta demonstrated a very good performance against other baselines and neural models. The RP3Beta model provided the most accurate recommendations on some of the considered datasets (i.e., Pinterest [31], CiteULike-a [32] and MovieLens1M [33]; on MovieLens1M authors used their own random splits). In our previous work, as yet unpublished, we showed that RP3Beta outperforms other methods on the OLX Jobs Interactions dataset. It is currently the state-of-the-art collaborative-filtering recommendations technique deployed at OLX Jobs.

C. Research gap

The RP3Beta model does not utilize any information about user-item relations. Additionally, there is no learning process that could optimize model parameters. Hence it is not possible to learn the importance of edges in the user-item bipartite graph. In this work, we fill this gap by proposing a machine learning model which generalizes RP3Beta.

III. PROPOSED METHOD

A. Model

Let \mathcal{U} be a set of users and \mathcal{I} a set of items. For each user $u \in \mathcal{U}$ and item $i \in \mathcal{I}$ let r_{ui} be the score assigned by the model to the pair (u, i) . We denote the matrix of all user-item scores by \mathbf{R} .

We represent users and items as the nodes of the bipartite graph, where edges represent interactions between users and items. Let $\mathcal{N}(x)$ represent the set of nodes connected with the node x .

Fig. 1. Path of length 3 with edge scores. The path is highlighted by bold red line. Dashed lines represent the interactions between users and items.

For a given user $u \in \mathcal{U}$ our model recommends the items with the highest score r_{ui} , excluding the items which the user interacted with.

The score r_{ui} is calculated as the sum of the scores assigned to the paths of length 3 connecting u and i , i.e.:

$$r_{ui} = \sum_{i' \in \mathcal{N}(u)} \sum_{u' \in \mathcal{N}(i')} p(u, i', u', i),$$

where $p(u, i', u', i)$ is the score assigned to the given path. Following the idea used in the RP3Beta model, we factorize this score as:

$$p(u, i', u', i) = p_{ui'}^{(1)} p_{i'u'}^{(2)} p_{u'i}^{(3)},$$

where $p_{xy}^{(k)}$ is the score assigned to the edge connecting nodes x and y in the k -th layer, $k = 1, 2, 3$. The edge scores of a given path are illustrated in Fig. 1. With this assumption, the calculation of the scores is simplified in the following way:

$$\mathbf{R} = \mathbf{P}^{(1)} \mathbf{P}^{(2)} \mathbf{P}^{(3)},$$

where $\mathbf{P}^{(k)} = (p_{xy}^{(k)})$, $\mathbf{P}^{(1)}, \mathbf{P}^{(3)}$ are $|\mathcal{U}| \times |\mathcal{I}|$ matrices and $\mathbf{P}^{(2)}$ is $|\mathcal{I}| \times |\mathcal{U}|$ matrix.

In this work we propose to calculate the edge scores as the function of node features f_n and edge features f_e , i.e.:

$$p_{xy}^{(k)} = \phi^{(k)}(f_x^n, f_y^n, f_{xy}^e),$$

where f_x^n is feature vector of node x , f_{xy}^e is a feature vector of the edge connecting nodes x and y and $\phi^{(k)}$ can be any real-valued function (e.g., neural network). We will call the functions $\phi^{(k)}$ **feature encoders** and propose them below.

Assume that for each (user, item) pair we know the type of interactions between them with corresponding timestamps. Let $\mathcal{E} = \{e_1, e_2, \dots, e_{|\mathcal{E}|}\}$ be a set of all possible types of interactions (e.g., click, reply, purchase).

Then we define the following features:

- $\text{deg}(x)$ – degree of the node x (number of distinct users/items which interacted with x),
- $\text{rec}(x, y)$ – number of days which passed between the most recent user (x or y) interaction with the item (y or x) and the most recent interaction of this user with any item,
- $\text{ev}(e_i, x, y)$ – number of interactions of type e_i between x and y ,
- $\text{ev}(x, y)$ – number of interactions between x and y .

Then the score is calculated as:

$$p_{xy}^{(k)} = \frac{(\text{deg}(y))^{-d^{(k)}}}{e^{-\text{rec}(x,y)r^{(k)}}} \cdot \sigma \left(\sum_{i \in |\mathcal{E}|} \frac{\text{ev}(e_i, x, y)}{\text{ev}(x, y)} e_i^{(k)} + b_e^{(k)} \right) \cdot \sigma(\text{ev}(x, y)e^{(k)} + b^{(k)}),$$

where $\sigma(x) = \frac{1}{1+e^{-x}}$ and $d^{(k)}$, $r^{(k)}$, $e_i^{(k)}$, $b_e^{(k)}$, $e^{(k)}$, $b^{(k)}$ are model parameters.

B. Model parameters

The total number of P3LTR model's parameters equals $3 \cdot (5 + |\mathcal{E}|)$.

The RP3Beta model is not learnable and has only two hyperparameters: α and β . Our model is equivalent to RP3Beta model when $d^{(1)} = d^{(2)} = \alpha$, $d^{(3)} = \beta$ and all other parameters equal 0.

RP3Beta is a generalization of P3Alpha [27] (for $\beta = 0$), P3 [27] (for $\alpha = 1$, $\beta = 0$) and #3-Paths [27] (for $\alpha = 0$, $\beta = 0$), so naturally P3LTR also includes these methods.

Parameters $d^{(k)}$ tell us how impactful (destination) nodes of a given degree should be, i.e., $d^{(k)} = 0$ means that we treat all nodes equally, $d^{(k)} > 0$ means that we reduce the impact of nodes with a greater degree, $d^{(k)} < 0$ means that we increase the impact of nodes with the greater degree.

Parameters $r^{(k)}$ are used to utilize the recency of interactions, i.e., when $r^{(k)} > 0$ more recent interactions have higher importance, when $r^{(k)} = 0$ the recency of interactions has no impact on recommendations and when $r^{(k)} < 0$ the older interactions are more impactful.

Parameters $e_i^{(k)}$, $b_e^{(k)}$ are designed to utilize the information about type of interactions between users and items. The parameters associated with events requiring higher user engagement (e.g., replying to an offer) might have higher values than the others (e.g., the parameter associated with visiting an offer).

Parameters $e^{(k)}$, $b^{(k)}$ were introduced to include the information about the frequency of interactions. Higher frequency is an indicator of higher user engagement and might be used to increase the importance of a particular item.

C. Model training

The goal of training the model is to learn the values of the parameters of our feature encoders $\phi^{(k)}$. We describe three

components of this process: a forward pass for a single user, a training loop, and a loss function.

1) *Forward pass for a single user*: We can present our model from the perspective of a message-passing paradigm used in graph convolutional neural networks [15], [24], [25], [26]. For the initial representation ($k = 0$) we set the score $r_u^{(0)} = 1$ for the node representing the given user and the score 0 for all other nodes. Then for all nodes x and for $k = 1, 2, 3$ we perform the message passing:

$$r_x^{(k)} = \sum_{y \in \mathcal{N}(x)} r_y^{(k-1)} \phi^{(k)}(f_x^n, f_y^n, f_{xy}^e).$$

This process can be interpreted as spreading the message across the graph. At the beginning, we send the message to the neighboring nodes depending on their relevancy calculated by $\phi^{(1)}$. Then each of these nodes sends the message to their neighbors with respect to the relevancy calculated by $\phi^{(2)}$. This process could be continued, but for efficiency reasons and based on the results of Cooper *et al.* [27], we limit it to 3 steps.

2) *Training loop*: A training process is described by Algorithm 1.

Algorithm 1 Training loop of the P3LTR model.

for iteration = 1, 2, ..., iterations **do**

 Update edge weights of the graph based on feature encoders

 Set the loss to 0.

for i = 1, 2, ..., batch size **do**

 Pick a random target user (by default: random user who interacted with at least 2 items) and take his most recent interacted item as a *validation node*.

 Make a forward pass for this user and calculate the scores of top k items and the score and position of a validation node.

 Calculate the loss for this user and add it to the current loss.

end for

 Backpropagate the loss and update the weights of feature encoders.

end for

3) *Loss function*: The idea of our loss function is to score the validation item higher than the other items. Let us define

$$\text{ratio} = \frac{\text{avg score of top k items}}{\text{validation node score}}.$$

To stabilize the training, we additionally calculated the sum of squares of the parameters and multiplied it by a constant regularization parameter. We considered three loss functions:

- **ratio**: ratio + regularization term,
- **log ratio**: $\ln(\text{ratio})$ + regularization term,
- **boosted log ratio**: $\ln(\text{ratio}) \cdot \text{validation node position} + \text{regularization term}$.

The idea of the log ratio was inspired by BPR loss [34] function and the idea of the boosted log ratio was inspired

by WARP loss [35]. The best loss function was chosen during the hyperparameter optimization.

D. Model advantages

We would like to emphasize the following advantages of the proposed approach:

- 1) P3LTR generalizes RP3Beta which is a strong baseline model.
- 2) P3LTR directly utilizes the information about the user-item relationship. For instance, our model may be used for encoding the importance of ratings in the explicit feedback dataset used for the top N recommendations task if we treat each rating as a different type of interaction.
- 3) P3LTR utilizes additional information regarding the users and the items. In our collaborative filtering dataset, we used only node degrees as such features, but we can easily extend the model to include additional user and item features.
- 4) P3LTR is an explainable model from two perspectives: we can explain because of which items a given item is recommended and explain why some items are more influential on recommendations.
- 5) P3LTR directly utilizes the information of the node's neighbors. Such an approach might give better results than embedding-based approaches for users with a low number of interactions.
- 6) The training pipeline is used only for optimizing the weights of feature encoders. Hence it can be trained sporadically (or even just once) and be utilized for providing predictions every day.
- 7) The model prediction is almost as efficient, as RP3Beta. The difference is in the preprocessing stage, where in P3LTR, we need to additionally calculate features and pass them through feature encoders.

IV. EXPERIMENTAL SETUP

A. Dataset

We utilized the OLX Jobs Interactions dataset which is publicly available on Kaggle¹. In our previous work, as yet unpublished, we compared several collaborative filtering non-neural approaches. The RP3Beta model outperformed other approaches in terms of accuracy and efficiency and, after online A/B tests, has been deployed at OLX.

The dataset contains 65 502 201 events made on <http://olx.pl/praca> by 3 295 942 users who interacted with 185 395 job ads in 2 weeks of 2020. Each event contains 4 pieces of information: user id, item id, event type (e.g., click or reply) and timestamp.

It is important to note that users usually do not interact with many job ads (average: 20, median: 6, first quartile: 2, third quartile: 18).

¹<https://www.kaggle.com/datasets/olxdatscience/olx-jobs-interactions>

Fig. 2. Precision for each model depending on parameters.

B. Train-test splitting

We split the events into train and test sets by time, i.e., 20% of the newest events (approximately 2.8 days) were included in the test set. We filtered out from the test set all user-item pairs which appeared in the train set (to avoid recommending already seen items).

C. Hyperparameter tuning

For the sake of efficiency, we extracted 20% of users and 20% of items from the original train set and, according to the train-test splitting technique described in the previous section, we divided them into train and test sets used for validation. For each model, we defined the hyperparameter space and performed 100 iterations chosen by Bayesian optimization using Gaussian processes. We were optimizing for precision@10 [36] calculated on 30 thousand users. In Fig. 2 we can observe that the hyperparameters significantly affect the performance of tuned models. Therefore, tuning was essential for providing reliable results for compared methods. We can also see that choosing suboptimal hyperparameters for the RP3Beta model can result in very poor performance, which is not the case for P3LTR. We report the optimal hyperparameters in Table I.

V. RESULTS

We used the best found hyperparameters to train our model on the full dataset and generate recommendations for all 619 389 users in the test set. We compared the following methods:

- **P3LTR**,
- **RP3Beta**,
- **P3**: which is the RP3Beta model for $\alpha = 1$ and $\beta = 0$,
- **#3-Paths**: which is the RP3Beta model for $\alpha = 0$ and $\beta = 0$. We initialized all the parameters of our P3LTR model to zeros, which makes the #3-Paths model equivalent to the P3LTR model before the learning process.

In this section, we compare the accuracy and diversity of these models. We will also discuss the parameters of our P3LTR model.

A. Accuracy

In Table II we list common accuracy evaluation metrics calculated with respect to the top 10 recommendations. The

TABLE I
MODEL HYPERPARAMETERS.

Model	Model hyperparameters
RP3beta	{'alpha': 0.61447198, 'beta': 0.1443548}
P3LTR	{'regularization': 0.001, 'learning_rate': 0.02, 'batch_size': 153, 'iterations': 80, 'top_k': 205, 'loss': 'log_ratio'}

TABLE II
ACCURACY RESULTS. ALL PRESENTED METRICS WERE DESCRIBED IN [36].

Model	P3LTR	RP3Beta	P3	#3-Paths
precision	0.0515	0.0484	0.0481	0.0391
recall	0.0817	0.0783	0.0782	0.0611
ndcg	0.0798	0.0759	0.0755	0.0599
mAP	0.0414	0.0393	0.0390	0.0302
MRR	0.1423	0.1365	0.1363	0.1107
LAUC	0.5408	0.5391	0.5391	0.5305
HR	0.3242	0.3131	0.3147	0.2605

values should not be directly compared with the results achieved on other datasets, because metrics heavily depend on the distribution of the dataset (for example high sparsity) and the train/test splitting strategy. We can observe that our method P3LTR outperforms RP3Beta with respect to all listed metrics.

To identify differences between the methods, we test the null hypothesis that all methods perform the same. We used the Friedman test with Iman and Davenport extension. The p -value from this test is equal to 0 which indicates that we can safely reject the null hypothesis that all the algorithms perform the same. We can therefore proceed with the post-hoc tests in order to detect significant differences among all of the methods. Demšar [37] proposes the use of the Nemenyi's test and preparing a plot to visually check the differences, the critical difference plot. In the plot, those algorithms that are not joined by a line can be regarded as different. In our case, with a significance of $\alpha = 0.05$ any two algorithms with a difference in the mean rank above 0.006 are regarded as non-equal (Fig. 3).

We can observe three disjoint groups of methods:

- 1) P3LTR,
- 2) RP3Beta and P3,
- 3) #3-Paths.

From this analysis, we see that P3LTR performs significantly better than other methods on the examined dataset.

B. Diversity

Most of the job ads refer to only one job position. Hence we should avoid recommending the same item to a great number of users. For that reason, we report also the diversity metrics in Table III. Test coverage is a fraction of items from the test set which were recommended to at least one user. We also report Shannon entropy [38] and Gini index [38]. We can see that P3LTR is the most diverse method with respect to all these metrics. We can also note that the #3-Paths method seems less

Fig. 3. Critical difference plot (for precision).

TABLE III
DIVERSITY RESULTS.

Model	P3LTR	RP3Beta	P3	#3-Paths
test coverage	0.757	0.573	0.617	0.374
Shannon entropy	10.090	9.527	9.631	8.712
Gini index	0.844	0.908	0.898	0.957

diverse than other methods. We suppose that the reason is that this method recommends the items based on the number of paths of length 3 connecting a given user and item, so the most popular items are more often recommended.

In order to decide whether to deploy a new recommendation system in production, we usually check how different are the recommendations produced by a new model compared to the old one. To assess it we calculated the overlap coefficient [39] with respect to user-item pairs. The results are reported in Table IV. We see that 70% of the top 10 recommendations provided by P3LTR and RP3Beta models are the same recommendations. We can also observe that RP3Beta and P3 provide pretty similar results on our dataset (overlap coefficient equals 84%).

C. Parameters of the P3LTR model

As we mentioned, the parameters of our model can be easily interpreted. In the Table V we report the values of $d^{(k)}$ (parameters related to node degrees) and $r^{(k)}$ (parameters related to recency).

In previous works regarding the RP3Beta model, usually positive values for α and β were chosen to discourage the model from recommending the most popular items [1], [3].

TABLE IV
AN OVERLAP OF MODELS.

Model	P3LTR	RP3Beta	P3	#3-Paths
P3LTR	100%	70%	64%	50%
RP3Beta	70%	100%	84%	68%
P3	64%	84%	100%	60%
#3-Paths	50%	68%	60%	100%

TABLE V
PARAMETERS OF THE P3LTR MODEL.

Parameter	$k = 1$	$k = 2$	$k = 3$
$d^{(k)}$	0.631	0.163	0.433
$r^{(k)}$	0.081	0.008	0.028

We can see that in our machine learning approach also positive values were learned for all $d^{(k)}$ parameters.

Additionally, in RP3Beta model we have $d^{(1)} = d^{(2)} = \alpha$. However, P3LTR model chose very different values for $d^{(1)}$ and $d^{(2)}$.

Regarding recency, the model chose positive values of $r^{(k)}$ parameters. It means that the more recent interactions should have higher importance.

We do not discuss parameters related to event type e.g., viewing or replying to an ad, because they did not converge within the number of iterations we have chosen. Hence the reported results might differ when we train the model multiple times. We believe the convergence could be achieved with a greater value of a batch_size hyperparameter, but it would also significantly increase the training time.

VI. SUMMARY

In the paper, we introduced a new graph vertex ranking recommendation method which we named P3LTR. It generalizes the RP3Beta model which provides very efficient and accurate recommendations on multiple datasets. We described several strengths of our approach, including explainability and prediction efficiency. We showed that our method is superior to RP3Beta on the OLX Jobs Interactions dataset in terms of accuracy and diversity of recommendations.

The proposed method may improve the quality of recommendations currently being generated using the RP3Beta model that is implemented at OLX Jobs in a production setting.

In future work, we plan to explore more advanced feature encoders which utilize user and item features. We would like to explore and compare different loss functions for the P3LTR model. Additionally, we would like to launch A/B tests on production to measure the model's effectiveness on real users.

Abstract—Recent advances in deep learning based language models have boosted the performance in many downstream tasks such as sentiment analysis, text summarization, question answering, etc. Personality prediction from text is a relatively new task that has attracted researchers’ attention due to the increased interest in personalized services as well as the availability of social media data. In this study, we propose a personality prediction system where text embeddings from large language models such as BERT are combined with multiple statistical features extracted from the input text. For the combination, we use the self-attention mechanism which is a popular choice when several information sources need to be merged together. Our experiments with the Kaggle dataset for MBTI clearly show that adding text statistical features improves the system performance relative to using only BERT embeddings. We also analyze the influence of the personality type words on the overall results.

I. INTRODUCTION

PERSONALITY research has a long history of studies mainly in psychology where stable patterns of thoughts, feelings, and behaviors have been associated with the so called personality traits. They are useful indicators for describing individual’s preferences in perceiving the world and making decisions [1].

Recent advances in natural language processing have made it possible to build machine learning models using online data on human behavior and preferences to automatically predict people’s personality traits. Applications include wide variety of internet services including recommender systems [2], product personalization [3], social network and sentiment analysis [4], [5].

In psychological science, there are two widely adopted models for formal description of the personality traits. The five factor model (Big Five) [6] consists of five broad dimensions of personality - Openness, Conscientiousness, Agreeableness, Extraversion, and Neuroticism. Individual’s scores on each of these dimensions is obtained using a standardized self-report questionnaires. In the other model, personality is formally described by 16 types known as MBTI (Myers-Briggs Type Indicator) [7]. MBTI is an introspection self-reported diagnostic test aimed at showing psychological preferences about how individuals perceive the world and make decisions. The subjects are classified into 16 personality types that are created from the combination of binary assignments to four dimensions: Introversion versus Extraversion (I/E), Sensing versus Intuiting (S/I), Thinking versus Feeling (T/F), and

Fig. 1. MBTI type personality keys [7]

Judging versus Perceiving (J/P) as shown in Fig. 1. It is been long considered that personality is reflected in individual’s use of language [8]. People with high score in extraversion use more positive emotion words while those higher in neuroticism favor first-person words such as “I”, “my”, and “me”.

A significant number of studies have been dedicated to automatic personality prediction. As an input modality, text data are widely used because they are easy to collect, though video has also been used lately [9]. Some of the first works have focused on text features based on lexicon, syntax, etc., and investigated their correlation with the personality traits as well as their classification performance using shallow machine learning models [10], [11], [12], [13]. Others rely on the commonly used TF-IDF features, for example [14], where personality traits are predicted using an XGBoost classifier.

Some recent works utilize the achievements in the neural networks based text processing by using word embeddings from pre-trained Word2Vec [15] or GloVe [16] models as well as big language models such as BERT [17], [18]. In [17], BERT embeddings are compared with a set of psycholinguistic features and has been found that the BERT derived features perform better.

In this study, as a starting point we also use BERT derived embeddings like in [17], but then we try to combine them with a set of different statistical features extracted from the input text documents. Those features include uni-gram and bi-gram histograms, topic distribution, post and word length statistics,

etc. In order to combine them with the BERT document embeddings in an efficient way, we use a self-attention based method.

II. SYSTEM DESCRIPTION

We assume that the text data consist of multiple posts from various users with known MBTI labels. The system takes all posts from a single user as input data and outputs four dimensional binary vector where each element corresponds to one of the four MBTI axes, i.e. E/I, N/S, T/F and P/J. For example, if the output is $[1, 0, 0, 1]$, the personality type is ESFP. Since there are only 16 possible personality types, we cast the personality prediction task as a classification task with 16 categories which are then projected onto the four MBTI axes.

Input text data from each user are transformed into a document vector using pre-trained BERT language model. In our base system, document vectors from all users are passed to a simple MLP classifier with 16 outputs. In the full system, in addition to the document vector, several statistical features are extracted from the input text data and linearly transformed to match the document vector's dimension. Then, using self-attention mechanism, all vectors are combined into a single final vector which is passed to the the same MLP classifier.

A. Text Embedding

In natural language processing applications it has become popular to adopt the transfer learning approach where pre-trained language models build from large amounts of data, such as BERT or GPT, are fine tuned or used to extract features from text for further processing by smaller machine learning models.

In this study, we selected the BERT-large model since it provides 1024-dimensional vector representation, i.e. embedding, for each input word token. In order to obtain a single vector for the whole document, we aggregate the BERT outputs by taking their average as was proposed in [17]. Fig. 2 shows the document vector extraction procedure.

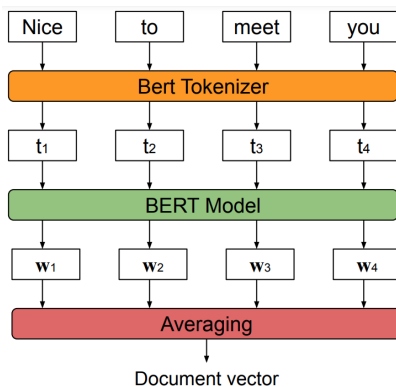

Fig. 2. Document vector extraction procedure.

Another popular way of obtaining representation vector for the whole input is to use the BERT output for the [CLS] token

[19]. This, however, works when the number of input tokens is less than maximum input length of the language model which was not the case for the majority of the users data in our experiments.

After document vectors for all the users are obtained, we use a simple MLP network to classify them into one of the 16 MBTI categories. The winning category is then transformed into four dimensional MBTI axes vector. This is our base system and its block diagram is shown in Fig. 3. It is similar to the system investigated in [17], but the main difference is the way we aggregate the BERT outputs.

Fig. 3. Base system using only text embedding.

B. Statistical Features

Although the BERT is a very powerful language model, it is designed to capture and learn dependencies mainly at word and sentence level. When the task is to extract information at a higher user level, as in our case, some useful user dependent characteristics of the input text may get "overlooked" by the BERT model. For example, the usage of some specific words or phrases, or special symbols like emojis is difficult to obtain from the language model. However, it is easy to obtain such information using statistical analysis of users text.

1) *Uni-gram and Bi-gram Histogram*: Different people tend to have their own vocabulary of most used words and phrases and we suppose that the personality plays some role in the formation of this vocabulary. In order to get user specific vocabulary representation we use a histogram of uni-grams (single words) and bi-grams (pairs of words) present in the use data.

First, we create a global vocabulary from all users text data. Then, for each user, the frequency of each uni-gram or bi-gram is obtained from the user's data forming a histogram feature vector. Stop words like "I", "and", "the" which are common and do not provide any discriminating information

are removed from the vocabulary. Rare words, i.e. words with frequency less than a specified threshold, are removed as well.

2) *Topic Distribution*: Another factor that may be influenced by the user’s personality is the topic of the user’s post. There various ways to determine the topic of a given text. Topic classification into pre-determined categories such as news, politics, sports, etc. has been studied for years [20]. In our case, however, we are more interested in the topic differences among the posts rather than their labels. Furthermore, the granularity level of the topic categories may result in quite different classification results. That is why we adopted an unsupervised topic learning approach.

First, each post from all users is transformed into a vector using the same approach as in our base system, i.e. using BERT language model. Post vectors obtained this way are clustered into several clusters with the K-means algorithm. Then for each user, cluster occupancy histogram of its posts is used as a topic distribution feature vector.

3) *Post and Word Length Statistics*: The number of words in a post can vary significantly depending on various factors one of which we assume is the personality type. If there is any correlation, it can be revealed by taking the first and second order statistics of the word number in a post. Extending this idea to the word length in letters, for each user we construct a feature vector from the mean and variance of word number per post and letter number per word.

4) *Emoticon Usage*: It’s a common practice to use emoticons in users posts to express emotions. Some examples of most often used emoticons are given in Table I. We suppose that different people may use different sets of emoticons and the frequency of their usage may be related to personality types. In fact, in [21], emoji embeddings have been concatenated with word embeddings in an attention-based BiLSTM model.

Based on the set of emoticons found in the dataset, for each user we obtain a histogram of emoticons present in its posts which is used as a feature vector.

TABLE I
SOME FREQUENTLY USED EMOTICONS AND THEIR MEANING

Emoticon	Meaning
:)	happy face
:D	laughing
:’(crying
:/	annoyed

C. Self-Attention based Embedding and Feature Combination

As we described in Section II-A, our base system uses text embedding to predict user’s personality type. By combining the text embedding with the feature vectors obtained from the statistical text analysis we aim at improving the system performance.

There are various way to combine vectors representing different information sources including simple concatenation, weighted sum, etc. In this study, we adopt the weighted sum approach where weights are calculated dynamically based

on the current input and a learned stream importance. This approach is implemented using a self-attention network [22].

Given vectors v_1, v_2, \dots, v_N , we first, pass them through a vector specific linear layer with sigmoid activation function

$$u_i = \text{sig}(W_i v_i + b_i) \quad (1)$$

The combined output vector o is then calculated as a weighted sum of vectors v_i as follows

$$o = \sum_i a_i v_i \quad (2)$$

where weights a_i are obtained using softmax function

$$a_i = \frac{\exp u_i}{\sum_j \exp u_j} \quad (3)$$

We have to note that the original text embedding vector and the statistical feature vectors have different sizes. In order to equalize their dimensionality, each statistical feature vector is passed through a linear layer with a proper weight matrix and no bias.

Fig. 4 shows the block diagram of our system where the output of the self-attention network o is used as input to the personality prediction MLP classifier.

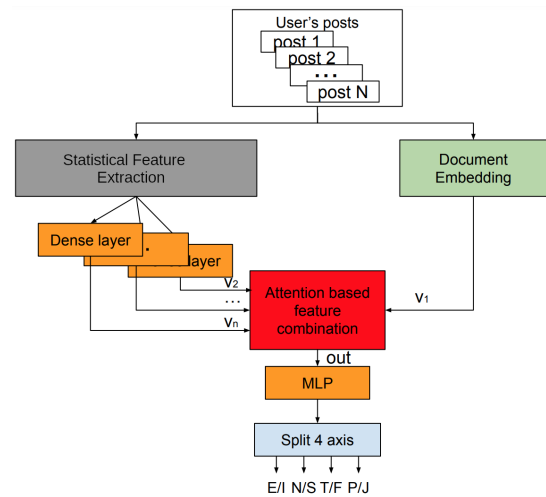

Fig. 4. Self-attention based text embedding and statistical features combination system.

III. EXPERIMENTS

A. Dataset

In this study we use the Kaggle MBTI personality type dataset [23]. The data were collected through the Personality-Cafe forum and include diverse selection of posts from people interacting in an informal online social setting.

This dataset contains records of the last 50 posts from 8600 PersonalityCafe users along with their MBTI binary personality type. The MBTI label distribution is given in Table II which shows that the data are quite unbalanced.

TABLE II
DISTRIBUTION OF THE MBTI TYPE LABELS.

MBTI type label	Number of labels
E/I	1999/6676
N/S	1197/7478
T/F	4694/3981
P/J	5241/3434

B. Data Pre-processing

First, all text data were cleaned which is a standard text pre-processing practice. This includes case conversion, reducing repeated characters and punctuations, expanding contractions, removing numbers, etc. There was a substantial number of URL links which we replaced with a special token [URL]. Posts consisting of URLs only were removed.

C. Model Training

For model training and evaluation we adopted a 10-fold cross-validation scheme shown in Fig. 5. In each fold, 10% of the data is reserved for testing. The rest is divided into training and validation sets with 9:1 proportion. This way, we train 10 different models and tune their hyper-parameters on the corresponding validation set. After that, each model is evaluated on the fold's test data and the results are averaged over the folds.

Fig. 5. 10-fold cross-validation scheme for model training and evaluation.

D. Evaluation Metrics

For classification tasks, the standard evaluation metrics are *Accuracy* and/or *F1-score* and we are reporting all the results in term of those two metrics.

In order to be able to compare our results with those already published, we calculate the *Accuracy* and *F1-score* separately for each of the four MBTI axes, i.e. E/I, N/S, T/F, P/J and for the overall system performance we take their average.

E. Results

How efficient would be a combination of several feature vectors depends not only on the way they are combined, but to a large extent to how much discriminating information each feature contributes. It is difficult to assess this contribution quantitatively, so we analysed the differences in feature vectors representing different users. For example, in the uni-gram case, these are the word usage histograms. A comparison of such histograms for two users is shown in Fig. 6. It is apparent

that they are quite different and could be helpful for the user discrimination.

Fig. 6. Uni-gram histogram of two users.

For the topic distribution feature, we needed to tune the number of topic clusters used to create it. This number is a hyper-parameter which can be determined manually since the range of possible values is not that wide. We created topic models with 2 to 16 clusters and evaluated them by combining the topic feature vectors with document vectors from BERT. The obtained average Accuracy and F1-score are given in Fig. 7. It is clear that the optimum number of topic clusters is 4.

Fig. 7. Classification performance with respect of the number of topic clusters.

The performances of our base system, i.e. using only document embedding as feature vector, and the proposed system with self-attention based combination with statistical features are summarized in Table III and Table IV. The first row in each table shows the base system results. The following rows show the result when the document embedding vectors are combined with one of the uni-gram (uni), bi-gram (bi), topic distribution (t), post and word length (p), and emoticon usage (e) features. The last row shows the performance of the best multiple statistical features combination.

As can be seen from these tables, each additional statistical feature slightly improved the base system results. Uni-gram and bi-gram features scored almost the same which may be explained by the limited vocabulary and the amount of training data per user. The highest result, however, was obtained with multiple features combination.

Finally, in Fig. 8 we compare our best result with the results from some other studies where the same Kaggle MBTI dataset

TABLE III

base+uni+p+e	0.762	0.695	0.844	0.773	0.769

was used. In [14], the TF-IDF features are used with XGBoost classifier while in [17] BERT model is combined with an MLP network.

Fig. 8. Comparison of our and other published systems.

IV. DISCUSSION

It is well known that "models are as good as the data" they are trained on. The data samples and truth labels quality plays essential role in the final systems performance. This is an important issue especially when the data are collected from social media.

During the analysis of the Kaggle MBTI dataset we noticed that all users refer to their own MBTI type more often than to the other personality types. Fig. 9 shows a heatmap of the frequency of the MBTI type word usage by each personality type users. It is clear that user's own MBTI type word is mentioned several times more frequently in their posts. This suggests that a histogram vector of personality type words usage can be highly discriminative for this dataset.

Thus, as an additional experiment, we trained an MLP classifier with only MBTI histogram feature vectors (one per user) as well as their combination with document embedding vectors. The results shown in Table V were surprising, though

Fig. 9. Heatmap of MBTI type word usage by users of different personality types.

not unexpected. The MBTI feature alone outperformed our

TABLE V
ACCURACY (%) OF THE BASE SYSTEM, MBTI FEATURES AND THEIR COMBINATION.

Features	E/I	N/S	T/F	P/J	Ave
base	83.1	88.5	84.1	78.0	83.4
mbti	86.2	90.5	84.8	80.3	85.4
base+mbti	87.2	91.3	86.1	81.8	86.6

best system and when combined with the BERT document features improved the result by almost 4%. Of course, this outcome is specific to the Kaggle dataset and will not hold with other data collections. Nevertheless, it underlines the importance of the data when building machine learning systems.

V. CONCLUSION

In this paper, we proposed a personality type prediction system which combines text document embedding vectors obtained from the BERT language model with statistical feature vectors extracted from the text data. Using powerful language models for downstream tasks has been proved quite effective and our results confirm this conclusion. However, there is always room for improvement when additional task specific knowledge is incorporated in the system as in our usage of statistical text information.

System evaluation with a single dataset reveals only the potential effect and efficiency of the proposed approach and further experimentation with other data collections is necessary in order to prove its merits.

4th International Symposium on Rough Sets: Theory and Applications

THE RSTA symposium is devoted to the state-of-the-art and future perspectives of rough sets considered from both a theoretical standpoint and real-world applications. Rough set theory is a highly developed discipline with a large number of mechanisms potentially useful in intelligent data analysis. In our special session, we aim to invite deep research papers that address the practical problem of modeling artificial intelligence processes using techniques derived from rough sets. We also encourage scientists from other research fields to participate to initiate discussions and collaborations on other methods of data exploration and approximate computations.

TOPICS

The list of topics includes, but is not limited to:

- Artificial Intelligence
- Algebraic Logic
- Logics from Rough Sets
- Approximate Reasoning
- Clustering and Rough Sets
- Dominance-based rough sets
- Distributed Cognition
- Granular Computing
- Rough mereology
- Near sets and Proximity
- Fuzzy-rough hybrid methods
- Hybrid techniques
- Rough neural computing
- Evolutionary computation and rough set
- Image and Video Processing
- Rough Sets in Education Research
- Knowledge discovery from Databases
- Missing values
- Big data
- Bio-informatics
- Three-Way Decision Making
- Data security
- Intelligent Robotics
- Knowledge engineering
- Multimedia applications
- AHP and Decision Making
- Assistive technology and adaptive sensing systems

TECHNICAL SESSION CHAIRS

Three-way Learnability: A Learning Theoretic Perspective on Three-way Decision

Andrea Campagner, Davide Ciucci

Dipartimento di Informatica, Sistemistica e Comunicazione,
 University of Milano–Bicocca, Viale Sarca 336/14, 20126 Milano, Italy

Abstract—In this article we study the theoretical properties of Three-way Decision (TWD) based Machine Learning, from the perspective of Computational Learning Theory, as a first attempt to bridge the gap between Machine Learning theory and Uncertainty Representation theory. Drawing on the mathematical theory of orthopairs, we provide a generalization of the PAC learning framework to the TWD setting, and we use this framework to prove a generalization of the Fundamental Theorem of Statistical Learning. We then show, by means of our main result, a connection between TWD and selective prediction.

I. INTRODUCTION

IN the recent years, there has been an increasing interest toward exploring the connections between learning theory and different uncertainty representation theories: This trend includes both the generalization of standard learning-theoretic tools and techniques to settings that involve representation formalisms that are more general than probability theory [1], [2], as well as the theoretical study of algorithms inspired by uncertainty representation [3], [4].

Among other uncertainty representation theories, Three-way decision (TWD) is an emerging computational paradigm, first proposed by Yao in Rough Set Theory [5], based on the simple idea of *thinking in three “dimensions”* (rather than in binary terms) when representing and managing computational objects [6]: in the Machine Learning (ML) [7] setting, this notion is usually declined in terms of allowing ML models to *abstain*. This approach attracted a large interest, also justified by promising empirical results in different ML tasks such as active learning [8], [9], cost-sensitive classification [10], clustering [11], [12], [9]. Despite these promising empirical results, the theoretical foundations of TWD-based ML received so far little attention [13], [14]. Indeed, even though, in the recent years, there has been an increasing interest toward generalizing computation learning theory (CLT) to cautious inference methods such as *selective prediction* [15] or the KWIK (*Knows what it Knows*) framework [16], such results cannot be easily applied to the TWD setting: While in the TWD setting abstention is a property of single classifiers; in the latter two frameworks abstention is usually achieved by consensus voting.

In this article, we study the generalization of a standard CLT mathematical framework, the so-called *Probably Approximately Correct* (PAC) learning framework, to the TWD setting: In particular, we will provide a generalization of the *Fundamental Theorem of Learning* to the TWD setting, and we

show that our result generalizes previous results in the selective prediction setting. More in detail, the rest of this article is structured as follows: In Section II we provide the necessary mathematical background on TWD (in Section II-A) and CLT (in Section II-B); in Section III we describe the generalization of the PAC learning framework to the TWD setting and we prove our main result; finally, in Section IV, we summarize our contribution and describe possible research directions.

II. BACKGROUND

A. Three-way Decision and Orthopairs

In this work we will refer to the formalization of TWD-based ML models (in the following, TW Classifiers) as *orthopairs*:

Definition 1. An orthopair [17] over the universe X (which represents the instance space) is a pair of sets $O = (P, N)$ such that $P, N \subseteq X$ and $P \cap N = \emptyset$, with P and N standing, respectively, for positive and negative. The boundary is defined as $Bnd = (P \cup N)^c$.

An orthopair represents an uncertain concept: Specifically, the status of the elements in the boundary is uncertain (i.e., it is not known whether they belong to the concept). Thus, a given orthopair stands as an approximation for a collection of consistent concepts:

Definition 2. We say that an orthopair $O = (P, N)$ is consistent with a concept $C \subset X$ if $x \in P \implies x \in C$ and $x \in N \implies x \notin C$.

Finally, we remark that it is possible to define different orderings between orthopairs: In particular, O_2 is *less informative* than O_1 , denoted $O_2 \leq_I O_1$ if $P_2 \subseteq P_1$ and $N_2 \subseteq N_1$.

B. Computational Learning Theory

Computational Learning Theory [18] (CLT) refers to the branch of Machine Learning and Theoretical Computer Science focusing on the theoretical study of learning algorithms. Various mathematical formalisms have been proposed toward this goal, in this article we will refer to the PAC (probably approximately correct) learning framework, first proposed in [19]. Formally, let X be the instance space and Y be the target space, in this article we will focus on the *binary classification* setting, that is $Y = \{0, 1\}$. We assume that the observable data is generated i.i.d. according to an unknown probability distribution \mathcal{D} over $X \times Y$. Let \mathcal{H} be a hypothesis

class, that is a collection of functions $h : X \mapsto Y$, we define the *true risk* of h w.r.t. \mathcal{D} as:

$$\mathcal{L}_{\mathcal{D}}(h) = \mathbb{E}_{\mathcal{D}} [l(h(x), y)] = \int_{X \times Y} l(h(x), y) d\mathcal{D}(x, y) \quad (1)$$

where $l : Y^2 \mapsto \mathbb{R}^+$ is a loss function. Since \mathcal{D} is unknown, the true risk cannot be computed: It is usually approximated through the so-called *empirical risk* based on a sample, called *training set*, $S = (\langle x_1, y_1 \rangle, \dots, \langle x_m, y_m \rangle)$:

$$L_S(h) = \frac{1}{m} \sum_{i=1}^m l(h(x_i), y_i) \quad (2)$$

Given a training set S , we denote by S_X the tuple $S_X = (x_1, \dots, x_m)$, and by S_Y the tuple $S_Y = (y_1, \dots, y_m)$. The *Empirical Risk Minimization* w.r.t. the hypothesis class \mathcal{H} is the family of algorithms $ERM_{\mathcal{H}, m} : (X \times Y)^m \mapsto \mathcal{H}$ s.t. $ERM_{\mathcal{H}, m}(S) \in \operatorname{argmin}_{h \in \mathcal{H}} L_S(h)$, where $S = (\langle x_1, y_1 \rangle, \dots, \langle x_m, y_m \rangle)$ is the training set.

The *Fundamental Theorem of Learning* [20] establishes a relation between the true risk and empirical risk for the *ERM* algorithm w.r.t. a hypothesis class \mathcal{H} which depends only on the so-called VC dimension, a combinatorial dimension of the complexity of \mathcal{H} .

Theorem 1. *Let \mathcal{H} be a hypothesis class with VC dimension d . For each $\epsilon, \delta \in (0, 1)$ and distribution \mathcal{D} , then if $ERM_{\mathcal{H}}$ is given a dataset S of size $m \geq n_0$, with*

$$n_0 = O\left(\frac{d + \ln(\frac{1}{\delta})}{\epsilon^2}\right) \quad (3)$$

with probability greater than $1 - \delta$, it holds that $|L_{\mathcal{D}}(ERM_{\mathcal{H}}(S)) - L_S(ERM_{\mathcal{H}}(S))| \leq \epsilon$. If, further, the realizability¹ assumption holds, then, if S is a dataset of size $m \geq n_1$, with

$$n_1 = O\left(\frac{d + \ln(\frac{1}{\delta})}{\epsilon}\right) \quad (4)$$

with probability greater than $1 - \delta$, it holds that $L_{\mathcal{D}}(ERM_{\mathcal{H}}(S)) \leq \epsilon$.

Few works have studied the generalization of CLT results to hypothesis that can be described as orthopairs (that is, classifiers that can abstain on selected instances), mainly under the framework of *selective prediction* [21]: In this setting, the goal is to design learning algorithms $\mathcal{A}_{\mathcal{H}, m} : (X \times Y)^m \mapsto \mathcal{O}_{\mathcal{H}}$, where $\mathcal{O}_{\mathcal{H}} \subseteq TW(\mathcal{H})$ (see Eq. (15)), s.t. $L_{\mathcal{D}}(A(S)) = 0$ but $A(S)$ is allowed to abstain on certain instances. This abstention is usually achieved either by the combination of a standard hypothesis $h : X \rightarrow Y$ with a rejection function $r : X \rightarrow \{\perp, \top\}$, or, equivalently, by consensus voting based on a version space $V \subseteq \mathcal{H}$ [21]. As we show in the following sections (specifically, in Section III-A) the setting we consider is a proper generalization of selective prediction. More recently, the application of orthopairs in CLT has been studied in the setting of adversarial machine learning [22], as well as to characterize the generalization

capacity of hypothesis classes under generative assumptions [23]. We note, however, that even though the above mentioned work and the framework we study in this article rely on the representation formalism of orthopairs, the aims of these three frameworks are essentially orthogonal, also in terms of the mathematical techniques adopted: Indeed, while the three-way learning framework we study relies on a generalization of the ERM paradigm, the frameworks studied in [23], [22] rely on a transductive learning approach.

III. THREE-WAY LEARNING

In this Section, we provide a first study of a generalization of standard Computational Learning Theory to the setting of TW Classifiers. As hinted in Section II-A, we will represent a TW Classifier as an orthopair O ; then, a hypothesis space of TW Classifier will be represented as a collection \mathcal{O} of orthopairs over X . In the TWD literature, the risk of a TW Classifier is usually evaluated by means of a cost-sensitive gener-

alization of the 0-1 loss: $l_{TW}(O(x), y) = \begin{cases} 1 & O(x) \perp y \\ \lambda_a & x \in Bnd_O \\ 0 & \text{otherwise} \end{cases}$,

where $\lambda_a \in [0, 0.5]$ is the cost of abstention, and $O(x) \perp y$ is the error case, that is $(x \in P_O \wedge y = 0) \vee (x \in N_O \wedge y = 1)$. Compared to the standard definition of risk adopted in the TWD literature we assume that the cost of error is always 1. Based on the loss function l_{TW} we can define both the true risk $\mathcal{L}_{\mathcal{D}}^{TW}$ and the empirical risk L_S^{TW} . Evidently, the risk of O can be decomposed as the sum of two functions:

$$\begin{aligned} \mathcal{L}_{\mathcal{D}}^{TW}(O) &= \mathbb{E}_{\mathcal{D}} [l_{TW}(O(x), y)] \\ &= \mathbb{E}_{\mathcal{D}} [\mathbb{1}_{O(x) \perp y}] + \lambda_a \mathbb{E}_{\mathcal{D}} [\mathbb{1}_{x \in Bnd_O}] \\ &= Pr_{x \sim \mathcal{D}}(O(x) \perp y) \\ &\quad + \lambda_a \cdot Pr_{x \sim \mathcal{D}}(x \in Bnd_O) \end{aligned} \quad (5)$$

The same decomposition can be similarly applied for the empirical risk. Let $\mathcal{E}_{\mathcal{D}}(O) = Pr_{x \sim \mathcal{D}}(O(x) \perp y)$ and $\mathcal{A}_{\mathcal{D}}(O) = \lambda_a \cdot Pr_{x \sim \mathcal{D}}(x \in Bnd_O)$. We denote with $\mathcal{O}^{OPT} = \{O \in \mathcal{O} : \mathcal{E}_{\mathcal{D}}(O) = \min_{O' \in \mathcal{O}} \mathcal{E}_{\mathcal{D}}(O')\}$. We say that \mathcal{D} is *weakly realizable* w.r.t. \mathcal{O} if $\forall O^* \in \mathcal{O}^{OPT}$ it holds that $\mathcal{E}_{\mathcal{D}}(O^*) = 0$. If, furthermore, $\exists O^* \in \mathcal{O}^{OPT}$ s.t. $\mathcal{A}_{\mathcal{D}}(O^*) = 0$, then we say that \mathcal{D} is *strongly realizable*. Through this article, we will assume only weak realizability. Compared to the realizability assumption, weak realizability assumption is indeed much weaker. As an example if the vacuous TW classifier $O_{\perp} = (\emptyset, \emptyset) \in \mathcal{O}$, then every distribution \mathcal{D} is trivially weakly realizable w.r.t. \mathcal{O} , while it is clearly not strongly realizable.

Let $\epsilon \in (0, 1)$, $\alpha \in (0, \lambda_a)$, then $O \in \mathcal{O}$ makes an (ϵ, α) -failure if one of the following holds:

$$\mathcal{E}_{\mathcal{D}}(O) > \epsilon, \quad \mathcal{A}_{\mathcal{D}}(O) > \min_{O \in \mathcal{O}^{OPT}} \mathcal{A}_{\mathcal{D}}(O) + \alpha \quad (6)$$

Thus, O (ϵ, α) -fails if either its error is greater than ϵ , or if its abstention rate is greater, by a margin of at least α , than the lowest abstention rate among those TW Classifiers that make no error. We thus define the notion of *Three-way learnability*:

Definition 3. *\mathcal{O} is Three-way learnable if exists an algorithm $C_m : (X \times Y)^m \mapsto \mathcal{O}$ and $m_{\mathcal{O}} : (0, 1)^2 \times (0, \lambda_a) \mapsto \mathbb{N}$ such*

¹Here realizability means that $\exists h \in \mathcal{H}$ s.t. $L_{\mathcal{D}}(h) = 0$.

that, for each distribution \mathcal{D} , $\epsilon \in (0, 1)$, $\delta \in (0, 1)$, $\alpha \in (0, \lambda_a)$ $\forall m \geq m_{\mathcal{O}}(\epsilon, \delta, \alpha)$, and given $S \sim \mathcal{D}^m$, C returns $O \in \mathcal{O}$, s.t. O (ϵ, α) -fails with probability lower than δ

We then want to provide a characterization for TW learnability, similar to Theorem 1. For this purpose, we first define a generalization of the ERM algorithm to the TWD setting, that we call Three-way Risk Minimization (TW-RM):

Definition 4. Let $S \in (X \times Y)^m$. Then,

$$\begin{aligned} TWRM(S) &= \operatorname{argmax}_{O \in \mathcal{O}} \mathcal{A}_{X \setminus S_X}(O) \text{ s.t.} \\ \mathcal{E}_S(O) &= \min_{O' \in \mathcal{O}} \mathcal{E}_S(O') \\ \mathcal{A}_S(O) &= \min_{O' \in \mathcal{O}^{OPT}} \mathcal{A}_S(O') \end{aligned} \quad (7)$$

Thus, the TWRM algorithm selects, among those TW classifiers with minimal empirical risk, the TW classifier with maximal abstention rate on the non-observed instances (that is, the instances in $X \setminus S_X$). This has the goal of minimizing errors on non-observed instances, and is analogous to the *maximum margin* principle, and the *disagreement coefficient* in version space learning, active learning and selective prediction [15].

In order to characterize TW learnability, given hypothesis class \mathcal{O} (i.e. a collection of orthopairs), we define two derived hypothesis classes. Given any orthopair $O \in \mathcal{O}$ we can define a classifier $h_O : X \mapsto \{0, 1\}$, as: $h_O(x) = \begin{cases} 1 & x \in \text{Bnd}_O \\ 0 & \text{otherwise} \end{cases}$.

We denote the collection of such binary classifiers as $\mathcal{H}_{\mathcal{O}} = \{h_O : O \in \mathcal{O}\}$. Thus, given \mathcal{O} , the derived hypothesis class $\mathcal{H}_{\mathcal{O}}$ describes the abstention capacity of \mathcal{O} : In the classical setting $\mathcal{H}_{\mathcal{O}} = \{h_0\}$, where $\forall x \in X$, $h_0(x) = 0$, as no classifier in \mathcal{O} is able to abstain: For all $O \in \mathcal{O}$, $\text{Bnd}_O = \emptyset$.

In regard to the second derived hypothesis class, we observe that the order \leq_I defined in Section II-A defines a meet semi-lattice [17] on \mathcal{O} with minimal element $O_{\perp} = (\emptyset, \emptyset)$. Then, we denote with $\mathcal{O}^{\top} = \{O \in \mathcal{O} : \nexists O' \in \mathcal{O} \text{ s.t. } O \leq_I O'\}$, i.e. \mathcal{O}^{\top} is the anti-chain of maximally informative elements of \mathcal{O} .

We now prove a generalization of Theorem 1 to the TWD setting, through which we show that the TW learnability of a hypothesis class \mathcal{O} , using the TWRM algorithm, can be characterized in terms of the derived hypothesis classes $\mathcal{H}_{\mathcal{O}}$ and \mathcal{O}^{\top} . In order to do so, we consider the VC dimension of the two derived hypothesis classes $\mathcal{H}_{\mathcal{O}}$ and \mathcal{O}^{\top} as follows:

$$AVC(\mathcal{O}) = VC(\mathcal{H}_{\mathcal{O}}) \quad (8)$$

$$EVC(\mathcal{O}) = \sup\{|S| : S \subseteq X \wedge \forall C \subseteq S \exists O \in \mathcal{O} \quad (9)$$

$$\text{s.t. } C = (P_O \cap S) \wedge (\text{Bnd}_O \cap S) = \emptyset\}$$

Then, the following result holds:

Theorem 2. Let \mathcal{O} be s.t. $AVC(\mathcal{O}) = d_a$ and $EVC(\mathcal{O}) = d_e$. Then, for any distribution \mathcal{D} weakly realizable w.r.t \mathcal{O} , $\epsilon, \delta \in (0, 1)$, $\alpha \in (0, \lambda_a)$, if $TWRM_{\mathcal{O}}$ is given a dataset of size m larger than :

$$O \left(\max \left\{ \frac{1}{\epsilon} \left(d_e + \ln \frac{1}{\delta} \right), \left(\frac{\lambda_a}{\alpha} \right)^2 \left(d_a + \ln \frac{1}{\delta} \right) \right\} \right) \quad (10)$$

then, $TWRM_{\mathcal{O}}(S)$ (ϵ, α) -fails with probability lower than δ .

Proof. We want to guarantee that the following bound holds:

$$\begin{aligned} Pr_{fail} &= P(S : \exists O \in \mathcal{O} \wedge \\ &\quad |\mathcal{E}_D(O) - \mathcal{E}_S(O)| > \epsilon \vee \\ &\quad |\mathcal{A}_D(O) - \mathcal{A}_S(O)| > \alpha) < \delta \end{aligned} \quad (11)$$

Then, the results would follow by uniform convergence. By the union bound, it holds that:

$$\begin{aligned} Pr_{fail} &\leq Pr(S : \exists O \in \mathcal{O}, |\mathcal{E}_D(O) - \mathcal{E}_S(O)| > \epsilon) \\ &\quad + Pr(S : \exists O \in \mathcal{O}, |\mathcal{A}_D(O) - \mathcal{A}_S(O)| > \alpha), \end{aligned} \quad (12)$$

thus, it is sufficient to jointly upper bound the two summands by $\frac{\delta}{2}$. As regards the error rate (i.e \mathcal{E}) bound, we note that:

$$\begin{aligned} Pr(S : \exists O \in \mathcal{O}, |\mathcal{E}_D(O) - \mathcal{E}_S(O)| > \epsilon) \\ Pr(S : \exists O \in \mathcal{O}^{\top}, \mathcal{E}_D(O) > \epsilon) \end{aligned} \quad (13)$$

Since \mathcal{O}^{\top} is a binary hypothesis class, then, by Theorem 1, the above bound holds with probability greater than $1 - \delta$ as long as $|S| \geq \frac{1}{\epsilon} (d_e + \ln \frac{1}{\delta})$. Furthermore, by uniform convergence this holds, in particular, for $TWRM_{\mathcal{O}}(S)$.

For the abstention part, the same line of reasoning can be applied, however, as we only assume weak realizability, only the result in Theorem 1 that applies to agnostic learning can be used. Then, as long as $|S| \geq \left(\frac{\lambda_a}{\alpha}\right)^2 (d_a + \ln \frac{1}{\delta})$ it holds that $|\mathcal{A}_D(O) - \mathcal{A}_S(O)| < \alpha$ with probability greater than $1 - \delta$. This holds, in particular for $TWRM_{\mathcal{O}}(S)$, and thus the theorem follows by uniform convergence and Eq. (12). \square

As a simple corollary, in the strong realizable setting, it can be easily verified that:

Corollary 1. Let \mathcal{O} be s.t. $AVC(\mathcal{O}) = d_a$ and $EVC(\mathcal{O}) = d_e$. Then, for any distribution \mathcal{D} strongly realizable w.r.t \mathcal{O} , $\epsilon, \delta \in (0, 1)$, $\alpha \in (0, \lambda_a)$, if $TWRM_{\mathcal{O}}$ is given a dataset of size m larger than :

$$O \left(\max \left\{ \frac{1}{\epsilon} \left(d_e + \ln \frac{1}{\delta} \right), \frac{\lambda_a}{\alpha} \left(d_a + \ln \frac{1}{\delta} \right) \right\} \right) \quad (14)$$

then, $TWRM_{\mathcal{O}}(S)$ (ϵ, α) -fails with probability lower than δ .

Note that, if $|\mathcal{O}| < \infty$, then it can be easily shown that $AVC(\mathcal{O}) \leq \log_2(\mathcal{H}_{\mathcal{O}})$. Furthermore, it also holds that $EVC(\mathcal{O}) \leq \log_2(\mathcal{O}^{\top})$, as if O satisfies Eq. (8), then it obviously holds that $\text{Bnd}_O = \emptyset$ and hence $O \in \mathcal{O}^{\top}$.

A. Three-way Learning and Selective Prediction

Finally, we show that the proposed mathematical framework and the obtained results can be used to establish a connection between TWD and *selective prediction*. This result relies on the connection between version space theory and orthopairs [17], and allows us to derive a generalization bound, originally proven by El-Yaniv et al. [21], for selective prediction: This shows that the latter setting can be understood as a special case of TWD. Let \mathcal{H} be a hypothesis class of binary classifiers, we call the Three-way Closure of \mathcal{H} , denoted as $TW(\mathcal{H})$, the hypothesis space obtained as:

$$TW(\mathcal{H}) = \bigcup \{O_H : H \subseteq \mathcal{H}\} \quad (15)$$

where, for each $H \subseteq \mathcal{H}$, $O_H = (\{x : \forall h \in H.h(x) = 1\}, \{x : \forall h \in H.h(x) = 0\})$. Basically, we associate with each possible version space H in \mathcal{H} a corresponding orthopair O_H which abstains on every instance for which the hypotheses in H disagree [17]. Then we can prove the following result:

Corollary 2. *Let $|\mathcal{H}| < \infty$, let $\mathcal{O} = TW(\mathcal{H})$ the Three-way Closure of \mathcal{H} , and let $\lambda_a = 1$. Then, for any distribution \mathcal{D} strongly realizable w.r.t \mathcal{O} , and for any $\delta \in (0, 1)$, if $TWRM_{\mathcal{O}}$ is given a dataset of size m , then:*

- 1) *With probability 1 it holds that $\mathcal{E}_{\mathcal{D}}(TWRM_{\mathcal{O}}(S)) = 0$;*
- 2) *With probability greater than $1 - \delta$ it holds that:*

$$A_{\mathcal{D}}(TWRM_{\mathcal{O}}(S)) \leq O\left(\frac{1}{m} \ln\left(\frac{|\mathcal{H}_{\mathcal{O}}|}{\delta}\right)\right) \quad (16)$$

$$= O\left(\frac{1}{m} \left(|\mathcal{H}| + \ln\frac{1}{\delta}\right)\right) \quad (17)$$

Proof. The first equality easily follows from strong realizability and by noting that, by definition of $TW(\mathcal{H})$, $x \notin Bnd_{TWRM_{\mathcal{O}}(S)}$ iff $(x \in S_X \vee \exists v \in \{0, 1\}.\forall h \in \{h' \in \mathcal{H} : \mathcal{E}_S(h) = 0\}, h(x) = v)$. In regard to the second statement, the first inequality follows by standard algebraic manipulations. The equality, on the other hand, follows by noting that $|\mathcal{H}_{\mathcal{O}}| = 2^{|\mathcal{H}|}$ (as $TW(\mathcal{H})$ contains a TW classifier for each possible subset of hypotheses in \mathcal{H}). \square

IV. CONCLUSION

In this article, we aimed at providing an initial study on the generalization of CLT results to the TWD setting. To this purpose, we first proposed an extension of the standard PAC learning framework to the TWD setting, that we called Three-way Learning and showed that our results generalize the previously known results in the selective prediction literature. As our results represent only a first direction in the theoretical study of TWD as applied to Machine Learning, we believe that the following questions would be of particular interest:

- Our analysis in Theorem 2 relies on a generalization of the VC dimension to the TWD setting. Tighter bounds can usually be obtained by relying on concepts such as Rademacher complexities or covering numbers [18]. How can these be generalized to TWD?
- In Corollary 2 we proved that, in the realizable case, selective prediction can be understood as a special case of TWD learning. Does this analysis also applies to the agnostic (i.e. non-realizable) setting [15]?
- PAC-Bayes bounds [24] study generalization bounds that apply when a probability distribution is defined over the hypothesis space. How can the PAC-Bayes framework be generalized to TWD? Interestingly, a very similar open problem has recently been posed also in Belief Function Theory (BFT) [25]. Due to the connection with random sets, a belief function can be seen as a probability distribution over orthopairs [26]: Then, the generalization of the PAC-Bayes framework to TWD would also enable studying the relationships between TWD and BFT.

Abstract—A relationship between the classical multiplicative pairwise comparisons that are based on $a_{ij}a_{ji} = 1$, the additive model based on $b_j^i + b_i^j = 1$, and qualitative pairwise comparisons that uses the relations $\approx, \sqsubset, \subset, <$ and \prec , is discussed in detail. A special attention is paid to the concept of consistency and weights calculations. An on-line tool is also discussed.

Index Terms—pairwise comparisons, consistency, weights calculation, qualitative judgements

I. INTRODUCTION

THE *pairwise comparisons* method is based on the observation that it is much easier to rank the importance of *two* objects than it is to rank the importance of *several* objects. This very old idea goes back to Ramon Llull in the end of XIII century. Its modern version is due to 1785 influential paper by Marquis de Condorcet and was later developed by Fechner (1860) and Thurstone (1927) [9], [18]. The modern version is usually associated with Saaty’s AHP (Analytical Hierarchy Process) [17].

Classical pairwise comparisons can be called *multiplicative* [6] as a coefficient a_{ij} is interpreted as an entity E_i is a_{ij} times preferred than an entity E_j . Alternatively we may define *additive* pairwise comparisons where a coefficient b_j^i is interpreted as b_j^i measures the importance of E_i in comparison with E_j assuming that their total importance is 1.0 (or 100%) [3], [6].

When mostly subjective judgment is involved, providing immediately reasonable quantitative relationship between two entities is usually difficult if not almost impossible. We usually start with some qualitative (relational) judgment like ‘ E_i is only slightly better than E_j ’, etc., so we need some good qualitative (relational) model as well [5], [9], [8]. In many cases the use of *combined* pairwise comparisons, that involve simultaneous use of multiplicative, additive and qualitative versions is the best and recommended solution [6], [7], [16].

In this paper we will provide a detailed comparison of multiplicative and additive pairwise comparisons, including the concept of consistency and optimal weights assignment. Since in reality, practically every pairwise comparisons process starts with some qualitative estimations, the qualitative pairwise comparisons [5], [9], [8] and their relationship to multiplicative and additive models is also discussed in detail. We will also provide an easy to use on-line tool, called PiXR,

that makes use of the method presented in the paper, rather easy.

II. MULTIPLICATIVE AND ADDITIVE PAIRWISE COMPARISONS

Let E_1, \dots, E_n be a finite set of objects (entities) to be judged and/or analyzed. The quantitative relationship between entities E_i and E_j is represented by a positive number a_{ij} . We assume $a_{ij} > 0$ and $a_{ij} = \frac{1}{a_{ji}}$, for $i, j = 1, \dots, n$ (which implies $a_{ii} = 1$ for all i). If $a_{ij} > 1$ then E_i is more important (preferred, better, etc.) than E_j and a_{ij} is a measure of this relationship (the bigger a_{ij} , the bigger the difference), if $a_{ij} = 1$ then E_i and E_j are indifferent. We call this model *multiplicative* since a_{ij} is interpreted as E_j is a_{ij} times preferred (more important, etc.) than E_j .

The matrix of such (multiplicative) relative comparison coefficients, $A = [a_{ij}]_{n \times n}$, is called a (multiplicative) *pairwise comparison matrix* [17].

A pairwise comparison matrix $A = [a_{ij}]_{n \times n}$ is *consistent* [17] if and only if

$$a_{ij}a_{jk} = a_{ik}, \quad (1)$$

for $i, j, k = 1, \dots, n$. Saaty’s Theorem [17] states that a pairwise comparison matrix A is consistent if and only if there exist positive numbers w_1, \dots, w_n such that $a_{ij} = w_i/w_j$, $i, j = 1, \dots, n$. The values w_i are unique up to a multiplicative constant. They are often called *weights* and interpreted as a measure of importance. Weights may be scaled to $w_1 + \dots + w_n = 1$ (or 100%) and they obviously create ‘natural’ ranking ($E_i < E_j \iff w_i < w_j$ and $E_i \approx E_j \iff w_i = w_j$). In practice, the values a_{ij} are very seldom consistent so some measurements of inconsistency are needed. Saaty [17] proposed an inconsistency index based on the value of the largest eigenvalue of A . The basic problem is that *it does not give any clue where most inconsistent values of A are located* [2], [9], [10]. On the other hand, *distance-based inconsistency* [10], for a given $A = [a_{ij}]_{n \times n}$, defined as:

$$cm_A = \max_{(i,j,k)} \left(\min \left(\left| 1 - \frac{a_{ij}}{a_{ik}a_{kj}} \right|, \left| 1 - \frac{a_{ik}a_{kj}}{a_{ij}} \right| \right) \right) \quad (2)$$

localizes the most inconsistent triad, so we can reduce inconsistency by some minor changes a_{ij}, a_{ik}, a_{kj} . Recently a fast algorithm for inconsistency reduction has been proposed [11].

To find suitable values of weights from an inconsistent, but with acceptable level of inconsistency, matrix A , one can either calculate the principal eigenvector of the matrix A [17], or use the geometric means of columns (or equivalently, rows) of the matrix A [1] (i.e. for $i = 1, \dots, n$, $w_i = \sqrt[n]{\prod_{j=1}^n a_{ij}}$). For small values of the inconsistency index, both methods produce very similar results [2].

When applying pairwise comparisons to various problems we have noticed that, especially when the entities E_i and E_j were not much different, experts felt often much more comfortable and more confident when they were asked to divide 100 quality points between entities E_i and E_j than to provide multiplicative relationship [6], [7], [16], i.e. ratio a_{ij} . Dividing of 100 between E_i and E_j means that we are replacing the multiplicative relationship $a_{ij}a_{ji} = 1$, with the additive relationship $b_j^i + b_i^j = 1$.

In this approach, we model the mutual relationship between E_i and E_j by two numbers b_j^i and b_i^j , where: b_j^i measures the importance of E_i in comparison with E_j assuming that their total importance is 1.0 (or 100%), and similarly for b_i^j . Formally we assume that, for all $i, j = 1, \dots, n$,

$$b_j^i \geq 0, b_i^j \geq 0 \text{ and } b_j^i + b_i^j = 1 \quad (3)$$

Clearly $b_i^i = 0.5$ (or 50%) for all $i = 1, \dots, n$.

The matrix of such additive relative comparison coefficients, $B = [b_j^i]_{n \times n}$, is called an *additive pairwise comparison matrix*.

When b_j^i is interpreted as the probability that judges would prefer the entity E_i over E_j , the equation (3) is exactly the same as in Bradley-Terry model [3].

To transform additive model into standard multiplicative one, we need a mapping $\phi : \langle 0, 1 \rangle \rightarrow \langle 0, \infty \rangle$ such that $a+b = 1$ implies $\phi(a) \cdot \phi(b) = 1$. When a and b are interpreted as *two parts of one whole* (which equals 1.0, or 100%), then $\frac{a}{b}$ represents *ratio* between a and b , and $\frac{a}{1-a}$ represents ratio between a and its complement.

Hence, the most natural mapping seems to be $\phi(a) = \frac{a}{1-a}$. This mapping has many different applications [13], and in our case leads to the transformation of 'additive' model into 'multiplicative' model [6], [9], [8].

For all $i, j = 1, \dots, n$:

$$a_{ij} = \frac{b_j^i}{1 - b_j^i} = \frac{b_j^i}{b_i^j} \quad (4)$$

From equation (4) we immediately get that for all $i, j = 1, \dots, n$, we have:

$$b_j^i = \frac{a_{ij}}{a_{ij} + 1} \text{ and } a_{ij}a_{ji} = 1 \iff b_j^i + b_i^j = 1 \quad (5)$$

We may now analyze and reduce inconsistency by using the formulas for multiplicative case.

III. QUALITATIVE AND COMBINED PAIRWISE COMPARISONS

Instead of numerical values a_{ij} or b_j^i , the binary relations $\approx, \sqsubset, \subset, <, \prec$ and $\sqsupset, \supset, >, \succ$ over the set of entities Ent =

$\{E_1, \dots, E_n\}$ are used [5], [8]. The relations are interpreted as

- $a \approx b$: a and b are *indifferent*,
- $a \sqsubset b$: *slightly in favor* of b ,
- $a \subset b$: *in favour* of b ,
- $a < b$: b is *strongly better*,
- b is *extremely better*.

The tuple $(Ent, \approx, \sqsubset, \subset, <, \prec)$ is called *qualitative pairwise comparisons systems*. The number of relations has been limited to five because of the known restrictions of human mind when it comes to subjective judgments [4], [15]. The above relations are disjoint and cover all the cases and the relation \approx is symmetric and includes identity.

In this case the consistency is defined by a set of 45 axioms [8] that consider all relational compositions of the above relations. The idea behind all these axioms is very simple and natural:

composition of relations should be relatively continuous and must not change preferences in a drastic way.

Consider the following composition of preferences: $a \approx b \wedge b \sqsubset c$. What relationship between a and c is consistent? Intuitively, $a \approx c$ and $a \sqsubset c$ are for sure consistent, $a \subset c$ is debatable, while $a < c$ and $a \prec c$ are definitively inconsistent. This reasoning leads to the Axiom 2.1 [9]:

2.1 $(a \approx b \wedge b \sqsubset c) \vee (a \sqsubset b \wedge b \approx c) \implies (a \approx c \vee a \sqsubset c \vee a \subset c)$. There are two algorithms that remove inconsistency for qualitative pairwise comparisons [8].

Define the relations $\hat{\succ} = \prec, \hat{\supset} = \prec \cup <, \hat{\subset} = \prec \cup < \cup \subset$ and $\hat{\sqsupset} = \prec \cup < \cup \subset \cup \sqsubset$. If the qualitative pairwise comparison system is consistent [9], [8], then the relations $\hat{\succ}, \hat{\supset}, \hat{\subset}$ and $\hat{\sqsupset}$ are (sharp) partial orders.

In reality, almost always we start with some qualitative relationship, then we try to assign some reasonable number (a_{ij} or b_j^i) to it, and after this we provide some consistency analysis [6], [7], [16]. In some cases we go back to qualitative relationship and eventually analyze the case again from the beginning [6], [7], [16]. Finding proper numbers corresponding to qualitative relations is usually tricky as a trusted methodology still does not exist. Usually numbers 1, 2, ..., 5 [10] or 1, 2, ..., 10 [17] are proposed as initial attempts, without much justification except limits of human mind [4], [15]. More systematic approach involves the concept of qualitative consistency [9], [8]. It was proven that if the b_j^i 's or a_{ij} 's are assigned to relations R_{ij} as shown in Table I, then the qualitative pairwise comparisons are consistent [9]. In fact, having a result in opposite direction would be more desirable but this is still an open problem. Nevertheless using Table I proved useful as it usually results in decent inconsistency [6], [7], [16].

The columns 1 and 3 contain intervals, to start the process one needs to pick one point from appropriate interval, and in general a choice is not obvious. To help users without experience default values are proposed in columns 2, 4 and 5. The column 2 contains just mean values of each interval, the column 4 contains the values of a_{ij} 's derived from appropriate values of column 2 interpreted as b_j^i 's, and the column 5

TABLE I

RELATIONSHIP BETWEEN *arithmetic*, *geometric* AND *relational* SCALES AS PROPOSED BY JANICKI AND ZHAI [9]. WE HAVE HERE $a_{ij} = \frac{b_j^i}{1-b_j^i}$.

arithmetic scale		geometric scale			rel. scale	Definition of importance (E_i vs E_j)
range of b_j^i		range of a_{ij}			relation	
range	default value	range	default value 1	default value 2	R_{ij}	
0.44-0.55	0.5	0.79-1.27	1.0	1.0	\approx	<i>indifferent</i>
0.56-0.65	0.6	1.28-1.94	1.5	1.6	\sqsubset	<i>slightly in favour</i>
0.66-0.75	0.7	1.95-3.17	2.3	2.6	\sqcup	<i>in favour</i>
0.76-0.85	0.8	3.18-6.14	4.0	4.7	\succ	<i>strongly better</i>
0.86-1.00	0.9	6.15-	9.0	7.0	\succ	<i>extremely better</i>

contains mean values of the intervals from column 3. When transforming initial relations R_{ij} , what value should we attach to appropriate a_{ij} , the one from column 4 (default 1) or from column 5 (default 2)? This problem will be discussed in detail the next section, however the difference is not a big one. When a choice is left to the users, usually default value 2 is used [6], [16].

IV. CONSISTENCY FOR ADDITIVE PAIRWISE COMPARISONS

In this section we will analyze an intuitively natural concept of consistency for additive pairwise comparisons.

Let $B = [b_j^i]_{n \times n}$ be an additive pairwise comparison matrix. Consider b_k^i , b_j^k and b_j^i . We have $b_k^i + b_i^k = b_j^k + b_k^j = b_j^i + b_i^j = 1$. How can we decide if b_k^i , b_j^k and b_j^i are consistent or not? The values of b_k^i and b_j^k alone do not seem to have any reasonable relations to the value of b_j^i . The value of b_k^i just indicates the part of one that is assigned to the entity E_i when E_i is compared with E_k , so it can hardly be compared to or associated with b_j^i . However we may try to use ratios $\frac{b_k^i}{b_i^k}$, $\frac{b_j^k}{b_k^j}$ and $\frac{b_j^i}{b_i^j}$ to define a relationship between the entities E_i , E_k and E_j that could lead to a sound concept of consistency. One might say that if the data represented by the matrix $B = [b_j^i]_{n \times n}$ are consistent then if the ratio of importance E_i to E_j is α_{ij} , then for each triple i, j, k we should have $\alpha_{ik}\alpha_{kj} = \alpha_{ij}$, and this could be used as basis for a formal definition of consistency.

We will say that an additive matrix $B = [b_j^i]_{n \times n}$ is *consistent*, if and only if, for all $i, j, k = 1, \dots, n$, we have

$$\frac{b_k^i}{b_i^k} \cdot \frac{b_j^k}{b_k^j} = \frac{b_j^i}{b_i^j} \tag{6}$$

For any given multiplicative matrix $A = [a_{ij}]_{n \times n}$, let $B(A) = [b_j^i]_{n \times n}$ be derived from A by $b_j^i = \frac{a_{ij}}{a_{ij}+1}$, and for any given additive matrix $B = [b_j^i]_{n \times n}$, let $A(B) = [a_{ij}]_{n \times n}$ be derived from B by $a_{ij} = \frac{b_j^i}{1-b_j^i}$. Now we have $\frac{b_k^i}{b_i^k} \cdot \frac{b_j^k}{b_k^j} = \frac{b_j^i}{1-b_j^i} \cdot \frac{b_j^k}{1-b_j^k} = a_{ik}a_{kj} = \frac{b_j^i}{1-b_j^i} = a_{ij}$.

Hence an additive matrix $B = [b_j^i]_{n \times n}$ is consistent if and only if the multiplicative matrix $A(B) = [a_{ij}]_{n \times n}$ is consistent.

This provides an additional justification for the mappings ϕ, ϕ^{-1} that transform A into B and B into A respectively. It

also supports the combined pairwise comparisons process [6], [7], [16] that uses consistency index of $A(B)$ as a consistency index of B without much explanation.

For both a multiplicative matrix $A = [a_{ij}]_{n \times n}$ and an additive matrix $B = [b_j^i]_{n \times n}$ the weights w_1, \dots, w_n are measures of importance of entities E_1, \dots, E_n . Consider the entity E_i . All information about E_i is stored in the sequence a_{i1}, \dots, a_{in} - in case of matrix A , or b_1^i, \dots, b_n^i - in case of matrix B . For the matrix A , the weight corresponding to E_i is defined as an eigenvalue λ_i of A [17], or a geometric mean $g_i = \sqrt[n]{a_{i1} \cdots a_{in}}$ [1]. When A is consistent $a_{ij} = \frac{\lambda_i}{\lambda_j} = \frac{g_i}{g_j}$, which is one of the justifications of both methods [1], [17]. Now consider the sequence b_1^i, \dots, b_n^i . While the value of a_{ij} can be interpreted as ‘absolute’, due to $b_j^i + b_i^j = 1$, the value of b_j^i is not ‘absolute’, it is ‘relative to sum equal one’. The value of $\frac{b_j^i}{b_i^j}$ is ‘absolute’ so it can be used for weight calculation, but $\frac{b_j^i}{b_i^j} = a_{ij}$.

This means the weights generated by B , similarly as for consistency, are the same as these generated but $A(B)$.

This again provides some justification to the combined pairwise comparisons procedure [6], [7], [16].

Additive and multiplicative pairwise comparisons can be seen as orthogonal approaches to the same problem. This argument is briefly illustrated in Table II. When the difference between importance of E_i and E_j is small, $E_i \approx E_j$ looks as well justified, but still one of them seems to be slightly better, using additive pairwise comparisons, i.e. b_j^i , is superior to multiplicative approach. Dividing one hundred into, say, 53 to E_i and 47 to E_j is trustworthy and usually can have some justifications based on merits. On the other hand a statement like ‘ E_i is 1.13 times better than E_j ’, which is equivalent to ‘53 to 47’ distribution of 100 points, can seldom be trusted or have convincing justification (unless as a derivation from b_j^i). Hence, when the initial qualitative judgment is \approx or \sqsubset , but there is a reason to believe that we might be a little bit more precise, then the use of b_j^i to represent qualitative relationship is superior to the use of a_{ij} . The situation seems to be opposite for the relations $>$ and *succ*. It is much easier to conclude that E_i is about 5 times more important (better, etc.) than E_j than to decide that the points distributions should be ‘83 to 17’ (unless as a derivation from a_{ij}). We claim that when the initial qualitative judgment is $>$ or \succ , but there is a reason

TABLE II
SOME RELATIONSHIPS BETWEEN a_{ij} , b_j^i AND R_{ij} ($a_{ij} = \frac{b_j^i}{1-b_j^i}$ AND $b_j^i = \frac{a_{ij}}{a_{ij}+1}$).

b_j^i	a_{ij}	R_{ij}	b_j^i	a_{ij}	R_{ij}	a_{ij}	b_j^i	R_{ij}	a_{ij}	b_j^i	R_{ij}
0.5	1.0	≈	0.51	0.104	≈	2.0	0.67	⊃	3.0	0.75	⊃
0.52	1.08	≈	0.53	1.13	≈	4.0	0.8	>	5.0	0.83	>
0.54	1.17	≈	0.55	1.22	≈	6.0	0.86	>	7.0	0.88	γ
0.56	1.27	⊃	0.57	1.33	⊃	8.0	0.89	γ	9.0	0.9	γ
0.58	1.38	⊃	0.59	1.44	⊃	10.00	0.91	γ			
0.60	1.5	⊃	0.63	1.7	⊃						
0.66	1.94	⊃	0.7	2.33	⊃						

to believe that we might be a little bit more precise, then the use of a_{ij} to represent qualitative relationship is superior to the use of b_j^i . The relationship \supset is a gray area, no approach seems to be superior to the other.

When the default values for multiplicative case are used, we recommend the default values 1 for the \approx and \sqsupset relationship and the default values 2 for $>$ and \succ (gray cells in Table I). The Table III illustrate the proposed combined approach that involves multiplicative, additive and qualitative pairwise comparisons.

V. DESCRIPTION OF PAIRWISE MATRIX INCONSISTENCY REDUCTION (PiXR)

To help with determining weights for attributes and parameters, pairwise inconsistency reduction is needed. The calculations and methods presented in this paper although simple and computable, may consume a lot of time and effort. Moreover, the number of calculations grows quadratically based on the number of parameters.

PiXR is an online tool that was developed to help with this computation and weight determination [14]. The tool consists of 4 main sections that guide the user through creating parameters, measurements, conversion between multiplicative & additive matrices, and inconsistency reduction. The tool also supports importing and exporting data as CSV files for ease of use.

PiXR operates on the following abbreviated process of inconsistency reduction and weight calculation [6]:

- 1) Pairwise matrix is provided to PiXR by Subject Matter Expert (SME)
 - a) Matrix may be provided in as quantitative (additive or multiplicative) or qualitative pairwise matrix
 - b) Consistency measure of the matrix is computed via equation 7
 - c) Pairwise matrix is reduced using formulas 13 & 14 from [11]
 - d) Consistency measure is then calculated again via equation 7, and SMEs can revise values and repeat the process
 - e) Weights are calculated using the geometric mean of the columns of the reduced matrix

$$w_i = \sqrt[n]{\prod_{j=1}^n a_{ij}} \quad (7)$$

PiXR has 4 main sections:

- 1) *Parameters* – used for configuring names and order of parameters when populating matrices in later sections
- 2) *Parameter relations* (Qualitative) – used to configure relations between parameters using qualitative relations outlined in section III and Table I. Default values from Table I will be used to feed the next section. The user may also convert the qualitative matrix to multiplicative or additive.
- 3) *Quantitative Matrix* – an editable version of the matrix shown to the user and changes to it will be reflected in the computed consistency measure *cm* index. A reduction threshold in the range of 0.00-1.00 (inclusive), may be specified when reducing the matrix.
- 4) *Reduced Matrix and Weights* – displays the reduced matrix and the percentages/importance of the parameters. Reduced matrix and weights may be exported this section as CSVs.

PiXR comes with 3 sample applications/matrices from [6] which may be used to demonstrate the capabilities of the tool. The import/export function may be used to revise the matrices and repeat the matrix reduction process. SMEs may be involved in this iterative process to generate new weights and rankings.

PiXR is written in Typescript and Javascript XML (JSX). Using this tech stack enables the tool to run in the browser, thus saving users the time and effort needed to download and install binaries. One may argue that Typescript and by extension JavaScript to be slow for this kind of computation style since the algorithm is at worst $O(n^3)$. However, in most cases the number n is relatively small. The approach is validated to converge quickly when using real world data [11] and by the theoretical results of [12].

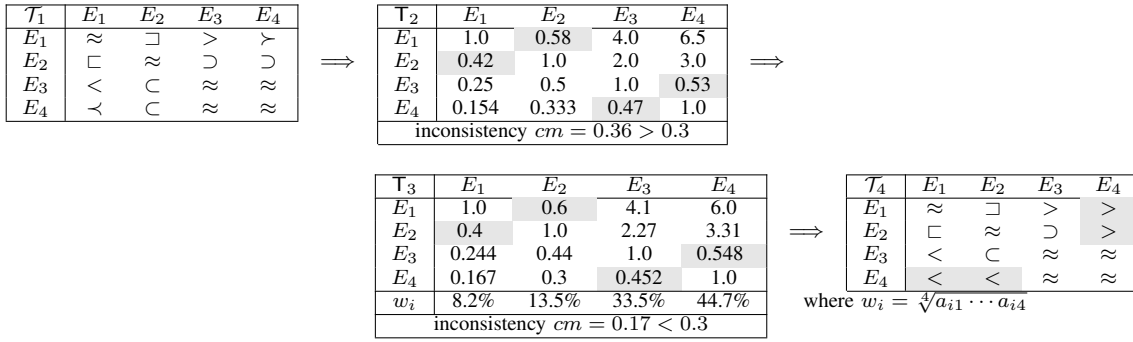

PiXR aims to be *lazy* in most of its evaluations. When computing the triads to measure matrix consistency or computing the localized reduction value, patterns such as generators and streams are used where applicable. This lazy nature allows the user to experiment with the tool and provide as many features as they wish. The computation of the localized inconsistency reduction is also done in a lazy fashion as to not block the main thread and freeze the web-page.

Once the matrix is marked ready for reduction, it goes through the following steps:

- 1) Compute the current consistency measure

TABLE III

A SIMPLE EXAMPLE OF MODIFIED COMBINED PAIRWISE COMPARISONS PROCESS. IN T_2 AND T_3 , GRAY CELLS CONTAIN b_{ij}^j 'S AND WHITE CELLS CONTAIN a_{ij} 'S. IN T_4 , GRAY CELLS INDICATE DIFFERENCES FROM T_1 .

2) While the consistency measure is larger than threshold ϵ , reduce the highest inconsistent triad i, j, k . The threshold ϵ has a default value of 0.3 because it is an acceptable consistency measure with some mathematical justification [10], however it is usually domain dependent.

The above algorithm in pseudo-code is Algorithm 1, where `consistencyMeasure()` is computed using equation 7. Algorithm 2 is the algorithm for reducing the most inconsistent triad. It is based on the results of [11].

Algorithm 1 Inconsistency Index cm

```

cm ← consistencyMeasure(matrix)
while cm ≥ ε do
    reduceTriad(matrix)
    cm ← consistencyMeasure(matrix)
end while
    
```

Algorithm 2 Most Inconsistent Triad

```

ij ← matrix[i][j]
ik ← matrix[i][k]
kj ← matrix[k][j]
a ← ik * kj [Following equation 13 & 14 from [11]]
factor ← 1
if a > ij then
    factor ← -1
end if
b ← factor * (ij + 2 * a)
c ← a - ij
Δc ← min(computeRoots(a, b, c)) [least positive root]
matrix[i][k] ← ik + (factor * ik * Δc)
matrix[k][j] ← kj + (factor * kj * Δc)
matrix[i][j] ← ij - (factor * ij * Δc)
    
```

VI. FINAL COMMENT

A relationships between multiplicative, additive and qualitative pairwise comparisons have been discussed in detail. It was shown that from purely mathematical point of view multiplicative and additive pairwise comparisons are equivalent, but for applications, dependently on the range of data and qualitative relations, one approach can be superior to another. Altogether, a combined approach is recommended. The on-line tool, PiXR, is also provided. The fundamental problem with all methods like the one presented here, is trust. We believe our approach

is more trustworthy than the standard AHP, mainly because we better address the problem of assigning numerical values to subjective qualitative judgements.

Abstract—To offer innovative malware evolution techniques, it is appealing to integrate approaches that handle imperfect data and knowledge. In fact, malware writers tend to target some precise features within the app’s code to camouflage the malicious content. Those features may sometimes present conflictual information about the true nature of the content of the app (malicious/benign). In this paper, we show how the Variable Precision Rough Set (VPRS) model can be combined with optimization techniques, in particular Bilevel-Optimization-Problems (BLOPs), in order to establish a detection model capable of following the crazy race of malware evolution initiated among malware-developers. We propose a new malware detection technique, based on such hybridization, named Variable Precision Rough set Malware Detection (ProRSDet), that offers robust detection rules capable of revealing the new nature of a given app. ProRSDet attains encouraging results when tested against various state-of-the-art malware detection systems using common evaluation metrics.

I. INTRODUCTION

THE amount of malware is increasing exponentially thanks to the use of advanced malware-development tools [1]. Detection models struggle to keep up with these tricky intrusion malicious apps that do not refrain from using the most effective techniques, like the obfuscated malware, to invade the targeted systems. In this course of malware development, one can encounter some data inconsistency specially when dealing with conflictual features that may appear in both benign and malicious apps. In this context, few research has focused on dealing with the inconsistency encountered when extracting relevant features to either produce or detect malware. Authors in [2] proposed to adjust the malware detectors in order to deal with the change that occurs in the data labeling. More precisely, authors tackled the problem that appears when the labels used in the training set are different from the labels used in the testing set and proposed to empirically quantify the epistemic uncertainty of four combined deep-learning based Android malware detectors. Santos et al., in [3], proposed a semi-supervised learning based method to deal with the existing unlabelled apps (unknown nature beforehand) in the training process of a detection process. Also, Nauman et al. [4] looked into a three-way decision-making process

based on acceptance, rejection, or deferment. When there is not enough knowledge, the extra deferment choice option gives the opportunity to postpone a decision. It also seeks to reduce incorrect decisions at the model level by finding a trade-off between decision-making attributes like accuracy, generality, and uncertainty. The authors focused on three-way decisions using two probabilistic rough set models: game-theoretic rough sets (GTRS) and information-theoretic rough sets (ITRS). RoughDroid [5] is a floppy analysis technique proposed by the authors that can detect Android malicious programs straight on the smartphone. It is based on seven feature sets extracted from the XML manifest file of an Android application and three feature sets extracted from the Dex file. Those feature sets pass through the Rough Set algorithm to classify the app either as benign or malicious. In this paper, we propose to specially focus on malware motif production and handling the “false” produced ones that may lead to data inconsistency. We genuinely propose to handle this challenging task and address it by evolving effective malicious motifs, a succession of frequent Application Programming Interface (API) call sequences, and exploit them afterwards in a bilevel-based method in order to produce detection rules capable of detecting them. In this work, we aim to attend the following contributions:

- Generate fraudulent motifs and then exploit them to produce robust detection rules by adopting a bilevel architecture where two Evolutionary Algorithms (EAs), an outer one (Genetic Programming algorithm (GP)) and an inner one (Genetic Algorithm (GA)), are in a mutual competition.
- Inspect the generated fraudulent motifs, which are generated by the inner algorithm within the second layer using the GA, using the Variable Precision Rough Set (VPRS) model before sending them to the outer algorithm within the first layer, i.e., the GP.
- Demonstrate the benefits of the selection made by VPRS reinforced by the bi-level competition between both algorithms since for every detection rule, there exists a whole search space of possible generated malicious motifs that should be effectively sampled to come up with fit and

This work is supported by ANR PIA funding: ANR-20-IDEE-0002.

challenging generated motifs that positively affect the detection quality of the corresponding first layer rule.

- Evaluate the outperformance of our ProRSDet approach compared to several state-of-the-art detection methods in terms of accuracy maximization and false alarms minimization.

The remainder of this paper is structured as follows: Section II emphasizes past work that is most similar to our approach. The fundamentals of BLOP and VPRS used in this work are presented in Section III. Our suggested detection method is described in Section IV. The experimental setup and performance analysis results are presented in Section V. Finally, the conclusion and a description of some future directions are presented in Section VI.

II. RELATED WORK

Different malware detection techniques [6], [7], [8] have been proposed in literature focusing, particularly, on generating new malware. These can be categorized into two heads. A first category is based on using machine learning based approaches and second category based on the use of evolutionary algorithms.

Among the works proposed in the first head, we mention the work of [9] where an Android malware detection system (DroidEvolver) was proposed that can automatically update itself during malware detection using online learning techniques with evolving feature set and pseudo labels. There were some methods which were based on generating adversarial samples. Among these, we mention, the work proposed in [10], where the feasibility of generating adversarial samples specifically through the injection of system API calls was investigated. In [11], a generative adversarial network based algorithm (MalGAN) was proposed to generate adversarial malware examples able to bypass black-box machine learning based detection models. The paper of Moti et al. [12] presented a deep generative adversarial network to generate the signature of unseen malware samples; the generated signature is potentially similar to the malware samples that may be released in the future.

Other works proposed automated signature generation systems, such as the work proposed in [13], where a system for automatic generation of intrusion signatures from honey net packet traces was developed. The work of [14], proposed an automated approach called “content sifting” that generates precise signatures that can then be used to filter or moderate the spread of a worm. In [15], a string signature generation system (Hancock) was designed to create a minimal set of N-byte sequences from a set of malware samples. Another work, the work of [16], used a 5-gram Markov chain model of good software to estimate the probability that a given byte sequence would show up in good software. In the paper of Li et al. [17], a network-based automated signature generation system (Hamsa) for polymorphic worms was proposed. The proposed model allowed to analyze the invariant content of polymorphic worms in order to make analytical attack-resilience granted for the signature generation algorithm. In

[18], Newsome et al. proposed a signature generation system, Polygraph, that produces signatures that match polymorphic worms. Polygraph generates signatures that consist of multiple disjoint content sub-strings and which typically correspond to protocol framing, return addresses, and poorly obfuscated code.

Within the second head, several works [19], [20], [21], [22], [23], focused on applying evolutionary algorithms to generate malware samples. Among the most recent and efficient ones, we mention the work of [24], where an Android Malware Detection System (AMD) was proposed that produces patterns using a GA in order to mimic real malware patterns. This is to keep the dataset used in the conception of the detection system as varied as possible, which allows AMD to be resistant to obfuscated malware. Also, the work of [23], opted for a system using co-evolutionary algorithms where a first population generates detection rules, and a second population generates artificial malware. In this work, both populations are executed in parallel without any hierarchy. In the works of [25], [26], authors adopted a co-evolutionary algorithm as a search engine to ensure better detection rules.

Despite the good reached results of the above mentioned state-of-the-art methods, they still suffer from some limitations. First, they refer to a limited number of malware samples which makes the produced base of malicious malware not varied enough which cannot be of much help for a detection system when facing real attacks. Second, there is no check of the structure of the generated malicious patterns as to be sure enough that they fit among the real samples. And third, the malware generation and detection tasks are achieved separately without interaction which leads to a lack of a “harmony” and hence creates an incompatibility between the tasks.

In in paper, we will introduce our newly developed ProRSDet malware detection technique that overcomes the state-of-the-art shortcomings via the hybridization of both evolutionary algorithms and the Variable Precision Rough Set model.

III. BLOP AND VPRS BASIC CONCEPTS

In this section, we introduce the main concepts and fundamentals of both BiLevel OPTimization and the Variable Precision Rough Set model as two tools, used in a hybrid fashion, to ensure the development of our proposed ProRSDet.

A. BiLevel Optimization

BLOP is a distinctive optimization process where one problem is embedded within another. The inner problem, which is also referred to as the lower-level task, represents a constraint of the outer problem, which is also referred to as the upper-level task, where only an optimal lower-level solution can be a possible solution to the upper-level one. Each level has its own fitness function to optimize where the considered solutions of each level affect the decision-making space of the other one. The technical formalization of a BLOP problem can be found in [27] and it can be presented as follows:

A BLOP contains two classes of variables: (1) the upper-level variables $x \in X \subset R^n$, and (2) the lower-level variables

Fig. 1. Representation of a bilevel optimization problem (Inspired by [28])

$y \in Y \subset R^m$. For the follower problem, the optimization task is performed with respect to the variables y while the variables x act as fixed parameters. Thus, each x corresponds to a different follower problem, whose optimal solution is a function on Y and needs to be determined. All variables (x, y) are considered in the leader problem for given values of $y (y^*)$. In what follows, we give the formal definition of BLOP.

Assuming $L : R^n \times R^m \rightarrow R$ to be the leader problem and $f : R^n \times R^m \rightarrow R$ to be the follower one, a BLOP could be defined as follows:

$$\min_{x \in X, y \in X_L} L(x, y) \text{ subject to } \begin{cases} G_k(x, y) \leq 0, k = 1, \dots, K. \\ y \in \operatorname{argmin}\{f(x, y)\} \\ g_j(x, y) \leq 0, j = 1, \dots, J \end{cases} \quad (1)$$

In the given formulation, L represents the first layer objective function, f represents the second layer objective function, x represents the first layer decision vector and y represents the second layer decision vector. G_k and g_j represent the inequality constraint functions at both layers, respectively. The representation of a bilevel optimization problem is illustrated in Figure 1.

B. Variable Precision Rough Set

VPRS [29], an extension of RST, is a mathematical tool that deals with inconsistent information and came mainly to overcome the maybe found strictness within the rough set notions which may be too restricted in the sense that they ignore the degree of an overlap between a set and a concept. Let us consider a universe of objects \mathbf{U} referred to as elementary events and let $s(\mathbf{U})$ be the ∂ -algebra of measurable subsets of \mathbf{U} referred to as random events. It is presumed that new objects e belonging to the universe are generated by a random process (on \mathbf{U}). For each new object e , the event $X \in s(\mathbf{U})$ occurred if the object $e \in X$. In addition, it is presumed the existence of the prior probability function P assigning probabilities $P(X)$ to sets X belonging to $s(\mathbf{U})$. $P(X) > 0$ means that all members of the family of sets $s(\mathbf{U})$ are likely to occur, and, $P(X) < 1$ means that their

occurrence is not certain. These assumptions are justified by the fact that there is no need to construct a predictive model for events about which it is known that they are unlikely to occur or that they do occur with certainty [29]. In the context of defining the structure of rough approximation space, R denotes an equivalence relation on \mathbf{U} with the finite number of equivalence classes (elementary sets) E_1, E_2, \dots, E_n such that $P(E_i) > 0$ for all $1 \leq i \leq n$. The assumption of finite number of equivalence classes does not mean that the universe \mathbf{U} is finite. Each elementary set E can be assigned a measure of overlap with the set X by the conditional probability function defined as $P(X | E) = P(X \cap E) / P(E)$. The values of the conditional probability function are normally estimated from sample data by taking the ratio $P(X | E) = \operatorname{card}(X \cap E) / \operatorname{card}(E)$. The VPRS generalization of the original rough set model is based on the values of the probability function P and two lower and upper limit certainty threshold parameters l and u such that $0 \leq l < P(X) < u \leq 1$. The requirement $l < P(X)$ is an extra constraint on the values of the parameters which was proposed in [29]. The VPRS model is said to be symmetric if $l = 1 - u$. In this study, the symbol β such that $0 < P(X) < \beta \leq 1$ is used instead of the symbol u to denote the model upper threshold parameter. Also, the symbol α will substitute the previously defined l parameter.

IV. PRORSDET: THE VARIABLE PRECISION ROUGH SET MALWARE DETECTION TECHNIQUE

Figure 2 depicts ProRSDet's overall running process, which is divided into two principal layers (levels): (1) *First layer* is built on a GP with the goal of generating a set of effective detection rules (*FDRB*) and (2) *Second layer* relies on a GA to generate harmful (malicious) motifs (*SHM*) (first step) and on a VPRS based component that exclusively preserves the most dependable set of harmful motifs with no structural flaws, referred to as "Relevant" motifs (*FMM*) (second step).

Each of these two layers runs through a series of iterations in order to find the optimal solutions in both levels, which are interdependent. As presented in Figure 2, the evaluation of every upper detection rule solution (among *DRB*) requires running a search algorithm to find the best undetectable harmful motifs (*FMM*) by this rule. The final set of detection rules produced by our ProRSDet (*FDRB*) is a set of detection rules that will perform the malware detection task.

1) *First layer*: The first layer's first step, as shown in Figure 2 and Algorithm 1, is to generate a set of detection rules (Algorithm 1, line 1), which will go through an evaluation procedure (Algorithm 1, lines 2-3). The coverage of the base of samples (input) as well as the coverage of the fraudulent motifs created by the second layer are used to make this evaluation. These two measures are used to be maximized by the population of detection rules solutions (Algorithm 1, lines 4-6). This module produces a collection of final detection rules (*FDRB*) that will be used by the detection job, which is in charge of classifying new apps as malicious or benign. The GP evolutionary operators require a specific formalization to cope

Fig. 2. Illustration of the ProRSDet functioning process.

with the generated solutions (i.e., the detection rules) by the first layer that relies on a GP process. These are the following:

- *Solution representation*: The solution is expressed as a series of terminals that relate to various motifs (API call sequences) and functions (Intersection (*AND*) and Union (*OR*)), respectively.
- *Solution variation*: By selecting one of the functions or terminals at random, the GP *mutation* operator is applied. If a terminal is selected then it is replaced by another terminal; if it is a function then it is replaced by a new function. As for the GP *crossover operator*, two parent individuals are selected, and a sub-node is picked on each selected parent. The *crossover* swaps the nodes and their related sub-nodes from one parent to the other.
- *Solution evaluation*: An individual's encoding is quantified using a mathematical metric called the "fitness function", which measures the quality of a proposed detection rule and fraudulent motifs. For the GP adaptation, we used the fitness function f_{outer} defined in Equation 2 to evaluate detection-rules solutions (*DR*).

$$f_{outer}(DR) = \text{Max}\left(\frac{\text{Precision}(DR) + \text{Recall}(DR)}{2} + \frac{\#damp}{\#amp}\right) \quad (2)$$

where $\#damp$ refers to the number of detected fraudulent motifs and $\#amp$ refers to the number of fraudulent motifs and

$$\text{Precision}(DR) = \frac{\sum_{i=1}^p DR_i}{t}, \text{Recall}(DR) = \frac{\sum_{i=1}^p DR_i}{p} \quad (3)$$

Algorithm 1 Outer Algorithm (First layer)

Input: *SMM*: set of malicious motifs, *SBM*: set of benign motifs, *FMM*: set of "Relevant" fraudulent motifs, *NDR*: number of detection rules, *NFM*: number of "Relevant" fraudulent motifs in *SHM*, *NF*: number of iterations in the first layer, *NS*: number of iterations in the second layer

Output: Final set of detection rules

FDRB

```

1: DRB0 ← Initialization(NDR, SHM, SBM) /*First generation of detection rules*/
2: for each DR0 in DRB0 do /*DR means detection rule*/
   SFM0 ← FMGeneration(DR0, FMM, NFM, NS) /*call second layer*/
   DR0 ← Evaluation(DR0, SHM, SFM0)
4: end for
   k ← 1
6: while k < NF do
   Qt ← Variation(DRBt-1)
8:   for each DRt in Qt do /*Evaluate each rule based on upper fitness function*/
     DRt ← OuterEvaluation(DRt, SHM)
10:    SFMt ← FMGeneration(DRt, SHM, NFM, NS)
     DRt ← EvaluationUpdate(DRt, SFMt)
12:   end for
   Ut ← Qt ∪ DRBt
14:   DRBt+1 ← Selection(NDR, Ut)
   k ← k+1
16: end while
FDRB ← FittestSelection(DRBt)

```

p is the number of detected malicious motifs after executing the solution, i.e., the detection rule, on the base of malicious motifs examples (SMM), t is the total number of malicious motifs within SMM , and DR_i is the i^{th} component of a detection rule DR such that:

$$DR_i = \begin{cases} 1 & \text{if the } i^{th} \text{ detected malicious motif exists in } SMM \\ 0 & \text{otherwise} \end{cases} \quad (4)$$

2) *Second layer*: The generation process of “Relevant” motifs (FMM , Algorithm 2, line 7) is performed as follows:

- *Step 1*: A GA is used to maximize the distance between the generated malicious motifs (SHM) and the reference benign motifs (input, not-generated motifs (SBM) while minimizing the distance between the generated malicious motifs (SHM) and the reference malicious ones (SMM). The GA also increases the amount of malicious motifs generated that are not detected by the first layer, i.e., the detection rules (DRB) (Algorithm 2, lines 1-5). The GA evolutionary operators need a special formalization to deal with the manipulated solutions in order to generate the motifs. The following are the adopted formalizations:

- *Solution representation*: The GA solutions are represented as chromosomes made up of API call sequences. These are identifiable by their identifiers (IDs) and defined by their class (labels), which indicate their nature (malicious or benign), calling depths, and a collection of binary values indicating whether or not an API call appears in the entire API call sequence.
- *Solution variation*: For the GA *crossover operator*, two parent individuals (chromosomes) are chosen, and a gene from each parent is chosen. Crossover involves the transfer of genes from one parent to the other. Only parents with the same nature can be used with the crossover operator (malicious or benign). The *mutation* operation starts by randomly selecting a gene on the chromosome. The selected gene is then replaced with another gene from the same class if it belongs to that class.
- *Solution evaluation*: A fraudulent motif (FM) is evaluated based on the following GA fitness function:

$$f_{inner}(FM) = Max((\#gamp - \#dagmp) + \sum_{i=1}^n f_{Qual}(FM_i)) \quad (5)$$

where $i \in [1, n]$; n indicates the total number of fraudulent motifs, and $\#gamp$ refers to the number of fraudulent motifs and $\#dagmp$ refers to the number of detected fraudulent motifs. The function $f_{Qual}()$ defined in Equation 6 ensures the diversification of the fraudulent motifs.

$$f_{Qual}(FM_i) = \frac{Sim_1 + Sim_2 + Overlap(FM_i)}{3} \quad (6)$$

$$Sim_1 = Sim(MS, FM_i) = \frac{\sum_{MS_j \in MS} Sim(FM_i, MS_j)}{|MS|} \quad (7)$$

where $j \in [1, m]$; m indicates the total number of malicious motifs. The similarity between the generated motif FM_i and the malicious set of motifs (MS). This measure of similarity needs to be maximized.

$$Sim_2 = Sim(BS, FM_i) = \frac{\sum_{BS_k \in BS} Sim(FM_i, BS_k)}{|BS|} \quad (8)$$

The similarity between the generated motif FM_i where $k \in [1, p]$; p indicates and the benign motifs (BS) the total number of benign set of motifs and which has to be the lowest.

$$Overlap(FM_i) = 1 - \frac{\sum_{FM_l, l \neq i} Sim(FM_i, FM_l)}{|FM|} \quad (9)$$

$Overlap()$ is measured as the average value of the individual $Sim(FM_i, FM_l)$ between the generated motif FM_i and all the other generated motifs FM_l in the generated dataset SFM . l refers to the total number of the generated motifs.

We updated the Needleman-Wunsch alignment algorithm formula [30] to our context to determine the similarity $Sim()$ between two motifs. This measure of similarity was employed in the above equations but with different parameters. A detailed description of the similarity function $Sim()$ can be found in [24].

- *Step 2*: The GA evolutionary operators mentioned above may cause the manipulated solutions to be distorted, and hence ambiguous, in different ways and with different degrees. Technically, a set of motifs is declared to be ambiguous when they share the same values of the features (API calls) but do have different label values (malicious/benign). An illustration of this ambiguity is presented in Table I. The manipulated motifs by the lower-level are API call sequences. Each API call sequence is named MFx_i (as shown in Table I) and is composed of different API calls named MLX_j . A conflict (or inconsistency) may exist between objects (fraudulent motifs). It is the case of the objects MFx_7 and MFx_9 because they are indiscernible by condition attributes MLX_1, \dots, MLX_n and have different decision attributes (Nature) (we assume that all attribute values MLX_j are the same). Similarly, another inconsistency exists between objects MFx_3 and MFx_8 .

To handle this ambiguity issue and to guarantee the reliability of the generated malicious motifs, a VPRS component, namely Variable Precision Rough Set Analyzer (VPRS Analyzer in Figure 3) which uses mainly

the VPRS lower and upper limit certainty thresholds concepts, is plugged to the inner algorithm. Specifically, the VPRS Analyzer checks first the reliability of the generated malicious motifs (SHM). Among this set, the VPRS Analyzer keeps the most relevant motifs (RFM) which do not need any further check, and investigates the remaining ambiguous set (AFM). Among the AFM set, the VPRS Analyzer calculates the lower limit certainty threshold to only keep the certain set of fraudulent motifs $SCFM$ (Algorithm 2, lines 11-12), and the upper limit certainty threshold to keep the approved fraudulent motifs among the *possible* set of generated fraudulent motifs $SPFM$, together with $SCFM$. During the pruning operation (Algorithm 2, line 14), redundant motifs are removed. Finally, the joint sets of $FCFM$ and $FPFM$ form the relevant, and the most relevant artificially generated fraudulent motifs (FMM) (Algorithm 2, line 15).

As *possible* fraudulent motifs cannot be considered relevant enough to be added to the initial set of malicious motifs, they need further evaluation that reflects their quality and measures

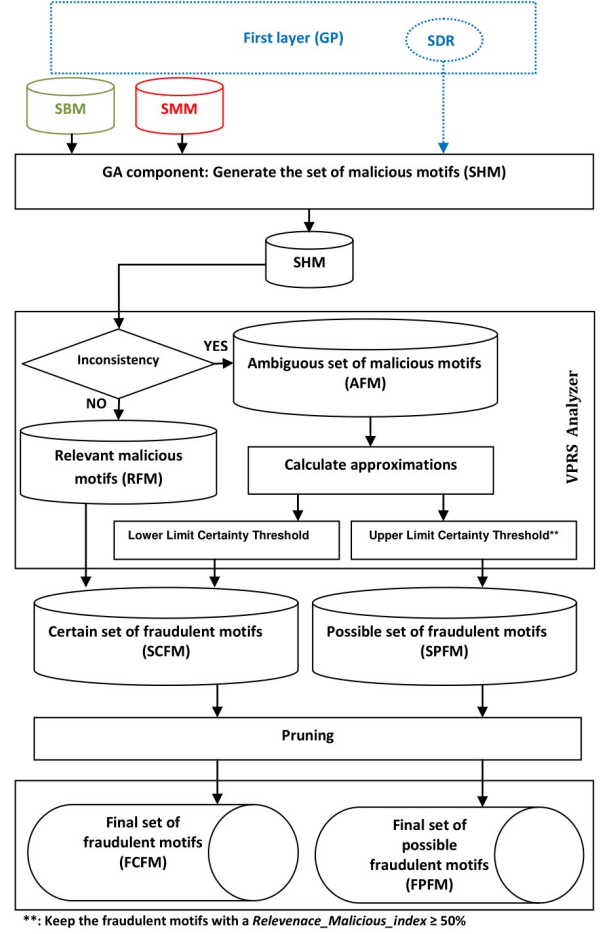

Fig. 3. Second layer functioning process.

their reliability. For every *possible* fraudulent motif, the VPRS-based component estimates its reliability using an index named *Relevance_Malicious_index*, which is defined as the ratio of the number of instances that belong to the *possible* set and having the same structure with a malicious label, and the number of the whole *possible* set of instances (Equation 10).

$$Relevance_Malicious_index = \frac{Instance_Possible_Malicious_Motif}{Instance_Possible_Original_Data} \quad (10)$$

where *Instance_Possible_Malicious_Motif* refers to the number of instances that share the same structure and are labelled malicious and *Instance_Possible_Original_Data* refers to the total number of instances within the whole possible set. This index can, therefore, be viewed as the probability of counting the ambiguous fraudulent motifs set (the *possible* generated motif set) correctly. It shows the extent to which a correct label can be given to a generated motif belonging to the *possible* set of generated motifs. Tacking into account that we are aiming to produce effective malicious fraudulent motifs, we will only keep the generated motifs that have a *Relevance_Malicious_index* > 50%. An illustrative example of this index is given below: Sup-

pose that when generating 123 new fraudulent motifs, 100 among them were labelled as malicious and 23 were labelled as benign. The *Relevance_Malicious_index* of those 123 possible generated motifs is (100/123). This means that the *Relevance_Malicious_index* = 81,30% which is clearly greater than 50% and hence the common shared structure of these generated motifs will be added to the set of malicious motifs sent to the outer algorithm.

3) *Detection task based on detection rules*: Throughout this phase, our model will perform its classification task where a new app, the executable, will be classified either as a malware or as a benign. This is achieved using the set of detection rules (*FDRB*). Formally, the first step aims to extract the motifs of the executable. Each motif will be labeled as benign or as malicious by comparing it to the motifs of the *SMM* and *SBM* databases. Then, the obtained motifs are compared to the antecedent of *FDRB*. The comparison will allow the executable to be either classified as a malware or as a benign app.

V. EXPERIMENTAL SETUP AND RESULTS

A. Experimental Setup

An experimental investigation was done to evaluate ProRSDet's performance in detecting new malware variants. For this purpose, we gathered data from a variety of sources (the Zoo dataset¹, from VirusTotal²) and from various portable benign tools such as Google play. We have gathered 5 540 Android apps where 3 440 are malicious and 2 100 apps are benign files. From those apps, a total of malicious motifs and a total of benign motifs were extracted. The conducted process is summarized in Table II. The Drebin dataset [31], which contains 123 453 benign applications and 5 560 malware samples, is used for the evaluation of our approach against the new variants of malware and 0-day attacks. The necessity for confirmation that ProRSDet is not fitting the base of examples led to the selection of a dataset that is different from the one used for the construction phase. For comparisons, various state-of-the-art methods were investigated. These are the classical classifiers named in Table V, tested using Weka with the proposed default parameters settings, three known methods (Rathore et al. [32], Gym-plus [33], and AMD [24]), and several commercial antimalware named in Table VII. The comparison made with the two recent state-of-the-art methods ([32] and [33]) is justified by the fact that those approaches are somehow similar to ProRSDet. In fact, there are common traits between our developed approach and those approaches: they propose a two-task solution (a malware generation task and a malware detection task). Also, to ensure the fairness of comparisons between evolutionary approaches (AMD [24] and ProRSDet), we used the parameter settings described in Table III.

Both evolutionary approaches perform 798 000 function evaluations in each run. Also, to help determine the most

TABLE II

appropriate α and β values, a set of experiments is conducted and the results are reported in Table IV. Indeed, Table IV shows that the best results were reached with a pair of α and β value that equals 0.5, respectively. When running the experiments, we concluded that the fitness functions become stabilized around the 36th generation. For these reasons, the algorithms did not suffer from premature convergence. The metrics used for the evaluation are: true positives (TP), false positives (FP), true negatives (TN), false negatives (FN), recall (RC), specificity (SP), accuracy (AC), precision (PR), F1_score (FS), and the Area Under the Receiver Operating Characteristics (ROC) Curve (AUC). All of the conducted experiments, based on a 10-fold cross validation, are run on an Intel[®] Xeon[®] Processor CPU E5-2620 v3, with a 16 GB RAM.

B. Results Analysis

In this section, we compare the ProRSDet obtained results to a set of classifiers (Table V), three state-of-the-art approaches (Rathore et al. [32], Gym-plus [33] and AMD [24]) and five antivirus engines (Table VI and Table VII). More precisely, to determine how accurate our predictive model will perform in practice, we used 10-fold cross-validation. We considered all of the collected programs and hence all of the obtained motifs stored in *SBM* and *SMM* (see Table II). So, concerning the comparison with the top-five classifiers (Table V), and based on all of the evaluation metrics, ProRSDet surpasses all other classifiers. In comparison to the *LDA* and *J48* classifiers, which produced the second best results among the rest of the classifiers with a pair of precision and accuracy of (98.36%, 97.82%) for *LDA* and (97.73%, 96.58%) for *J48* and a pair of F1_score and specificity of (97.32%, 97.31%) for *LDA* and (98.37%, 97.13%) for *J48*, ProRSDet achieved a precision of 98.20%, an accuracy of 98.22%, an F1 score of 98.21%, and a specificity of 98.20%. These remarkable ProRSDet results are based on its high true positives (98.20%) and low false positives (1.80%), which are the best achieved values among the results of the classifiers. These encouraging findings show that ProRSDet is capable of distinguishing between the two possible designations (malicious and benign). Also, regarding the comparison between the EA-based approaches (ProRSDet and AMD [24]), we used an unknown dataset (Drebin dataset

[31]) and ProRSDet outperformed AMD in terms of the used evaluation metrics as stated in Table VI. This can be explained by the contribution brought by the VPRS Analyzer which helped keep the most "relevant" malicious motifs.

Moreover, we may derive from Table VI and Table VII that, when compared to competing state-of-the-art approaches, (Rathore et al. [32], Gym-plus [33] and AMD [24]) using the unknown dataset [31], ProRSDet came in top with an accuracy of 97.66%, a specificity of 97.32%, a recall of 97.99%, a precision of 97.31%, and an AUC of 86.15%. Rathore et al., Gym-plus and AMD, obtained an accuracy of 93.81%, 93.50% and 92.28%, respectively, which are lower than those obtained by our proposed technique. In addition, the interesting detection results obtained by ProRSDet are endorsed by the results presented in Table VII which refers to the comparison with the commercial antivirus engines. Table VII shows that ProRSDet reached an accuracy rate of 97.66% whereas the ESET NOD32 engine, which is ranked first among all the other malware antivirus engines, registered only 66.68% of accuracy. It is to be noted that the accuracy values of the four remaining antivirus engines varied approximately between 56% and 66%.

The results reported from Tables V, VI and VII highlight the ability of ProRSDet – thanks to its set of efficient produced rules which are generated using the most relevant set of the generated fraudulent malware; both guaranteed via the use of the BLOP architecture and the VPRS component – to achieve accurate detection operations against new and unknown variants of malware.

To better clarify the efficiency and benefits of relying on the bilevel architecture within ProRSDet, we analyse the results in terms of false positive and the false negative rates. The registered ProRSDet values of those two metrics (Table VI) confirm the usefulness of a bilevel architecture to detect a malicious code efficiently. The continuous competition between both levels (first layer and second layer) permitted generation of good solutions (detection rules and fraudulent motifs) and this had positive impact on the values of FPR (02.69%) and FNR (01.99%). In comparison to ProRSDet, the registered FPR and FNR values for AMD [24], which rely on a single-layer based architecture via the use of evolutionary algorithms, are 06.37% and 08.84%, respectively. In addition, referring to Table VIII, we can state that the Variable Precision Rough Set based module succeeded to set apart 198 522 ambiguous instances (*possible* set) among the generated fraudulent motifs *SHM*

(468 000 instances). More precisely, a set of 92 689 of false motifs were removed from the whole set of ambiguous motifs. The removal of those false motifs was performed thanks to the *Relevance_Malicious_Index* and after being processed by the lower and upper limit certainty thresholds explained and illustrated in Section IV-2. This distinction brings to light the VPRS component's important contribution in improving the quality of the fraudulent motifs by the second layer and which, consequently, positively affected the false alarms rate. Let us recall that ProRSDet provides a set of robust detection rules thanks to the set of malicious motifs produced by the second layer's GA reinforced by the VPRS module. The VPRS module helps determine the set of "certain" malicious motifs and the set of "possible" malicious motifs. When dealing with this set of *possible* motifs, a *Relevance_Malicious_index* (Equation 10) that estimates the reliability degree of each *possible* malicious motif is also provided to the user (as presented in Section IV-2). This metric, specific to the evaluation of each *possible* malicious motif, will help determine the fate of this specific motif: add it to the set of malicious motifs or remove it. To be more specific, Figure 4 represents the number of the obtained *possible malicious motifs* with regards to their *Relevance_Malicious_index*. Figure 4 shows that 51.28% of possible malicious motifs have a *Relevance_Malicious_index* that exceeds 50%. Also, 17.98% of possible rules succeeded to correctly classify apps with rates that lie between 41% and 50%. 18.23% of those rules ranked just below with a *Relevance_Malicious_index* comprised between 31% and 40%. Approximately only 13% of the rules failed to have a *Relevance_Malicious_index* above 30%. An example of the use of this index was previously given in Section IV-2. Also, an important aspect in our proposed ProRSDet approach that needs to be clarified concerns the setting of the α and β VPRS parameters. In fact, in this study we adopted the the trial and error method which consists of choosing randomly values and apply them in our algorithm. For instance, we conducted four different experiments (Table IV) which helped us determine the best pair of α and β values that leads to better detection results. More precisely, we tried different combination of α and β values and each time we assessed the recall (*RC*), specificity (*SP*), accuracy (*AC*), precision (*PR*), F1_score (*FS*), Area under ROC curve (*AUC*), false positive rate (*FPR*) and false negative rate (*FNR*). The best values were reached with $\alpha = 0.5$ and $\beta =$

VI. CONCLUSION AND FUTURE DIRECTIONS

In this research, we developed ProRSDet, a malware detection technique that combines the Variable Precision Rough Set model and bilevel optimization. Within the bilevel architecture, the malware generation task (inner algorithm or second layer) and the rules generation task (detection task, outer algorithm or first layer) are in mutual competition. The second layer generates “Relevant” malicious motifs which are generated by a GA and thoroughly checked by a VPRS component that only keeps the most “pertinent” ones, and which are capable of eluding the GP’s set of detection rules in the first layer.

0.5. Indeed, we specifically registered an *AC* of 97.66%, a *PR* of 97.31% a *FPR* of 02.69% and a *FNR* of 01.99%. Those significant values found their way thanks to great reached percentages of true positives and true negatives.

These effective created detection rules, in turn, attempt their hardest to detect the second layer's set of fraudulent patterns.

ProRSDet outperformed a variety of state-of-the-art approaches and commercial engines, achieving encouraging detection rates of 97.66% accuracy and 2.69% false positives. We plan to investigate other methods to help determine the best values of α and β concerning the VPRS. It would be interesting to design an adaptive parameter tuning strategy that aims to approximate the best values of the VPRS parameters. Also, we can consider other theories that deal with the inconsistency in the future (i.e., [34], [35]), as well as consider expanding the scope of the proposed work to encompass other operating systems.

Abstract—This paper proposes an approach that is suitable for solving multi-criteria decision-making problems characterized by fuzzy (subjective) criteria. A finite set (universe) of alternatives will be expressed as a decision table that represents a fuzzy information system in which every fuzzy criterion is connected with a set of its linguistic values. We apply subjective preference degrees for linguistic values that should be provided by a decision-maker. To simplify the process of decision-making in big data environments, an additional stage will be introduced that can produce a smaller set of alternatives represented by fuzzy linguistic labels of similarity classes. We select a small set of similarity classes for the final ranking. A measure of compatibility will be defined that should express the accordance of a selected alternative with preferences given for the linguistic values of a particular fuzzy criterion.

I. INTRODUCTION

MULTI-CRITERIA decision-making is a very important task that has to be performed in various areas of human activity, especially in technique, industry, economy, business, and in everyday life. Depending on the number of considered criteria and the size of the solution space (number of alternatives), the process of determining the best alternative can be problematic, therefore, only small-sized and relative simple decision-making tasks can be effectively solved by humans. Moreover, as a general rule, there is no accordance in monotonicity between particular criteria, i.e., one obtains different rankings of alternatives for each criterion, hence a compromise solution should be determined. In recent decades, several approaches were proposed for solving multi-criteria decision-making problems, e.g., AHP, TOPSIS, VIKOR, PROMETHE, and ELECTRE [1]. In the case of very large solution spaces, for example when dealing with the combinatorial optimization problems, metaheuristic approaches such as simulated annealing, swarm optimization, and genetic algorithms can be applied.

Another issue, often encountered in practical optimization tasks, is uncertainty and vagueness in the characteristic of evaluated alternatives. Standard optimization methods only base on classic knowledge representation by utilizing deterministic objective functions and constraints, crisp set theory, and bi-valued logic. In order to take vagueness and subjectivity into account, many decision-making and optimization algorithms have been extended or combined with various soft computing methods in the form of hybrid approaches.

The fuzzy set theory has proved to be one of the most successful paradigms for dealing with problems that are vague in nature and require the use of linguistic terms or subjective evaluation. This makes it possible to use notions such as “quite large” or “very young”. Linguistic values expressed as fuzzy sets were widely applied and adopted by many researchers, who introduced several generalization, e.g., intuitionistic, type-2, hesitant fuzzy sets, and hybrid fuzzy-rough set models [2], [3].

Because in many decision-making algorithms a fuzzy representation of knowledge could be successfully implemented [4], [5], popular multi-criteria optimization algorithms have also been extended to deal with fuzzy terms instead of crisp numbers [6], [7].

In our previous work [8], we introduced the concept of fuzzy linguistic label that can be utilized in the framework of fuzzy or fuzzy-rough decision systems. The principle of the label-based approach consists in a simplified way of comparing and classifying the elements of a universe that are described with fuzzy attributes. Such an approach can be helpful in analysis of complex information systems that have large number of attributes and fuzzy linguistic values. The obtained results strongly depend on the used fuzzy operators and they may be not easy to interpret. This is why the label-based approach does not use standard fuzzy relation for determining classes of similar elements (alternatives) of the universe. Instead, by finding positive (dominant) linguistic values of attributes (criteria), a common description of similar objects can be easily obtained in the form of fuzzy linguistic labels.

In the current work, we propose a label-based approach to multi-criteria decision-making. We introduce several new ideas. First, we extend the requirements imposed on the membership degree of elements in linguistic values of attributes in the information system. This can be helpful in the process of preparing a consistent high-quality decision table by an expert. As only two neighbouring linguistic values of criteria can be activated, the decision table can be given in a compact form. Secondly, we propose a method of finding the best alternatives in the case of subjective fuzzy criteria. We define compatibility measure that can be used to evaluate the accordance of alternatives with the subjective preferences for linguistic values that are required by a decision-maker. Furthermore, the approach consists of two stages. This can be useful when the process of decision-making is performed

in a big-data environment. We avoid detailed evaluation of each alternative in a huge solution space. Instead, the best linguistic labels can be easily discovered at the first stage. The final solution can then be obtained by examining only a small number of the promising similarity classes of alternatives connected with the selected linguistic labels.

II. FUZZY DECISION SYSTEMS

To formalize the process of multi-criteria decision-making in a fuzzy environment, we should use the notion of fuzzy information system [9] that is expressed as a 4-tuple

$$\text{FDS} = \langle U, A, \mathbb{V}, f \rangle, \quad (1)$$

where:

U – is a nonempty set (universe) of elements (alternatives),

A – is a finite set of fuzzy attributes (criteria),

\mathbb{V} – is a set of linguistic values of criteria, $\mathbb{V} = \bigcup_{a \in A} \mathbb{V}_a$,
 \mathbb{V}_a is the set of linguistic values of a criterion $a \in A$,

f – is an information function, $f : U \times \mathbb{V} \rightarrow [0, 1]$,
 $f(x, V) \in [0, 1]$, for all $x \in U$, and $V \in \mathbb{V}$.

Any fuzzy criterion $a_i \in A$, where $i = 1, 2, \dots, n$, can take value from the family of its linguistic values denoted by $\mathbb{A}_i = \{A_{i1}, A_{i2}, \dots, A_{in_i}\}$. For all elements $x \in U$, the membership degree in the linguistic values of all fuzzy criteria will be assigned by experts. We require the following conditions to be satisfied, when the membership is assigned:

$$\begin{aligned} \exists A_{ik} \in \mathbb{A}_i \quad & (\mu_{A_{ik}}(x) \geq 0.5, \\ & \mu_{A_{ik-1}}(x) = 1 - \mu_{A_{ik}}(x) \vee \\ & \mu_{A_{ik+1}}(x) = 1 - \mu_{A_{ik}}(x)), \end{aligned} \quad (2)$$

$$\text{power}(\mathbb{A}_i(x)) = \sum_{k=1}^{n_i} \mu_{A_{ik}}(x) = 1. \quad (3)$$

The requirements (2), and (3) constitute a generalization of the properties that can be observed in crisp information systems. They are necessary for creating well-defined and consistent information systems.

Every information system can be represented by a decision table in which the rows correspond to the elements of the universe U , and the columns to the linguistic values of criteria. Due to the requirement (2), we would obtain a large sparse decision matrix, when the number of criteria and the number of their linguistic values is large. Therefore, it is more convenient to introduce a compact form of a decision table that only contains the information about the dominant linguistic values, which satisfy the requirement (2), for every element of the universe U .

Membership degree of any element $x \in U$, in the dominant k -th linguistic value of a selected fuzzy criterion $a_i \in A$, will be expressed in the following form

$$\mu_{A_{ik}}(x)(\text{neighbour})/A_{ik} \quad (4)$$

where:

$\text{neighbour} = L$ indicates a nonzero membership degree in the neighbouring left linguistic value, with $\mu_{A_{ik-1}}(x) = 1 - \mu_{A_{ik}}(x)$,

$\text{neighbour} = R$ indicates a nonzero membership degree in the neighbouring right linguistic value, with $\mu_{A_{ik+1}}(x) = 1 - \mu_{A_{ik}}(x)$,

$\text{neighbour} = C$ indicates no membership in the right and left neighbouring linguistic values.

The introduced concepts are used in an illustrative example in Section V.

III. LINGUISTIC LABELS

The elements of a given universe of discourse can be compared to each other by using a binary relation for determining the degree of their similarity. In the standard rough set theory [10], a crisp indiscernibility relation is utilized that generates a partition of the universe into classes of elements that cannot be discerned, because they have the same value of (selected) attributes. Comparison of elements in a fuzzy model can be done in different ways, because various fuzzy operators can be used to determine the similarity of elements [2]. Another difficulty arises in analysis of big information systems that have not only large number of elements, but also many fuzzy attributes and linguistic values. In consequence, one can obtain a vast number of similarity classes, which complicates the calculations and, above all, makes it difficult to interpret the results. This issue was an inspiration for proposing a straightforward method of classifying the elements of fuzzy decision systems [8].

The principle of this approach consists in finding classes of characteristic elements of the universe that have the same description given in the form of tuple of dominant linguistic values of attributes. According to the requirement (2), for every element of the universe U , and every attribute $a \in A$, a distinct linguistic value can be found for which the membership degree has the greatest value. Hence, we do not apply a standard fuzzy similarity relation, but only identify dominant linguistic values in all rows of the decision table. This way we can easily discover the groups of (characteristic) elements that have the same dominant linguistic values of all attributes.

A tuple of dominant linguistic values of attributes is called a linguistic label. We can say that the characteristic elements of a linguistic label belong to the same similarity class. The degrees of membership in the dominant linguistic values are in a general case different numbers from the interval $[0.5, 1]$ for every element of the similarity class. However, we can also introduce an ideal element with the membership degree equal to 1 for all dominant linguistic values. Such ideal elements can be seen as an abstract representation of the linguistic labels.

By using linguistic labels, one is able to imitate the process of classifying objects that can be observed in human experts. Instead of performing an exhaustive comparison for every pair of elements of the universe, they rather try to discover a limited subset of ideal elements having a common characteristic.

Now, let us recall the basic notions of the label-based approach. The characteristic elements of the universe will be determined directly from the decision table, by respecting their membership in the linguistic values of all fuzzy attributes. Since the dominance of a linguistic value is a matter of the membership degree, we need to use a threshold of similarity, denoted by β , which satisfies the inequality

$$0.5 < \beta \leq 1. \quad (5)$$

A suitable value of the parameter β should be chosen as the threshold of similarity for classifying linguistic values of attributes.

Given a fuzzy information system FDS, we define [8] for any element $x \in U$, and any fuzzy attribute $a \in A$: the set $\widehat{\mathbb{V}}_a(x) \subseteq \mathbb{V}_a$ of positive linguistic values

$$\widehat{\mathbb{V}}_a(x) = \{V \in \mathbb{V}_a : f(x, V) \geq \beta\}, \quad (6)$$

the set $\overline{\mathbb{V}}_a(x) \subseteq \mathbb{V}_a$ of boundary linguistic values

$$\overline{\mathbb{V}}_a(x) = \{V \in \mathbb{V}_a : 0.5 \leq f(x, V) < \beta\}, \quad (7)$$

and the set $\check{\mathbb{V}}_a(x) \subseteq \mathbb{V}_a$ of negative linguistic values

$$\check{\mathbb{V}}_a(x) = \{V \in \mathbb{V}_a : 0 \leq f(x, V) < 0.5\}. \quad (8)$$

Due to the constraints (2) and (3), the sets $\widehat{\mathbb{V}}_a(x)$, $\overline{\mathbb{V}}_a(x)$, and $\check{\mathbb{V}}_a(x)$ have the following properties [8]:

$$(P1) \quad \text{card}(\widehat{\mathbb{V}}_a(x)) \leq 1,$$

$$(P2) \quad \text{card}(\overline{\mathbb{V}}_a(x)) \leq 2,$$

$$(P3) \quad \text{card}(\check{\mathbb{V}}_a(x)) < |\mathbb{V}_a|.$$

Every element $x \in U$ can be described with a combination of those linguistic values that are positive for that particular element. In this way, we determine the linguistic labels for all elements of the universe.

Formally, the set of linguistic labels $\widehat{\mathbb{L}}(x)$ is equal to the Cartesian product of the sets of positive linguistic values $\widehat{\mathbb{V}}_a(x)$, for all $a \in A$:

$$\widehat{\mathbb{L}}(x) = \prod_{a \in A} \widehat{\mathbb{V}}_a(x). \quad (9)$$

When inspecting the decision table, we can also discover elements $x \in U$ which have a common linguistic label $L(x)$.

By X_L , we denote the subset of the elements $x \in U$ that correspond to a linguistic label $L \in \mathbb{L}$, for all fuzzy attributes $a \in A$:

$$X_L = \{x \in U : L(x) = L\}. \quad (10)$$

The subset X_L is called the set of characteristic elements of the linguistic label L .

A linguistic label $L \in \mathbb{L}$ can be represented by an ordered tuple of positive linguistic values, for all attributes $a \in A$:

$$L = (\widehat{V}_{a_1}^L, \widehat{V}_{a_2}^L, \dots, \widehat{V}_{a_n}^L). \quad (11)$$

In the present paper, the notion of an attribute denotes a criterion, and an element of the universe is called an alternative.

IV. LABEL-BASED EVALUATION OF ALTERNATIVES

We divide the process of searching for the best alternatives into two stages. First, all rows of the decision table have to be inspected for determining the linguistic labels which are present in the information system.

A. Stage I

At the first stage, every linguistic label will be evaluated by determining its accordance with the preferences for linguistic values provided by a decision-maker. We also take into account the weights of criteria. The decision-maker should give the vector of weights $W = [w_1, w_2, \dots, w_n]$, which usually satisfy the requirement: $\sum_{i=1}^n w_i = 1$.

Let us denote by $pref(V)$ the preference for the linguistic value $V \in \mathbb{V}$. The compatibility of a linguistic label with the preferences for linguistic values of criteria can be presented in a detailed manner as a fuzzy set C_L on the domain of positive linguistic values of the label L

$$C_L = \{pref(\widehat{V}_{a_1}^L)/\widehat{V}_{a_1}^L, pref(\widehat{V}_{a_2}^L)/\widehat{V}_{a_2}^L, \dots, pref(\widehat{V}_{a_n}^L)/\widehat{V}_{a_n}^L\}. \quad (12)$$

Now, we define the measure of weighted compatibility of the linguistic label L with the preferences of the decision-maker as follows

$$compat(L) = \sum_{i=1}^n w_i \cdot pref(\widehat{V}_{a_i}^L). \quad (13)$$

where $\widehat{V}_{a_i}^L$ denotes the positive linguistic value of the criterion a_i in the linguistic label L , as given in the formula (11).

By applying the measure (13), a ranking of all linguistic labels can be determined. Basing on the ranking of the linguistic labels, we can select a group of the best linguistic labels and their characteristic elements as the promising candidates for generating the set of the best alternatives.

B. Stage II

At the second stage, evaluation of alternatives from the classes of characteristic elements of the selected linguistic labels is performed. The analyzed alternatives are represented in the form (4).

We define the measure of the weighted compatibility of an alternative $x \in U$ with the preferences for the linguistic values of attributes as follows

$$compat(x) = \sum_{i=1}^n w_i \cdot pref(V(x, i)) \cdot \mu_{V(x, i)}(x) + \sum_{i=1}^n w_i \cdot pref(N(x, i)) \cdot \mu_{N(x, i)}(x), \quad (14)$$

where:

$V(x, i)$ – is the positive linguistic value of the criterion a_i in the linguistic label $L(x)$, $V(x, i) = \widehat{V}_{a_i}^L(x)$,

$N(x, i)$ – is the neighbouring linguistic value of a_i in the linguistic label $L(x)$, $\mu_{N(x, i)}(x) = 1 - \mu_{V(x, i)}(x)$.

The measure (14) will be used to generate a set of the best alternatives.

V. EXAMPLE

Let us consider a fuzzy information system that includes alternatives: x_1, x_2, \dots, x_{15} . There are three fuzzy criteria: c_1, c_2 , and c_3 . The criteria c_1 and c_3 can take three linguistic values, whereas the criterion c_2 five linguistic values.

We assume that the decision regarding the degree of membership of every alternative in the linguistic values of all fuzzy criteria was made taking into account the requirements (2) and (3). The fuzzy information system was prepared in a compact form (Table I), according to the formula (4).

TABLE I
COMPACT DECISION TABLE

	a_1	a_2	a_3
x_1	0.8(L)/ A_{12}	0.7(L)/ A_{23}	0.7(L)/ A_{33}
x_2	0.8(L)/ A_{12}	0.7(L)/ A_{24}	0.8(L)/ A_{32}
x_3	0.8(R)/ A_{12}	0.7(R)/ A_{22}	0.8(L)/ A_{32}
x_4	0.8(R)/ A_{12}	0.7(R)/ A_{23}	0.7(L)/ A_{33}
x_5	0.8(R)/ A_{12}	0.7(R)/ A_{24}	0.8(R)/ A_{32}
x_6	0.8(L)/ A_{12}	0.7(L)/ A_{22}	0.8(R)/ A_{32}
x_7	0.8(L)/ A_{12}	0.7(R)/ A_{23}	0.7(L)/ A_{33}
x_8	0.7(R)/ A_{11}	0.7(L)/ A_{23}	0.6(L)/ A_{33}
x_9	0.7(L)/ A_{13}	0.8(L)/ A_{23}	0.7(L)/ A_{33}
x_{10}	0.7(L)/ A_{13}	0.8(R)/ A_{23}	0.7(L)/ A_{33}
x_{11}	0.8(L)/ A_{13}	0.8(L)/ A_{25}	0.7(L)/ A_{32}
x_{12}	0.8(R)/ A_{12}	0.7(L)/ A_{23}	0.7(L)/ A_{33}
x_{13}	0.8(L)/ A_{13}	0.8(L)/ A_{25}	0.7(R)/ A_{32}
x_{14}	0.8(R)/ A_{11}	0.7(R)/ A_{23}	0.8(L)/ A_{33}
x_{15}	0.8(R)/ A_{11}	0.7(R)/ A_{21}	1.0(C)/ A_{33}

We also present the full decision table (Table II) with emphasized values of membership degree for the linguistic values which are dominant.

To assess mainly the influence of preferences of linguistic values, we can take the same weight for every criterion by using the following vector of weights: $W = [0.33, 0.33, 0.34]$. The preferences for the linguistic values of all criteria are given in Table III.

By inspecting the decision table, we obtain the following linguistic labels with their characteristic elements:

$$\begin{aligned}
 L_1 &= (A_{12}A_{23}A_{33}) : X_{L_1} = \{x_1, x_4, x_7, x_{12}\}, \\
 L_2 &= (A_{11}A_{23}A_{33}) : X_{L_2} = \{x_8, x_{14}\}, \\
 L_3 &= (A_{12}A_{24}A_{32}) : X_{L_3} = \{x_2, x_5\}, \\
 L_4 &= (A_{12}A_{22}A_{32}) : X_{L_4} = \{x_3, x_6\}, \\
 L_5 &= (A_{13}A_{23}A_{33}) : X_{L_5} = \{x_9, x_{10}\}, \\
 L_6 &= (A_{13}A_{25}A_{32}) : X_{L_6} = \{x_{11}, x_{13}\}, \\
 L_7 &= (A_{11}A_{21}A_{33}) : X_{L_7} = \{x_{15}\}.
 \end{aligned}$$

A. Stage I

For all obtained linguistic labels, we determine the sets representing the compatibility with the preferences of the

decision-maker, according to the formula (12)

$$\begin{aligned}
 C_{L_1} &= \{0.50/A_{12}, 1.00/A_{23}, 1.00/A_{33}\}, \\
 C_{L_2} &= \{1.00/A_{11}, 1.00/A_{23}, 1.00/A_{33}\}, \\
 C_{L_3} &= \{0.50/A_{12}, 0.75/A_{24}, 0.50/A_{32}\}, \\
 C_{L_4} &= \{0.50/A_{12}, 0.50/A_{22}, 0.50/A_{32}\}, \\
 C_{L_5} &= \{0.25/A_{13}, 1.00/A_{23}, 1.00/A_{33}\}, \\
 C_{L_6} &= \{0.25/A_{13}, 0.25/A_{25}, 0.50/A_{32}\}, \\
 C_{L_7} &= \{1.00/A_{11}, 0.00/A_{21}, 1.00/A_{33}\}.
 \end{aligned}$$

Next, we determine the weighted compatibility of all linguistic labels according to the formula (13). The obtained ranking of the linguistic labels is included in Table IV.

B. Stage II

Those similarity classes of the linguistic labels that have the greatest compatibility with the preferences for linguistic values of criteria will be selected for a detailed analysis of their alternatives. In a real-world application with a huge number of alternatives, the worst similarity classes would be discarded from further consideration. In our small example, all linguistic labels are taken into account for determining the ranking of all alternatives.

We demonstrate the evaluation of the alternative x_8 that is a characteristic element of the linguistic label L_2 . From Table I, we take the entry 0.7(R)/ A_{11} expressing the fuzzy value of x_8 for the criterion a_1 . The alternative has a membership degree in the positive linguistic value A_{11} equal to 0.7, hence we have $V(x_8, 1)(x_8) = A_{11}$, and $\mu_{V(x_8, 1)}(x_8) = 0.7$. There is also a nonzero membership in the right neighbouring linguistic value A_{12} , that is, $N(x_8, 1)(x_8) = A_{12}$, and $\mu_{N(x_8, 1)}(x_8) = 1 - 0.7 = 0.3$.

By the same way, the terms for the attributes a_2 and a_3 can be obtained. Therefore, according to the formula (14), the value $compat(x_8)$ is equal to:

$$\begin{aligned}
 &w_1 \cdot (pref(A_{11}) \cdot \mu_{A_{11}}(x_8) + pref(A_{12}) \cdot \mu_{A_{12}}(x_8)) + \\
 &w_2 \cdot (pref(A_{23}) \cdot \mu_{A_{23}}(x_8) + pref(A_{22}) \cdot \mu_{A_{22}}(x_8)) + \\
 &w_3 \cdot (pref(A_{33}) \cdot \mu_{A_{33}}(x_8) + pref(A_{32}) \cdot \mu_{A_{32}}(x_8)) = 0.833
 \end{aligned}$$

The results obtained for all alternatives are presented in Table IV. We get the following ordering of alternatives: $x_{14}, x_8, x_7, x_1, x_4, x_{12}, x_{10}, x_9, x_2, x_5, x_6, x_3, x_{13}, x_{11}$. As we can see, the alternatives which are characteristic elements of the best linguistic labels have a high degree of compatibility with the preferences of the decision-maker.

VI. CONCLUSIONS

Linguistic labels can be effectively used in analysis of fuzzy information systems, including multi-criteria optimization tasks. The concept of fuzzy linguistic label was inspired by observation of the decision-making activity performed by human experts. The label-based approach presented in this paper takes into account subjective preferences for linguistic values of fuzzy criteria given by a decision-maker. The proposed method can be applied especially in big-data environments, because it avoids a detailed evaluation of every alternative in a huge solution space. At the first stage, we

Abstract—In this paper we apply vague quantification to fuzzy rough sets to introduce *fuzzy quantifier-based fuzzy rough sets (FQFRS)*, an intuitive generalization of fuzzy rough sets. We show how several existing models fit in this generalization as well as how it inspires novel models that may improve these existing models. In addition, we introduce several new binary quantification models. Finally, we introduce an adaptation of FQFRS that allows seamless integration of outlier detection algorithms to enhance the robustness of the applications based on FQFRS.

I. INTRODUCTION

FUZZY quantification is an important part of fuzzy logic that models quantified sentences such as “Most Dutch people are tall” and “Nearly half of the S&P 500 stocks are down 10%”. Quantifiers are an effective tool to describe the quantity of elements that satisfy a certain condition. This is especially true if the condition is of a vague nature, as for example in the quantified sentence “Most Dutch people are tall”, since the quantity of elements satisfying a fuzzy condition (being tall) is hard to assess. The two most studied types of quantifiers are unary and binary quantifiers, unary quantifiers being of the form “ Q_1 elements are A ” (e.g. “Some people are tall”) and binary quantifiers being of the form “ Q_2 A ’s are B ’s” (e.g. “Most Dutch people are tall”). The first evaluation method for fuzzy quantified statements was introduced by Zadeh [1]. His idea was to define a cardinality measure for fuzzy sets to evaluate the quantity of elements satisfying a condition. The problem with this approach is that the cardinality measure is cumulative, implying that a situation involving two people with a degree of tallness of 0.5 is regarded the same as one with one tall person (tallness 1) and one short person (tallness 0). An improved evaluation method was proposed by Yager [2], which is based on the Ordered Weighted Averaging (OWA) operator. This method is semantically more reasonable for unary quantifiers but still lacks soundness for binary quantifiers. To resolve these issues, Glöckner [3] developed a general framework for fuzzy quantification. In this framework, fuzzy quantifiers are fully determined by how they act on classical (i.e. non-fuzzy) sets and by the choice of a quantifier fuzzification mechanism (QFM). A QFM thus reduces the evaluation of any quantified statement to the evaluation of quantified statements with crisp arguments.

Rough set theory, introduced by Pawlak [4], provides a lower and upper approximation of a concept with respect to

the indiscernibility relation between objects. The lower and upper approximation contain all objects that are certainly, respectively possibly part of the concept. That is to say, an element is a member of the lower approximation of a concept if every element indiscernible from it belongs to the concept; and an element is a member of the upper approximation of the concept if there exists an element indiscernible from it that belongs to the concept. Rough set theory was first extended to fuzzy rough set theory by Dubois and Prade [5], where both the concept and the indiscernibility relation can be fuzzy. Fuzzy rough set theory has been used successfully for classification and other machine learning purposes, such as feature and instance selection [6], but due to the fact that the approximations in classical fuzzy rough sets are determined using the minimum and maximum operators, these approximations (and the applications based on them) are sensitive to noisy and outlying samples. To mitigate this problem, many noise-tolerant versions of fuzzy rough sets (FRS) have been proposed, such as Vaguely Quantified FRS (VQFRS) [7], β -Precision FRS [8], [9], Variable Precision FRS [10], Variable Precision (θ, σ)-FRS [11], Soft Fuzzy Rough Sets [12], Automatic Noisy Sample Detection FRS [13], Data-Distribution-Aware FRS [14], Probability Granular Distance based FRS [15], Ordered Weighted Averaging (OWA) based FRS (OWAFRS) [16] and Choquet-based FRS (CFRS) [17]. VQFRS and, as noted in [17], OWAFRS and CFRS are fuzzy rough set models based on vague quantification. In this paper, we introduce a generalization of fuzzy rough sets, called fuzzy quantifier-based fuzzy rough sets (FQFRS), that takes the idea behind VQFRS and CFRS one step further. It does this by using binary and unary quantification models to determine the lower and upper approximation of a concept, respectively. Furthermore, we explain how to adapt FQFRS to use normalized outlier scores [18] to boost the robustness of the lower and upper approximations in fuzzy rough sets.

This paper is structured as follows: in Section II, we recall the required prerequisites for (Choquet-based) fuzzy rough sets and vague quantification. Section III discusses different binary quantification models and introduces several new ones. In Section IV, fuzzy quantifier-based fuzzy rough sets (FQFRS) and confidence-based FQFRS are introduced and their relation with existing models is discussed as well as the possible benefits they may have. Sections V and VI conclude this paper and describe opportunities for future research.

II. PRELIMINARIES

A. Fuzzy logic

In this subsection, we recall the necessary notions of fuzzy set and fuzzy logical connectives. We start with the definition of a fuzzy set and a fuzzy relation.

Definition II.1. [19] A fuzzy set or membership function A on X is a function from X to the unit interval, i.e. $A : X \rightarrow [0, 1]$. The value $A(x)$ of an element $x \in X$ is called the degree of membership of x in the fuzzy set A . The set of all fuzzy sets on X is denoted as $\tilde{\mathcal{P}}(X)$.

Definition II.2. A fuzzy relation R on X is an element of $\tilde{\mathcal{P}}(X \times X)$. A fuzzy relation R is called reflexive if $R(x, x) = 1$ for every $x \in X$. For an element $y \in X$ and a fuzzy relation $R \in \tilde{\mathcal{P}}(X \times X)$, we define the R -foreset of y as the fuzzy set $Ry(x) := R(x, y)$.

We will also make use of conjunctors, implicators and negators which extend their Boolean counterparts to the fuzzy setting.

Definition II.3.

- A function $\mathcal{C} : [0, 1]^2 \rightarrow [0, 1]$ is called a conjunctor if it is increasing in both arguments and satisfies $\mathcal{C}(0, 0) = \mathcal{C}(0, 1) = 0$ and $\mathcal{C}(1, x) = x$ for all $x \in [0, 1]$. A commutative and associative conjunctor \mathcal{T} is called a t-norm. We will use the following notation $x \wedge_{\mathcal{C}} y := \mathcal{C}(x, y)$.
- A function $\mathcal{S} : [0, 1]^2 \rightarrow [0, 1]$ is called a t-conorm if it is non-decreasing in both arguments, commutative, associative, and satisfies $\mathcal{S}(0, x) = x$ for all $x \in [0, 1]$. We will use the following notation $x \vee_{\mathcal{S}} y := \mathcal{S}(x, y)$.
- A function $\mathcal{I} : [0, 1]^2 \rightarrow [0, 1]$ is called an impicator if $\mathcal{I}(0, 0) = \mathcal{I}(0, 1) = \mathcal{I}(1, 1) = 1$, $\mathcal{I}(1, 0) = 0$ and for all x_1, x_2, y_1, y_2 in $[0, 1]$ the following holds:

- 1) $x_1 \leq x_2 \Rightarrow \mathcal{I}(x_1, y_1) \geq \mathcal{I}(x_2, y_1)$ (non-increasing in the first argument),
- 2) $y_1 \leq y_2 \Rightarrow \mathcal{I}(x_1, y_1) \leq \mathcal{I}(x_1, y_2)$ (non-decreasing in the second argument),

We will use the following notation $x \rightarrow_{\mathcal{I}} y := \mathcal{I}(x, y)$.

- A function $\mathcal{N} : [0, 1] \rightarrow [0, 1]$ is called a negator if it is non-increasing and satisfies $\mathcal{N}(0) = 1$ and $\mathcal{N}(1) = 0$. A negator is called a strong negator if it is an involution.
- Suppose \mathcal{S} is a t-conorm and \mathcal{N} is a negator. The mapping

$$\mathcal{I}(x, y) = \mathcal{N}(x) \vee_{\mathcal{S}} y, \quad \forall x, y \in [0, 1],$$

is called the \mathcal{S} -implicator induced by \mathcal{S} and \mathcal{N} .

Example II.1. The Kleene-Dienes impicator is defined as $\mathcal{I}_{KD}(x, y) := \max(1 - x, y)$. It is the \mathcal{S} -implicator induced by the standard negator $\neg(x) := 1 - x$ and the standard t-conorm $x \vee y = \max(x, y)$.

Since t-norms are required to be associative, they can be extended naturally to a function $[0, 1]^n \rightarrow [0, 1]$ for any natural number $n \geq 2$.

Definition II.4. The notation $A \subseteq B$ for two fuzzy sets A and B , expresses that $A(x) \leq B(x)$ for all $x \in X$. The fuzzy set $A \cap B \in \tilde{\mathcal{P}}(X)$ is defined by $(A \cap B)(x) = \min(A(x), B(x))$. We denote Zadeh's Sigma count as $|A| := \sum_{x \in X} A(x)$ for every fuzzy set $A \in \tilde{\mathcal{P}}(X)$, it is a conservative extension of classical set cardinality to fuzzy sets.

Definition II.5. Given a negator \mathcal{N} , conjunctor \mathcal{C} , t-conorm \mathcal{S} , impicator \mathcal{I} , and two fuzzy sets $A, B \in \tilde{\mathcal{P}}(X)$, we define the following:

$$(\neg_{\mathcal{N}} A)(x) = \mathcal{N}(A(x)),$$

$$(A \cap_{\mathcal{C}} B)(x) := A(x) \wedge_{\mathcal{C}} B(x),$$

$$(A \cup_{\mathcal{S}} B)(x) := A(x) \vee_{\mathcal{S}} B(x),$$

$$(A \rightarrow_{\mathcal{I}} B)(x) := A(x) \rightarrow_{\mathcal{I}} B(x),$$

for all $x \in X$.

B. OWA-based fuzzy rough sets

A downside to the classical definition of lower and upper approximation in fuzzy rough set theory is their lack of robustness. The value of the membership of an element in the lower and upper approximation is fully determined by a single element because of the minimum and maximum operators in the definition. To solve this undesirable behaviour, many alternative definitions of fuzzy rough sets were introduced. One of these is OWA-based fuzzy rough sets [16], which has been shown to have an excellent trade-off between performance (robustness) and theoretical properties [20]. The Ordered Weighted Average [21] is an aggregation operator that is defined as follows:

Definition II.6 (OWA). Let $X = \{x_1, x_2, \dots, x_n\}$, $f : X \rightarrow \mathbb{R}$ and $\mathbf{w} = (w_1, w_2, \dots, w_n)$ be a weighting vector, i.e. $\mathbf{w} \in [0, 1]^n$ and $\sum_{i=1}^n w_i = 1$, then the ordered weighted average of f with respect to \mathbf{w} is defined as

$$OWA_{\mathbf{w}}(f) := \sum_{i=1}^n f(x_{\sigma(i)})w_i,$$

where σ is a permutation of $\{1, 2, \dots, n\}$ such that

$$f(x_{\sigma(1)}) \geq f(x_{\sigma(2)}) \geq \dots \geq f(x_{\sigma(n)}).$$

Example II.2. The maximum, mean and minimum operators can all be seen as OWA-operators with weight vectors $(1, 0, \dots, 0, 0)$, $(\frac{1}{n}, \frac{1}{n}, \dots, \frac{1}{n})$ and $(0, 0, \dots, 0, 1)$ respectively.

In OWA-based fuzzy rough sets, OWA operators replace the minimum and maximum in the lower and upper approximations in classical fuzzy rough sets. To not deviate too strongly from the original definitions, some requirements may be enforced on the weight vectors of the OWA-operators used [16]. In particular, the authors required that the OWA-operator for the lower approximation is a soft minimum and for the upper approximation a soft maximum.

Definition II.7. The orness and andness of a weight vector $\mathbf{w} = (w_i)_{i=1}^n$ are defined as

$$\text{orness}(\mathbf{w}) = \frac{1}{n-1} \sum_{i=1}^n ((n-i) \cdot w_i), \quad (1)$$

$$\text{andness}(\mathbf{w}) = 1 - \text{orness}(\mathbf{w}).$$

If $\text{orness}(\mathbf{w}) < 0.5$, then $OWA_{\mathbf{w}}$ is called a soft minimum. If $\text{orness}(\mathbf{w}) > 0.5$, $OWA_{\mathbf{w}}$ is called a soft maximum.

As can be seen from Equation (1), the orness indicates how much weight is given to the largest elements. The orness tells us how “close” the OWA-operator is to the maximum. Using this definition OWA-based fuzzy rough sets are then defined as:

Definition II.8. [16] Given $R \in \tilde{\mathcal{P}}(X \times X)$, weight vectors \mathbf{w}_l and \mathbf{w}_u with $\text{orness}(\mathbf{w}_l) < 0.5$ and $\text{orness}(\mathbf{w}_u) > 0.5$ and $A \in \tilde{\mathcal{P}}(X)$, the OWA lower and upper approximation of A w.r.t. R , \mathbf{w}_l and \mathbf{w}_u are given by:

$$(\underline{apr}_{R, \mathbf{w}_l} A)(x) = OWA_{\mathbf{w}_l}(\mathcal{I}(R(x, y), A(y))), \quad (2)$$

$$(\overline{apr}_{R, \mathbf{w}_u} A)(x) = OWA_{\mathbf{w}_u}(\mathcal{C}(R(x, y), A(y))), \quad (3)$$

where \mathcal{I} is an implicator, \mathcal{C} a conjunctor and $\mathcal{I}(R(x, y), A(y))$ and $\mathcal{C}(R(x, y), A(y))$ are seen as functions in y .

C. The Choquet integral

The Choquet integral induces a large class of aggregation functions, namely the class of all comonotone linear aggregation functions [22]. Since we will view the Choquet integral as an aggregation operator, we will restrict ourselves to measures (and Choquet integrals) on finite sets. For the general setting, we refer the reader to e.g. [23].

Definition II.9. Let X be a finite set. A function $\mu : \mathcal{P}(X) \rightarrow [0, 1]$ is called a monotone measure if:

- $\mu(\emptyset) = 0$ and $\mu(X) = 1$,
- $(\forall A, B \in \mathcal{P}(X))(A \subseteq B \implies \mu(A) \leq \mu(B))$.

A monotone measure is called:

- additive if $\mu(A \cup B) = \mu(A) + \mu(B)$ when A and B are disjoint,
- symmetric if $\mu(A) = \mu(B)$ when $|A| = |B|$.

Definition II.10. [23] Let μ be a monotone measure on X and $f : X \rightarrow \mathbb{R}$ a real-valued function. The Choquet integral of f with respect to the measure μ is defined as:

$$\int f d\mu = \sum_{i=1}^n \mu(A_i^*) \cdot [f(x_i^*) - f(x_{i-1}^*)],$$

where $(x_1^*, x_2^*, \dots, x_n^*)$ is a permutation of $X = \{x_1, x_2, \dots, x_n\}$ such that

$$f(x_1^*) \leq f(x_2^*) \leq \dots \leq f(x_n^*),$$

$A_i^* := \{x_i^*, \dots, x_n^*\}$ and $f(x_0^*) := 0$.

The class of aggregation operators induced by the Choquet integral contains the weighted mean and the OWA operator. In

fact, the weighted mean and OWA operator are the Choquet integrals with respect to additive and symmetric measures, respectively.

Proposition II.11. [22] The Choquet integral with respect to an additive measure μ is the weighted mean $M_{\mathbf{w}}$ with weight vector $\mathbf{w} = (w_i)_{i=1}^n = (\mu(\{x_i\}))_{i=1}^n$. Conversely, the weighted mean $M_{\mathbf{v}}$, with weight vector $\mathbf{v} = (v_i)_{i=1}^n$ is a Choquet integral with respect to the uniquely defined additive measure μ for which $(\mu(\{x_i\}))_{i=1}^n = (v_i)_{i=1}^n$.

Proposition II.12. [22] The Choquet integral with respect to a symmetric measure μ is the OWA operator with weight vector $\mathbf{w} = (w_i)_{i=1}^n = (\mu(A_i) - \mu(A_{i-1}))_{i=1}^n$, where A_i denotes any subset with cardinality i . Conversely, the OWA operator with weight vector $\mathbf{v} = (v_i)_{i=1}^n$ is a Choquet integral with respect to the symmetric measure μ defined as

$$(\forall A \subseteq X)(\mu(A)) := \sum_{i=1}^{|A|} v_i.$$

D. Glöckner’s framework for fuzzy quantification

Glöckner’s framework for fuzzy quantification deals with defining vague quantifiers in two steps. The first step is the specification of the vague quantifier on crisp sets, i.e. to specify the “underlying” semi-fuzzy quantifier. The second step is to extend this description to fuzzy arguments, i.e. applying a quantifier fuzzification mechanism.

Definition II.13. [3] An n -ary semi-fuzzy quantifier on $X \neq \emptyset$ is a mapping $Q : (\mathcal{P}(X))^n \rightarrow [0, 1]$. An n -ary fuzzy quantifier on $X \neq \emptyset$ is a mapping $\tilde{Q} : (\tilde{\mathcal{P}}(X))^n \rightarrow [0, 1]$.

Definition II.14. [3] A quantifier fuzzification mechanism (QFM) \mathcal{F} assigns to each semi-fuzzy quantifier $Q : (\mathcal{P}(X))^n \rightarrow [0, 1]$ a corresponding fuzzy quantifier $\mathcal{F}(Q) : (\mathcal{P}(X))^n \rightarrow [0, 1]$ of the same arity $n \in \mathbb{N}$ and on the same universe X .

Glöckner defined an axiomatic framework for plausible models of fuzzy quantification which he called the Determiner Fuzzification Scheme (DFS) axioms. Since introducing DFS would take up too much space we refer the reader to chapter three, four, and five of [3].

We now take a look at Zadeh’s and Yager’s traditional approaches, where they describe fuzzy quantifiers using fuzzy sets of the unit interval.

Definition II.15. [1] A fuzzy set $\Lambda \in \tilde{\mathcal{P}}([0, 1])$ is called a regular increasing monotone (RIM) quantifier if Λ is a non-decreasing function such that $\Lambda(0) = 0$ and $\Lambda(1) = 1$.

Example II.3. The following RIM quantifiers represent the quantifiers “more than $100 * k\%$ ” and “at least $100 * k\%$ ”:

$$\Lambda_{>k}(p) = \begin{cases} 1 & \text{if } p > k \\ 0 & \text{elsewhere} \end{cases} \quad \Lambda_{\geq k}(p) = \begin{cases} 1 & \text{if } p \geq k \\ 0 & \text{elsewhere} \end{cases}$$

These RIM quantifiers also include (a representation of) the universal and existential quantifier, $\Lambda_{\forall} := \Lambda_{>0}$ and $\Lambda_{\exists} :=$

$\Lambda_{\geq 1}$. Linguistic quantifiers such as “most” and “some” can be modelled using Zadeh’s S-function ($0 \leq \alpha < \beta \leq 1$):

$$\Lambda_{(\alpha, \beta)}(p) = \begin{cases} 0 & p \leq \alpha \\ \frac{2(p-\alpha)^2}{(\beta-\alpha)^2} & \alpha \leq p \leq \frac{\alpha+\beta}{2} \\ 1 - \frac{2(p-\beta)^2}{(\beta-\alpha)^2} & \frac{\alpha+\beta}{2} \leq p \leq \beta \\ 1 & \beta \leq p \end{cases},$$

for example, we could use $\Lambda_{(0.3, 0.9)}$ and $\Lambda_{(0.1, 0.4)}$ to model “most” and “some”, respectively.

In Zadeh’s model, unary sentences of the form “ Λ X ’s are A ’s” and binary sentences of the form “ Λ A ’s are B ’s”, where Λ is a RIM quantifier and $A, B \in \tilde{\mathcal{P}}(X)$, are evaluated as

$$\tilde{Z}_{\Lambda}(A) = \Lambda\left(\frac{|A|}{|X|}\right), \quad (4)$$

$$\tilde{Z}_{\Lambda}^2(A, B) = \Lambda\left(\frac{|A \cap B|}{|A|}\right), \quad (5)$$

respectively, while in Yager’s OWA model, the unary sentence “ Λ X ’s are A ’s” is evaluated as

$$\tilde{Y}_{\Lambda}(A) := OWA_{\mathbf{w}^{\Lambda}}(A), \quad (6)$$

where

$$w_i^{\Lambda} := \Lambda\left(\frac{i}{n}\right) - \Lambda\left(\frac{i-1}{n}\right). \quad (7)$$

For the binary sentence “ Λ A ’s are B ’s”, there is no definite evaluation, although there are two that are most common in literature (cf. [24], [25]). The first one evaluates the sentence as

$$\tilde{Y}_{\Lambda}^{\mathcal{I}}(A, B) := \tilde{Y}_{\Lambda}(\mathcal{I}(A, B)) = OWA_{\mathbf{w}^{\Lambda}}(\mathcal{I}(A, B)), \quad (8)$$

where \mathcal{I} is an implicator, while the second one evaluates it as:

$$\tilde{Y}_{\Lambda}^2(A, B) := OWA_{\mathbf{v}^{\Lambda}}(\mathcal{I}(A, B)), \quad (9)$$

where

$$v_i := \Lambda\left(\frac{\sum_{j=1}^i A(x_j^*)}{|A|}\right) - \Lambda\left(\frac{\sum_{j=1}^{i-1} A(x_j^*)}{|A|}\right), \quad (10)$$

with $A(x_i^*)$ being the i th smallest $A(x)$ for $x \in X$ and $\sum_{j=1}^0 A(x_j^*) = \sum_{x \in \emptyset} x = 0$. Note that both \tilde{Z}_{Λ} and \tilde{Y}_{Λ} extend the semi-fuzzy quantifier

$$Q_{\Lambda}(A) := \Lambda\left(\frac{|A|}{|X|}\right). \quad (11)$$

E. Choquet-based fuzzy rough sets

Choquet-based fuzzy rough sets (CFRS) [17] have been introduced by noting that by Proposition II.12, we can rewrite OWAFRS as follows:

$$(\underline{\text{apr}}_{R, \mu_l} A)(y) = \int \mathcal{I}(R(x, y), A(x)) d\mu_l(x),$$

$$(\overline{\text{apr}}_{R, \mu_u} A)(y) = \int \mathcal{C}(R(x, y), A(x)) d\mu_u(x),$$

where μ_l and μ_u are two symmetric measures. Allowing non-symmetric measures gives us the definition of CFRS:

Definition II.16. [17] Given $R \in \tilde{\mathcal{P}}(X \times X)$, monotone measures μ_l and μ_u on X and $A \in \tilde{\mathcal{P}}(X)$, then the Choquet lower and upper approximation of A w.r.t. R , μ_l and μ_u are given by:

$$(\underline{\text{apr}}_{R, \mu_l} A)(y) = \int \mathcal{I}(R(x, y), A(x)) d\mu_l(x) \quad (12)$$

$$(\overline{\text{apr}}_{R, \mu_u} A)(y) = \int \mathcal{C}(R(x, y), A(x)) d\mu_u(x), \quad (13)$$

where \mathcal{I} is an implicator and \mathcal{C} is a conjunctor.

Example II.4. Suppose we have a crisp set O containing all the instances that are outliers, unreliable or inaccurate, then a useful pair of quantifiers could be “for all except (maybe) elements of O ” and “there exists an element in $X \setminus O$ ”. These quantifiers can be modelled by the partial minimum and maximum, which in turn are Choquet-integral operators with respect to non-symmetric measures (cf. [17]).

Using these non-symmetric measures in Equation (12) and (13), we get that the degree of membership of an element y to the lower approximation is equal to the truth value of the proposition “All trustworthy elements that are indiscernible to y are in A ”. An analogous interpretation holds for the upper approximation.

As we will see in Subsection II-F, it is possible to extend this approach of the previous example to fuzzy sets O and quantifiers representing “most of the trustworthy objects”. The following examples show how such fuzzy sets O can be constructed in practice.

Example II.5. Suppose we have a decision system $(X, A \cup \{d\})$ where d is a categorical attribute. Then we can define $O(x)$ as the normalized outlier score [18] of x (obtained from a certain outlier detection algorithm) when compared to other elements of $[x]_d$ (based on the conditional attributes). An outlier score measures the degree to which a data point differs from other observations, and normalization transforms this score in such a way that it can be interpreted as a degree of outlieriness.

Example II.6. Suppose X consists of patients from several different hospitals, A is the subset of patients that have a disease and R is a similarity relation between patients based on a set of symptoms. Then a confidence score c_i can be attached to each hospital i based on the accuracy of the tests performed to trace the disease (and the symptoms). The membership degree of a patient x of hospital i to O can then be defined as $O(x) = 1 - c_i$.

F. Examples of non-symmetric measures

As described in the previous subsection we can accommodate non-symmetry by introducing a fuzzy set O in X that represents the lack of confidence. The value $O(x)$ could, for example, be seen as an outlier score in $[0, 1]$ (Example II.5) or it could represent the unreliability or inaccuracy of the observation (Example II.6). We now recall several non-symmetric measures that were introduced in [17] using the fuzzy set O .

1) *Fuzzy removal*: the first option that was proposed to define a non-symmetric measure using O is as follows:

$$\mu_{\forall x \in X \setminus O}(S) = \begin{cases} 1 & \text{if } S = X \\ 0 & \text{if } S = \emptyset \\ \mathcal{T}(\underbrace{O(x)}_{x \in X \setminus S}) & \text{elsewhere} \end{cases}, \quad (14)$$

where \mathcal{T} is a t-norm (e.g. minimum) and $S \in \mathcal{P}(X)$. This measure is called the *fuzzy removal* measure, since in the case O is crisp, the Choquet integral with respect to this measure is equal to the partial minimum. The vague quantifier interpretation of the fuzzy removal measure could thus be “for all except (maybe) elements of O ”.

2) *Weighted ordered weighted average*: the second idea for a non-symmetric measure was:

$$\mu_{\Lambda}^{-O}(S) := \Lambda \left(\frac{|\neg O \cap S|}{|\neg O|} \right) = \Lambda \left(\sum_{x_i \in S} p_i \right), \quad (15)$$

where Λ is a RIM quantifier and \mathbf{p} a weight vector describing the confidence, reliability, accuracy or non-outlierness of each observation:

$$p_i = \frac{1 - O(x_i)}{n - \sum_{j=1}^n O(x_j)}. \quad (16)$$

The measure in Equation (15) corresponds to the Weighted Ordered Weighted Averaging (WOWA) operator [26], [27], which is a generalization of the OWA and the weighted mean. The RIM quantifier Λ determines the OWA part of the WOWA and the weight vector \mathbf{p} the weighted mean part. The WOWA operator is also equivalent with Yager’s importance weighted quantifier guided aggregation [2]. These measures could be interpreted as quantifiers of the form “ Λ of the trustworthy/reliable objects”.

III. BINARY QUANTIFICATION MODELS

We now take a deeper look at binary quantifiers (i.e. 2-ary fuzzy quantifiers), and in particular, proportional quantifiers such as “Most A ’s are B ’s”. To focus our attention we will make use of Zadeh’s approach of using RIM-quantifiers to model these quantifiers in their bare form.

A. QFM-based binary quantification models

To define binary fuzzy quantifiers using QFM’s, we first need semi-fuzzy quantifiers. The following definition proposes the two most viable options for semi-fuzzy quantifiers that model “ Λ A ’s are B ’s”, with Λ a RIM-quantifier.

Definition III.1. *Given a RIM-quantifier Λ , we define the following semi-fuzzy quantifiers:*

$$Q_{\Lambda}^2(A, B) := \Lambda \left(\frac{|A \cap B|}{|A|} \right),$$

$$Q_{\Lambda}^{\rightarrow}(A, B) = \Lambda \left(\frac{|A \rightarrow B|}{|X|} \right) := \Lambda \left(\frac{|\neg A| + |A \cap B|}{|X|} \right),$$

for crisp sets $A, B \in \mathcal{P}(X)$.

The first one is the most intuitive definition, but the second one is (as we will see) used a lot in practice, perhaps due to

its simplicity as we shall see later in this section (Corollary III.6). The semantical difference between Q_{Λ}^2 and $Q_{\Lambda}^{\rightarrow}$ is that of “Most A ’s are B ’s” and of “For most X ’s, if they are in A , they are in B ”. This is a very subtle difference and in day to day life both mean the same. In the first one only elements of A matter, while for the second one all elements matter. The following example demonstrates how important the difference is.

Example III.1. *Let us look at the difference between “Most Belgian people are not Belgian” and “For most people in the world, if they are Belgian, they are not Belgian”. Most people would say both sentences are plainly wrong. Let X denote the set of all people and $B \in \mathcal{P}(X)$ the subset of Belgian people, if we evaluate the first sentence using Q_{Λ} and the second one using $Q_{\Lambda}^{\rightarrow}$, we get the following:*

$$Q_{\Lambda}^2(B, \neg B) = \Lambda \left(\frac{|\emptyset|}{|B|} \right) = 0,$$

$$Q_{\Lambda}^{\rightarrow}(B, \neg B) = \Lambda \left(\frac{|\neg B|}{|X|} \right) \approx 1,$$

because the percentage of Belgians in the world is minuscule. So the second one is still correct, since for most people it holds that if they are Belgian, then they are not Belgian, since they are simply not from Belgium.

If \mathcal{F} is a QFM, we can use $\mathcal{F}(Q_{\Lambda}^2)$ and $\mathcal{F}(Q_{\Lambda}^{\rightarrow})$ to evaluate sentences of the form “ Λ A ’s are B ’s” for $A, B \in \tilde{\mathcal{P}}(X)$. We now take a look at the differences between the two. The first difference is the monotonicity. In the second argument both Q_{Λ} and $Q_{\Lambda}^{\rightarrow}$ are non-decreasing, hence so are $\mathcal{F}(Q_{\Lambda})$ and $\mathcal{F}(Q_{\Lambda}^{\rightarrow})$ for a DFS \mathcal{F} (argument monotonicity [3]). The difference between the two is in the first argument; let us add an element a to A and suppose Λ is a strictly increasing RIM-quantifier, if $a \in B$, then $Q_{\Lambda}^2(A, B)$ will strictly increase, while $Q_{\Lambda}^{\rightarrow}(A, B)$ stays unchanged, if $a \notin B$, then $Q_{\Lambda}^2(A, B)$ and $Q_{\Lambda}^{\rightarrow}(A, B)$ will strictly decrease. So in summary, $Q_{\Lambda}^{\rightarrow}$ is non-increasing in the first argument (hence $\mathcal{F}(Q_{\Lambda}^{\rightarrow})$ is as well), while Q_{Λ}^2 is not monotone in the first argument.

Proposition III.2. *We have the following inequality:*

$$Q_{\Lambda}^{\rightarrow}(A, B) \geq Q_{\Lambda}^2(A, B),$$

for every $A, B \in \mathcal{P}(X)$.

Proof.

$$\begin{aligned} & \Lambda \left(\frac{|\neg A| + |A \cap B|}{|X|} \right) \geq \Lambda \left(\frac{|A \cap B|}{|A|} \right) \\ \iff & \frac{|\neg A| + |A \cap B|}{|\neg A| + |A|} \geq \frac{|A \cap B|}{|A|} \\ \iff & (|\neg A| + |A \cap B|) * |A| \geq |A \cap B| * (|\neg A| + |A|) \\ \iff & |\neg A| * |A| \geq |A \cap B| * |\neg A| \\ \iff & |A| \geq |A \cap B| \end{aligned}$$

□

Corollary III.3. We have the following inequality for every DFS \mathcal{F} :

$$\mathcal{F}(Q_{\Lambda}^{\rightarrow})(A, B) \geq \mathcal{F}(Q_{\Lambda}^2)(A, B),$$

for every $A, B \in \tilde{\mathcal{P}}(X)$.

Proof. Every DFS satisfies quantifier monotonicity [3]. \square

We will now show that evaluating the binary quantifier $\mathcal{F}(Q_{\Lambda}^{\rightarrow})$ for fuzzy sets A, B and a DFS \mathcal{F} simply amounts to evaluating the fuzzy set $A \rightarrow B$ using the unary quantifier $\mathcal{F}(Q_{\Lambda})$, where \rightarrow is the implicator induced by the DFS \mathcal{F} (cf. [3]).

Definition III.4. Let $\tilde{Q} : (\tilde{\mathcal{P}}(X))^n \rightarrow [0, 1]$ be a fuzzy quantifier, then the fuzzy quantifier $Q \rightarrow : (\tilde{\mathcal{P}}(X))^{n+1} \rightarrow [0, 1]$ is defined as:

$$\tilde{Q} \rightarrow (A_1, \dots, A_{n+1}) := \tilde{Q}(A_1, \dots, A_{n-1}, (A_n \rightarrow A_{n+1})).$$

For a semi-fuzzy quantifier Q the semi-fuzzy quantifier $Q \rightarrow$ is defined analogously.

Proposition III.5. For every semi-fuzzy quantifier Q and DFS \mathcal{F} we have:

$$\mathcal{F}(Q \rightarrow) = \mathcal{F}(Q) \rightarrow.$$

Proof. This follows from

$$Q \rightarrow = Q \cap \neg$$

and the fact that a DFS is compatible with internal meets and internal negations [3]. \square

Corollary III.6. Let \mathcal{F} be a DFS and Q_{Λ} the unary quantifier from Equation (11), then:

$$\mathcal{F}(Q_{\Lambda}^{\rightarrow})(A, B) = \mathcal{F}(Q_{\Lambda})(A \rightarrow B),$$

for every $A, B \in \tilde{\mathcal{P}}(X)$.

Applying this to one of the most used QFM's, Glöckner's \mathcal{F}_{owa} [3], we can write one of Yager's binary quantification models as a QFM-based model:

Corollary III.7.

$$\mathcal{F}_{owa}(Q_{\Lambda}^{\rightarrow})(A, B) = \int \mathcal{I}_{KD}(A, B) d\mu_{\Lambda} = \tilde{Y}_{\Lambda}^{\mathcal{I}_{KD}}(A, B)$$

Proof. Follows from the fact that \mathcal{F}_{owa} is a standard DFS (thus the induced implicator is \mathcal{I}_{KD}) [3] and

$$\mathcal{F}_{owa}(Q)(A) = \int A dQ,$$

for every $A \in \tilde{\mathcal{P}}(X)$ and every semi-fuzzy quantifier Q that is also a monotone measure [3]. \square

Remark III.2. We can apply the exact same reasoning as in the previous corollary to the standard DFS \mathcal{M}_{CX} [3], to obtain

$$\mathcal{M}_{CX}(Q_{\Lambda}^{\rightarrow})(A, B) = (S) \int \mathcal{I}_{KD}(A, B) d\mu_{\Lambda},$$

where $(S) \int$ denotes the Sugeno integral [23].

B. Integral-based binary quantification models

We start off with rewriting Zadeh's and Yager's models using the Choquet integral to get a unifying view of these models.

Proposition III.8. Let Λ be a RIM-quantifier, $A, B \in \tilde{\mathcal{P}}(X)$ and \mathcal{I} an implicator. We can rewrite Zadeh's and Yager's evaluation models as follows:

$$\tilde{Z}_{\Lambda}(A) = \Lambda \left(\int A d\mu_{id} \right)$$

$$\tilde{Z}_{\Lambda}^2(A, B) = \Lambda \left(\frac{\int A \cap B d\mu_{id}}{\int A d\mu_{id}} \right)$$

$$\tilde{Y}_{\Lambda}(A) = \int A d\mu_{\Lambda}$$

$$\tilde{Y}_{\Lambda}^{\mathcal{I}}(A, B) = \int \mathcal{I}(A, B) d\mu_{\Lambda}$$

$$\tilde{Y}'_{\Lambda}(A, B) = \int \mathcal{I}(A, B) d\mu'_{\Lambda},$$

where

$$\mu_{\Lambda}(S) := \Lambda \left(\frac{|S|}{|X|} \right)$$

$$\mu'_{\Lambda}(S) := \Lambda \left(\frac{\sum_{j=1}^{|S|} A(x_j^*)}{|A|} \right),$$

with $A(x_i^*)$ being the i th smallest $A(x)$ for $x \in X$ and $S \in \mathcal{P}(X)$.

Proof. Follows from Propositions II.11 and II.12. \square

So both models can be written using integrals, but whereas Zadeh's model first integrates and then applies the RIM quantifier, Yager's model already incorporates the RIM quantifier in the measure used for integration.

Looking at Yager's model $\tilde{Y}_{\Lambda}^{\mathcal{I}}$ we can see that an element not in A contributes as much to the truth value as an element that is in A and in B , therefore the model has the same issues as mentioned in Example III.1. Quantifiers based on the semi-fuzzy quantifier Q_{Λ}^2 and a DFS do not suffer from this issue, but are computationally more complex. Therefore we now introduce a new binary quantification model that does an extra weighting on elements of A to compensate for the issues of $\tilde{Y}_{\Lambda}^{\mathcal{I}}$:

Definition III.9. Let Λ be a RIM-quantifier, \mathcal{I} an implicator and $A, B \in \tilde{\mathcal{P}}(X)$. We define the fuzzy quantifier $\tilde{W}_{\Lambda}^{\mathcal{I}} : \tilde{\mathcal{P}}(X) \rightarrow [0, 1]$ as:

$$\tilde{W}_{\Lambda}^{\mathcal{I}}(A, B) := \int \mathcal{I}(A, B) d\mu_{\Lambda}^A, \quad \mu_{\Lambda}^A(S) := \Lambda \left(\frac{|S \cap A|}{|A|} \right),$$

where $S \in \mathcal{P}(X)$.

Remark III.3. By replacing the Choquet integral in the previous definition with the Sugeno integral, or even general pan-integrals (for more information about these integrals see [23]), we obtain other novel quantifiers that are worth studying. Because Glöckner's model \mathcal{M}_{CX} corresponds to the Sugeno

integral (Remark III.2), this can give us a good compromise (between computational simplicity and semantical soundness) for the $\mathcal{M}_{CX}(Q_\Lambda^2)$ model.

This quantifier indeed resembles $\tilde{Y}_\Lambda^{\mathcal{I}}(A, B)$ but with an extra weighting on A . The quantifier \tilde{Y}_Λ^2 also does this but in a less intuitive and elegant way, by doing an extra ordering of the elements. Comparing the two, we see that the new definition uses a weighted ordered weighted averaging (WOWA) with Λ for the OWA part and $p_i = A(x_i)/|A|$ for the weighted mean part, while the quantifier \tilde{Y}_Λ^2 uses an OWA operator with weights given by Equation (10).

The following proposition describes how all of these fuzzy quantifiers act on crisp sets, i.e., what their underlying semi-fuzzy quantifiers are.

Proposition III.10. *The following equalities hold:*

$$\begin{aligned}\tilde{W}_\Lambda^{\mathcal{I}}(A, B) &= Q_\Lambda(A, B), \\ \tilde{Y}_\Lambda^2(A, B) &= Q_\Lambda(A, B), \\ \tilde{Z}_\Lambda^2(A, B) &= Q_\Lambda(A, B), \\ \tilde{Y}_\Lambda^{\mathcal{I}}(A, B) &= Q_\Lambda^{\rightarrow}(A, B),\end{aligned}$$

for all crisp sets $A, B \in \mathcal{P}(X)$.

Proof. We will only prove the first and second equality, the rest are analogous or trivial. Let $A, B \in \mathcal{P}(X)$ be two crisp sets, then:

$$\begin{aligned}\mathcal{U}(\tilde{W}_\Lambda^{\mathcal{I}})(A, B) &= \int \mathcal{I}(A, B) d\mu_\Lambda^A = \mu_\Lambda^A(\mathcal{I}(A, B)) \\ &= \mu_\Lambda^A(\neg A \cup B) \\ &= \Lambda\left(\frac{|A \cap B|}{|A|}\right) = Q_\Lambda(A, B),\end{aligned}$$

which proves the first equality. For the second equality:

$$\begin{aligned}\mathcal{U}(\tilde{Y}_\Lambda^2)(A, B) &= \int \mathcal{I}(A, B) d\mu'_\Lambda = \mu'_\Lambda(\mathcal{I}(A, B)) \\ &= \mu'_\Lambda(\neg A \cup B) \\ &= \mu'_\Lambda(\neg A \cup (A \cap B))\end{aligned}$$

But for crisp sets A the measure μ'_Λ reduces to:

$$\mu'_\Lambda(S) = \begin{cases} 0 & \text{if } |S| \leq |\neg A| \\ \frac{|S| - |\neg A|}{|A|} & \text{if } |S| > |\neg A| \end{cases},$$

from which we get the desired

$$\begin{aligned}\mathcal{U}(\tilde{Y}_\Lambda^2)(A, B) &= \mu'_\Lambda(\neg A \cup (A \cap B)) \\ &= \Lambda\left(\frac{|\neg A \cup (A \cap B)| - |\neg A|}{|A|}\right) \\ &= \Lambda\left(\frac{|A \cap B|}{|A|}\right).\end{aligned}$$

□

The previous proposition thus shows that both \tilde{Y}_Λ^2 and $\tilde{W}_\Lambda^{\mathcal{I}}$ apply the correct weighting on A such that for crisp arguments the quantifiers act intuitively.

IV. FUZZY QUANTIFIER-BASED FUZZY ROUGH SETS

Let us take another look at OWAFRS and rewrite its approximations as follows:

$$\begin{aligned}(\underline{\text{apr}}_{R, \mu_l} A)(y) &= \int \mathcal{I}(R(x, y), A(x)) d\mu_l(x), \\ &= \tilde{Y}_\Lambda^{\mathcal{I}}(Ry, A)\end{aligned}\quad (17)$$

$$\begin{aligned}(\overline{\text{apr}}_{R, \mu_u} A)(y) &= \int \mathcal{C}(R(x, y), A(x)) d\mu_u(x) \\ &= \tilde{Y}_\Upsilon(Ry \cap_C A),\end{aligned}\quad (18)$$

where μ_l and μ_u are symmetric measures, and Λ and Υ are their corresponding RIM-quantifiers (cf. Section 3.4 in [17]). Thus, the lower and upper approximations of OWAFRS are evaluated by evaluating vaguely quantified propositions using Yager's quantification model ($\tilde{Y}_\Lambda^{\rightarrow}$ and \tilde{Y}_Λ). We now introduce fuzzy quantifier-based fuzzy rough sets (FQFRS) by allowing general (binary for lower approximation and unary for upper approximation) quantification models.

Definition IV.1 ($(\tilde{Q}_l, \tilde{Q}_u)$ -fuzzy rough set). *Given a reflexive fuzzy relation $R \in \mathcal{F}(X \times X)$, fuzzy quantifiers $\tilde{Q}_l : (\tilde{\mathcal{P}}(X))^2 \rightarrow [0, 1]$ and $\tilde{Q}_u : \tilde{\mathcal{P}}(X) \rightarrow [0, 1]$, and $A \in \mathcal{F}(X)$, then the lower and upper approximation of A w.r.t. R are given by:*

$$\begin{aligned}(\underline{\text{apr}}_{R, \tilde{Q}_l} A)(y) &= \tilde{Q}_l(Ry, A), \\ (\overline{\text{apr}}_{R, \tilde{Q}_u} A)(y) &= \tilde{Q}_u(Ry \cap_C A),\end{aligned}$$

where \mathcal{C} is a conjunctor.

Suppose \tilde{Q}_l and \tilde{Q}_u represent the (linguistic) quantifiers “most” and “some”, respectively. Then the degree of membership of an element y to the lower approximation of A is equal to the truth value of the statement “Most elements similar to y are in A ”. The degree of membership of y to the upper approximation is equal to the truth value of the statement “Some elements are similar to y and are in A ”.

A. Examples of FQFRS models

1) $(\tilde{Z}_\Lambda^2, \tilde{Z}_\Upsilon)$ -FRS: let us take a look at the model derived from the most simple quantification model, the one from Zadeh. Let Λ and Υ be two RIM-quantifiers, then the lower and upper approximation for $(\tilde{Z}_\Lambda^2, \tilde{Z}_\Upsilon)$ -fuzzy rough sets are defined as:

$$\begin{aligned}(\underline{\text{apr}}_{R, \Lambda} A)(y) &:= \tilde{Z}_\Lambda^2(Ry, A) = \Lambda\left(\frac{|Ry \cap A|}{|Ry|}\right), \\ (\overline{\text{apr}}_{R, \Upsilon} A)(y) &:= \tilde{Z}_\Upsilon(Ry \cap A) = \Upsilon\left(\frac{|Ry \cap A|}{|X|}\right).\end{aligned}$$

This closely resembles the Vaguely Quantified Fuzzy Rough Sets (VQFRS) model [7], which uses the following lower and upper approximations:

$$\begin{aligned}(\underline{\text{apr}}_{R, \Lambda}^{\text{VQFRS}} A)(y) &:= \Lambda\left(\frac{|Ry \cap A|}{|Ry|}\right) = \tilde{Z}_\Lambda^2(Ry, A), \\ (\overline{\text{apr}}_{R, \Upsilon}^{\text{VQFRS}} A)(y) &:= \Upsilon\left(\frac{|Ry \cap A|}{|Ry|}\right) = \tilde{Z}_\Upsilon^2(Ry, A).\end{aligned}$$

For both models the lower approximations are identical, but whereas for VQFRS the lower and upper approximation only differ in their used RIM-quantifier, $(\tilde{Z}_\Lambda^2, \tilde{Z}_\Upsilon)$ -FRS evaluates the upper approximations using Zadeh's unary quantifier \tilde{Z}_Υ . Comparing the upper approximations of these two models, we can see that VQFRS will always be larger ($|X| \geq |Ry|$ and Υ is a RIM-quantifier). In some cases the upper approximation of VQFRS might be too large. For example, as soon as an element does not have a similar element ($Ry = \emptyset$) it is in the upper approximation of any concept A , even if there are many elements that are not that similar to y (e.g. $(Ry)(x) = 0.01$) but are in A (and not many elements similar to y) it will be in the upper approximation (cf. next example). Thus if one wants to discard the outlying elements from the upper approximation, this is problematic. This happens to a lesser extent with $(\tilde{Z}_\Lambda^2, \tilde{Z}_\Upsilon)$ -FRS, but it is still susceptible to it due to the accumulative nature of the Σ -count, as the following example shows.

Example IV.1. Suppose there are 10 elements in A with a similarity of 0.1 to $y \notin A$ and the rest of the elements are not similar to y at all ($|Ry \cap A| = 1$ and $|Ry| = 2$), then the upper approximation would always be 1 in the VQFRS approach:

$$(\overline{apr}_{R,\Upsilon}^{VQFRS} A)(y) = \tilde{Z}_\Upsilon^2(Ry, A) = \Upsilon(0.5) := 1,$$

since Υ should represent "some". In $(\tilde{Z}_\Lambda^2, \tilde{Z}_\Upsilon)$ -FRS we get a less extreme result:

$$(\overline{apr}_{R,\Upsilon} A)(y) = \tilde{Z}_\Upsilon(Ry \cap A) = \Upsilon\left(\frac{1}{|X|}\right).$$

So in conclusion, with VQFRS the outliers will always belong more to the upper approximation than with $(\tilde{Z}_\Lambda^2, \tilde{Z}_\Upsilon)$ -FRS. Lastly we note that using the existential quantifier (i.e. $\Upsilon = \Lambda_\exists$) the two upper approximations are equivalent ($|Ry| \geq 1$ since R is reflexive).

2) $(\tilde{Y}_\Lambda^{\rightarrow}, \tilde{Y}_\Upsilon)$ -FRS: since Yager's model is generally accepted as a better model compared to Zadeh's, we now take a look at $(\tilde{Y}_\Lambda^{\rightarrow}, \tilde{Y}_\Upsilon)$ -fuzzy rough sets. As shown in Equations (17) and (18), $(\tilde{Y}_\Lambda^{\rightarrow}, \tilde{Y}_\Upsilon)$ -FRS corresponds to OWAFRS which is preferred over VQFRS [20]. So this justifies the improvement from a fuzzy quantifier perspective why OWAFRS are better than VQFRS. To justify even more why this is a good model we know from Corollary III.7 that when using the Kleene-Dienes implicator, OWAFRS are equal to $(\mathcal{F}_{owa}(Q_\Lambda^{\rightarrow}), \mathcal{F}_{owa}(Q_\Upsilon))$ -FRS. So OWAFRS use a DFS mechanism, which is known to be semantically sound.

3) Other FQFRS: a problem with OWAFRS from a fuzzy quantifier perspective is that it makes use of the semi-fuzzy quantifier Q_Λ^{\rightarrow} , which is not that intuitive. Therefore $(\mathcal{F}_{owa}(Q_\Lambda^2), \mathcal{F}_{owa}(Q_\Upsilon))$ -FRS are preferable, since they make more sense on crisp sets (semi-fuzzy quantifiers), and are thus better suited for explainability when used for classification e.g. "Most people similar to y are not able to pay off their mortgage". Instead of \mathcal{F}_{owa} other DFS could also be used like the M_{CX} model [3], which is known to be a standard

DFS with many good properties, or the \mathcal{F}^A a non-standard DFS [28]. For a compromise between semantical soundness and computational efficiency, one could also use the quantifier $\tilde{Y}_\Lambda^2, \tilde{W}_\Lambda^2$ or \tilde{W}_Λ^2 using another integral (Remark III.3).

Example IV.2. Evaluating " ΛRy are A " using Q_Λ^{\rightarrow} gives us:

$$\Lambda\left(\frac{|Ry \rightarrow A|}{|X|}\right) = \Lambda\left(\frac{|\neg Ry| + |Ry \cap A|}{|X|}\right).$$

Thus the smaller the cardinality of Ry , the more true the statement is. This is not really what one would expect, because this causes the lower approximation to be large. Let $y \notin A$ be an instance that is an outlier (Ry only contains y), then the membership of y to the lower approximation of A is always very high (regardless of A). Using Q_Λ^2 instead would not result in this problem.

So this example suggests that using quantifiers with Q_Λ^2 as underlying semi-fuzzy quantifier might be preferable.

4) Choquet-based fuzzy rough sets: Choquet-based fuzzy rough sets correspond to $(C_{\mu_l}^{\mathcal{I}}, C_{\mu_u})$ -FRS with the fuzzy quantifiers $C_{\mu_l}^{\mathcal{I}}, C_{\mu_u}$ being defined as

$$C_{\mu_l}^{\mathcal{I}}(A, B) := \int \mathcal{I}(A, B) d\mu_l,$$

$$C_{\mu_u}(A) := \int A d\mu_u,$$

for every implicator \mathcal{I} and monotone measures μ_l and μ_u . When the measures μ_u and μ_l are symmetric these quantifiers are quantitative (i.e. each element is regarded as the same) and reduce to Yager's quantifiers like mentioned before. Note that all quantifiers mentioned in this section up until this point are quantitative. The interesting part of CFRS, when compared to OWAFRS, was that it allowed non-symmetric measures. We will now take a look at this from a FQFRS perspective for the non-symmetric measures discussed in Section II-F.

- Fuzzy removal measure Equation (14):

If $\mu_l = \mu_\forall$, then the quantifier $C_{\mu_l}^{\mathcal{I}}$ represents "for all except (maybe) elements of O ", thus it can be seen as the quantifier $\tilde{Y}_{\Lambda_\forall}^{\mathcal{I}}$ but not regarding elements of O .

- WOVA measure Equation (15):

If $\mu_l = \mu_\forall$, then the quantifier $C_{\mu_l}^{\mathcal{I}}$ represents " Λ elements except (maybe) elements of O ", thus it can be seen as the quantifier $\tilde{Y}_\Lambda^{\mathcal{I}}$ but not regarding elements of O . Do note that for $\Lambda = \Lambda_\forall$ this quantifier represents the same quantifier as the fuzzy removal measure, but the evaluation is different.

B. Confidence-based FQFRS

In the previous section we have seen that we are able to seamlessly incorporate outlier information in FQFRS by making use of non-quantitative quantifiers (an implicit way). But it is also possible to do this using quantitative quantifiers (a more explicit way):

Definition IV.2. Given a reflexive fuzzy relation $R \in \mathcal{F}(X \times X)$, $O \in \mathcal{F}(X)$, fuzzy quantifiers $\tilde{Q}_l : (\tilde{P}(X))^3 \rightarrow [0, 1]$ and

$\tilde{Q}_u : (\tilde{P}(X))^2 \rightarrow [0, 1]$ and $A \in \mathcal{F}(X)$, then the lower and upper approximation of A w.r.t. R , \tilde{Q}_l and \tilde{Q}_u are given by:

$$\begin{aligned} (\underline{apr}_{R, \tilde{Q}_l} A)(y) &= \tilde{Q}_l(O, Ry, A), \\ (\overline{apr}_{R, \tilde{Q}_u} A)(y) &= \tilde{Q}_u(O, Ry \cap_C A). \end{aligned}$$

For example, let CS be a fuzzy set describing the accuracy-/confidence of the instances in X , \tilde{Q}_l a quantifier modelling “Most elements except maybe non confident elements” and \tilde{Q}_u a quantifier modelling “Some confident elements”, then an element y is “in” the lower approximation if most accurate/confident elements indiscernible from y are in A , and an element y is “in” the upper approximation if there are some accurate/confident elements that are indiscernible to y and are “in” A .

Example IV.3. Using a binary quantifier \tilde{Q}_l (e.g. representing “Most”) and a unary quantifier \tilde{Q}_u (e.g. representing “Some”) we can do this as follows:

$$\begin{aligned} (\underline{apr}_{R, \tilde{Q}_l} A)(y) &= \tilde{Q}_l((\tilde{\neg}O) \cap_C Ry, A), \\ (\overline{apr}_{R, \tilde{Q}_u} A)(y) &= \tilde{Q}_u((\tilde{\neg}O) \cap_C Ry \cap_C A). \end{aligned}$$

V. CONCLUSION

We have introduced *fuzzy quantifier-based fuzzy rough sets* (FQFRS), a general definition of fuzzy rough sets based on fuzzy quantifiers. FQFRS allows to position existing models and compare them on the basis of their associated fuzzy quantifiers. In addition, this general model can lead to improved models in terms of performance and interpretability. Currently, there are only a few models that make explicit use of quantifiers, but these can be improved by using more semantically sound evaluation models. Furthermore, we have introduced novel binary quantification models based on integrals, that might give us a good compromise between computational efficiency and semantical soundness. Finally, we have introduced confidence-based FQFRS that are able to perform active outlier/noise reduction, i.e., taking into account outlier information (e.g., obtained by an outlier detection algorithm), in a more explicit and general way compared to CFRS.

VI. FUTURE WORK

From a theoretical perspective, it is interesting to find out how the properties of the used quantifiers translate to properties of the corresponding fuzzy rough sets, and vice versa. Also, it is possible to study the new fuzzy quantifiers including the quantifiers corresponding with the fuzzy removal and WOWA measures, and comparing them with existing quantifiers. Lastly we plan to perform an experimental study of the performance of the different fuzzy quantifier-based fuzzy rough sets by testing it in fuzzy rough set based classifiers similar to those considered by Lenz et al [29].

Abstract—In this paper we propose a novel rough-fuzzy hybridization technique to feature selection and feature ranking problem. The idea is to model the local preference relation between pair of features by intuitionistic fuzzy values and search for a feature ranking that is consistent with those constraints. We apply the techniques used in group decision making where constraints are presented in form of intuitionistic fuzzy preference relation. The proposed method has been illustrated by some simple examples and verified on a benchmark dataset.

Index Terms—Intuitionistic fuzzy matrix, feature ranking, reducts, rough sets.

I. INTRODUCTION

DECISION making plays an extremely important role in the real life problems. With strong development of datasets having a great deal of features, recognizing preferred features is a challenging task. In recent years, rough-fuzzy hybridization becomes a hot trend with great success in machine learning, data mining, decision making, etc. [1].

Usually, a group decision-making process must collect all decision-makers's opinions, establish a suitable method for measuring them, obtain the final scores of all alternatives, and then rank them. Decision makers have to rank the alternatives, find the most preferred feature in order to make decision. So, preference relations are effective techniques to gather the overviews of a group of decision makers. Recently, many researchers have developed many methods of preference relations [2], [3], [4], [5], [6][7]. To solve decision-making problems with uncertain information or not precise judgments, preference relations with Zadeh's fuzzy sets are proposed. There are two number values to measure the degree of membership and nonmembership in Zadeh's fuzzy theory with sum is one, but ignore the decision maker's hesitation in the decision making process. The Atanassov's intuitionistic fuzzy sets consider fully expressing affirmation, negation and hesitation. Particularly, the usage of intuitionistic fuzzy preference relation to affirmative, negative and hesitant characteristics makes the research problem more and more attractive and competitive.

Real world problems may have numerous irrelevant features, and in such cases feature selection can help decision makers choose important information hidden in the full dataset. Feature selection (FS) method belongs to one of the

three main groups: embedded, filter or wrapper methods and can be defined as selecting a subset of available features in a dataset that is associated with the response variables by excluding irrelevant and unnecessary features. An alternative to FS for dimensionality reduction is feature extraction (FE) in which original features are united and then projected into a new feature space with smaller dimensionality. In this paper, we interpret the feature selection and feature ranking as decision making problems and apply the recent techniques for solving it.

In the process of group making decisions, there are often many different opinions of defining the degree of certainty, uncertainty or hesitation among decision makers (DMs). Therefore, it's necessary to define an intuitionistic fuzzy preference relation which have the capability of representing all selections. The consistency of intuitionistic fuzzy preference relations (IFPRs) and the priority weights of DMs gathered from these preference relations play a vital role in group making decision to lead to the most best result. In some works, the consequences of additive consistent and multiplicative consistent IFPRs on priority weights is examined and considered to calculate the priority weights. Numerical analyses have shown that the ranking of the individual priority weights do not differ seriously despite of the different priority weight vectors of the individual priority weights. The intuitionistic fuzzy preference relation is introduced as an indispensable tool for enabling decision-makers to judge the superiority or inferiority of one object to another, in the presence of fuzziness. Ranking methods for alternatives with intuitionistic fuzzy information are expressed straightforwardly and efficiently to get the solution of group decision problems.

The paper is organized as follows: in Section II we recall some basic notions in intuitionistic fuzzy set theory and rough set theory. Section III describes ranking methods that are consistent or semi-consistent with one or more intuitionistic fuzzy preference relations. In Section IV, we present a rough-fuzzy hybridization method for feature ranking and illustrate the proposed method on the base of some simple examples. The results of experiments on the accuracy of the feature ranking methods in the context of classification task are reported in Section V. The conclusions and plan for future research are presented in Section VI.

II. BASIC NOTIONS

In this section we present some fundamental knowledge about intuitionistic fuzzy set, intuitionistic fuzzy relation and feature reduction in rough set theory.

A. Intuitionistic fuzzy sets and Intuitionistic fuzzy matrices

Fuzzy set (FS) theory which was introduced by Zadeh in 1975 [8] just considers the problems with the degree of membership and non-membership without mentioning the degree of hesitation of no decision-making. The Atanassov's intuitionistic fuzzy set (IFS) theory [9] considers fully expressing affirmation, negation and hesitation of decision-makers. Therefore, with real-life situations, IFS theory solves the problems more successfully than FS theory. In this part, some basic notions related to IFS are recalled.

Definition 1 (IFS [9]). Let $X = \{x_1, x_2, \dots, x_m\}$ be a finite universal set. An intuitionistic fuzzy set in X is a set $A = \{(x_i, \mu_A(x_i), \nu_A(x_i)) : x_i \in X\}$, where $\mu_A(x_i), \nu_A(x_i) \in [0, 1]$ and $0 \leq \mu_A(x_i) + \nu_A(x_i) \leq 1$ for any $x_i \in X$. The functions $\mu_A : X \rightarrow [0, 1]$ and $\nu_A : X \rightarrow [0, 1]$ are called the membership and non-membership functions, respectively.

The value $\pi_A(x_i) = 1 - \mu_A(x_i) - \nu_A(x_i)$ is called the intuitionistic index of the element x_i in the set A . It describes a degree of hesitation (or uncertainty) whether x_i is in A or not. For any $x_i \in X$, we have $0 \leq \pi_A(x_i) \leq 1$.

The class of IFS in a universe X is denoted by $\mathcal{IFS}(X)$.

Let \mathcal{F} be the set of tuples (a_1, a_2) , where $a_1, a_2 \in [0, 1]$ and $a_1 + a_2 \leq 1$, i.e.,

$$\mathcal{F} = \{(a_1, a_2) \in [0, 1]^2 : a_1 + a_2 \leq 1\}.$$

A partial order $\leq_{\mathcal{F}}$ over \mathcal{F} defined by:

$$(a_1, a_2) \leq_{\mathcal{F}} (b_1, b_2) \Leftrightarrow a_1 \leq b_1 \text{ and } a_2 \geq b_2.$$

The elements of \mathcal{F} are called the intuitionistic fuzzy values (IFV), of which $(0, 1)$ is the least element and $(1, 0)$ is the greatest element. The operations in $(\mathcal{F}, \leq_{\mathcal{F}})$ are defined by

$$(a_1, a_2) \vee (b_1, b_2) = (\max\{a_1, b_1\}, \min\{a_2, b_2\}).$$

$$(a_1, a_2) \wedge (b_1, b_2) = (\min\{a_1, b_1\}, \max\{a_2, b_2\})$$

$$(a_1, a_2)^c = (a_2, a_1).$$

Each IFS of a universe X is in fact a map from X to \mathcal{F} . If A and B are two IFSs defined by (μ_A, ν_A) and (μ_B, ν_B) , correspondingly, then the union, intersection and complement are defined as follows:

$$\begin{aligned} (\mu_{A \cup B}, \nu_{A \cup B}) &= (\mu_A, \nu_A) \vee (\mu_B, \nu_B) \\ &= (\max\{\mu_A, \mu_B\}, \min\{\nu_A, \nu_B\}) \end{aligned}$$

$$\begin{aligned} (\mu_{A \cap B}, \nu_{A \cap B}) &= (\mu_A, \nu_A) \wedge (\mu_B, \nu_B) \\ &= (\min\{\mu_A, \mu_B\}, \max\{\nu_A, \nu_B\}) \end{aligned}$$

$$(\mu_{A^c}, \nu_{A^c}) = (\mu_A, \nu_A)^c = (\nu_A, \mu_A)$$

$$A \subseteq B \Leftrightarrow (\mu_A, \nu_A) \leq_{\mathcal{F}} (\mu_B, \nu_B)$$

Relations (between two sets X and Y) in traditional set theory are defined as subsets of the Cartesian product $X \times Y$.

It is quite natural to define intuitionistic fuzzy relations as IFSs in $X \times Y$. If $X = \{x_1, \dots, x_m\}$ and $Y = \{y_1, \dots, y_n\}$, then any intuitionistic fuzzy relation in $X \times Y$ can be represented by an $m \times n$ matrix $R = (\rho_{ij})_{m \times n}$, where $\rho_{ij} = (\mu_{ij}, \nu_{ij}) \in \mathcal{F}$ is the IFV describing the membership and non-membership of (x_i, y_j) to this relation.

Definition 2 (Intuitionistic fuzzy matrices - IFM). Any matrix P of order $n \times m$ with values from $\mathcal{F} = \{(a_1, a_2) \in [0, 1]^2 : a_1 + a_2 \leq 1\}$ is called Intuitionistic Fuzzy Matrices. An IFM is said to be square intuitionistic fuzzy matrix (SIFM) if the number of rows is equal to the number of columns. Moreover:

- 1) An identity IFM \mathbb{I} of order n is the square intuitionistic fuzzy matrix (SIFM) of order n with all diagonal entries $(1, 0)$ and non-diagonal entries $(0, 1)$.
- 2) A null intuitionistic fuzzy matrix (IFM) \mathbb{O} of order n is the square intuitionistic fuzzy matrix (SIFM) of order n with all entries $(0, 1)$.

The concepts of intuitionistic fuzzy relation and intuitionistic fuzzy matrix (IFM) have been studied by many authors [10], [11], [12]. IFM is a generalization of Fuzzy Matrix and has been useful in dealing with decision-making, clustering analysis, relational equations, etc.

Since IFM is an extension of FM by replacing the values from $[0, 1]$ by IFV, i.e. elements of $\mathcal{F} = \{(a_1, a_2) \in [0, 1]^2 : a_1 + a_2 \leq 1\}$, and the fuzzy operations \vee and \wedge were extended for the elements of \mathcal{F} . Most of operations on fuzzy matrices can be also extended for IFMs. In particular, if $A = (a_{ij}), B = (b_{ij}) \in \mathcal{F}_{m \times n}$, where $a_{ij} = (\mu_{ij}^a, \nu_{ij}^a), b_{ij} = (\mu_{ij}^b, \nu_{ij}^b)$, for $i = 1, \dots, m; j = 1, \dots, n$ then

- disjunction and conjunction are defined by:

$$A \vee B = (a_{ij} \vee b_{ij})_{m \times n} = (\delta_{ij})_{m \times n}$$

$$\text{where } \delta_{ij} = (\min\{\mu_{ij}^a, \mu_{ij}^b\}, \max\{\nu_{ij}^a, \nu_{ij}^b\}).$$

$$A \wedge B = (a_{ij} \wedge b_{ij})_{m \times n} = (\gamma_{ij})_{m \times n}$$

$$\text{where } \gamma_{ij} = (\max\{\mu_{ij}^a, \mu_{ij}^b\}, \min\{\nu_{ij}^a, \nu_{ij}^b\}).$$

- Comparison: $A \leq B \Leftrightarrow a_{ij} \leq b_{ij}$ for all $i = 1, 2, \dots, m$ and $j = 1, 2, \dots, n$.
- The tranpose of $A = (a_{ij})_{m \times n}$ is $A^T = (x_{ij})_{n \times m}$, where $x_{ij} = a_{ji}$.
- The composition of two relations or the product of two matrices $A \in \mathcal{F}_{m \times n}$ and $C \in \mathcal{F}_{n \times l}$ is the matrix $D = (d_{ij}) \in \mathcal{F}_{m \times l}$, where

$$\begin{aligned} d_{ij} &= \bigvee_{k=1}^n (a_{ik} \wedge c_{kj}) = \left(\bigvee_{k=1}^n (\mu_{ik}^a \wedge \mu_{kj}^c), \bigwedge_{k=1}^n (\nu_{ik}^a \vee \nu_{kj}^c) \right) \\ &= \left(\max_{k=1, \dots, n} \{\min\{\mu_{ik}^a, \mu_{kj}^c\}\}, \min_{k=1, \dots, n} \{\max\{\nu_{ik}^a, \nu_{kj}^c\}\} \right). \end{aligned}$$

This operation is denoted by $D = A \circ C$.

B. Feature selection and feature ranking problem

In machine learning, a classification task is defined as the problem of learning the partition of a set of objects into subsets called decision classes (or briefly classes). The partition should

be expressed in terms of object features. Let U be a set of objects. Any function $a : U \rightarrow V_a$, where V_a is the domain (the set of possible values) of a , is called a feature or attribute for U . If a is a measurement such as a person's weight, height, blood pressure or the weather temperature, i.e. V_a is a real interval, then a is called the numeric or quantitative feature. Otherwise, if the values in V_a are not comparable, or if they can not be ordered in a linear order, then a is called categorical, symbolic or qualitative feature.

Decision table is a tuple $T = (U, A \cup \{d\})$, where $U = \{u_1, u_2, \dots, u_n\}$ is a finite set of objects, $A = \{a_1, a_2, \dots, a_m\}$ is a finite set of features called conditional attributes and d is the decision attribute, i.e. the attribute defining the partition of objects into decision classes. Any decision table $T = (U, A \cup \{d\})$ stores a training data set $D = \{(\mathbf{x}_1, y_1), \dots, (\mathbf{x}_n, y_n)\}$ for machine learning algorithms, where $\mathbf{x}_i = (a_1(u_i), \dots, a_m(u_i))$ and $y_i = d(u_i)$.

The goal of the feature selection (FS) problem for decision table $T = (U, A \cup \{d\})$ is to determine the minimal subsets of A satisfying a particular classification performance requirement. Feature ranking problem is to order the feature in a ranking list so that the more important features are at the beginning of the ranking list while the less important features are at the end of the ranking list.

C. Rough Sets and feature selection problem

In rough set theory, the FS problem is formulated as a problem of searching for reducts. Intuitively, reducts of a decision table $T = (U, A \cup \{d\})$ are the minimal subsets (with respect to inclusion) of the set of all attributes A that guarantee the classification performance of the reduced decision table. In the pioneering paper in rough set theory [13], [14], [15], the classification performance was defined in terms of the discernibility between the objects. Formally, for any subset $B \subset A$ and two objects $u, v \in U$, we say that

$$\begin{aligned} B \text{ discerns } u \text{ and } v \text{ (or } u, v \text{ are discernible by } B) \\ \Leftrightarrow \text{there exists } b \in B \text{ such that } b(u) \neq b(v) \end{aligned}$$

The set $B \subset A$ is called the reduct of decision table T if

- For any $u, v \in U$, if u, v are discernible by A and discernible by $\{d\}$ then u, v are discernible by B ;
- No proper subset of B satisfies the previous condition.

This original concept of reducts has been generated by many researchers [16], [17], [18]. However, the solution space for the problem of searching for the reduct with minimal cardinality is $2^m - 1$ where $m = |A|$.

The first approach to minimal reduct problem has been proposed in [14]. For the given decision table $T = (U, A \cup \{d\})$ with $U = \{u_1, u_2, \dots, u_n\}$ and $A = \{a_1, a_2, \dots, a_m\}$, the authors constructed a discernibility matrix $\mathbb{M}(T)$, which is in fact a function $\mathbb{M}(T) : U \times U \rightarrow \mathcal{P}(A)$, where $\mathcal{P}(A)$ denotes the power set of A . For each two objects $u_i, u_j \in U$, we denote $\mathbb{M}(T)(u_i, u_j) = S_{ij}$, where

$$S_{ij} = \begin{cases} \emptyset & \text{if } d(x_i) = d(x_j) \\ \{a \in A : a(x_i) \neq a(x_j)\} & \text{otherwise} \end{cases}$$

The example of discernibility matrix is presented in Table II.

One can notice that a subset of attributes $B \subset A$ discerns a pair of objects $u_i, u_j \in U$ if and only if $B \cap S_{ij} \neq \emptyset$.

Let us notice that for any $u_i, u_j \in U$ we have $S_{ij} = S_{ji}$. That's why, in case of the decision table with two decision classes, the discernibility matrix can be simplified into $p \times q$ matrix where p and q are the cardinalities of the two decision classes.

Since minimal reduct calculation problem is NP-hard, many heuristics algorithms are using random permutations of features [16], [19] as a nondeterministic policy and the algorithm is searching for the reduct according to the attribute order defined by the given permutations.

III. FROM INTUITIONISTIC FUZZY PREFERENCE RELATION TO RANKING.

In this Section we present a method of using Intuitionistic Fuzzy Sets to approximate the concept of fuzzy preference [20] [21], [22].

Definition 3 (intuitionistic fuzzy preference relation). *An intuitionistic fuzzy preference relation B on $X = \{x_1, \dots, x_n\}$ is defined as a matrix $B = (b_{ij})_{n \times n}$, where $b_{ij} = (\mu_{ij}, \nu_{ij})$ for all $i, j = 1, 2, \dots, n$ is an intuitionistic fuzzy value, composed by the certainty degree μ_{ij} to which x_i is preferred to x_j and the certainty degree ν_{ij} to which x_i is non-preferred to x_j , and $\pi_{ij} = 1 - \mu_{ij} - \nu_{ij}$ is interpreted as the hesitation degree to which x_i is preferred to x_j . Moreover, μ_{ij} and ν_{ij} satisfy the following conditions:*

$$\mu_{ij} + \nu_{ij} \leq 1, \quad \mu_{ij} = \nu_{ji}, \quad \mu_{ii} = \nu_{ii} = 0.5$$

for all $i, j = 1; 2; \dots, n$.

Usually, the intuitionistic fuzzy preference relation expresses the opinions of the decision makers about each pair of choices (alternatives), but we would like to convert this relation into a linear order (a ranking list). We can do it by assigning a weight w_i to the i -th choice so that the higher weight means the more preferred choice. Without loss of generality, we can assume that the weight vector can be determined in form of a probability vector, i.e. a vector $\mathbf{w} = (w_1, w_2, \dots, w_n)^T$ such that $w_i \in [0, 1]$ for $i = 1, \dots, n$ and $\sum_{i=1}^n w_i = 1$. We can define the concept of consistent preference relation as follows:

Definition 4 (Additive consistent preference relation). *An intuitionistic fuzzy preference relation $B = ((\mu_{ij}, \nu_{ij}))_{n \times n}$ on $X = \{x_1, \dots, x_n\}$ is an additive consistent preference relation if there exists a probability vector $\mathbf{w} = (w_1, w_2, \dots, w_n)^T$ satisfying the condition:*

$$\mu_{ij} \leq 0.5(w_i - w_j + 1) \leq 1 - \nu_{ij} \quad (1)$$

for all $1 \leq i < j \leq n$.

It is obvious that not every intuitionistic fuzzy preference relation is also an additive consistent relation. In this case the

condition in Eq. (1) can be relaxed by introducing the non-negative deviation variables l_{ij} and r_{ij} for $1 \leq i < j \leq n$ such that

$$\mu_{ij} - l_{ij} \leq 0.5(w_i - w_j + 1) \leq 1 - \nu_{ij} + r_{ij} \quad (2)$$

for all $1 \leq i < j \leq n$. As the deviation variables l_{ij} and r_{ij} become smaller, B becomes closer to an additive consistent intuitionistic fuzzy preference relation. Therefore, in order to find the smallest deviation variables one can developed the following linear optimization model [23], [21]:

Model (A1):

$$\delta = \min \sum_{i=1}^{n-1} \sum_{j=i+1}^n (l_{ij} + r_{ij})$$

$$s.t. \left\{ \begin{array}{l} 0.5(w_i - w_j + 1) + l_{ij} \geq \mu_{ij} \\ 0.5(w_i - w_j + 1) - r_{ij} \leq 1 - \nu_{ij} \\ l_{ij}, r_{ij} \geq 0 \\ w_i \geq 0 \quad \text{for } i = 1, \dots, n, \\ \sum_{i=1}^n w_i = 1 \end{array} \right\} \quad (*)$$

where (*) must be true for all $1 \leq i < j \leq n$.

Let δ^o be the optimal value and let l_{ij}^o and r_{ij}^o for $1 \leq i < j \leq n$ be optimal deviation values of the optimization model (A1). One can see that if $\delta^o = 0$ then B is an additive consistent intuitionistic fuzzy preference relation. Otherwise, we can improve the additive consistency of B by defining the new intuitionistic fuzzy preference relation $\hat{B} = ((\hat{\mu}_{ij}, \hat{\nu}_{ij}))_{n \times n}$, where

$$\hat{\mu}_{ij} = \begin{cases} \mu_{ij} - l_{ij}^o & \text{if } i < j \\ 0.5 & \text{if } i = j \\ \hat{\nu}_{ij} & \text{if } i > j \end{cases} \quad \hat{\nu}_{ij} = \begin{cases} \nu_{ij} - r_{ij}^o & \text{if } i < j \\ \nu_{ij} = 0.5 & \text{if } i = j \\ \hat{\mu}_{ij} & \text{if } i > j \end{cases}$$

Based on matrix \hat{B} we can calculate the priority weight vector $\mathbf{w} = (w_1, \dots, w_n)^T$ by establishing the weight intervals $[w_k^-, w_k^+]$ for each $k = 1, \dots, n$. In order to do that, we solve the following optimization models

Model (A2): for each $k = 1, 2, \dots, n$:

$$(w_k^-, w_k^+) = (\min w_k, \max w_k)$$

$$s.t. \left\{ \begin{array}{l} 0.5(w_i - w_j + 1) \geq \hat{\mu}_{ij} \\ 0.5(w_i - w_j + 1) \leq 1 - \hat{\nu}_{ij} \\ w_i \geq 0 \quad \text{for } i = 1, \dots, n, \\ \sum_{j=1}^n w_j = 1. \end{array} \right\} \quad (*)$$

where (*) must be true for all $1 \leq i < j \leq n$.

It has been shown [23] that if \hat{B} is additive consistent then Model (A2) will return an unique solution for the considered optimization problem.

Definition 5 (Multiplicative consistent preference relation:). *An intuitionistic fuzzy preference relation $B = ((\mu_{ij}, \nu_{ij}))_{n \times n}$*

on $X = \{x_1, \dots, x_n\}$ is an multiplicative consistent preference relation if there exists a probability vector $\mathbf{w} = (w_1, w_2, \dots, w_n)^T$ satisfying the condition:

$$\mu_{ij} \leq \frac{w_i}{w_i + w_j} \leq 1 - \nu_{ij} \text{ for all } 1 \leq i < j \leq n. \quad (3)$$

Checking for the multiplicative consistency is quite similar to the additive consistency. In this case, we can establish the optimization model (M1). In contrast to model (A1), this model is nonlinear.

Model (M1):

$$\delta = \min \sum_{i=1}^{n-1} \sum_{j=i+1}^n (l_{ij} + r_{ij})$$

$$s.t. \left\{ \begin{array}{l} \frac{w_i}{w_i + w_j} + l_{ij} \geq \mu_{ij} \\ \frac{w_i}{w_i + w_j} - r_{ij} \leq 1 - \nu_{ij} \\ l_{ij}, r_{ij} \geq 0 \\ w_i \geq 0 \quad \text{for } i = 1, \dots, n, \\ \sum_{i=1}^n w_i = 1 \end{array} \right\} \quad (*)$$

where (*) must be true for all $1 \leq i < j \leq n$.

Let δ^* be the optimal value and let l_{ij}^* and r_{ij}^* for $1 \leq i < j \leq n$ be optimal deviation values of the optimization model (M1). One can see that if $\delta^* = 0$ then B is an multiplicative consistent intuitionistic fuzzy preference relation. Otherwise, we can improve the multiplicative consistency of B by defining the new intuitionistic fuzzy preference relation $B^* = ((\mu_{ij}^*, \nu_{ij}^*))_{n \times n}$, where

$$\mu_{ij}^* = \begin{cases} \mu_{ij} - l_{ij}^* & \text{if } i < j \\ 0.5 & \text{if } i = j \\ \nu_{ij}^* & \text{if } i > j \end{cases} \quad \nu_{ij}^* = \begin{cases} \nu_{ij} - r_{ij}^* & \text{if } i < j \\ 0.5 & \text{if } i = j \\ \mu_{ij}^* & \text{if } i > j \end{cases}$$

Based on matrix B^* we can calculate the priority weight vector $\mathbf{w} = (w_1, \dots, w_n)^T$ by establishing the weight intervals $[w_k^-, w_k^+]$ for each $k = 1, \dots, n$. In order to do that, we solve the following optimization models

Model (M2): for each $k = 1, 2, \dots, n$:

$$(w_k^-, w_k^+) = (\min w_k, \max w_k)$$

$$s.t. \left\{ \begin{array}{l} \frac{w_i}{w_i + w_j} \geq \mu_{ij}^* \\ \frac{w_i}{w_i + w_j} \leq 1 - \nu_{ij}^* \\ w_i \geq 0 \quad \text{for } i = 1, \dots, n, \\ \sum_{j=1}^n w_j = 1. \end{array} \right\} \quad (*)$$

where (*) must be true for all $1 \leq i < j \leq n$.

IV. HYBRID METHOD FOR FEATURE RANKING PROBLEM

In this section we present a rough-fuzzy hybridization technique for searching for the optimal ranking list of features, called RAFAR (Rough-fuzzy Algorithm For Attribute Ranking). We introduce the concept of fuzzy discernibility matrix,

which is a generalization of discernibility matrix in rough set theory, and combine it with the ranking calculation methods from intuitionistic fuzzy preference relations.

A. Construction of IFPR from decision table

The general framework of our proposition is presented in the Fig. 1:

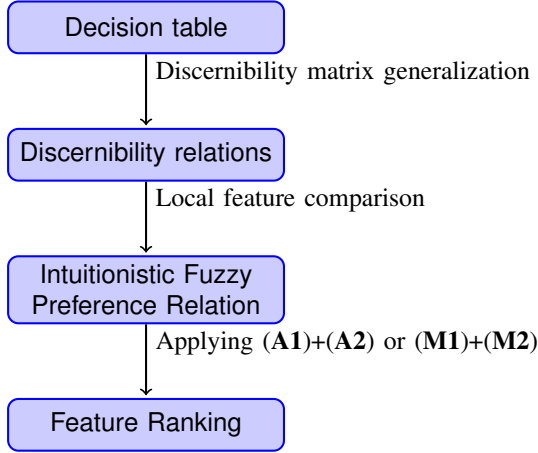

Fig. 1: The general framework of our proposition.

For a given decision table $T = (U, A \cup \{d\})$, where $U = \{u_1, u_2, \dots, u_n\}$ and $A = \{a_1, a_2, \dots, a_m\}$. To simplify the description, let us assume that d is a binary decision attribute, e.g., $V_d = \{-1, 1\}$. The proposed methods also work for the multi-class case.

Let $\mathcal{RED}(T) = \{R \in A : R \text{ is a reduct in } T\}$ denotes the set of all reducts of the decision table T . In [24], the authors classified the attributes into 3 categories:

- Core attributes: the attributes that occur in all reducts:

$$CORE(T) = \bigcap_{R \in \mathcal{RED}} R$$

- Reductive attributes: the attributes that present in at least one reduct:

$$REAT(T) = A - \bigcup_{R \in \mathcal{RED}} R$$

- The attribute is called redundant if it is not a reductive attribute.

Our aim is to generate a feature ranking that at least follows this classification.

Let consider the case of decision table with symbolic values. We define the two decision classes by

$$U_- = \{u \in U : d(u) = -1\}; \quad U_+ = \{u \in U : d(u) = 1\}$$

For each feature $a_k \in A$, we define a function $P_{a_k} : U_+ \times U_- \rightarrow \{0, 1\}$ by

$$P_{a_k}(u_i, u_j) = \begin{cases} 1 & \text{if } a(u_i) \neq a(u_j), \\ 0 & \text{otherwise.} \end{cases}$$

We can see that if a_k is a symbolic feature then P_{a_k} is a relation between U_- and U_+ in the traditional meaning. This relation is called the discernibility relation [14]. Moreover, if $\mathbb{M}(T) = (S_{ij})_{n \times n}$ is the discernibility matrix of T , then

$$P_{a_k}(u_i, u_j) = 1 \text{ if and only if } a_k \in S_{ij}.$$

In case of numeric features, instead of the discernibility relation, we will define a fuzzy discernibility relation. If $a_k \in A$ be a real value feature, we define a fuzzy membership function in $U_+ \times U_-$ for the relation $P_{a_k}^{\alpha, \beta}(u_i, u_j)$ as follows:

$$P_{a_k}^{\alpha, \beta}(u_i, u_j) = \begin{cases} 0 & \text{if } d_k(u_i, u_j) \leq \alpha; \\ 1 & \text{if } d_k(u_i, u_j) \geq \beta; \\ \frac{d_k(u_i, u_j) - \alpha}{\beta - \alpha} & \text{otherwise.} \end{cases}$$

where $0 < \alpha < \beta$ are real parameters and $d_k(u_i, u_j) = |a_k(u_i) - a_k(u_j)|$.

Now, we propose the following method for construction of IFPR over the set of features A . For each $a_k \in A$, we define a function $Score_{a_k} : U_- \times U_+ \rightarrow [0, 1]$ such that

$$Score_{a_k}(u_i, u_j) = \frac{1}{\sum_{a_k \in A} P_{a_k}(u_i, u_j)}$$

Intuitively, the value $Score_{a_k}(u_i, u_j)$ determines the probability that a_k should be selected in order to discern u_i from u_j . For any pair of features $a_k, a_l \in A$, we define the following sets:

$$\begin{aligned} X_{kl} &= \{(u_i, u_j) \in U_+ \times U_- : \\ &\quad Score_{a_k}(u_i, u_j) > Score_{a_l}(u_i, u_j)\} \\ Y_{kl} &= \{(u_i, u_j) \in U_+ \times U_- : \\ &\quad Score_{a_k}(u_i, u_j) = Score_{a_l}(u_i, u_j)\} \\ Z_{kl} &= \{(u_i, u_j) \in U_+ \times U_- : \\ &\quad Score_{a_k}(u_i, u_j) < Score_{a_l}(u_i, u_j)\} \end{aligned}$$

Using those sets, we can calculate the following values

$$\begin{aligned} x_{kl} &= \sum_{(u_i, u_j) \in X_{kl}} Score_{a_k}(u_i, u_j) - Score_{a_l}(u_i, u_j) \\ y_{kl} &= \sum_{(u_i, u_j) \in Y_{kl}} Score_{a_k}(u_i, u_j) \\ z_{kl} &= \sum_{(u_i, u_j) \in Z_{kl}} Score_{a_l}(u_i, u_j) - Score_{a_k}(u_i, u_j) \end{aligned}$$

The discernibility IFPR: $P_{dis} = ((\mu_{kl}, \nu_{kl}))_{m \times m}$ as follows

$$\begin{aligned} \mu_{kl} &= \frac{x_{kl}}{x_{kl} + y_{kl} + z_{kl}} \\ \nu_{kl} &= \frac{z_{kl}}{x_{kl} + y_{kl} + z_{kl}} \end{aligned}$$

B. The illustrated examples

Consider an exemplary decision table shown in Table I. This table was created by taking first 10 objects from the famous ‘‘weather data set’’ and adding one more feature (smog) as the fifth feature.

TABLE I: The decision table extended by one new feature.

T_1	a_1	a_2	a_3	a_4	a_5	dec
ID	outlook	temp.	hum.	windy	smog	play
1	sunny	hot	high	FALSE	no	no
2	sunny	hot	high	TRUE	no	no
3	overcast	hot	high	FALSE	yes	yes
4	rainy	mild	high	FALSE	yes	yes
5	rainy	cool	normal	FALSE	no	yes
6	rainy	cool	normal	TRUE	no	no
7	overcast	cool	normal	TRUE	no	yes
8	sunny	mild	high	FALSE	no	no
9	sunny	cool	normal	FALSE	no	yes
10	rainy	mild	normal	FALSE	no	yes

The simplified version \mathbb{M}'_1 of the discernibility matrix for T_1 is presented in Table II. One can see that this new decision table has exactly 2 reducts: $R_1 = \{a_1, a_2, a_4\}$ and $R_2 = \{a_1, a_3, a_4\}$. According to [24], the features a_1 and a_4 are called the *core attributes* and a_5 is the *redundant attribute*.

TABLE II: The simplified discernibility matrix for decision table from Table I.

$\mathbb{M}'(T_1)$	1	2	6	8
3	a_1, a_5	a_1, a_4, a_5	a_1, a_2, a_3, a_4, a_5	a_1, a_2, a_5
4	a_1, a_2, a_5	a_1, a_2, a_4, a_5	a_2, a_3, a_4, a_5	a_1, a_5
5	a_1, a_2, a_3	a_1, a_2, a_3, a_4	a_4	a_1, a_2, a_3
7	a_1, a_2, a_3, a_4	a_1, a_2, a_3	a_1	a_1, a_2, a_3, a_4
9	a_2, a_3	a_2, a_3, a_4	a_1, a_4	a_2, a_3
10	a_1, a_2, a_3	a_1, a_2, a_3, a_4	a_2, a_4	a_1, a_3

Since all features of T_2 are symbolic, the discernibility relations are presented in Table III. The corresponding *Score* functions for features are showing in Table IV.

Now we can calculate the IFPR P_{dis} . Let consider the two features a_1 and a_2 :

$$X_{12} = \{(3, 1), (3, 2), (4, 8), (7, 6), (9, 6), (10, 8)\}$$

$$Z_{12} = \{(4, 6), (9, 1), (9, 2), (9, 8), (10, 6)\}$$

$$Y_{12} = \text{the rest of features.}$$

The sums of scores in previous sets are:

$$x_{12} = 0.5 + 0.33 + 0.5 + 1 + 0.5 + 0.5 = 3.33$$

$$z_{12} = 0.25 + 0.5 + 0.33 + 0.5 + 0.5 = 2.083$$

$$y_{12} = 3.54$$

Therefore:

$$\mu_{12} = \nu_{21} \approx \frac{3.33}{3.33 + 2.083 + 3.54} \approx 0.3759$$

$$\nu_{12} = \mu_{21} \approx \frac{2.083}{3.33 + 2.083 + 3.54} \approx 0.2349$$

The IFPR P_{dis} for decision table T_1 is presented as follows:

$$\begin{pmatrix} (0.50, 0.50) & (0.38, 0.23) & (0.45, 0.19) & (0.51, 0.23) & (0.62, 0.04) \\ (0.23, 0.38) & (0.50, 0.50) & (0.23, 0.08) & (0.41, 0.25) & (0.61, 0.19) \\ (0.19, 0.45) & (0.08, 0.23) & (0.50, 0.50) & (0.39, 0.36) & (0.61, 0.33) \\ (0.23, 0.51) & (0.25, 0.41) & (0.36, 0.39) & (0.50, 0.50) & (0.55, 0.28) \\ (0.04, 0.62) & (0.19, 0.61) & (0.33, 0.61) & (0.28, 0.55) & (0.50, 0.50) \end{pmatrix}$$

TABLE III: The discernibility relation for symbolic features from decision table T_1 .

(u_i, u_j)	P_{a_1}	P_{a_2}	P_{a_3}	P_{a_4}	P_{a_5}
(3,1)	1	0	0	0	1
(3,2)	1	0	0	1	1
(3,6)	1	1	1	1	1
(3,8)	1	1	0	0	1
(4,1)	1	1	0	0	1
(4,2)	1	1	0	1	1
(4,6)	0	1	1	1	1
(4,8)	1	0	0	0	1
(5,1)	1	1	1	0	0
(5,2)	1	1	1	1	0
(5,6)	0	0	0	1	0
(5,8)	1	1	1	0	0
(7,1)	1	1	1	1	0
(7,2)	1	1	1	0	0
(7,6)	1	0	0	0	0
(7,8)	1	1	1	1	0
(9,1)	0	1	1	0	0
(9,2)	0	1	1	1	0
(9,6)	1	0	0	1	0
(9,8)	0	1	1	0	0
(10,1)	1	1	1	0	0
(10,2)	1	1	1	1	0
(10,6)	0	1	0	1	0
(10,8)	1	0	1	0	0

TABLE IV: The *Score* functions for features from T_1 .

(u_i, u_j)	$Score_{a_1}$	$Score_{a_2}$	$Score_{a_3}$	$Score_{a_4}$	$Score_{a_5}$
(3,1)	0.5	0	0	0	0.5
(3,2)	0.33	0	0	0.33	0.33
(3,6)	0.2	0.2	0.2	0.2	0.2
(3,8)	0.33	0.33	0	0	0.33
(4,1)	0.33	0.33	0	0	0.33
(4,2)	0.25	0.25	0	0.25	0.25
(4,6)	0	0.25	0.25	0.25	0.25
(4,8)	0.5	0	0	0	0.5
(5,1)	0.33	0.33	0.33	0	0
(5,2)	0.25	0.25	0.25	0.25	0
(5,6)	0	0	0	1	0
(5,8)	0.33	0.33	0.33	0	0
(7,1)	0.25	0.25	0.25	0.25	0
(7,2)	0.33	0.33	0.33	0	0
(7,6)	1	0	0	0	0
(7,8)	0.25	0.25	0.25	0.25	0
(9,1)	0	0.5	0.5	0	0
(9,2)	0	0.33	0.33	0.33	0
(9,6)	0.5	0	0	0.5	0
(9,8)	0	0.5	0.5	0	0
(10,1)	0.33	0.33	0.33	0	0
(10,2)	0.25	0.25	0.25	0.25	0
(10,6)	0	0.5	0	0.5	0
(10,8)	0.5	0	0.5	0	0

Now we can use the models (A1) and (A2) to find the feature ranking that is additively consistent with P_{dis} . As a result we receive:

$$(w_1, w_2, w_3, w_4, w_5) = (0.468, 0.214, 0.214, 0.104, 0)$$

This means a_1 is the best and a_5 is the worst feature.

Let us consider the decision table T_2 , which is almost the same as T_1 . The only difference is that, a_2 (temperature) and a_3 (humidity) are numeric features.

The discernibility relations for a_1, a_4, a_5 remain unchanged. As an example, for a_2 , we use the fuzzy discernibility relation $P_{a_2}^{\alpha, \beta}$ with $\alpha = 2$ and $\beta = 12$ and for a_3 , we use the

TABLE V: The decision table with numeric features

T_2	a_1	a_2	a_3	a_4	a_5	dec
ID	outlook	temp.(F)	hum.(%)	windy	smog	play
1	sunny	85.0	85.0	FALSE	no	no
2	sunny	80.0	90.0	TRUE	no	no
3	overcast	83.0	86.0	FALSE	yes	yes
4	rainy	70.0	96.0	FALSE	yes	yes
5	rainy	68.0	80.0	FALSE	no	yes
6	rainy	65.0	70.0	TRUE	no	no
7	overcast	64.0	65.0	TRUE	no	yes
8	sunny	72.0	95.0	FALSE	no	no
9	sunny	69.0	70.0	FALSE	no	yes
10	rainy	75.0	80.0	FALSE	no	yes

fuzzy discernibility relation $P_{a_3}^{\alpha, \beta}$ with $\alpha = 5$ and $\beta = 15$. The fuzzy discernibility relations as well as the corresponding *Score* functions for features are presented in Table VI and Table VII.

TABLE VI: The fuzzy discernibility relations for features from decision table T_2 .

(u_i, u_j)	P_{a_1}	P_{a_2}	P_{a_3}	P_{a_4}	P_{a_5}
(3,1)	1	0	0	0	1
(3,2)	1	0.1	0.5	1	1
(3,6)	1	1	1	1	1
(3,8)	1	0.9	0	0	1
(4,1)	1	1	1	0	1
(4,2)	1	0.8	1	1	1
(4,6)	0	0.3	0	1	1
(4,8)	1	0	1	0	1
(5,1)	1	1	1	0	0
(5,2)	1	1	1	1	0
(5,6)	0	0.1	0	1	0
(5,8)	1	0.2	1	0	0
(7,1)	1	1	1	1	0
(7,2)	1	1	1	0	0
(7,6)	1	0	0.4	0	0
(7,8)	1	0.6	1	1	0
(9,1)	0	1	1	0	0
(9,2)	0	0.9	1	1	0
(9,6)	1	0.2	0	1	0
(9,8)	0	0.1	1	0	0
(10,1)	1	0.8	0.8	0	0
(10,2)	1	0.3	1	1	0
(10,6)	0	0.8	0.3	1	0
(10,8)	1	0.1	0	0	0

The *Score* functions can be used to construct the IFPR in the same way as previously. As the result we receive the following matrix:

$$\begin{pmatrix} (0.50, 0.50) & (0.55, 0.22) & (0.36, 0.24) & (0.51, 0.25) & (0.65, 0.06) \\ (0.22, 0.55) & (0.50, 0.50) & (0.16, 0.41) & (0.44, 0.43) & (0.64, 0.28) \\ (0.24, 0.36) & (0.16, 0.41) & (0.50, 0.50) & (0.47, 0.29) & (0.66, 0.20) \\ (0.25, 0.51) & (0.43, 0.44) & (0.29, 0.47) & (0.50, 0.50) & (0.56, 0.25) \\ (0.06, 0.65) & (0.28, 0.64) & (0.20, 0.66) & (0.25, 0.56) & (0.50, 0.50) \end{pmatrix}$$

And the optimal coefficients for this matrix are:

$$(w_1, w_2, w_3, w_4, w_5) = (0.327, 0.227, 0.322, 0.124, 0)$$

We can see that in this case the feature a_3 become almost important as the feature a_1 , and the redundant feature a_5 is still located at the end of the ranking.

TABLE VII: The *Score* functions for features from T_2 .

(u_i, u_j)	$Score_{a_1}$	$Score_{a_2}$	$Score_{a_3}$	$Score_{a_4}$	$Score_{a_5}$

C. Simplified ranking method.

The presented above method for feature ranking has quite high computational complexity. The time complexity of this proposition is $O((n \cdot m)^2)$, where n is the number of objects and m is the number of attributes. In this Section we propose a heuristic solution called sRAFAR (simplified Rough-fuzzy Algorithm For Attribute Ranking), which is applicable for the data sets with larger number of objects. The idea is to generate a simplified IFPR instead of the full method presented in Section IV.A. In particular, for any continuous feature $a_k \in A$, we discretize its domain into k equal length intervals and use the binary discernibility relation for the discretized feature.

$$A_k = \{(u_i, u_j) \in U_+ \times U_- : u_i, u_j \text{ are discerned by } a_k\}$$

$$= \{(u_i, u_j) \in U_+ \times U_- : P_{a_k}(u_i, u_j) = 1\}$$

Then the simplified IFPR: $P_s = ((\mu'_{kl}, \nu'_{kl}))_{m \times m}$ can be defined by

$$\mu'_{kl} = P(A_k - A_l | A_k \cup A_l) = 1 - \frac{|A_l|}{|A_k \cup A_l|}$$

$$\nu'_{kl} = P(A_l - A_k | A_k \cup A_l) = 1 - \frac{|A_k|}{|A_k \cup A_l|}$$

Thus, μ'_{kl} is the probability that a pair of objects is discernible a_k but not discernible by a_l , and ν'_{kl} is the probability that a pair of objects is discernible a_l but not discernible by a_k . We have the following theorem:

Theorem 1. For any pair of features $a_k, a_l \in A$, the values $|A_k \cup A_l|, |A_k|, |A_l|$ can be calculated in time $O(n)$, where n is the number of objects. Therefore, the heuristic IFPR can be calculated in $O(n \cdot m^2)$, where m is the number of features.

The proof of this fact is similar to the properties of the MD-heuristic in [24].

V. EXPERIMENT RESULTS

In this section, we present the application of our feature ranking methods for the WDBC data set [25]. The WDBC dataset contains features extracted from digitized image of a fine needle aspirate of a breast mass which describes the characteristics of the cell nuclei in the image. This dataset consists of 569 instances with 30 attributes and two decision classes. The features are encoded by V_1, V_2, \dots, V_{30} . We will compare the quality of feature ranking lists generated by:

- RAFAR: Rough-fuzzy Algorithm For Attribute Ranking;
- sRAFAR: simplified version of RAFAR;
- Random Forest Feature Importance; ¹
- No ranking, i.e. using the original feature list: V_1, V_2, \dots, V_{30} .

Fig. 2: The accuracy of kNN classifier for different values of k . The highest accuracy is achieved for $k = 9$.

Fig. 3: Comparison of ranking lists with respect to kNN classifier with $k = 9$.

In order to analyze the quality of a ranking list of features (attributes), we select a classifier (classification algorithm) and apply it to the sub-dataset restricted to the first m features

¹https://scikit-learn.org/stable/auto_examples/inspection/plot_permutation_importance_multicollinear.html

for $m = 1, 2, \dots, 30$. For a fixed value of m we evaluate the accuracy of the classifier using 5-fold-cross-validation technique.

The first classifier in our experiment is kNN. Figure 2 presents the accuracy of kNN on the whole data set for different values of the parameter k . We can see that the optimal value of k for kNN classifier equals 9. Therefore we will select kNN with $k = 9$ in the first experiment.

In Fig. 3 the accuracy of kNN with $k = 9$ using first m features of the ranking list for $m = 1, 2, \dots, 30$ is presented. One can see that the accuracy of ranking lists generated by both of our algorithms outperform the other ranking lists.

In Fig. 4 the accuracy comparison of decision tree classifier using first features in the ranking lists is presented. We can see that in this case, the ranking list generated by the RAFAR algorithm seems to be best, especially when we want to use up to 17 features.

Fig. 4: Comparison of ranking lists with respect to decision tree.

Fig. 5: Comparison of ranking lists with respect to SVM classifier.

Figures 5 present the accuracy comparison for SVM classifier. In this case we notice the fact that the ranking list generated by the sRAFAR algorithm is the best one.

VI. CONCLUSIONS AND FUTURE RESEARCH

In this paper we proposed a new method for feature ranking. We constructed the Intuitionistic Fuzzy Preference Relation (IFPR) for the set of features and searched for the optimal feature ranking that is consistent with the IFPR. All experiments are showing that the proposed rough-fuzzy algorithms for attribute ranking outperform the state of the art method (Random Forest Feature Ranking is the main feature ranking method in the Python scikit-learn library <https://scikit-learn.org/stable/>). We can conclude that the proposed methods are promising and should be thoroughly investigated.

One of the future research direction is multi-criteria feature ranking instead of a single preference relation defined on the based of discernibility power of the features as t has been proposed in RAFAR. The general framework is shown in Fig 1. This idea is motivated by the real life decision making process, where a decision is usually made by a group of experts, $E_k (k = 1, 2, \dots, m)$ with different weights $\lambda = (\lambda_1, \dots, \lambda_m)$, where $\sum_{k=1}^m \lambda_k = 1$ and $\lambda_k \geq 0$ for $k = 1, \dots, k$. In such cases, the individual preference relations of the experts are aggregated to derive a collective preference relation. Let $B^{(k)} = ((\mu_{ij}^{(k)}, \nu_{ij}^{(k)}))_{n \times n}$ be the intuitionistic fuzzy preference relation of the expert E_k , the aggregated preference relation \bar{B} is defined by $\bar{B} = \sum_{k=1}^m \lambda_k \cdot B^{(k)}$. In other words $\bar{B} = ((\bar{\mu}_{ij}, \bar{\nu}_{ij}))_{n \times n}$, where

$$\bar{\mu}_{ij} = \sum_{k=1}^m \lambda_k \mu_{ij}^{(k)}; \quad \bar{\nu}_{ij} = \sum_{k=1}^m \lambda_k \nu_{ij}^{(k)};$$

Theorem 2. *If $B^{(k)}$ are intuitionistic fuzzy preference relation of the expert E_k for $k = 1, \dots, m$ and the weight vector $\lambda = (\lambda_1, \dots, \lambda_m)$ is a probabilistics vector, i.e. $\sum_{k=1}^m \lambda_k = 1$ and $\lambda_k \geq 0$ for $k = 1, \dots, k$, then \bar{B} is also an intuitionistic fuzzy preference relation.*

In such situations, we can apply both ranking methods (i.e. either the models (A1), and (A2) for the additive consistency requirement or the models (M1) and (M2) for the multiplicative consistency requirement) for the collective intuitionistic fuzzy preference relation \bar{B} .

Following this idea, in case of feature ranking problem, we can create more IFPR with different aspects and include them into the calculation process. For example, another preference relation could be calculate on the base of the class homogeneity of features.

We also plan to verify the accuracy of RAFAR and sRAFAR for bigger and more challenging data sets.

ACKNOWLEDGMENT

The authors would like to thank the Vietnam Institute for Advanced Study in Mathematics (VIASM) for the support during the time they had been visiting and working at the Institute.

15th International Workshop on Computational Optimization

MANY real world problems arising in engineering, economics, medicine and other domains can be formulated as optimization tasks. These problems are frequently characterized by non-convex, non-differentiable, discontinuous, noisy or dynamic objective functions and constraints which ask for adequate computational methods.

The aim of this workshop is to stimulate the communication between researchers working on different fields of optimization and practitioners who need reliable and efficient computational optimization methods.

TOPICS

The list of topics includes, but is not limited to:

- combinatorial and continuous global optimization
- unconstrained and constrained optimization
- multiobjective and robust optimization
- optimization in dynamic and/or noisy environments
- optimization on graphs
- large-scale optimization, in parallel and distributed computational environments
- meta-heuristics for optimization, nature-inspired approaches and any other derivative-free methods
- exact/heuristic hybrid methods, involving natural computing techniques and other global and local optimization methods
- numerical and heuristic methods for modeling

The applications of interest are included in the list below, but are not limited to:

- classical operational research problems (knapsack, traveling salesman, etc)
- computational biology and distance geometry
- data mining and knowledge discovery
- human motion simulations; crowd simulations
- industrial applications
- optimization in statistics, econometrics, finance, physics, chemistry, biology, medicine, and engineering
- environment modeling and optimization

BEST PAPER AWARD

The best WCO'22 paper will be awarded during the social dinner of FedCSIS 2022.

The best paper will be selected by WCO'22 co-Chairs by taking into consideration the scores suggested by the reviewers, as well as the quality of the given oral presentation.

Abstract—This paper presents an improved Gap-based Memetic Differential Evolution (GaMeDE2), the modification of the GaMeDE method, which took second place in the GECCO 2020 Competition on Niching Methods for Multimodal Optimization. GaMeDE2 has reduced complexity, fewer parameters, redefined initialization, selection operator, and removed processing phases. The method is verified using standard benchmark function sets (classic ones and CEC2013) and a newly proposed benchmark set comprised of deceptive functions. A detailed comparison to state-of-the-art methods (like HVCMO and SDLCSDE) is presented, where the proposed GaMeDE2 outperforms or gives similar results to other methods. The document is concluded by discussing various insights on the problem instances and the methods created as a part of the research.

I. INTRODUCTION

MULTIMODAL Optimization (MMO) is a well-established problem in the literature (e.g.[1]). Due to its practical applications, it has been studied over the years. In real-world practical problems, the number of optimal solutions is not known *a priori*. It means, that valuable results might be ruled out by the assumption of sole optimal solution existence. As a result of real-life unpredictability and constraints, the optimal solution might not be feasible, and a suboptimal one may be preferred. What is more, the knowledge of other valuable solutions can support decision-making and allows for agile switches without the need for running the optimization process from the beginning with the risk of convergence to the same optima, which is the drawback of the standard unimodal optimization approaches.

The well-established competition in the multimodal optimization area is the annual GECCO Conference and Competition on Niching Methods for Multimodal Optimization based on the benchmark function suit [2]. GaMeDE2 proposed in this article is an extension of the GaMeDE [3] method, which took second place in the 2020 competition edition. The paper presents several modifications to boost the generality, which has been shown on the additional benchmark suits. Three other methods were selected to compare the final results. Self-adaptive Double-Layer-Clustering Speciation Differential

Evolution (SDLCSDE) [4] is the recently published approach and gives very promising results. Unfortunately, it has not been evaluated on the GECCO Competition benchmark set, and the source code was not available to carry out the experiments - the results for another benchmark set of classical multimodal functions [5] have been used. The next reference method used is the Hill-Valley-Clustering-based VMO (HVCMO) [6], a novel method based on the HillVallea [7] - a winning method in GECCO 2019 Competition on Niching Methods for Multimodal Optimization. The third compared method is the original GaMeDE approach.

The rest of the article is structured as follows. Section 2 covers the short literature review related to multimodal problems. The proposed GaMeDE2 method is introduced in section 3. The experimental setup, datasets descriptions, and results for the evaluated methods with the discussion of the results are given in Section 4. Lastly, the paper is concluded in section 5.

II. SCIENTIFIC BACKGROUND AND RELATED WORKS

A series of articles show the importance of multimodal problems in multiple practical and various valuable areas, such as Drug Scheduling Problem, Protein Structure Prediction, Resource-Constrained Multiproject Scheduling Problem, cosmological applications, and an iconic machine-learning classification problem (e.g [8]) and many others. In literature, multimodality tends to be combined with multi-objectiveness, wherefore research in one area benefits both.

Besides real-world applications, sets of benchmark functions for the MMO have been proposed over the years. They are either manually fabricated to emphasise certain features or forged by combining multiple unimodal benchmark functions. Among the most recognizable in the literature [9] are multimodal benchmark functions based on: Rastrigin's function, Shubert's function, Vincent's function, Griewank's function, Schwefel's function, and Ackley's function. As a result of the number of combinations, a unified evaluation set has been introduced [2]. It consists of highly varied functions in terms of number of dimensions (1-20), domain and peak height scale, number of local and global optima (0-many/1-216),

optima distribution, and landscape variability. Additionally, it contains a single instance of a deceptive function - the Five-Uneven-Peak Trap. This set has been used in the GECCO 2020 Niching Competition on Multimodal Optimization and the following editions. The alternative function composition has been proposed in [10] which shows the flexibility of combining the functions. Another benchmark set grounded in the literature [5] introduces new instances related to the competition set and modifies the budget for the subset of those already present. These functions are divided into six categories: Deceptive Functions, 1D Multimodal Functions, 2D Multimodal Functions, ≥ 2 D More Challenging Multimodal Functions, Inverted Rastrigin Function, and Generic Hump Functions. The added deceptive/trap functions are: 1D Two-Peak Trap and 1D Central Two-Peak Trap. The deceptiveness factor is an essential aspect of Multimodal Optimization [11]. There are limited works related to high dimensional multimodal trap functions. The one proposed approach is to apply function composition [12], yet it has not been openly adapted as the benchmark function, nor extended research in the area has been found at the moment of writing this article.

As stated in the introduction, a diverse set of valuable solutions is expected when solving a multimodal problem. For this reason, an efficient exploratory method is crucial. Evolutionary Computation is known to be effective in complex multimodal optimization, e.g. [1][13][12][14]. A significant amount of attention has been paid to Continuous Multimodal Optimization, where Differential Evolution (DE) [15] is a reference method. It is still a widely used approach in the literature. Work [16] introduces a Dual-Strategy Mutation, adaptive individual selection, and converged individuals archive. Authors in [17] proposed a novel mutation strategy based on the Local Binary Pattern used for niche detection. Another modification was introduced in [18], where Distributed Individual for Multiple Peaks (DIMP) has been used to track optima. It has been extended by adding two novel mechanisms. First, Lifetime Mechanism is inspired by the natural phenomenon of organism aging and limited lifespan. Second, Elite Learning Mechanism (ELM) is introduced to refine the accuracy and efficiency of the archiving mechanism.

High-quality solutions in the multimodal landscape may often be found in different parts of the search space, complicating the single population convergence. Niching's [8] technique was introduced to prevent this effect by dividing the domain into multiple subsets called niches. The general idea in multimodal optimization is to detect niches, ideally located around the optima, and explore them separately. Niching is a widely applied concept in MMO and several modifications can be found in the literature. Nearest-neighbor niching introduced in [19] aids in achieving a well-balanced species. Another approach to increasing the solutions' (swarm) diversity is introducing the Equilibrium Factor to modify the individual's velocity [20]. Parameter-less niching mechanism (affinity propagation clustering) [21] is a valuable direction that reduces the method's parameter number and helps to locate the nearest peak, which boosts the convergence. Double-layer-clustering

[4] has been proposed to increase the diversity and global exploration to locate more global optima. The DE method is applied on the niche level to support escaping local optima and detecting new promising areas in the search space. It also benefits from a self-adaptive strategy to reduce the number of parameters by self-adapting the crossover probability and scaling factor used by DE. On the other hand, it still requires the population size defined per problem instance. Hill-ValLEA [22] is the GECCO 2019 Niching Competition on Multimodal Optimization competition winner. It introduced the Hill-Valley Clustering approach to adaptively cluster the search space in niches residing around a single optimum. It utilizes the Hill-Valley test [23] to determine whether two solutions belong to the same niche. Combined with a core search algorithm to optimize the niches and restart scheme, it outperformed its competitors. Hill-Valley-Clustering-based VMO (HVcMO) [6] merges the HillValLEA method with Variable Mesh Optimization [24], which significantly boosted the optima detection and improved the efficient use of budget.

The original GaMeDE [3] is a novel method, drawing concepts from the MMO using DE as its base. It benefits from GAP selection (and archive management mechanism) to keep high diversity, clustering for identification of promising areas, and local search optimization. Its core functionality is a two-phase approach - the *WIDE* phase uses standard random selection followed by the HillValley Clustering to split the population into niches. Each niche is further optimized by the AMaLGaM Univariate[25] local optimizer, and the best individual per cluster is stored in the archive. *FOCUS* phase uses two selections alternately - standard tournament selection and GAP selection. The latter is a novel approach proposed by the authors. It follows the idea of tournament selection, but instead of fitness (or objective function value), it uses a 'gap' distance. The 'gap' distance is simply the Euclidean distance to the nearest existing individual in the decision space. Its goal is to guide the exploration of 'blank spaces' of the landscape. The last step of the *FOCUS* phase is the HillClimber local optimization of new points in the archive. The method starts with the *FOCUS* phase and switches to the *WIDE* when no longer can find new optima.

III. PROPOSED METHOD

GaMeDE2 is a redesigned GaMeDE [3] method developed for the GECCO 2020 Competition on Niching Methods for MMO. It means a high probability of overtuning and overfitting for the competition benchmark suite. Experiments conducted using new instances presented a lack of generalization and exposed the need for improvements in this area. Mentioned results are shown in the experiments chapter. The goal of modifications introduced in this work is to simplify the original GaMeDE algorithm and improve its effectiveness across multiple benchmark sets. The main objective of the MMO aspects remains unchanged. In this article, it is defined as the search for global optima only (in contrast to the search for all, including local, optima), which is a common approach in literature [3], [4], [25]. Each multimodal problem instance

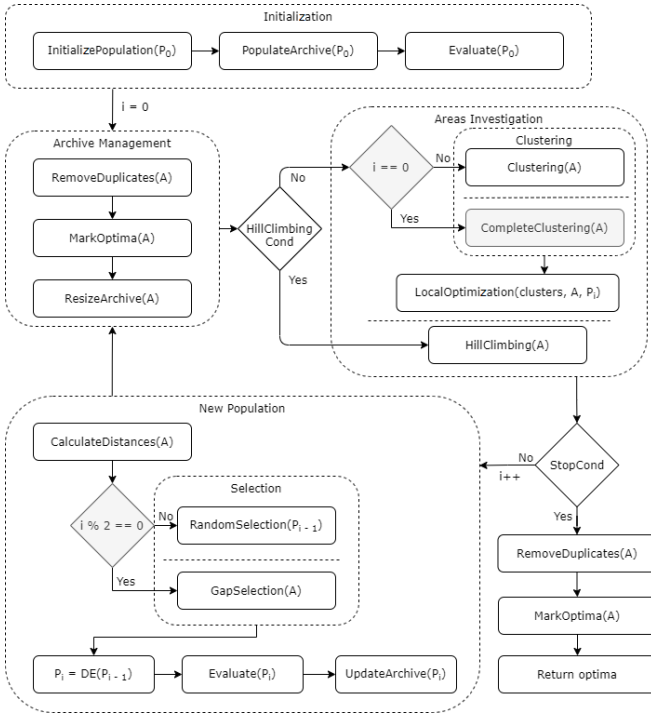

Fig. 1. A general schema of GaMeDE2

is being solved independently with an objective function described as:

$$\max_x f(x) = y, \quad x \in R^d \quad (1)$$

The aim is to find as many different x vectors as possible where the minimum distance between two optima is given.

In this section, GaMeDE2 with a set of introduced modifications has been described. The Algorithm 1 presents the complete version of the GaMeDE2 pseudo-code, while Figure 1 illustrates the modifications described below.

GaMeDE2 is based mainly on a DE that explores/exploits new areas in the problem landscape. DE is steered by the archive (concept strictly incorporated from multi-objective problems), which stores candidates for global optima, and concentrates on 'gaps' between already found solutions. DE optimization is additionally boosted by a clustering mechanism to identify promising areas. Subsequently, local search speeds up the convergence in those areas. The *HillClimbing* procedure further optimizes local optima.

GaMeDE2 initialization (see The Algorithm 1 or/and Figure 1) starts with a random initialization as presented in pseudocode line 3, the initial population is evaluated and used to populate an archive. The archive is used to store the global optima and promising individuals. The *PopulateArchive* method tries to add each individual to the archive. It utilizes the simplified HillValley Test[7] - creates the middle-point M between the tested individual A and his nearest neighbor B in the archive. If the middle-point is worse than both points (A and B), they are kept as there is a chance they come from two

different niches. Otherwise, only the best individual (A , B , or C) is stored. In lines 6 and 12, distances between points in the archive are calculated and stored for future usage. In lines 7 and 26, *ArchiveManagement* takes place. Its pseudocode is presented in Algorithm 2 and remained unchanged from the original GaMeDE version. It removes duplicates from the archive, marks current optima, and truncates the archive by sorting it and removing worst solutions until it fits the *MaxArchiveSize*.

37: Return: Optima

```

Before the first loop starts, *CompleteClustering* takes place (see line 8). It applies for an additional clustering pass as described in the modifications section. In line 9, *LocalOptimization* utilizes AMaLGaM Univariate (as in the original GaMeDE). Lines 10-34 present the main loop, which runs until *StopCondition* is fulfilled - in this case, until the budget (number of evaluated individuals) is fully used. A new, empty population is initialized in line 13 and populated in lines 14-25. It uses *GapSelection* and *RandomSelection* alternately without the need for having any phases as described in the modifications section.

Lines 20-23 present a standard DE process. New individuals are processed in twos. Each of the two individuals returned

from the selection undergoes the basic DE mutation process (based on two different, randomly selected, individuals and factor F). Genes are truncated to make sure all individuals are feasible. In the end, Uniform Crossover is applied. In line 24, the archive is updated with the same procedure used in *PopulateArchive*. Lines 27-32 present the local optimization step, which takes place at the end of each algorithm iteration. The default path is to run *LocalOptimization* for the promising clusters (see line 9). Alternative *HillClimbing* method is used if many new optima candidates appear in this iteration.

Algorithm 2 ArchiveManagement pseudocode

```

1: Params:  $A, Optima$ 
2:  $A \leftarrow RemoveDuplicates(A)$ 
3:  $Optima \leftarrow MarkOptima(A)$ 
4:  $A \leftarrow ResizeArchive(MaxArchiveSize, Optima, A)$ 

```

GaMeDE2 method is based on the original GaMeDE, however it comprises several modifications that reduce the complexity of the method.

A. GaMeDE2 – major proposed modifications

GaMeDE2 consists of several modifications as follows:

- 1) **Skip first selection** - In the GaMeDE, the first selection took place right after the population initialization. Both selection and initialization in GaMeDE are random, which does not introduce any improvement other than increasing the initial pool of random search. However, the evaluation cost is doubled, which might significantly reduce the number of further evaluations for the low-budget problem instances.
- 2) **Remove phase switching** - Based on the conducted experiments, it is not necessary to switch between *WIDE* and *FOCUS* phases between generations. Local optimization performed by a *HillClimber* stays crucial for a group of problems, but it does not have to be paired with global algorithm phases. The condition to run a *HillClimber* in Area investigation step remains unchanged, but it is not propagated further to the next steps.
- 3) **Double initial clustering** - An alternative clustering has been proposed to be used in the initial generation. Its purpose is to detect all the 'easy' optima faster. In the base algorithm, points found in the archive are spread around the search space, and many lay in the same niche. While it might increase the diversity in population, it significantly increases the number of clusters to search and the chance of crossing over the given budget. In GaMeDE2, an alternative approach to cluster generation uses candidates from the archive focusing on new areas. Solutions are clustered using additional Hill-Valley Clustering described in [7] to further reduce the number of candidates from the same global optimum (as an attractor). The Hill-Valley Test itself is simplified by reducing the middle points count to one. Adding second clustering was inspired by the approach in [4], where

performing another DE iteration, based on top of the seeds found in the first pass, appeared to be successful. However, in this work, only the clustering was repeated with no additional DE run.

- 4) **Selection type is not related to phase** - Results of experiments confirm that the selection phases do not have to be bound to the *WIDE/FOCUS* phases. However, the experiments showed that it is still crucial to keep both *Random* and *GAP* selections. Those two selections are used alternately through the subsequent generations, which allows to fully drop the need for defining two phases. The experiments showed that such selection composition gives the best results: one (*Random*) provides high diversity, while the other (*GAP*) focuses on search in poorly explored areas.

Both methods GaMeDE and GaMeDE2 are verified using 3 benchmark datasets, and the results are compared to two state-of-the-art methods. The research results are presented in the next section.

IV. EXPERIMENTS

Modifications proposed in GaMeDE2 have been experimentally verified across three different test sets. Each problem instance has been evaluated, and results are compared using GaMeDE, GaMeDE2 and Hill-Valley-Clustering-based VMO (HVcMO) [6]. For the second test set, results have also been compared with the recently presented Double-layer-clustering (SDLCSDE) [4]. Unfortunately, SDLCSDE cannot be used as the reference method for all test sets – the source code was not available to perform the experiments.

A. Setup

MMO aims to find as many global optima as possible in a budget defined per each problem instance. The only metric used is the **Peak Ratio** (PR) which is a fraction of the global optima detected. Thus, the **Success Rate** (SR) has been calculated as the number of runs with all optima detected divided by the number of all runs. To verify if the global optimum has been reached, accuracy $\epsilon = 10^{-5}$ has been selected, the same as in [7]. For the SDLCSDE, accuracy levels were different across the test set. To compare performance precisely, GaMeDE2 has been tested on the problem instances where SDLCSDE accuracy levels were higher than the standard.

Both methods (GaMeDE and GaMeDE2) include non-deterministic elements, and experiments were repeated 30 times on all problem instances to average the results. The Wilcoxon signed-rank test has been applied to verify statistical significance using averaged results. The key advantage of the GaMeDE and GaMeDE2 is their generality, which means they can be successfully applied to a set of different problem instances without any configuration changes. Therefore, for both methods, only a single configuration has been used – in contrast to SDLCSDE, where the 'Population size' parameter was manually selected per each instance – which is not efficient while solving new, unknown problem instances.

To tune GaMeDE2 and find its optimal configuration, 5-Level Taguchi [26] Parameter Design procedure has been used. A set of experiment configurations was generated using an orthogonal matrix, and each configuration was repeated 10 times. This procedure was further repeated for a subset of test functions. The parameters with the highest *Signal-to-Noise* change were fine-tuned first based on the average results. All the parameters have been processed in that manner, subsequently in the descending order of Signal-to-Noise change. Table I presents selected values used by GaMeDE2. The GaMeDE uses the configuration proposed in [3].

TABLE I
GAMEDE2 – BEST FOUND CONFIGURATION

Parameter	Value
PopulationSize	1000 * dim
TournamentSize	10
MaxArchiveSize	25 * dim^2
DiversityPhaseMinNewOptima	5
LocalOptInitialStep	0.01
MutationProbability	0.6
CrossoverProbability	0.2
F	0.01

All presented experiments were carried out on three test sets, consisted of multimodal real-value problems.

B. Test sets

The key attributes of each instance are presented in tables (see. Tab.II, Tab.III, Tab.IV and Tab.X) – it shows the number of global and local optima, number of dimensions and fitness evaluation budget. Three test sets are used in research: **CEC2013**, **Classical** Functions and **Deceptive** Functions, presented respectively in the rest of this section.

First test set - **CEC2013** / **GECCO2020** presented in Table II is commonly used in literature benchmark (e.g. [6][3]) and the same set which has been used in GECCO 2020 Competition on Niching Methods for Multimodal Optimization. It contains a variety of functions with different properties such as: deceptiveness (F1), wide spread of global optima count (F3 vs F9), wide spread of local optima count (F4 vs F6), composite functions (CF11 - CF20), flat and steep niches (CF20).

The second test set, called **Classical** Functions presented in Table III is a benchmark described in [5] and the one that has been selected by the authors of SDLCSDE [4]. The test set contains a number of functions already introduced in the CEC2013 set, yet it significantly decreases the budget given for each instance. The only fully repeated entries are B13 and B14. It also introduces a few new variants: Two-Peak Trap, Central Two-Peak Trap, Decreasing Maxima, Uneven Maxima, and Shekel's Foxholes. Due to the small budget, this set is used to verify the efficiency of the algorithms.

The last test set (**Deceptive** Functions, see Table IV) has been proposed to explore further the aspect of resistance to deceptive traps, which is an essential aspect in the optimization area. It is based on the Classical Functions set, and it consists

B14	Vincent	3	216	0	400K

of three deceptive functions: Two-Peak Trap, Central Two-Peak Trap and Five-Uneven-Peak Trap. All have been expanded into the higher dimension number by using the simple formula:

$$y = \frac{\sum_{i=1}^D f(x_i)}{D} \quad (2)$$

The main difficulty introduced by those Deceptive Functions is a small niche area for the global optima and their location in the far 'corners' of the domain, where niches for the local optima are wide and located in the 'center' of the search space. Figure 2 illustrates selected function landscapes in 2D versions.

The Deceptive Functions test set has been evaluated using two budgets (see Table IV) for solving methods. The standard budget has been defined as more restrictive to create a challenge for the methods. However, the experiments have shown that so small number of births does not allow for convergence for any of the researched methods. Hence, in additional experiments extended budget has been used, where

Fig. 2. **Deceptive functions visualization.** All three functions: Two-Peak Trap, Central Two-Peak Trap, Five-Uneven-Peak Trap in 2D variants.

TABLE IV
DECEPTIVE MULTIMODAL FUNCTION SET

#	Function Name	D	#GOPT	#LOPT	Budget	Budget+

D8	Central Two-Peak	3	1	7	40K	200K
D9	Five-Uneven-Peak	3	8	117	40K	200K

examined methods were given enough 'time' to converge and stabilize the results.

C. Results

To measure the efficiency of the examined method, two standard measures are used – PR and SR (defined in the previous section). In Table V the values of PR and SR of the GaMeDE and modified algorithms for the CEC2013 set are given. It is worth mentioning that scores for GaMeDE do not exactly match those achieved in the GECCO competition. The results are slightly diverse because of the non-deterministic character of GaMeDE but are within one standard deviation.

However, the average PR from all 20 problems maintains second place in the GECCO competition leader board. The GaMeDE2 managed to achieve comparable and even slightly better performance than GaMeDE. SDLCSDE algorithm results have not been found for this test set.

The values of PR and SR of all three methods for the Classical Functions set are given in Table VI. Results of GaMeDE and GaMeDE2 were calculated for the $\epsilon = 10^{-5}$ accuracy level, where those for SDLCSDE algorithm have been acquired from the original publication [4](see Table VIII) and with matching accuracy levels. Results show that for the functions B4, B5, B6, B7, B9, accuracy is higher (see Table VIII), but it is either the same or lower for the rest. To get more fair results, GaMeDE2 has been re-evaluated on functions B4–B9 with a matching accuracy which was presented in Table VII. Experiments on function 8 have been repeated due to lower performance than SDLCSDE while using higher accuracy. Thus, results show that GaMeDE2 achieves better results for B13 and B14 than SDLCSDE algorithm while maintaining a higher or the same accuracy level for all functions. Additionally, results show that GaMeDE struggles with a number of functions.

TABLE V
RESULTS FOR THE CEC2013 / GECCO2020 MULTIMODAL FUNCTION SET

#	GaMeDE		GaMeDE2		HVCMO

Results of experiments in Table IX present GaMeDE, GaMeDE2 and HVCMO applications to the Deceptive Functions set. GaMeDE2 proved to achieve better results for every function except for D2 and D3 where both algorithms found all the solutions. Due to the novelty (and lack of SDLCSDE code) of this set there are no results for SDLCSDE.

In the methods evaluation process and experiments, there are some suggestions that for the Deceptive Multimodal Function Set it is worth extending the budget for several functions

(especially for D7-D9) to explore the three-dimensional landscape more extensively. The standard and extended budgets are presented in Table IV. In Table X the summary of results for examined methods is presented.

Table X includes results with extended budgets for all examined methods. It can be concluded that each method uses the extended budget effectively and achieves better results. However, GaMeDE2 is the most effective: $PR = 1.0$ and $SR = 1.0$, as it solves each function and outperforms other methods.

To summarise, the results for three test sets: CEC2013, Classic and Deceptive are presented in Table XI. Presented data show the average values for PR and SR for four examined methods: GaMeDE, GaMeDE2, HVCMO and SDLCSDE. Results show that GaMeDE2 outperforms referenced methods.

The results presented in this section contain four methods and three test sets. It gives a rather bird’s eye view of examined methods. More detailed results, analysis and discussion, are included in the next section.

D. Discussion

The GaMeDE2 maintained the average $PR = 0.883$ ($W = 6 > W_{\rho < 0.05}$) on the CEC2013 (see Table V) test set but improved the SR for F3, F12, F13. CF14 is the only instance where PR value decreased, but the improvement on the remaining ones has balanced it. It was not expected to observe any significant change in this benchmark set used for the original GaMeDE method development. On the other hand, it is a crucial result suggesting that proposed modifications do not harm any original components. Difference between GaMeDE2 and HVCMO $PR = 0.884$ is not a significant

difference either ($W = 7 > W_{\rho < 0.05}$). In comparison to the HVCMO method, the key advantage of the GaMeDE2 method is a SR difference, especially for functions F8 and F9, where it found all optima in every run, while HVCMO failed to do so even once. These two functions’ main feature is the uneven distribution of high optima number (same as B13 - see Figure 5). Later in this chapter, it is explained which element is responsible for this improvement.

The second test set, containing Classical Multimodal Benchmark Functions (see Table VI), introduces novel instances for the GaMeDE. While some of the functions are repeated, they have narrowed the evaluation budget. Plots in Figure 3 visualize that selection in the first iteration doubles the initial evaluation cost, which is the 80% for both B8 and B10. With only 20% budget left, it is unlikely for the algorithm to locate all global optima. Skipping the first selection proposed as the first modification reduced the initial cost to 40% of the total budget.

Moreover, to fully take advantage of the extended evaluation budget, the clustering procedure in GaMeDE2 has been replaced with the initial iteration. In GaMeDE, the current population is clustered around the set of archived points. Those archive points are selected to reward unexplored areas. It is a valuable mechanism. However, there is no application in the first iteration, where the whole area is unexplored. The

TABLE XI
SUMMARY RESULTS FOR CEC2013, CLASSIC AND DECEPTIVE SETS

Set	GaMeDE		GaMeDE2		HVCMO		SDLCSDE	
	PR	SR	PR	SR	PR	SR	PR	SR

alternative version introduces additional clustering of archive points just before the current population is clustered around them. It allows for filtering out archive points if there is a probability that they lay in the same niche. The modification results are presented on the Figure 4.

While having the explicit *WIDE* and *FOCUS* phases is not crucial for GaMeDE2, it is still important to maintain both types of selection: *GAP* and *Random*. The important difference is that the former is archive-based, while the latter is population-based. Based on the experiments, both selections proved to be crucial. Using solely *Random* Selection gives comparable results for most of the instances, except for those with a high number of optima (F8, F9, B13, B14), where method struggled with finding the narrow optima in far corners of the search space. On the contrary, while using *GAP* selection only, all the optima in mentioned instances have been found. Figure 5 presents the difference in population distribution after using *Random* or *GAP* selection. A drawback of this approach has been however observed in decreased *PR* for high-dimensional instances (CF19, see Table V). It confirms that using both alternately gives the best results. Further research could support further simplification of the method by limiting to *GAP* selection only. Statistical tests for the Classical Functions Set (see Table VI) confirm all these

changes introduce a significant improvement of $PR = 1.0$ ($W = 0 \leq W_{\rho < 0.05}$) and $SR = 1.0$ ($W = 0 \leq W_{\rho < 0.05}$) over the original GaMeDE method. It allowed achieving similar effectiveness to the HVCMO method.

The proposed Deceptive Multimodal Function Set introduces Trap functions in two- and three- dimensions. The essential difficulty is the moderate budget scaling which creates a challenge in three-dimension variants. Another difficulty is the very steep global optima in the far corners of the search space opposite the large area of deceptive local optima. The GaMeDE struggles with those functions because a significant fraction of the archive points lies on the local optima, and there is a bigger chance of selecting them for optimization. GaMeDE2 has been statistically verified to improve the $PR = 1.0$ ($W = 0 \leq W_{\rho < 0.05}$) and $SR = 1.0$ ($W = 0 \leq W_{\rho < 0.05}$) in relation to the original GaMeDE method for both budget sets (see Table IX and Table X).

V. CONCLUSIONS AND FUTURE WORK

Developing a method for a specific benchmark suite allows to focus on the improvements and quickly verify their effectiveness. However, it may lead to overfitting of the proposed solution. The original GaMeDE could be such a case. While very competitive on the CEC2013 benchmarks,

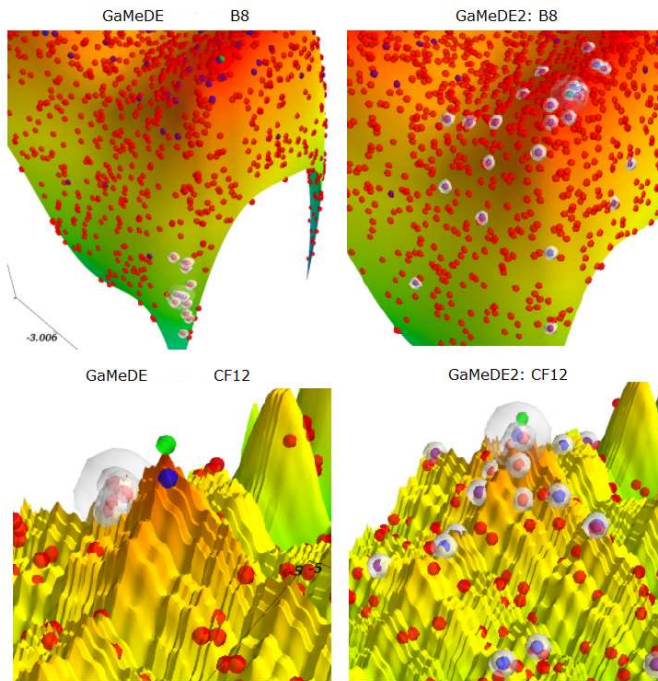

Fig. 4. **Modification #3 improvement.** After additional archive points clustering, the actual clusters (marked by grey spheres) and located around the global optima (green spheres) instead of on their side.

it does not maintain the effectiveness on novel instances. Two additional test sets have been proposed to verify the method’s generalization ability. First, two deceptive functions (Two-Peak Trap, Central Two-Peak Trap), Decreasing Maxima, Uneven Maxima, and Shekel’s Foxholes have been added. Additionally, the computational budget for the number of already present functions has been limited. The second proposed test set further explores the range of the deceptive function – it expands three trap functions into 2 and 3 dimensions.

The Hill-Valley-Clustering-based VMO (HVcMO), a novel solution based on the HillValIEA, has been selected to provide a fair comparison.

In tuning procedure GaMeDE2, the Taguchi parameter design procedure has been used to evaluate the GaMeDE parameters and fine-tune them across all three sets. While it provided a promising outcome for a single instance, it could not point a one configuration valid for all instances of the test suites. Such an outcome is that specific instances introduce different challenges, sometimes overlapping each other. For example, Vincent function has strongly irregularly distributed yet smooth optima. Composition Functions such as CF17/CF20 consist of two steep optima. Shekel’s Foxholes is a nearly binary landscape with a minimal variety among the optima. Furthermore, there is a wide span of provided budget, even for the same functions: 50K evaluations for Himmelblau in F4 and only 10K in B8. Decreasing the budget might expose the weak spots of methods that otherwise work successfully. Fine-tuning parameters per instance ensures the best results yet requires far more studies of the problem and time. However, the number of optima, their distribution, and local landscape disturbance have not been known *a priori*. For all those reasons, having a single configuration could be a superior approach, and optimization methods that do not require tuning many parameters are far more practical.

Based on the results of the experiments, a set of changes has been proposed to improve the original method’s generality, leading to better results for the two novel test sets. Moreover, it maintains the CEC2013 benchmark functions’ competitive level while using just a single parameter configuration. In comparison to another state-of-the-art method – HVcMO, GaMeDE2 manages to completely solve instances with a high number of unevenly distributed optima (F8, F9, B14), while maintaining the average *PR* at the same level. The only case where introduces method has lower effectiveness is a novel Deceptive Functions Set if a very restrictive budget is provided.

The proposed GaMeDE2 method mainly addresses the initialization and clustering process. Skipping the initial mutation frees a significant amount of budget, which prevents premature algorithm stopping for the low-budget instances. The alternative (double) clustering in the first iteration allows for faster exploring all the promising niches. While it has low chances of finding narrow optima, it marks the ‘easy’ ones. The idea is similar to the mechanism of two natural metabolism phases (*Anaerobic* and *Aerobic*) in the human body. The first is used in short, burst activity (a big number of ‘easy’ optima). The second can be for long-duration activities and far goals (narrow, ‘hard’ steep optima). Additionally, GaMeDE2 is further simplified by removing the selection dependency from the phase.

The proposed Deceptive Functions set illustrates that Trap functions are not a bigger challenge for the multimodal solving methods. Multimodal optimization, by definition, does not seek a sole solution, which makes it more resistant to deceptiveness. Further research on the more irregular high-

dimensional composition of different Trap Functions could be valuable for further research direction.

Though GaMeDE2 uses a single configuration, its further version could also benefit from adaptive parameters steering, such as population size, archive size, mutation or crossover probability. Moreover, simplifying the original method, e.g. the parameter used in enabling *HillClimbing* step was not fully eliminated – it requires further work to make it fully adaptive. Indeed, improvements in clustering could be a promising research area. At the current state, the first iteration allows searching all the promising niches, leading to extensive use of the evaluation budget. An efficient mechanism in balancing and prioritizing the clusters to explore could introduce a significant value.

Abstract—Social Engagement is a novel business model transforming final users of a service from passive into active components. In this framework, people are contacted by a company and they are asked to perform tasks in exchange for a reward. This arises the complicated optimization problem of allocating the different types of workforce so as to minimize costs. We address this problem by explicitly modeling the behavior of contacted candidates through consolidated concepts from utility theory and proposing a chance-constrained optimization model aiming at optimally deciding which user to contact, the amount of the reward proposed, and how many employees to use in order to minimize the total expected costs of the operations. A solution approach is proposed and its computational efficiency is investigated through experiments.

I. INTRODUCTION AND RELATED WORKS

SOcial Engagement (SE) is a new business paradigm involving the customers of a company in its operations. More precisely, people agree to perform specific services in exchange for a reward. This model has been enabled by the increase of the number of users connected on the web and technologies able to get people information [1]. This gives to the companies the possibility to easily communicate with *candidates* and then to propose *tasks* in exchange for a reward.

A concrete application of the SE paradigm is the so called *crowd-shipping* logistics, in which the companies ask the people to collect the packages to a certain location and deliver it to the final user [2][3]. By doing this, companies do not only decrease the costs, but also the environmental impact since people accepting the delivery usually would take advantage of travels that they have to do anyhow for other activities. Another interesting application of SE occurs in an evolution of the Internet of Things (IoT) concept called opportunistic IoT (oIoT) [4]. Since the IoT development is considerably slowed down by the difficulty and costs involved in building telecommunication networks capable of continuously transmitting large amounts of data collected by sensors, through oIoT the citizens share (in exchange for a reward) the internet of their devices (mobile phones, modems) so that the nearby sensors can exploit it to communicate the gathered data. In this work, we do not want to concentrate on a specific application rather on a very general SE-based setting in order to embrace all the basic characteristics of such a business model.

An effective planning of operations under the SE paradigm yields an interesting optimization problem. The decision-maker must decide how much he is willing to pay to a candidate for each task, when and where to rely on employees and on candidates, which tasks to assign to the employees and for which tasks the candidates must be contacted, in order to minimize the total operational costs. It is important to note that the reward paid to a candidate is generally lower on average than the cost that the company bears for an employee. However, while an employee is obliged to accept and carry out the tasks assigned to him, there is no certainty that a candidate will accept a proposed task.

Little attention has been devoted to the development of optimization models aimed at effectively scheduling companies operations that exploit SE. Just few works [5][6][7] have tried to tackle the problem and, therefore, there is a large room for improvement of existing approaches as well as for the design of more innovative and complete ones (as claimed regarding crowd-shipping in [3]). In particular, to the best of our knowledge, there is no published optimization model that explicitly accounts for individual candidate behaviour when planning SE-based operations. As already mentioned, one characteristic that makes challenging the optimization problems deriving from the implementation of the SE paradigm is the fact that candidates are not constrained a priori to respect a contract. This means that, once contacted, the candidate may not accept the task and, if we assume a pure rational profit-maximization behavior of the candidate, the reject can happen because the proposed reward is lower than the candidate expectation. It is therefore important to integrate tools in the decision-making process that allow monitoring the individual behavior of potential candidates.

In this work, to account for individual behaviour, we rely on the candidate's *willingness to accept* (wta) a task, i.e., the minimum reward expected by a candidate to accept a task. The wta is a well consolidated concept in utility theory and has been used since long to explain human subject preferences in economics [8]. From the decision-maker point of view, the candidate's wta is not deterministically known, since it depends on some factors that are intrinsic of the candidates. Therefore, we consider the candidate wta as a random variable.

Thus, the probability of acceptance for a candidate will be equal to the probability that the offered reward is greater or equal to the wta of the candidate. The adopted perspective is similar to [6]. However, instead of relying on a single random variable describing the number of candidates, we model each single candidate behavior through a Bernoulli random variable. The parameter of such a Bernoulli random variable, i.e. the probability that the candidate accepts the task, is not fixed but depends by the proposed reward.

This paper's contribution is twofold. First, we propose a novel mathematical model for SE-based services optimization. The formulation, which includes chance constraints [9], results to be the first one that explicitly accounts for each individual candidates behaviour. Second, since the complexity of the proposed model and the explicit consideration of stochastic parameters do not allow to obtain a simple solution, we derive a mixed-integer quadratic programming model that approximates the original model. This is done by making some reasonable hypothesis on the probability distribution of the wta of each candidate, and by exploiting the Markov inequality. Several computational experiments validate the suitability of our proposed model and solution approach.

The rest of the paper is organized as follows. The optimization problem is defined and modeled in Section II. Our solution approach is described in Section III. Section IV presents the experimental results, while Section V concludes the paper.

II. THE SOCIAL ENGAGEMENT OPTIMIZATION PROBLEM

The social engagement optimization problem that we want to study considers a decision-maker (in general a company) whose goal is to use people, in the following called *candidate*, in addition to employees in order to perform a set of tasks. In particular, we consider a urban environment divided in several geographical areas such as mobile phone cells, neighborhoods of different markets or just geographical areas. Each of these areas is characterized by a number of tasks to perform and each task is characterized by different workloads, thus a single task may require more candidates to be done. For example, in the crowd shipping setting these tasks are the delivery required by customers out of the store, while in the oIoT application these tasks consist in sharing the internet connection with smart sensors in the city.

Each task can either be performed by using employees or candidates. Employee are more expensive, are available in a small number but they execute the tasks assigned. Instead, candidates are less expensive, their quantity is virtually unlimited (since the number of people considered for SE is far greater than the number of tasks) but they can refuse to perform a task with a given probability. We assume that the acceptance probability increases as the offered reward increase. Please note that, in practice, an employee has greater productivity than a candidate. The goal of the decision-maker is to minimize the total operative costs while enforcing that with high probability all the tasks must be performed.

Let us consider a set \mathcal{I} of tasks and a set \mathcal{M} of candidates. For each task i , let W_i be the workload required, α_i be the

required probability for its accomplishment, Δ_i^m be a random variable representing the wta of candidate m , and c_i be the cost of using an employee. Moreover, let B be the number of available employees and $r > 1$ be the ratio between the productivity of an employee and that of a candidate, i.e., the workload that a single employee can afford as compared to a candidate in the same time frame.

We define the decision variables $Q_i^m \in \mathbb{R}^+$ as the reward offered to candidate m to accept task i and $z_i \in \mathbb{N}$ as the number of employee assigned to tasks i . Moreover, we consider the probability for candidate m to accept task i called $x_i^m \in [0, 1]$ and the random variables Y_i^m distributed according to a Bernoulli distribution of probability x_i^m which assume value 1 if candidate m accepts to perform task i . Then, the Social Engagement Optimization Problem (SEOP) can be formulated as follows:

$$\min \sum_{i \in \mathcal{I}} \sum_{m \in \mathcal{M}} Q_i^m x_i^m + \sum_{i \in \mathcal{I}} c_i z_i \quad (1)$$

$$\text{s.t. } x_i^m = \mathbb{P}[Q_i^m \geq \Delta_i^m], i \in \mathcal{I}, m \in \mathcal{M} \quad (2)$$

$$\mathbb{P}[Y_i^m = a] = (x_i^m)^a (1 - x_i^m)^{(1-a)}, i \in \mathcal{I}, m \in \mathcal{M} \quad (3)$$

$$a \in \{0, 1\} \quad (4)$$

$$\mathbb{P} \left[\sum_{m \in \mathcal{M}} Y_i^m + r z_i \geq W_i \right] \geq \alpha_i, i \in \mathcal{I} \quad (5)$$

$$\sum_{i \in \mathcal{I}} z_i \leq B \quad (6)$$

$$z_i \in \mathbb{N}, i \in \mathcal{I}, \quad (7)$$

$$Q_i^m \in \mathbb{R}^+, x_i^m, Y_i^m \in [0, 1], i \in \mathcal{I}, m \in \mathcal{M}. \quad (8)$$

The total cost in (1) is expressed as the summation between the total expected cost offered as rewards (the reward Q_i^m is paid with probability x_i^m), and the sum of the costs paid for employees. Constraints (2) define the variables x_i^m as the acceptance probability, while constraints (3) and (4) ensure Y_i^m to follow a Bernoulli distribution. Constraints (5) are chance constraints enforcing a minimum probability of doing a given task either by using employees or candidates. It is worth noting that ensuring that each task is performed with a given probability is less strict than requiring that all the tasks will be performed with a given probability. Nevertheless enforcing this second condition would lead to too conservative solutions. Finally, constraint (6) accounts for the limited number of employees.

III. SOLUTION APPROACH

The optimization problem in (1)-(6) is difficult to solve due to the definition of x_i^m in constraints (2), of Y_i^m in constraints (3) and (4), and the chance constraints in (5). Hence, we approximate these constraints in order to get a model which can be readily solved with off-the-shelf solvers.

Constraints (2) involve the cdf of the random variable Δ_i^m . We approximate it by means of a piece-wise linear function with J breakpoints. In particular, instead of constraints (2) we add a set of constraints of the form

$$x_i^m \leq k_j Q_i^m + q_j, \quad j = 1, \dots, J, i \in \mathcal{I}, m \in \mathcal{M}, \quad (9)$$

where k_j and q_j are obtained by imposing proper conditions (e.g. the passage in J points of the cdf). This choice is equivalent to enforce $x_i^m \leq \min[1, m_1 Q_i^m + q_1, \dots, m_J Q_i^m + q_J]$, where the first term of the minimum comes from the definition of x_i^m . Since the approximation proposed in (10) just lead to concave functions (being the pointwise minimum of affine functions) and since the a general cdf may be convex in some portion of the domain, the proposed approximation is not guarantee to converge to the cdf for all the distributions. In the following, for the sake of simplicity, we consider just $J = 1$ and we impose the passage for the point $(0, 0)$ meaning that with 0 reward the probability that the candidate will perform the task is 0, and for the point $(\bar{Q}_i^m, 1)$ where \bar{Q}_i^m is a reward for which the candidate m is willing to perform the task i with a probability that we may approximate to be 1. By making this choice, the obtained final approximation of Constraints (2) is:

$$x_i^m \leq Q_i^m / \bar{Q}_i^m, \quad i \in \mathcal{I}, m \in \mathcal{M}. \quad (10)$$

Now let us consider the constraints in (5), note that these constraints can be written as:

$$\mathbb{P} \left[\sum_{m \in \mathcal{M}} Y_i^m \geq W_i - rz_i \right] \geq \alpha_i, \quad i \in \mathcal{I}. \quad (11)$$

By using the Markov inequality, for each $i \in \mathcal{I}$, it holds:

$$\frac{\mathbb{E}[\sum_{m \in \mathcal{M}} Y_i^m]}{W_i - rz_i} \geq \mathbb{P} \left[\sum_{m \in \mathcal{M}} Y_i^m \geq W_i - rz_i \right] \geq \alpha_i. \quad (12)$$

Hence, since $\mathbb{E}[\sum_{m \in \mathcal{M}} Y_i^m] = \sum_{m \in \mathcal{M}} \mathbb{E}[Y_i^m] = \sum_{m \in \mathcal{M}} x_i^m$, Eq. (12) leads to the following constraint:

$$\sum_{m \in \mathcal{M}} x_i^m \geq \alpha_i (W_i - rz_i), \quad i \in \mathcal{I}. \quad (13)$$

Eq. (13) is enforcing that the expected workload form the candidates must be greater than the α_i percent of the people needed. Moreover, by considering the bound provided by Eq. (13), we are reducing the feasible set, thus the condition in (11) will be satisfied for greater value of α_i .

Then, the resulting approximation of the SEOP ($SEOP_{ap}$) is the following mixed integer quadratic model:

$$\min \sum_{i \in \mathcal{I}} \sum_{m \in \mathcal{M}} Q_i^m x_i^m + \sum_{i \in \mathcal{I}} c_i z_i \quad (14)$$

$$\text{s.t. } x_i^m \leq \frac{Q_i^m}{\bar{Q}_i^m}, \quad i \in \mathcal{I}, m \in \mathcal{M} \quad (15)$$

$$\sum_{m \in \mathcal{M}} x_i^m \geq \alpha_i (W_i - rz_i), \quad i \in \mathcal{I} \quad (16)$$

$$\sum_{i \in \mathcal{I}} z_i \leq B \quad (17)$$

$$z_i \in \mathbb{N}, \quad i \in \mathcal{I}, \quad (18)$$

$$Q_i^m \in \mathbb{R}^+, x_i^m \in [0, 1], \quad i \in \mathcal{I}, m \in \mathcal{M}. \quad (19)$$

IV. EXPERIMENTAL RESULTS AND ANALYSIS

We now present CPU experiments validating the proposed solution approach. All the experiments were performed on a *Intel(R) Core(TM) i7-5500U CPU@2.40GHz* computer with 16GB of RAM and running *Ubuntu v20.04*. The exact solver used was Gurobi v9.1.1 via its Python3 APIs. The instances, according to realistic crowd-shipping scenarios, were generated considering $|\mathcal{I}| = \{5, 10, 20, 50, 100\}$, $|\mathcal{M}| = 4|\mathcal{I}|$, $w_i = 7 * (0.8 + 0.4 * \mathcal{U}(0, 1))$, $B = 2$, and $\alpha_i = \bar{\alpha}, \forall i \in \mathcal{I}$ with $\bar{\alpha}$ drawn from $\mathcal{U}(0.6, 0.9)$. Finally, the random variables Δ_i^m were drawn from a Gumbel distribution, while \bar{Q}_i^m was set to be equal to the 99 percentile of Δ_i^m .

A. CPU results

We first study the CPU solving time with respect to the dimension of the $SEOP_{ap}$. In particular, versus the growth of $|\mathcal{I}|$ and $|\mathcal{M}|$, we evaluate the CPU time (sec), the time-to-best (sec) (the number of seconds from the start of the execution of Gurobi to the time in which it finds the best solution of the run), and the MIP gap (%) (computed as the percentage difference between the lower and upper objective bound. In particular, we consider the least gap value that Gurobi has to reach before stopping its execution). The average and standard deviation on 10 instances are shown in Table I. In all the runs we set the solver time limit to 1 hour.

TABLE I
AVERAGE $[\mu]$ AND STANDARD DEVIATIONS $[\sigma]$ OF THE CPU TIME, TIME TO BEST, AND MIP GAP FOR DIFFERENT VALUES OF \mathcal{I} AND \mathcal{M} .

Instance		CPU time(sec)		time-to-best (sec)		MIP gap (%)	
$ \mathcal{I} $	$ \mathcal{M} $	μ	σ	μ	σ	μ	σ
5	20	0.09	0.01	0.09	0.01	0	0
10	40	1569.56	175.83	614.31	235.43	0	0
20	80	2780.84	573.26	2634.94	897.98	0	0
50	200	3600.00	0.00	1054.31	562.25	56	47
100	400	3600.00	0.00	1679.57	720.77	100	0

Instances with $|\mathcal{I}| = 5$, and $|\mathcal{M}| = 20$ are solved almost instantaneously with 0 gap. The time-to-best is equal to the CPU time since the difference are below the hundredths of a second. For instances with $|\mathcal{I}| = 10, |\mathcal{M}| = 40$, and $|\mathcal{I}| = 20, |\mathcal{M}| = 80$, the CPU time increases, but the solver is still able to find the optimal solution inside the time limit. For the instances with $|\mathcal{I}| = 10, |\mathcal{M}| = 40$ the time to best is near one half of the total CPU time but solutions with gap below the 5% are found by the solver already in the first minutes of the run. Instead, for the instance with $|\mathcal{I}| = 20, |\mathcal{M}| = 80$, the time-to-best is close to the whole computation time and no solution with gap below the 5% is found in the first minute of the run. For instances of greater dimensions, the solver is not able to find the optimal solution in the given time limit, for this reason the CPU time is equal to 3600 seconds with a standard deviation of 0. Nevertheless, for instances with $|\mathcal{I}| = 50$, and $|\mathcal{M}| = 200$, several times, the final gaps are smaller than 10%, while for instances with $|\mathcal{I}| = 100$, and $|\mathcal{M}| = 400$, the solver is not able to find a good bound in the allocated computational time, hence, a 100% MIP gap with 0 standard deviation is reported.

B. Approximation analysis

We now analyze the goodness of the $SEOP_{ap}$ approximation. Since Δ_i^m is distributed as a Gumbel distribution with concave cdf, the approximation proposed converges to the exact function and several techniques for developing good piece-wise approximation are available [10]. Thus, we are interested in quantifying how much conservative is the Markov inequality with respect to Eq. (5). Hence, we compute the optimal solution of $SEOP$ and we use it to calculate $\hat{\alpha} := \mathbb{P}[\sum_{m \in \mathcal{M}} Y_i^m + rz_i \geq W_i]$. This can be done easily by noting that the Y_i^m are independent with respect to the index m since the knowledge about candidate m performing a task does not provide any information related to the execution of the same task by other candidates. Thus, $\sum_m Y_i^m$ is a sum of independent random variable distributed according to Bernoulli distribution of parameter x_i^m . Central Limit Theorems for non identically distributed random variables are available and, in particular, by applying the Lyapunov Central Limit Theorem it is possible to prove [11] that for large values of $|\mathcal{M}|$ (in practice $|\mathcal{M}| \geq 30$), it holds that:

$$\sum_{m \in \mathcal{M}} Y_i^m \sim \mathcal{N} \left(\sum_{m \in \mathcal{M}} x_i^m, \sum_{m \in \mathcal{M}} x_i^m(1 - x_i^m) \right), \quad i \in \mathcal{I}. \quad (20)$$

By using (20), we can compute α by solving:

$$\alpha_i = 1 - \Phi \left(\frac{W_i - rz_i - \sum_{m \in \mathcal{M}} x_i^m}{\sqrt{\sum_{m \in \mathcal{M}} x_i^m(1 - x_i^m)}} \right), \quad i \in \mathcal{I}, \quad (21)$$

where Φ is the cdf of a standard normal distribution. We report the value of the $\alpha \in [0.5, 1]$ in $SEOP_{ap}$ versus the $\hat{\alpha}$ computed with Eq. (21) in Figure 1. All the results are averaged over 10 runs and the standard deviation of the observation is represented as an uncertain area. We compute the results for $|\mathcal{I}| = 10$ and $|\mathcal{M}| = 40$ since we are able to get the optimal solution in a reasonable amount of time. Moreover, with $|\mathcal{M}| = 40$ there are enough candidates to apply results in (20)–(21).

Fig. 1. Values of α set in the model vs real value of α .

As we expected, the curve is above the line $\hat{\alpha} = \alpha$ since by using the Markov inequality we are considering an upper bound on the probability. Nevertheless, the results are close to the exact value being on average 10% higher than the α set in the model. Thus, in the real field, the decision-maker

may lower by 10% the values of the α s and get a solution compliant with the wanted probability of execution.

V. CONCLUSIONS AND FUTURE WORKS

We proposed a new probabilistic model for SE-based services optimization encompassing the wta of the candidate involved in the business model. We prove, by means of CPU experiment that, despite the difficult formulation, the model can be approximated into a nice tractable form able to provide timely solution for crowd-shipping applications. However, being the SE a very seminal topic within the optimization field, we believe that a full-fledged experimental design to explore all the solution characteristics is needed. Some questions to answer are related to the performance of the method in the case in which non-concave distributions for the wta are considered or how the solutions of the model are related to the number of breakpoints used by the piece-wise wta approximation.

Abstract—Most recently, a link between principal component analysis (PCA) based on L1-norm and independent component analysis (ICA) has been discovered. It was shown that the ICA can actually be performed by L1-PCA under the whitening assumption, inheriting the improved robustness to outliers. In this paper, a novel ICA algorithm based on Jacobi iterative framework is proposed that utilizes the non-differentiable L1-norm criterion as an objective function. We show that such function can be optimized by sequentially applying Jacobi rotations to the whitened data, wherein optimal rotation angles are found using an exhaustive search method. The experiments show that the proposed method provides a superior convergence as compared to FastICA variants. It also outperforms existing methods in terms of source extraction performance for Laplacian distributed sources. Although the proposed approach exploits the exhaustive search method, it offers a lower computational complexity than that of the optimal L1-PCA algorithm.

I. INTRODUCTION

INDEPENDENT component analysis (ICA) [1] is one of the most widely used techniques in multivariate signal processing. The major goal of the ICA is to transform observed mixtures to components that are as independent from each other as possible. Since the only assumption about the components is that they are mutually independent, the ICA can be viewed as a special case of blind source separation (BSS) problem [2]. Such a problem arises in a wide range of applications, including speech/image source separation, noise reduction, feature extraction, watermark detection.

Most of the ICA algorithms are based on the central limit theorem. Among them, FastICA approach [3], [4], [5] is probably the most well-known example. It attempts to find directions in multidimensional space in which some measure of non-Gaussianity is maximized, thereby enforcing mutual independence between components. The projections of the observed multivariate data onto these directions are viewed as independent components, and often reveal much of the data's structure.

The ICA could also be seen as a generalization of the classical principal component analysis (PCA) [6] by assuming independent and non-Gaussian source distributions. In more detail, the PCA only tries to identify orthogonal directions, along which the data exhibit the greatest variability. Traditionally, this variability is measured using the Frobenius

norm (L2-norm on matrices), which allows to decorrelate the components but not to make them independent. Though, the PCA is often used in many ICA algorithms as a pre-processing step for whitening or sphering the data.

In recent years, a growing interest in approaches to the PCA based on the L1-norm can be observed [7], [8], [9]. Unlike conventional PCA, the L1-norm techniques offer an improved robustness to outliers, i.e., data points that differ significantly from the other observations. Most recently, it was shown in [10] that the ICA can actually be performed by L1-norm PCA under the whitening assumption. When the source distribution fulfills certain conditions, it is possible to extract independent components using optimal L1-PCA algorithms with guaranteed global convergence. It was demonstrated that such algorithms may give better accuracy and robustness than those of conventional ICA methods. Unfortunately, optimal L1-PCA algorithms are computationally expensive. In addition, the global convergence is guaranteed only for distributions with negative kurtosis sign. In the work [10], a new variant of the FastICA algorithm with absolute value nonlinearity was considered. Although the accuracy and robustness of this approach were comparable to that of the optimal L1-PCA algorithm, it shows serious convergence difficulties.

In this paper, a novel approach to ICA based on direct optimization of the L1-norm criterion is proposed. The method follows Jacobi iterative framework, whereby the global solution is reached by successively applying Jacobi/Givens rotations to whitened observation vectors [11], [1], [12], [13]. In this way high-dimensional ICA problem is reduced to solving a set of the simpler one-dimensional subproblems. Namely, at every iteration step, we are looking for the angle that maximizes negentropy of the transformed components. Unlike conventional Jacobi methods, the proposed algorithm exploits the contrast function based on the L1-norm, inheriting increased robustness to outliers. Since the local cost functions are of simple form, the optimal rotation angle is found using an exhaustive search method. Therefore, the differentiability of the objective function is no longer required and the method can deal with saddle points and multiple extrema. The simulation results show that the proposed method offers a superior convergence compared to the FastICA method with absolute value function nonlinearity. Furthermore, it outperforms conventional methods in source extraction performance for the mixtures with Laplacian distributions.

This work was supported by Bialystok University of Technology under the grant WZ/W1-IIT/4/2020

The paper is organized as follows. Section II describes the connection between the ICA and L1-norm criterion. It also introduces the mathematical formulations behind the FastICA technique and its recent variant using absolute value function as non-linearity. In Section III, a novel ICA algorithm is proposed based on the Jacobi iterative framework and non-differentiable L1-norm criterion. Section IV investigates the performance of the presented method via numerical simulations. Finally, the conclusions are given in Section V.

II. LINK BETWEEN ICA AND L1-PCA

Let us denote by $\mathbf{x} = [x_1, x_2, \dots, x_N]^T \in \mathbb{R}^N$ observable, zero-mean N -dimensional random vector and by $\mathbf{y} = [y_1, y_2, \dots, y_N]^T \in \mathbb{R}^N$ its linear transform, i.e. $\mathbf{y} = \mathbf{B}\mathbf{x}$. Then, the ICA problem consists of finding an unmixing matrix $\mathbf{B} \in \mathbb{R}^{N \times N}$ such that the components of \mathbf{y} are as independent as possible. Since statistical independence implies uncorrelatedness, many ICA algorithms assume explicitly that $E\{\mathbf{y}\mathbf{y}^T\} = \mathbf{I}$, where $E\{\cdot\}$ stands for expectation operator. This is usually enforced by the following factorization of the unmixing matrix:

$$\mathbf{B} = \mathbf{W}\mathbf{C}_{\mathbf{xx}}^{-1/2}, \quad (1)$$

where $\mathbf{C}_{\mathbf{xx}}^{-1/2}$ denotes the whitening matrix which is computed by inverting a square root of the observation signal covariance matrix. It can be easily verified that the constraint $E\{\mathbf{y}\mathbf{y}^T\} = \mathbf{I}$ holds for any orthogonal matrix \mathbf{W} . Since the whitening transformation is always possible, the ICA problem can be viewed as finding an orthogonal transformation of the whitened data vector $\mathbf{z} = \mathbf{C}_{\mathbf{xx}}^{-1/2}\mathbf{x}$, i.e. $\mathbf{y} = \mathbf{W}\mathbf{z}$, such that the components of \mathbf{y} are as independent as possible. This can in particular be achieved by maximizing the negentropy of the random vector \mathbf{y} defined as follows:

$$J(\mathbf{y}) = h(\mathbf{v}) - h(\mathbf{y}), \quad (2)$$

where $h(\cdot)$ is the differential entropy [14] and \mathbf{v} is the Gaussian random variable of the same covariance matrix as \mathbf{y} . Unfortunately, computation of (2) is not an easy task and in practice some approximations of negentropy [3], [5] have to be used. Let $y = \mathbf{w}^T\mathbf{z}$ denote a random variable being a linear projection of the whitened data vector onto some direction $\mathbf{w} \in \mathbb{R}^N$. Then, the negentropy of this projection can be approximated as follows:

$$J_g(y) \approx c[E\{g(y)\} - E\{g(v)\}]^2, \quad (3)$$

where c is irrelevant constant and g is any non-quadratic, sufficiently smooth even function. The variables v, y are assumed to be of zero mean and unit variance, with v being a Gaussian-distributed variable. The approximation (3) is interpreted as a measure of non-Gaussianity as it is always non-negative, and it equals to zero if and only if y is Gaussian.

In the case of the deflationary FastICA algorithm [4], the independent components are found sequentially, one after

another. For each source, the criterion (3) is optimized iteratively, using an approximate Newton technique. Namely, the following fixed-point iteration is used:

$$\hat{\mathbf{w}} = E\{\mathbf{z}g'(\mathbf{w}^T\mathbf{z})\} + E\{g''(\mathbf{w}^T\mathbf{z})\}\mathbf{w}, \quad (4)$$

$$\mathbf{w}^+ = \hat{\mathbf{w}}/\|\hat{\mathbf{w}}\|_2, \quad (5)$$

where \mathbf{w}^+ stands for the direction vector of the estimated independent component after the current iteration. These vectors are projected onto the space orthogonal to the space spanned by the earlier found vectors, so that at the end, we obtain the set $\{\mathbf{w}_i^T\}_{i=1}^N$ of orthogonal projectors that are stored in the rows of the matrix \mathbf{W} .

A. FastICA based on absolute value function

A crucial step in optimizing the FastICA algorithm is to choose the best non-linearity $g(\cdot)$ [15]. Many ICA algorithms [11], [1], [12], [16] use kurtosis-based contrast functions, which correspond to the fourth-power non-linearity $g(y) = 1/4y^4$. Such a choice can be justified on statistical grounds only for estimating sub-Gaussian sources (i.e. those with negative kurtosis) when there are no outliers. However, in practice we mostly deal with super-Gaussian variables [17] that have positive kurtosis. It was suggested in [3], [4] that for super-Gaussian densities, the optimal contrast function is a function that grows slower than quadratically. In particular, as a general-purpose contrast function, one should choose,

$$g(y) = |y|^\alpha, \quad \alpha < 2. \quad (6)$$

Nevertheless, no attempt has been made to implement this idea in practice. The reason is that the FastICA algorithm assumes the differentiability of $g(y)$, whereas for the absolute value function, this property fails at origin. Therefore, the following differentiable approximation of the absolute value function has been proposed:

$$g(y) = \frac{1}{a} \log \cosh(ay), \quad (7)$$

with $1 \leq a \leq 2$. However, this approximation may not provide the same independent source extraction performance as the absolute value function.

In the recent work [10], the authors admitted differentiability of $g(y) = |y|$ by assuming that $g'(y) = \text{sign}(y)$ and $g''(y) = 2\delta(y)$, where $\delta(y)$ denotes Dirac's delta function. It resulted in the modified FastICA method with the following iteration step in place of (4):

$$\hat{\mathbf{w}} = E\{\mathbf{z} \text{sign}(\mathbf{w}^T\mathbf{z})\} - 2f_y(0)\mathbf{w}, \quad (8)$$

where $f_y(0)$ stands for the probability density function (PDF) of y evaluated at the origin. As proposed in [10], it can be computed through the kernel density estimate with Gaussian kernel. It was also demonstrated that, for small data sizes (e.g. $N = 2, 3$), this algorithm can provide some improvements in source extraction performance when dealing with outliers. However, the iteration (8) may present difficulties converging to the right solution. Please note that, at each iteration, the PDF of the extractor output must be estimated, which may be impractical.

B. ICA via L1-PCA

Let $\mathbf{Z} = [\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_M] \in \mathbb{R}^{N \times M}$ denotes data matrix, where $\{\mathbf{z}_m\}_{m=1}^M$ are realizations of a zero-mean random vector \mathbf{z} . Assuming ergodicity conditions and that $g(y) = |y|$, it can be shown that for large enough sample size the L1-norm of the projection $\mathbf{w}^T \mathbf{Z}$ becomes proportional to $E\{g(y)\}$,

$$\|\mathbf{w}^T \mathbf{Z}\|_1 = \sum_{m=1}^M |\mathbf{w}^T \mathbf{z}_m| \rightarrow ME\{g(y)\}. \quad (9)$$

Please note that the second term in (3) is always constant. Thus, the solution is reached at a certain optimum (i.e. maximum or minimum) of $E\{g(y)\}$ under the constraint $\|\mathbf{w}\|_2 = 1$. For this reason, the ICA can also be accomplished by whitening, followed by the minimization or maximization of the L1-norm. It was shown in [10] that symmetric sources with negative (respectively, positive) kurtosis are maximizers (respectively, minimizers) of $E\{|y|\}$. Whereas, the optimization problem of finding L1 principal component can be formulated as follows [8], [9]:

$$\mathbf{w}_{L1} = \underset{\mathbf{w} \in \mathbb{R}^N, \|\mathbf{w}\|_2=1}{\operatorname{argmax}} \|\mathbf{w}^T \mathbf{Z}\|_1. \quad (10)$$

Since the objective function is non-differentiable, the problem is difficult to solve by means of conventional optimization techniques such as gradient-based methods. However, it was shown in [8] that $\mathbf{w}_{L1} = \mathbf{Z}\mathbf{c}_{\text{opt}}/\|\mathbf{Z}\mathbf{c}_{\text{opt}}\|_2$, where

$$\mathbf{c}_{\text{opt}} = \underset{\mathbf{c} \in \{\pm 1\}^M}{\operatorname{argmax}} \|\mathbf{Z}\mathbf{c}\|_2. \quad (11)$$

Hence, the L1-norm maximization can be viewed as a combinatorial problem over the binary field. A globally convergent L1-PCA algorithm with complexity $\mathcal{O}(M^{\operatorname{rank}(\mathbf{Z})})$ was proposed in [8]. A faster, yet suboptimal version of this approach [9] is based on consecutive bit-flipping operations. Though, its time complexity can still be prohibitive for large data sizes. The most computationally efficient L1-PCA method was proposed earlier in [7]. It is based on the fixed-point iterative scheme similar to that used in FastICA algorithm. Unfortunately, the method often gets trapped in local extrema. Despite these shortcomings, the L1-PCA algorithms can be used directly to extract independent sources with negative kurtosis sign (i.e. sub-Gaussians) under whitening assumption. It was shown in [10] that globally convergent L1-PCA algorithm may give better accuracy and robustness than those of the conventional ICA methods, especially when dealing with outliers. The L1-PCA algorithm can also be modified to perform L1-norm minimization. However, in such case the global convergence property is lost because the L1-norm and the L2-norm minimization problems are not related as in (10)-(11). In addition, computational complexity of this algorithm can become prohibitive for large sample size and/or observation dimensions. In most applications, only suboptimal L1-PCA algorithms [9], [7] can be considered.

III. PROPOSED METHOD

The proposed method is based on the Jacobi iterative framework [12]. Namely, an objective function is optimized by applying successively orthogonal transformations to the whitened observation data vectors:

$$\mathbf{y}^{(k+1)} = \mathbf{G}(p_k, q_k, \theta_k) \mathbf{y}^{(k)}, \quad k = 1, 2, \dots, \quad (12)$$

where $\mathbf{y}^{(1)} = \mathbf{z} = \mathbf{C}_{\mathbf{xx}}^{-1/2} \mathbf{x}$. The matrix $\mathbf{G}(p, q, \theta)$ represents Jacobi rotation [18] by the angle θ in the plane determined by the p and q coordinates, i.e.:

$$\mathbf{G}(p, q, \theta) = \begin{bmatrix} \mathbf{I}_{p-1} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \cos \theta & \mathbf{0} & \sin \theta & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{I}_{q-p-1} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & -\sin \theta & \mathbf{0} & \cos \theta & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{I}_{N-q-1} \end{bmatrix}, \quad (13)$$

with $1 \leq p < q \leq N$. Thus, the unmixing matrix after the k th iteration can be expressed as follows:

$$\hat{\mathbf{B}}^{(k)} = \left(\prod_{i=1}^k \mathbf{G}(p_i, q_i, \theta_i) \right) \mathbf{C}_{\mathbf{xx}}^{-1/2}. \quad (14)$$

Please note that for N -dimensional space we have $N(N-1)/2$ possible rotation planes, each uniquely represented by pair (p, q) . A sequence of rotations represented by these pairs is arranged in a so-called sweep. In fact, any rotation order is allowed, but some may work better than others [19], [20]. In this work, a typical row-cycling ordering is used as described in Tab. I. Usually, it is necessary to go through several sweeps before convergence is achieved. The algorithm is terminated when, for all rotations in the current sweep, we have $|\theta_k| < \theta_{\min}$, or when the maximum number of sweeps is reached. The parameter θ_{\min} is an empirically chosen small angle [12], which controls the accuracy of the optimization.

It is crucial for this estimation framework to compute the rotation angles θ_k so that a given objective function is gradually optimized. Motivated by the ideas presented in the previous section, we propose to maximize negentropy approximation (3) with $g(y) = |y|$ directly. Since we deal with a sequence of two-dimensional ICA problems, the objective function for two units must be considered. As suggested in [4], such a function can be defined as the sum of the one-unit functions:

$$\mathcal{J}^{(k)}(\theta) = \sum_{i \in \{p_k, q_k\}} |E\{|\hat{y}_i^{(k)}(\theta)|\} - E\{|v|\}|, \quad (15)$$

where

$$\hat{y}_{p_k}^{(k)}(\theta) = y_{p_k}^{(k)} \cos \theta + y_{q_k}^{(k)} \sin \theta, \quad (16)$$

TABLE I: Arrangement of rotation planes using a row-cycling ordering for $N = 3$.

sweep no.	1			2			...
k	1	2	3	4	5	6	...
(p_k, q_k)	(1,2)	(1,3)	(2,3)	(1,2)	(1,3)	(2,3)	...

$$\hat{y}_{q_k}^{(k)}(\theta) = y_{q_k}^{(k)} \cos \theta - y_{p_k}^{(k)} \sin \theta, \quad (17)$$

are respectively the p_k th and q_k th coefficient of the currently transformed data vector $\mathbf{y}^{(k)}$. Please note that for a normally distributed random variable v with mean μ and variance σ^2 , the random variable $u = |v|$ has a folded normal distribution. The mean of the folded distribution is given by [21]:

$$\mu_u = \sigma \sqrt{2/\pi} \exp\left(-\frac{\mu^2}{2\sigma^2}\right) + \mu \operatorname{erf}\left(\frac{\mu}{\sqrt{2}\sigma}\right) \quad (18)$$

For $\mu = 0$ and $\sigma^2 = 1$, the expectation $E\{|v|\}$ in (15) reduces to the constant factor $\sqrt{2/\pi}$. Examples of the objective function (15) evaluated at 12 consecutive data rotations are presented in Fig. 1. As we see, these functions are always periodic with period $\pi/2$. Therefore, the search for the optimal angle can be restricted to the interval $[-\pi/4; \pi/4]$, i.e.:

$$\hat{\theta}_k = \operatorname{argmax}_{-\pi/4 \leq \theta < \pi/4} J^{(k)}(\theta). \quad (19)$$

In order to construct Newton-type iteration scheme, one can admit differentiability of $g(y) = |y|$ in a similar way as for the FastICA approach. In Fig. 1 we see that the objective function contains multiple local maxima and saddle points, thus even if we use a differentiable approximation for the absolute value function, it would be difficult to reach the global maximum of (15). However, in this case, each plane rotation depends on a single parameter θ_k , reducing the N -dimensional optimization problem to the sequence of the $N(N-1)/2$ one-dimensional search subproblems per sweep. Therefore, as opposed to the FastICA approach, the solution can be found using an exhaustive method in a reasonable execution time. In particular, for each data rotation, the function (15) can be evaluated at the set of D equidistant points:

$$\theta \in \{-\pi/4 + i\pi/(2D) : i = 0, 1, \dots, D-1\}. \quad (20)$$

The greater the value of D , the better the accuracy of the optimization. For even D , the set (20) always contains a zero value. Hence, in order to ensure local convergence, the parameter θ_{\min} for stop condition should be set to any value in the interval $(0; \pi/(2D))$. We have found empirically that the rotation angles tend to decrease in subsequent sweeps, and some optimizations are possible. For example, it may not be necessary to search for optimal angle over entire interval at the later sweeps. The exhaustive search algorithm can also be replaced by more sophisticated non-gradient techniques such as simplex bisection method [22], particle swarm optimization [23], genetic algorithms [24], simulated annealing [25].

The Matlab implementation of the proposed approach is given in Alg. 1. The expectations in (15), are replaced by sums with observables in place of random variables. Please note that since the matrix $\mathbf{G}(p, q, \theta)$ modifies only (p, q) rows, it is not necessary to compute it explicitly. It is easy to see that in each sweep, we must perform $N(N-1)/2$ data rotations. Each rotation costs $4M$ multiplications, but this operation must be repeated D times as the objective function is evaluated at D points. Thus, the time complexity of the single sweep can be roughly estimated as of order $\mathcal{O}(N^2MD)$.

Fig. 1: Examples of the function (15) evaluated at 12 consecutive data rotations for a randomly generated mixture of $N = 4$ Laplacian distributed sources with sample size $M = 400$.

Algorithm 1 Matlab implementation of the proposed method

```

function [Y,B,k] = JICA_abs(X, k_max, D)
[N, M] = size(X);
X = X - mean(X, 2);
B = inv(sqrtm((X*X')/M));
Y = B*X;
D = D + mod(D, 2);
theta = linspace(-pi/4, pi/4-pi/2/D, D);
c = cos(theta)';
s = sin(theta)';
Gp = [ c s ];
Gq = [ -s c ];
mu = M * sqrt(2/pi);
k = 1; encore = 1;
while k <= k_max && encore
    encore = 0;
    for p = 1:N-1
        for q = p+1:N
            r = [p q];
            Yp = Gp*Y(r,:);
            Yq = Gq*Y(r,:);
            J = abs(sum(abs(Yp), 2)-mu) + ...
                abs(sum(abs(Yq), 2)-mu);
            [~, I] = max(J);
            if abs(theta(I)) > pi/4/D
                encore = 1;
                Y(r,:)=[Yp(I,:);Yq(I,:)];
                B(r,:)=[Gp(I,:);Gq(I,:)]*B(r,:);
            end
        end
    end
    k = k + 1;
end

```

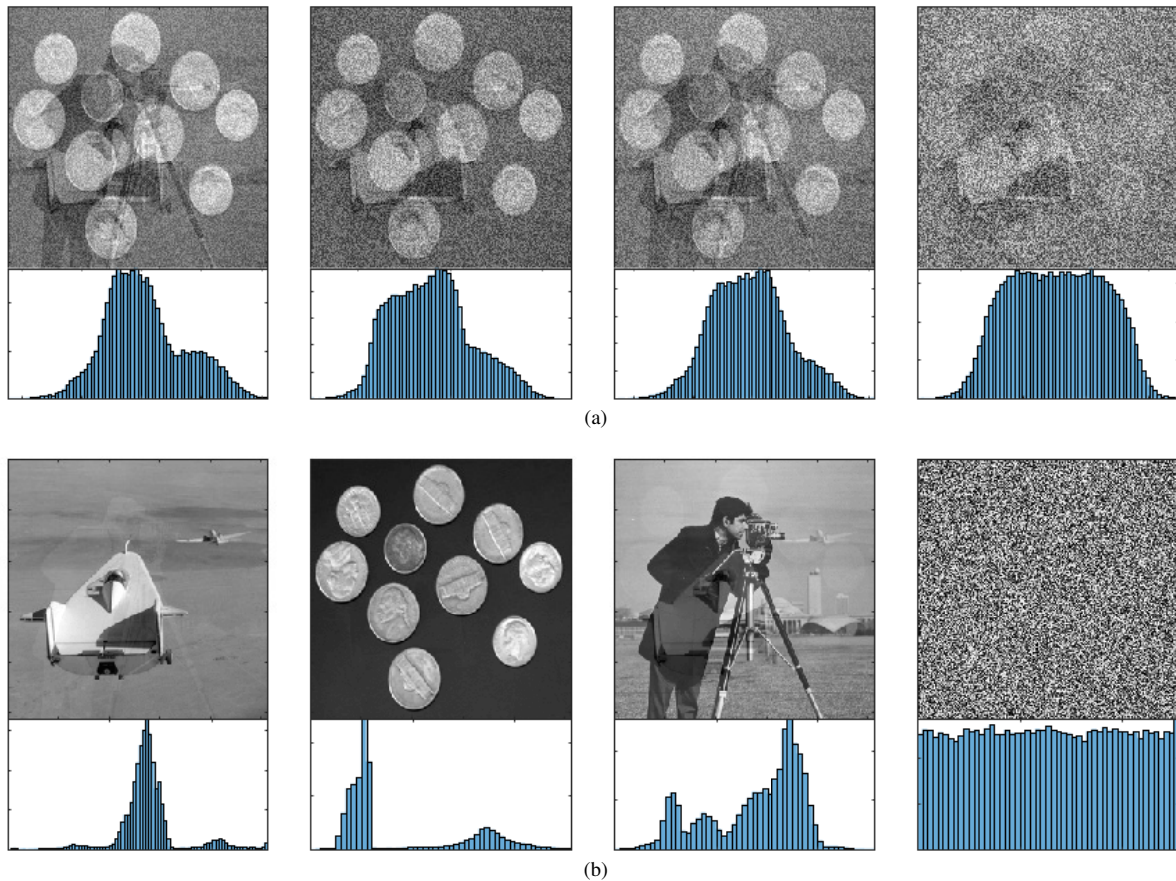

Fig. 2: Separation of the images with various distributions of pixel gray levels. (a) Randomly mixed images and histograms. (b) Recovered images and histograms.

IV. EXPERIMENTS

A. Illustrative examples

As a toy example, we considered a mixture of three Matlab built-in images and uniform noise. The images were resized to the same size 256×256 pixels with an 8-bit grayscale. The mixtures and their histograms are depicted in Fig. 2a. As can be seen, the source images have been significantly degraded, but also the form of the mixed data histograms is more like the Gaussian function. Fig. 2b shows the images recovered using the proposed method and the corresponding histograms. This example clearly shows that the algorithm is capable of transforming data from normality to independent marginal distributions.

B. Independent source extraction performance

In this experiment, the source extraction performance of the proposed algorithm is evaluated. In order to distinguish the algorithm from the existing techniques, it was denoted by the acronym JICA-abs, which stands for “Jacobi-type ICA based on absolute value function.” Also, several existing techniques including state-of-art methods were chosen for comparison, namely: joint approximate diagonalization of eigenmatrices (JADE) [11], the conventional FastICA algorithms with the

fourth-power non-linearity (FastICA-4power) and the differentiable approximation of the absolute value (FastICA-logcosh) [4], the modified FastICA algorithm based on direct use of the absolute value criterion (FastICA-abs) [10], the iterative L1-PCA [7] and more accurate bit-flipping L1-PCA method (L1-BF) [9]. In this comparison, we do not consider the optimal L1-PCA algorithm [8] due to high computational demands. On the other hand, it was shown in [10] that for the sources with uniform densities, the source extraction performance of the iterative L1-PCA method is similar to that of the optimal algorithm.

It is rather common that the performance of an iterative algorithm may vary depending on the stop conditions and initialization. Therefore, in all methods, the matrix \mathbf{W} was initialized to the identity matrix. The FastICA and iterative L1-PCA algorithms were stopped when for all sources the following condition was met: $1 - |\mathbf{w}^T \mathbf{w}^+| < \epsilon$, or when a maximum number of 1000 iterations was reached. For all these methods, except FastICA-abs, the ϵ parameter was set to 10^{-4} . In the case of the FastICA-abs, it was necessary to increase its value to 10^{-3} due to convergence difficulties. For the JICA-abs and JADE methods, the reliable and stable results were obtained when the maximum number of sweeps was set to 20

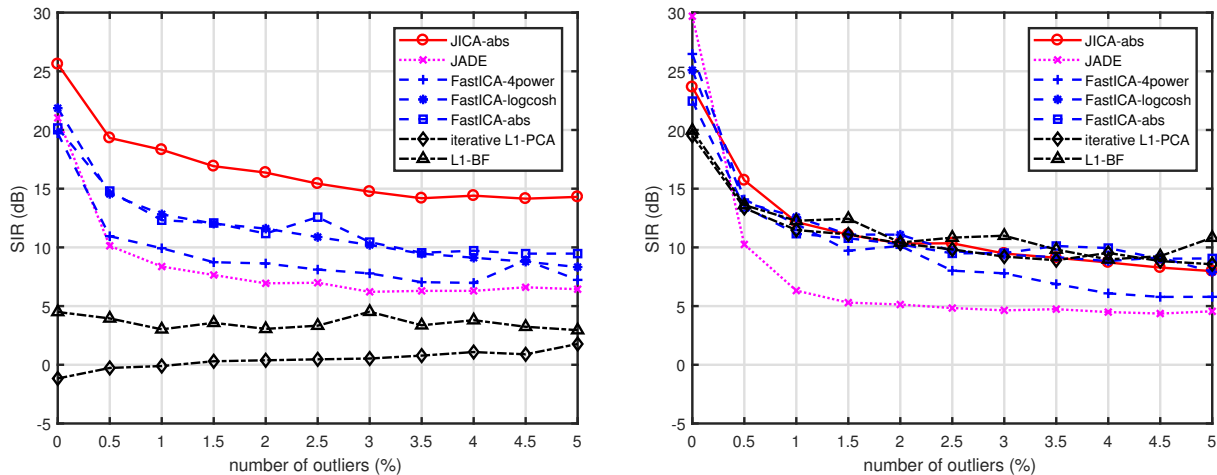

Fig. 3: Independent source extraction performance as a function of the outlier contamination rate, for $N = 4$ sources with Laplacian distribution (left), and uniform distribution (right). The length of source signals is fixed at $M = 400$ samples.

and the angle $\theta_{\min} = \pi/(4D)$ with $D = 128$. We verified empirically that rotations at a smaller angle than $\pi/512$ are not statistically significant.

For comparative purposes, we considered the linear mixtures of $N = 4$ synthetic sources, all with negative or positive kurtosis sign generated from uniform and Laplacian distribution, respectively. The length of each source signal was set to $M = 400$ samples. The coefficients of the mixing matrix were generated from the uniform distribution. Ill-conditioned matrices (with a condition number greater than 100) were excluded from the evaluation. In order to evaluate the robustness of the algorithms against outliers, randomly chosen observations were replaced with noise spikes drawn from a Gaussian distribution $\mathcal{N}(10, 1)$ at varying contamination rates.

The independent source extraction performance was estimated using the average signal-to-interference ratio (SIR) [26], [27], [28]. Please note that the higher the value of the SIR is, the better performance we get. The performance indexes were averaged over 1000 random realizations of the sources and the mixing matrices, but at each Monte Carlo run, all methods were operating on the same data. Fig. 3 presents the source extraction performance of different algorithms for various percentages of outliers. As can be seen, the proposed method clearly outperforms existing algorithms on average by 5dB for Laplacian distributed sources. In this case, the iterative L1-PCA algorithm provides the worst performance, as it is designed to only maximize L1-norm, whereas for distributions with positive kurtosis sign the L1-norm should be minimized. For Laplacian distributed sources, the L1-BF algorithm was modified to minimize the L1-norm according to the suggestion in [10]. In result, the source extraction performance of this method is slightly better than that of the iterative L1-PCA algorithm. Though, it is still poor compared to the ICA approaches. This confirms our earlier remark that the L1-norm and L2-norm minimization problems are not related in the same way as the corresponding maximization

problems (10)-(11). Although there is no clear winner for uniformly distributed sources, the JADE and FastICA-4power methods provide the best performance in the absence of outliers. Clearly, the absolute value criterion may not be the best choice for sub-Gaussian distributed sources. On the other hand, the approaches, whether based on absolute value criterion or on differentiable approximations thereof, show increased robustness to outliers as compared to the kurtosis-based methods.

C. Convergence and execution time

The total execution time of an iterative algorithm depends on the convergence rate. Unfortunately, rigorous convergence analysis of the proposed approach is not an easy task and is out of the scope of this paper. Though, we measured the average number of iterations (sweeps) taken by the presented algorithm until convergence was reached for various data sizes. The results averaged over 1000 independent runs are depicted in Fig. 4a. As can be seen that the number of iterations increases with the number of sources, but this dependency is weaker than linear, for sufficiently large M . It is rather not surprising, because as the sample size increases, an objective function usually becomes smoother and thus a faster convergence can be achieved. In this case, the algorithm converges to the stationary solution in a relatively small number of sweeps. However, please note that each sweep consists of $N(N-1)/2$ data rotations. In order to better illustrate the convergence properties of the algorithm, in Fig. 4b, we also show the global cost function measured after each data rotation for 10 independent Monte Carlo runs. It is rather clear that the algorithm converged quickly in all cases.

In order to compare the computational complexity of the proposed algorithm with the existing methods, we measured their execution times. The experiments were carried out in the Matlab environment, running on AMD Ryzen 5 3550H processor. Tab. II presents the minimum, maximum, and

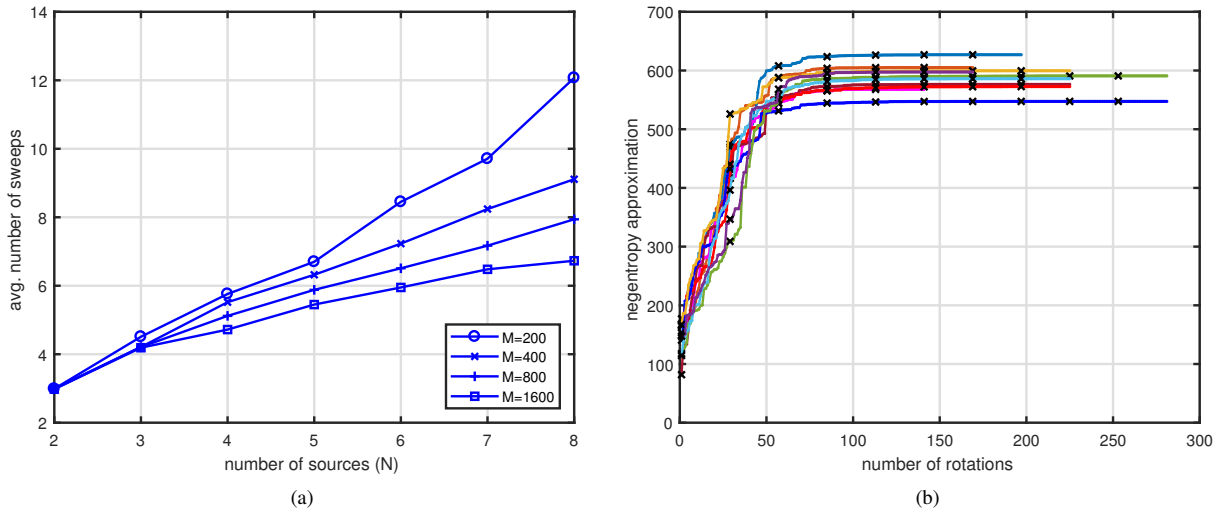

Fig. 4: Evaluation of the convergence properties of the proposed method. (a) Average number of sweeps. (b) Global contrast functions measured after each data rotation in 10 independent Monte Carlo runs. It was computed as a sum of the approximations (3) with $g(y) = |y|$ for all rows of the data matrix. The first data rotation in each sweep is denoted by cross mark.

TABLE II: Execution times (in milliseconds) and percentage of runs where the maximum number of iterations is reached in the experiments of Fig. 3 without outliers.

algorithm	Laplacian				uniform			
	t_{\min}	t_{\max}	t_{avg}	failures (%)	t_{\min}	t_{\max}	t_{avg}	failures (%)
JICA-abs	3.99	17.04	8.47	0	5.43	26.15	9.02	0
JADE	0.69	9.94	1.09	0	0.78	10.73	1.20	0

FastICA-logcosh	0.46	34.00	0.84	0.3	0.45	1.82	0.69	0
FastICA-abs	0.60	120.26	38.98	62.3	0.53	86.90	6.66	9.5
iter. L1-PCA	0.21	2.94	0.42	0	0.19	2.84	0.37	0
L1-BF	23.36	37.23	28.62	0	27.82	72.35	42.94	0

TABLE III: Execution times (in milliseconds) and percentage of runs where the maximum number of iterations is reached in the experiments of Fig. 3 with 5 percent of outliers.

algorithm	Laplacian				uniform			
	t_{\min}	t_{\max}	t_{avg}	failures (%)	t_{\min}	t_{\max}	t_{avg}	failures (%)
JICA-abs	3.72	18.44	8.88	0	5.37	25.12	9.07	0
JADE	0.70	10.88	1.24	0	0.68	10.54	0.99	0
FastICA-4power	0.30	16.22	0.55	0.1	0.30	18.32	1.52	5.7
FastICA-logcosh	0.47	33.86	1.16	0.3	0.51	63.12	4.51	9.4
FastICA-abs	0.52	111.34	26.01	59.8	0.62	109.39	39.93	82.1
iter. L1-PCA	0.23	3.38	0.36	0	0.24	3.59	0.36	0
L1-BF	24.80	39.64	30.34	0	26.64	81.41	46.48	0

average execution times collected in the experiment of Fig. 3 for data without outliers. The columns denoted as “failures” show the percentage of the Monte Carlo runs where the maximum iteration number was reached. The same statistics are presented in Tab. III, but for data with 5 percent of outliers. Although the JICA-abs method has relatively long average execution time, it is much faster than L1-BF algorithm. The proposed method also provides better convergence properties than those of the FastICA-based algorithms. Similarly to the JADE method and approximate L1-PCA algorithms, the JICA-

abs approach always converged to a stationary solution within the iteration limit. The FastICA-4power and FastICA-logcosh methods sometimes reach the iteration limit, which results in the increased maximum execution time. It is especially evident for uniformly distributed sources with outliers, where these methods reach the iteration limit in around 6-9 percent of runs. Unfortunately, the FastICA-abs method present even more serious convergence difficulties when dealing with outliers. In this case, the iteration limit is reached in around 82 and 60 percent of runs, for uniform and Laplacian distributions,

respectively. Obviously, the upper bound of the execution time can be reduced by decreasing the iteration limit, but it can also deteriorate the accuracy of the optimization. Therefore, a method with a smaller upper bound of the execution time may be a better choice when the timeliness of the system becomes a prominent problem.

V. CONCLUSION

A novel ICA algorithm has been proposed that directly utilizes non-differentiable absolute value criterion as a contrast function for the ICA problem. The algorithm is based on Jacobi iterative framework and exhaustive search method. Experimental studies show that the proposed approach provides better accuracy and robustness to outliers than existing methods for Laplacian distributed sources. Unlike the FastICA approaches, it does not show any convergence issues. Though, it has on average relatively high execution time as compared to the state-of-art ICA methods. On the other hand, it is faster than currently most accurate suboptimal L1-PCA algorithm that also works in an exhaustive manner.

A rigorous convergence analysis of the proposed method is of great theoretical importance, thus it should be the subject of further research. We also believe that the computational complexity can potentially be reduced. In addition, future works may include developing practical applications in speech, audio and image denoising.

Abstract—The Electric Vehicle Shortest Path Problem (EVSP) aims at finding the shortest path for an electric vehicle (EV) from a given origin to a given destination. During long trips, the limited autonomy of the EV may imply several stops for recharging its battery. We consider combining such stops with visiting points of interest near charging stations (CSs). Specifically, we address a version of the EVSP in which the charging decisions are harmonized with the driver’s preferences. The goal is to maximize the total gained score (assigned by the driver to the CSs), while respecting the time windows and the EV autonomy constraints. We define the problem as a MILP and develop an A* search heuristic to solve it. We evaluate the method by means of extensive computational experiments on realistic instances.

I. INTRODUCTION

DEVisING tools that facilitate the use of Electric Vehicles (EVs) is key to successfully electrifying transport, e.g., [5]. The limited autonomy of EVs coupled with the scarcity of charging stations (CSs) entails that long trips may involve several charging stops. Given that such stops are likely to be time consuming, we explore the idea of matching the charging stops with user preferences.

Considering an EV that needs to travel between an origin and a destination, we consider that the user attributes a score to each CS. Such scores are based on the vicinity to Points of Interest (POIs) to the CS. For example, a user may prefer to stop at cultural venues. In this case, a high score is given to CSs nearby such venues. Using those scores, we consider the problem of optimizing the shortest path respecting all energy feasibility constraints, while maximizing the total score that the user can achieve. To handle this problem we propose the Maximum Profit Model (MPM). To avoid excessively long trips, we limit the duration of the route. We establish this limit by solving the Shortest Path Model (SPM), which is the shortest EV path in time. We allow the MPM to deviated from the shortest path length within a given tolerance.

We adapt the Mixed Integer Linear programming (MILP) model proposed in [6] to handle the MPM and the SPM. Furthermore, we develop a heuristic algorithm based on the A* search which handles large instances of MPM. To this end, we propose the Maximum Discounted Profit Model (MDPM),

This work was partially supported by the Portuguese Foundation for Science and Technology (FCT) under project grants UID/MAT/00324/2020 and UID/MULTI/00308/2020.

which discounts the scores of the nodes into the arc costs that connect them. By doing so, we are able to efficiently adapt the A* search Algorithm to the MPM.

In general, the Electric Vehicle Shortest Path Problem (EVSP) is a shortest path problem that accounts for battery limitation and charging constraints. Due to their limited autonomy, EVs may need to detour to CSs in order to recharge their battery. This is particularly true in medium and long range routes, like in [11]. A key decision in this context is where and how much to charge the EVs. The problem of minimizing the overall trip time for EVs in road networks was studied by [1]. A heuristic algorithm for solving large EVSP instances was proposed in [14]. Baum et al. [2] introduced a functional representation of the optimal energy consumption between two locations, which led to developing an efficient heuristic algorithm that computes energy optimal paths.

One of the main EVSP modeling assumption relate to how the EV batteries are recharged. Some researchers assume that the EV must completely recharge before leaving a CS, e.g. [4], [9]. Other works (e.g., [6], [10], [12]) consider the charging quantity as a decision within the optimization. As in most studies we assume that the energy consumption is directly and exclusively related to the traveled distance.

In practice, the EV charging function is nonlinear with respect to time, and depends on the used charging technology. The nonlinear charging functions were modeled as piecewise linear concave functions by [6], [10].

Time window (TW) constraints have been introduced in EV problems by [12]. TWs oblige EVs to arrive in predetermined CSs before or during a particular time interval. Contrary to what is done in the literature, we assume that TW types are given (e.g., lunch breaks), yet their location is determined from a set of CSs which accommodate this type of TW. Furthermore, we consider required and weakly mandatory TWs.

Considering that CSs have different scores and a given maximum path length (in time), the aim of the MPM is to maximize the total score of visited CSs. As such, CSs that better match the user preferences are prioritized. We consider a single EV, with partial recharging decisions and nonlinear charging functions. Furthermore, we consider only public CSs, having different technologies and scores. We also consider TWs with a limit on the total travel time.

The contributions of this paper are threefold: 1) we propose an EV shortest path model that accounts for user preferences (**MPM**); 2) we develop a heuristic based on the A* algorithm to solve that problem; 3) and we verify the performance of both the MILP model and the heuristic algorithm on realistic test instances.

We introduce the **MPM** in Sec. II and develop an A* algorithm for it in Sec. III. We present our computational experiments in Sec. IV, and state our conclusions in Sec. V.

II. PROBLEM DEFINITION

The **MPM** maximizes the score of the CSs visited by the EV, such that the resulting path is feasible and within a tolerance from the shortest EV path. In the literature, the goal of maximizing scores obtained by visiting nodes is often called prize collection [13]. To model the **MPM** we adapt the arc based MILP model of [6]. Due to space limitations, we do not present the full formulation. Instead, we give an overview of that work and then detail the major adaptations made to handle the **MPM**.

Froger et al. [6] introduced the Fixed Route Vehicle Charging Problem (FRVCP). Given a sequence of customer nodes (i.e., not CSs) to visit, the objective of the FRVCP is to determine the charging operations (which CSs to visit and how much to charge), in order to minimize the total route duration while satisfying the following conditions: The customers in the resulting route are visited according to the given order, the resulting route is energy feasible and satisfies a maximum duration limit T^{\max} . The state of charge (SoC) of the EV is tracked on each traversed arc and visited node. The EV may be partially recharged at a set of charging stations \mathcal{S} , which may have different technologies. For each technology we consider a nonlinear charging function, approximated via a piecewise linear function following the models by [10]. In the **MPM** the fixed sequence of nodes to visit goes from an origin \mathcal{O} node to a destination \mathcal{D} node.

Building on the FRVCP, we now describe the **MPM**. Let $\mathcal{G} := (\mathcal{S}_{\mathcal{O},\mathcal{D}}, \mathcal{A})$ be a directed graph, where $\mathcal{S}_{\mathcal{O},\mathcal{D}} := \mathcal{S} \cup \{\mathcal{O}, \mathcal{D}\}$ and \mathcal{A} is the set of arcs that connect pairs of nodes in $\mathcal{S}_{\mathcal{O},\mathcal{D}}$. Let $t_{ij} \geq 0$ and $e_{ij} \geq 0$ be the driving time and energy consumption of arc $(i, j) \in \mathcal{A}$, both satisfying the triangular inequality. The EV departs from \mathcal{O} with a fully charged battery of capacity Q . We impose that the SoC of the EV is at least q_{\min} throughout the route. Since we consider long trip planning, we assume that the number of nights is a user input.

The user will spend some time in the neighborhood of the selected CS. Moreover, in certain moments of the day, the user may prefer to visit a CS near a POI, e.g., restaurants or hotels. CSs are typically strategically placed near those types of POIs. It is important that the user visits CSs that best suit her preferences. We attribute a score σ_j for $j \in \mathcal{S}$, which are input to the **MPM**. We assume that they can be derived based on the user's ranking of POIs. Furthermore, the user may personalize her trip by imposing TWs related to an activity (e.g., lunch breaks). The classical definition of TWs determines a time to visit a given node. In the **MPM**, such TWs may be realized

Figure 1: Path from \mathcal{O} to \mathcal{D} with a night at a hotel and lunch breaks. The timestamp near a node represents the corresponding departure time, including the recharging time (not reported in the figure). For \mathcal{D} , instead, the timestamps represent the arrival time. The number on each arc is its travel time. The red path is optimal, stopping in the hotel as required and reaching node E . If also the lunch break is required, then the EV is forced to arrive to \mathcal{D} with stopping at L (blue path). Instead, with the weakly mandatory flag, from E the EV can go directly to \mathcal{D} 3h in advance (green path).

at a number of CSs. We therefore denote the TWs related to our **MPM** as Activity-based Time Windows (ATWs). In our experiments in Sec. IV, we assign to each CS a randomly generated score between 0 and 5. In practice, these values will be established by the user in real applications.

Let \mathcal{W} be the set of all ATWs, which is partitioned into two subsets, $\mathcal{W}^R, \mathcal{W}^M \subseteq \mathcal{W}$, formed by the required and the weakly mandatory ATWs. The EV is forced to stop in each $k_R \in \mathcal{W}^R$, but it must stop in $k_M \in \mathcal{W}^M$ only if there exists at least one k_R such that $k_M \prec k_R$. Otherwise, k_M may be skipped. We assume that the sets $\mathcal{W}^R, \mathcal{W}^M$ are ordered by chronological order of starting time of the TWs. Each ATW is defined as:

$$k := (\gamma_k^L, \gamma_k^U, t_k^{\min}, o_k, \nu_k), \quad k \in \mathcal{W},$$

where the interval $[\gamma_k^L, \gamma_k^U]$ (with $\gamma_k^L < \gamma_k^U$) describes its initial and ending times (the EV must arrive before γ_k^U); t_k^{\min} is the minimum time that the EV needs to stop during k ; o_k is a binary value, equal to 1 if $k \in \mathcal{W}^M$, and 0 otherwise. The set \mathcal{W} is ordered, thus, if $k \prec h$, then $\gamma_k^L < \gamma_h^L$, for any $k, h \in \mathcal{W}$. The EV is allowed to arrive at a node with a maximum anticipation time $\tilde{\varphi}$. In this case, the activity will nevertheless start at γ_k^L . Thus, if the EV arrives in node i in the interval $[\gamma_k^L - \tilde{\varphi}, \gamma_k^U]$, then it may decide to stop at i for at least t_k^{\min} or instead perform k in a subsequent node. In addition, we use hard TWs, which means that it is not possible to perform the ATW k before $\gamma_k^L - \tilde{\varphi}$ nor after γ_k^U . Finally, two ATWs can overlap, but they cannot be contained in one another. Each CSs is associated with multiple POIs, and each TW requires a specific POI. This information is stored in the label ν_k and is different for each TW. For instance, if $k \in \mathcal{W}$ refers to the first night, then $\nu_k = \text{"Hotels"}$ and the EV is forced to stop at a CSs near a hotel. So, it is possible to construct the set of chargers $\mathcal{S}_k \subseteq \mathcal{S}$ that have in their neighborhood the POI stated in ν_k .

To determine T^{\max} we solve an EV Shortest Path Problem **SPM**, subject to the same constraints as **MPM**, but with the goal of minimizing the total trip duration (i.e., ignoring the scores). Let T^{opt} be the optimal objective function value of **SPM**, which is a theoretical lower bound on T^{\max} . Then, let T^{add} be the tolerance of the total additional detouring time from the shortest path to stop in nodes with higher scores. Therefore, we set T^{\max} to $T^{\text{opt}} + T^{\text{add}}$.

To avoid routes with many stops at SCs, we introduce the parameter r^{\min} , as $r^{\min} := \lfloor 0.4(Q - q_{\min})/\eta \rfloor$, where η is the average energy consumption per kilometer (expressed in kWh/km), and is dependent on the EV type. The ratio $(Q - q_{\min})/\eta$ represents the maximum autonomy of the vehicle, excluding the minimal amount of energy that is always required. With this arrangement it is possible to prune all the arcs associated with a distance less than r^{\min} , which also avoids stops for charging the EV in consecutive locations that are very close to each other.

Let ξ denote a lower bound on the distance of a trip from \mathcal{O} to \mathcal{D} (its computation is described in Sec. IV). Then the maximum number of legs N in a path is defined as $\lceil 1.5[\xi/r^{\min}] \rceil$.

III. A* SEARCH ALGORITHM

In the following we propose a heuristic algorithm for the **SPM** and extend it for solving the **MPM**. Recall that the **SPM** solution serves as an input to **MDPM**. The algorithm is based on the A* search, which finds a path from an origin \mathcal{O} to a destination \mathcal{D} with the smallest cost. To do that, it maintains the tree of all the paths originated from \mathcal{O} and extends each of them one arc at a time until \mathcal{D} is reached. It uses a best-first search by selecting the node that minimizes

$$f(i) := g(i) + h(i),$$

where i is the current node, $g(i)$ is the cost of the path from \mathcal{O} to i , and $h(i)$ is an estimate of the cost of the shortest path from i to \mathcal{D} . If $h(i)$ never overestimates the real cost to reach \mathcal{D} from i , for all i , then the A* algorithm finds the optimal solution.

The A* algorithm is based on minimizing cost mechanisms, thus it is not directly applicable to prize collection settings such as the **MDPM**. Therefore, we propose the **MDPM** which approximates the **MPM**, searching for a shortest path while maximizing the total score. To do that, we assign a weight \tilde{s}_{ij} with each arc, defined as

$$\tilde{s}_{ij} := t_{ij} + \Delta_j - \mu\sigma_j, \quad \forall (i, j) \in \mathcal{A} \quad \text{s.t.} \quad i, j \in \mathcal{S},$$

where Δ_j is the time spent waiting while the EV is charging at the CS j , and μ is a parameter that indicates the relative importance of the score with respect to the time required to go from i to j , charging time included. The objective function of the **MDPM** model is then

$$\min \sum_{(i,j) \in \mathcal{A}, j \in \mathcal{S}} \tilde{s}_{ij} x_{ij}.$$

This expression is nonlinear, but it can be linearized by introducing new decision variables s_{ij} , and changing the objective function as

$$\min \sum_{(i,j) \in \mathcal{A}, j \in \mathcal{S}} [(t_{ij} - \mu\sigma_j)x_{ij} + s_{ij}]$$

We first discuss the computation of the potentials used to estimate the heuristic function h . We then incorporate the TWs in the heuristic. Finally, we modify the algorithm to account for the scores in h .

Let q_i and \bar{q}_i be the SoC when the EV arrives and departs from CS i . The variables \underline{c}_i and \bar{c}_i are respectively the start and end time for charging an EV. Variables $\underline{\tau}_i, \bar{\tau}_i$ track the time when the EV arrives and leaves CS $i \in \mathcal{S}$, respectively. There is also a tolerance φ_i that represents how much time in advance, with respect to γ_k^L , the EV can arrive in i , for any $i \in \mathcal{S}_{\mathcal{D}}$. The maximum anticipation time is set to $\bar{\varphi}$, but even if the EV arrives in advance, the minimum stopping time t_k^{\min} starts at γ_k^L and not before.

Let x_{ij} be a binary variable which equals 1 if the EV arrives at node j from node i , 0 otherwise. The variable y_{jk} is also binary and it is 1 if the EV stops in j in TW k , 0 otherwise. The maximum duration of the trip is T^{\max} (in Sec. III we show how to compute an upper bound for this value). The variable z_k is binary and is equal to 1 if the EV arrives in \mathcal{D} after TW k , 0 otherwise, for any $k \in \mathcal{W}^M$. It is used to link the arrival time in node \mathcal{D} and avoidable TWs.

A. Potentials

We now find an initial estimate of the total time from any CS i to \mathcal{D} , building on techniques used in [14]. We start by dropping the charging and the TW constraints, thus we obtain a problem that can be solved using the Dijkstra's algorithm. Let $\mathcal{G} := \langle \mathcal{S}_{\mathcal{O}, \mathcal{D}}, \mathcal{A} \rangle$ be the directed graph from \mathcal{O} to \mathcal{D} , where $\mathcal{S}_{\mathcal{O}, \mathcal{D}}$ is the set of nodes and $\mathcal{A} := \mathcal{S}_{\mathcal{O}} \times \mathcal{S}_{\mathcal{D}}$ the set of arcs. We then apply the backward Dijkstra's algorithm, which operates on the reversed graph $\mathcal{G}' := \langle \mathcal{S}_{\mathcal{O}, \mathcal{D}}, \mathcal{A}' \rangle$ where

$$\mathcal{A}' := \mathcal{S}_{\mathcal{D}} \times \mathcal{S}_{\mathcal{O}} \text{ such that } (i, j) \in \mathcal{A} \Rightarrow (j, i) \in \mathcal{A}',$$

while considering \mathcal{D} as the origin and \mathcal{O} as the destination. This allows us to obtain a lower bound on the driving time from any $i \in \mathcal{S}_{\mathcal{O}, \mathcal{D}}$ to \mathcal{D} , which we denote by $\pi_{\text{dr}}(i)$. To account for energy consumption, we apply the backward Dijkstra's algorithm considering the energy consumption as the weight for the arcs. This allows us to derive the minimum amount of energy required from $i \in \mathcal{S}_{\mathcal{O}, \mathcal{D}}$ to \mathcal{D} . We denote this lower bound by $\pi_{\text{cons}}(i)$.

The EV arrives partially charged at each node, with an amount of energy equal to $\text{SoC}(i)$. Since the minimal amount of SoC q_{\min} needs to be respected at every node, we can think of $\text{SoC}(i) - q_{\min}$ as the available energy at node $i \in \mathcal{S}_{\mathcal{O}, \mathcal{D}}$. Then, to compute the minimal amount of energy from i to \mathcal{D} , we define

$$\tilde{\pi}_{\text{cons}}(i) := \pi_{\text{cons}}(i) - (\text{SoC}(i) - q_{\min}).$$

We now compute a lower bound for the charging time, based on the minimal required energy at a node $i \in \mathcal{S}_{\mathcal{O}, \mathcal{D}}$. We define $\mathcal{G}_i := \langle \mathcal{T}_i, \mathcal{A}_i \rangle$ as a subgraph of \mathcal{G} , where \mathcal{T}_i is the set of reachable nodes from i , and \mathcal{A}_i is the set of arcs comprising a path from i to any $j \in \mathcal{T}_i$ (see Fig. 2).

Figure 2: Illustration of \mathcal{G}_H

Let $s_{\max}(i)$ denote the maximum charging rate of all the CSs in \mathcal{T}_i . We denote the maximum charging rate of CS j as $\bar{\rho}_j$, which corresponds to the largest slope of the piecewise charging function of j . We then set $s_{\max}(i)$ as $\max\{\bar{\rho}_j : \forall j \in \mathcal{T}_i\}$. This improves the computation of the charging potential with respect to [14], where s_{\max} is constant and does not depend on the nodes that are reachable from i .

If the energy available at i is greater than the remaining energy needed to reach \mathcal{D} , then $\tilde{\pi}_{\text{cons}}$ can be negative. Thus, two cases are considered when computing a lower bound for the charging time:

$$\pi_{\text{ch}}(i) := \begin{cases} \frac{\tilde{\pi}_{\text{cons}}(i)}{s_{\max}(i)} & \text{SoC}(i) - q_{\min} \leq \pi_{\text{cons}}(i) \\ 0 & \text{otherwise} \end{cases}$$

This gives a potential that returns the minimal charging time from any node i to \mathcal{D} . Thus, a lower bound on the total trip time is given by

$$\tilde{\pi}_{\text{tt}}(i) := \pi_{\text{dr}}(i) + \pi_{\text{ch}}(i) \quad \forall i \in \mathcal{S}_{\mathcal{O}, \mathcal{D}}.$$

We improve this lower bound by accounting for TWs. Let $\pi_{\text{tw}}(i)$ be the minimal stopping time that the EV must perform from i to \mathcal{D} according to the ATWs. The trip accounts for the sum of all the minimum stopping times. Let \tilde{k} be the last TW in the ordered set \mathcal{W}^R . Suppose that, when at node i , the EV has not performed all TWs in \mathcal{W}^R . Then, $g(i) \leq \gamma_{\tilde{k}}^L + t_{\tilde{k}}^{\min}$, where $g(i)$ is the arrival time at i and $\gamma_{\tilde{k}}^L$ is the starting time of TW \tilde{k} . In this case, we compute a lower bound for the TWs potential as the sum of all the stopping times that have not been performed by the time $g(i)$. If instead, in node i , the EV has already done all the TWs in \mathcal{W}^R , then $g(i) > \gamma_{\tilde{k}}^L + t_{\tilde{k}}^{\min}$ and so the potential for the TWs must be zero. Therefore, if $\pi_{\text{tw}}(i)$ is the TWs potential for node i , we have

$$\pi_{\text{tw}}(i) := \begin{cases} \sum_{k \in \mathcal{W}^R: g(i) < \gamma_k^L} t_k^{\min} & \text{if } g(i) \leq \gamma_{\tilde{k}}^L + t_{\tilde{k}}^{\min} \\ 0 & \text{otherwise} \end{cases}$$

For instance, suppose that \mathcal{W}^R contains a 1 hour stop for lunch, one tourism stop for 2 hours and one for sleeping for

11 hours. Then, before lunch $\pi_{\text{tw}}(i) = 14$, after lunch $\pi_{\text{tw}}(i) = 13$, and the next day $\pi_{\text{tw}}(i) = 0$.

We now incorporate π_{tw} in $\tilde{\pi}_{\text{tt}}$. The EV charges during each stop. Thus, we cannot simply sum π_{tw} and π_{ch} , since they may overlap. Instead, we can obtain a better lower bound considering the maximum between π_{ch} and π_{tw} , and then adding the driving potential π_{dr} . So,

$$\pi_{\text{tt}}^1(i) := \pi_{\text{dr}}(i) + \max\{\pi_{\text{ch}}(i), \pi_{\text{tw}}(i)\}$$

defines the lower bound for the total stopping time from i to \mathcal{D} . We are not overestimating the real cost, since taking the maximum we consider for each node the best possible charging scenario that at least the EV has to perform.

B. Labels

Label L_{j_m} represents the state of the EV when arriving at the m -th copy of node j , that is dynamically allocated. With this label we keep track of the state of the EV. For notational convenience, we denote $g(j_m)$ by g_j^m . Each label includes the total time needed to reach j_m , so it includes both driving and charging times. For instance, suppose that the EV goes from the n -th copy of i to the m -th copy of j , namely from i_n to j_m . Then the label L_{j_m} considers driving from i to j and the charge in i that is needed to reach j for the m -th time. It excludes the time the EV spends charging in j . The label of the m -th copy of node j , with i_n as its direct predecessor, is:

$$L_{j_m} := (i, g_j^m, h_j^m, f_j^m, p_j^m, \beta_j^m, q_j^m, \underline{q}_j^m, \lambda_j^m, \Delta_j^m, \omega_j^m)$$

where

- i is the node from which the EV arrives to j_m ;
- g_j^m is the total travel time from \mathcal{O} to j_m ;
- h_j^m is the estimated travel remaining time from j_m to \mathcal{D} ;
- f_j^m is the estimated arrival time at \mathcal{D} if the path from \mathcal{O} to j_m is performed. It is given by $f_j^m := g_j^m + h_j^m$;
- p_j^m is the label from which the EV arrives, i.e., L_{i_n} , which is the label of the n -th copy of node i , with $n \in \{1, \dots, M_i\}$;
- β_j^m is the additional time spent at j for charging, it is chosen from an ordered set $\beta := \{\beta_1, \beta_2, \dots, \beta_s\}$;
- q_j^m is the amount of energy that is charged in the predecessor node i_n . It is computed to at least respect the consumption e_{ij} and is given by $q_j^m := \bar{q}_j^m - \underline{q}_j^m$, where

$$\bar{q}_j^m := \max\{q_i^n + e_{ij}, Q\};$$

- \underline{q}_j^m is the amount of energy of the EV when arriving at j_m . It is computed as $\underline{q}_j^m := q_i^n + q_j^m - e_{ij}$;
- λ_j^m is the minimum time the EV must charge at j_m . This amount of time is considered in the next label and not in L_{j_m} . It is defined as

$$\lambda_j^m := \begin{cases} \max\{0, \gamma_k^L - g_j^m\} + t_k^{\min} & \text{if TW } k \text{ is} \\ & \text{performed in } i_n \\ 0 & \text{otherwise} \end{cases}$$

where γ_k^L is the starting time of TW k and t_k^{\min} is its minimum stopping time. TW k is retrieved using ω_j^m (see below);

- Δ_j^m is the charging time in i_n . It is given by

$$\Delta_j^m := \max \{ \lambda_i^n, \bar{c}_j^m - \underline{c}_j^m \} + \beta_j^m,$$

where $\bar{c}_j^m := \Phi_j^{-1}(\bar{q}_j^m)$ and $\underline{c}_j^m := \Phi_j^{-1}(\underline{q}_j^m)$, with Φ_j^{-1} the inverse of the charging function in node j . The term β_j^m is added to consider the cases in which the EV charges more than needed;

- ω_j^m is the index of the last TW k prior to node j_m .

Parameters Δ , q and \underline{q} are strictly related to β . As a consequence, also g , h and f depend on β . The value of λ instead depends strictly on ω .

C. A* search algorithms for the MPM and MDPM

Using the labels described above we now outline the A* search algorithm. We start by implementing a heuristic approach to find the fastest path from \mathcal{O} to \mathcal{D} , referring to this as **AsM**.

The origin node \mathcal{O} is initialized as follows:

$$L_{\mathcal{O}}^1 := (\mathcal{O}, g_{\mathcal{O}}^1 = t_{\text{start}}, h_{\mathcal{O}}^1 = h^1(\mathcal{O}), f_{\mathcal{O}}^1 = g_{\mathcal{O}}^1 + h_{\mathcal{O}}^1, p_{\mathcal{O}}^1 = -, 0, 0, \underline{q}_{\mathcal{O}}^1 = Q, 0, 0, 0),$$

where $g_{\mathcal{O}}^1$ is the starting time of the trip. Thus, $f_{\mathcal{D}}^m$ represents the arrival time in \mathcal{D} and not the duration of the trip. Let \mathcal{L} be the set of all labels, and M_j be a counter of the number of copies of $j \in \mathcal{S}_{\mathcal{O}, \mathcal{D}}$. The algorithm keeps track of open labels using a priority queue \mathcal{Q} . Every time a new label is created, it is added to \mathcal{Q} in a way that the first element of \mathcal{Q} is always the one with the lowest f_j^m , among all labels L_j^m , so

$$\bar{j}_m := \arg \min_{j_m: j \in \mathcal{S}_{\mathcal{O}, \mathcal{D}}, m=1, \dots, M_j} \{ f_j^m \}.$$

We now introduce some of the functions used later in the pseudocode. The function $\text{POP}(\mathcal{Q})$ returns the label with the lowest f in \mathcal{Q} , while function $\text{PUSH}(\mathcal{Q}, L_{j_m})$ adds the label L_{j_m} to the queue. Function $\text{STAR}(\mathcal{G}, j)$ returns the set of nodes $h \in \mathcal{S}_{\mathcal{D}}$ such that $(j, h) \in \mathcal{A}$, in descending order with respect to t_{jh} . The function $\text{NEXTTW}(\mathcal{W}^R, \omega_j^m)$ returns the next TW in \mathcal{W}^R that is not visited when the EV arrives at node j_m . The EV is allowed to arrive at a node with a maximum anticipation time of $\bar{\varphi}$. The boolean function $\text{NODEHASPOI}(i, \nu)$ returns one if there is at least one POI of the category ν in the neighborhood of node i , and zero otherwise.

Function $\text{MAXSLOPE}(\hat{S})$ applied to a generic subset \hat{S} of CS \mathcal{S} , returns the maximum slope between all the charging functions of nodes in \hat{S} . To speed up the algorithm, all the subtrees are precomputed. The function $\text{ROUTING}(i, j)$ returns the pair (t_{ij}, e_{ij}) , that are respectively the time and the energy required to go from i to j , for any $i \in \mathcal{S}_{\mathcal{O}}, j \in \mathcal{S}_{\mathcal{D}}$. The function $\text{MINSTOP}(g_i)$ returns $\pi_{\text{tw}}(i)$.

The A* algorithm is described in Alg. 1. It starts by initializing the counters for all the copies and storing the subtree of each node. Then the label associated with the origin is created and added to the queue and to the set of all the labels.

Algorithm 1 ASTARSEARCH Algorithm

```

1: function ASTARSEARCH( $\mathcal{G}$ ,  $Q$ ,  $q_{\min}$ ,  $t_{\text{start}}$ ,  $t_{\text{end}}$ ,  $\mathcal{W}^R$ ,  $\beta$ )
2:   for all node  $h \in \mathcal{S}_{\mathcal{O}, \mathcal{D}}$  do
3:      $\mathcal{T}[h] := \text{SUBGRAPH}(\mathcal{G}, h)$ ,  $M_h := 0$ 
4:   end for
5:    $M_{\mathcal{O}} := 1$ , Initialize  $L_{\mathcal{O}}^1$ ;  $\mathcal{L} := \{L_{\mathcal{O}}^1\}$ ;  $\mathcal{Q} := \{\mathcal{O}\}$ 
6:   while  $\mathcal{Q}$  do
7:      $L_i^n := \text{POP}(\mathcal{Q}) = (\bar{i}, g_i^n, h_i^n, f_i^n, p_i^n, \beta_i^n, q_i^n, \underline{q}_i^n, \lambda_i^n, \Delta_i^n, \omega_i^n)$ 
8:      $k := \text{NEXTTW}(\mathcal{W}^R, \omega_i^n)$

41:          $L_j^m := \text{CREATELABEL}(i, j, g_i^n, \underline{q}_i^n, \Delta, q, t_{ij}, e_{ij}, 0, \omega_i^n, \beta, L_i^n)$ 
42:          $\mathcal{L} := \mathcal{L} \cup \{L_j^m\}$ ;  $\text{PUSH}(\mathcal{Q}, L_j^m)$ 
43:       end for
44:     end for
45:   end while
46:   return NONE, NONE // Node not found

```

^A Check if the subtree of current node contains the category of POI that is needed for the next TW and the subsequent ones. Otherwise, goes to the next element in the queue.

The label L_i^n with the lowest value of f is selected and then the algorithm finds the next TW k that must be performed. A check is performed to verify if the current label entails the arrival to the destination point: if so, we verify whether the index ω_i^n of the last visited TW is at least equal $|\mathcal{W}^R|$. If this is not the case, the EV has not visited yet all the non-avoidable TWs, and thus the current label must be discarded. Otherwise, the current label and the set of all the generated labels are returned and the search terminates.

At this point, if k is not NONE the algorithm checks whether or not there exists at least one node in \mathcal{T}_i of the current node i in which the POI constraint of TW k is satisfied. Then it checks the same for all the TWs in \mathcal{W}^R that must be performed after k .

The algorithm proceeds by considering the nodes j such that $(i, j) \in \mathcal{A}$. A sequence of operations assures that the trip from i_n to j_m is feasible, where m is the index of the m -th copy of j that will be created if all the checks are passed. First the energy

constraints. If the energy required on arc (i, j) is greater than the maximum amount for the EV, we discard this label, and the algorithm proceeds to the next node in $\text{STAR}(\mathcal{G}, i)$. Otherwise, if $e_{ij} < Q - q_{\min}$, we consider charging a greater amount of energy with respect to e_{ij} by looping on β .

At line 25 of Alg. 1, the charging time and the charged energy are computed, given the current SoC q_i^n and the amount of energy required e_{ij} . The two values are then updated on line 26, taking the current SoC and the arrival time.

We then compute a temporary value g_{temp} of the arrival time in j . In case $g_{\text{temp}} > t_{\text{end}}$, the current label is discarded. We then verify if the selected TW k is in \mathcal{W}^R . If so, then the algorithm must satisfy the constraints associated with k . First, if $g_{\text{temp}} > \gamma_k^U$, then the arrival time at j will be after the ending time of k , which is not feasible. If instead, g_{temp} is included in the range $[\gamma_k^L - \varphi, \gamma_k^U]$, then the EV arrives at j during the TW k . In this situation, the user may decide to stop in j , and respect the TW constraints, or to continue driving to the next node h and see if it is possible to respect k in node h . This scenario models the case in which, for instance, instead of respecting the lunch constraints in node j , the user prefers to drive longer and eat at another place. In the case we stay in j to respect TW k , we check whether node j has the POI that is required for k . If so, a label L_j^m is created, imposing that $\omega_j^m := \omega_i^n + 1$ (from j_m on, TW k is respected) and $\lambda_j^m = \max\{0, \gamma_k^L - g_{\text{temp}}\} + t_k^{\min}$. The max function is used to compute how much time in advance the EV arrives in j , so the minimum stopping time imposed from any arc from j_m is λ_j^m . If instead node j does not have any POI of the given category ν_k , we can step over and create a label that goes from i_n to j_m without imposing a minimum stopping time λ_j^m . In this case $\lambda_j^m := 0$ and $\omega_j^m := \omega_i^n$. In both cases, the newly created label L_{j_m} is added to the set of labels \mathcal{L} and pushed to the queue \mathcal{Q} . Finally, the loop on β continues after updating β . Algs 2 and 3 outline the creation of a new label, and its heuristic. Finally, if it is not possible to reach \mathcal{D} respecting all the imposed constraints, the algorithm returns NONE.

Algorithm 2 CREATELABEL function. It creates the label from node a to node b , given the arrival time g in a , the SoC q , the charging time Δ , the charged energy q , the driving time and energy, t, e , the minimum amount of time needed to charge in node b in the next label, the index of the last performed TW ω , the charger additional time β and the previous label L .

```

1: function CREATELABEL( $a, b, g, \underline{q}, \Delta, q, t, e, \lambda, \omega, \beta, L$ )
2:    $g := g + \Delta + t; q := \underline{q} + q - e$ 
3:    $h := \text{HEURISTIC}(\underline{b}, \underline{q}, g)$ 
4:    $\underline{f} := g + f$ 
5:    $L := (a, g, h, f, L, \beta, q, \underline{q}, \lambda, \Delta, \omega)$ 
6:   return  $\tilde{L}$ 
7: end function

```

We modify the previously described A* search algorithm for the **MDPM**. We refer to this algorithm as **AsDM**. We add

Algorithm 3 HEURISTIC function. It returns the estimated remaining time from node i to \mathcal{D} in graph \mathcal{G} , considering the SoC \underline{q} and arrival time g .

```

1: function HEURISTIC( $i, q, g$ )
2:    $\pi_{\text{tw}}(i) := \text{MINSTOP}(g)$ 
3:   if  $q - q_{\min} \geq \pi_{\text{cons}}(i)$  then
4:      $\pi_{\text{ch}}(i) := 0$ 
5:   else
6:      $s_{\max} := \text{MAXSLOPE}(\text{SUBGRAPH}(\mathcal{G}, i))$ 
7:      $\pi_{\text{ch}}(i) := \lceil \pi_{\text{cons}}(i) - (q - q_{\min}) \rceil / s_{\max}$ 
8:   end if
9:   return  $\pi_{\text{dr}}(i) + \max\{\pi_{\text{tw}}(i), \pi_{\text{ch}}(i)\}$ 
10: end function

```

two parameters in the labels, as follows

$$L_{j_m} := (i, g_j^m, h_j^m, f_j^m, p_j^m, \beta_j^m, q_j^m, \underline{q}_j^m, \lambda_j^m, \Delta_j^m, \omega_j^m, \Sigma_j^m, \tau_j^m).$$

The first parameter is Σ_j^m , which represents the total score gained from \mathcal{O} to the current label. For copy j_m ,

$$\Sigma_j^m := \Sigma_i^n + \sigma_j, \quad \Sigma_{\mathcal{O}}^1 := 0.$$

The second parameter is τ_j^m , it represents the arrival time in copy j_m . All the TWs constraints are now satisfied using this parameter instead of the arrival time g . This means, for instance, that $\tau_{\text{temp}} = \tau_j^m + \Delta - t_{ij}$, and every g_{temp} is replaced with τ_{temp} . The minimum waiting time becomes $\lambda_j^m := \max\{0, \gamma_k^L - \tau_j^m\} + t_k^{\min}$. For the origin node we have $\tau_{\mathcal{O}}^1 := t_{\text{start}}$ and $g_{\mathcal{O}}^1 := 0$. Finally, due to the different definition of labels, the function CREATELABEL is replaced by CREATELABELDISCOUNTED, and is outlined in Alg. 4.

Algorithm 4 CREATELABELDISCOUNTED function. It creates the label from node a to node b , given the discounted cost g to a , the SoC \underline{q} , the charging time, Δ , the charged energy q , the driving time and energy, t, e , the minimum amount of time needed to charge in node b in the next label, the index of the last performed TW ω , the charger additional time β , the previous label L , the arrival time τ , and the gained profit Σ .

```

1: function CREATELABELDISCOUNTED( $a, b, g, \underline{q}, \Delta, q, t, e, \lambda, \omega, \beta, L, \tau, \Sigma$ )
2:    $\tau := \tau + \Delta + t; \underline{q} := \underline{q} + q - e$ 
3:    $\sigma := \text{SCORE}(b)$ 
4:    $g := g + \Delta + t - \mu\sigma$ 
5:    $h := \text{HEURISTICDISCOUNTED}(B, \underline{q}, \tau, \Sigma)$ 
6:    $\underline{f} := g + f$ 
7:    $L := (A, g, h, f, L, \beta, q, \underline{q}, \lambda, \Delta, \omega, \Sigma, \tau)$ 
8:   return  $\tilde{L}$ 
9: end function

```

Furthermore, function HEURISTIC, is replaced with HEURISTICDISCOUNTED, described in Alg. 5. The new function takes as input the additional parameter Σ and returns the following discounted estimated time to reach \mathcal{D} :

$$\pi_{\text{u}}^2(i) := \pi_{\text{u}}^1(i) - \mu\Sigma.$$

Thus, the final value of f computed for node \mathcal{D} can be compared to the one computed with **MDPM**.

Algorithm 5 HEURISTICDISCOUNTED function. It returns the estimated time from node i to \mathcal{D} , considering the SoC q , the arrival time g and the gained score Σ

```

1: function HEURISTICDISCOUNTED( $i, q, g, \Sigma$ )
2:    $\pi_{\text{tw}}(i) := \max\{0, \gamma_k^L - g + t_k^{\text{min}}\}$ 
3:   if  $q - q_{\text{min}} \geq \pi_{\text{cons}}(i)$  then // See A
4:      $\tilde{\pi}_{\text{cons}}(i) := 0$ 
5:   else
6:      $s_{\text{max}} := \text{MAXSLOPE}(\text{SUBGRAPH}(\mathcal{G}, i))$ 
7:      $\pi_{\text{ch}}(i) := \frac{\pi_{\text{cons}}(i) - (q - q_{\text{min}})}{s_{\text{max}}}$ 
8:   end if
9:   return  $\pi_{\text{dr}}(i) + \max\{\pi_{\text{tw}}(i), \pi_{\text{ch}}\}(i) - \mu\Sigma$ 
10: end function

```

^A Available energy is potentially sufficient to reach \mathcal{D} .

IV. COMPUTATIONAL EXPERIMENTS

A. Data description and preprocessing

We obtain CS locations and specifications from a company, whose name we cannot disclose due to privacy reasons. The CSs were extracted from a bounding box that goes from 43.55° to 49.05° latitude and from 8.68° to 13.11° longitude, covering parts of Italy, Germany, Austria, Switzerland and the totality of Liechtenstein and San Marino (see Fig. 3).

Figure 3: Distribution of the CSs (created with mapcustomizer.com [7]).

CS i has a charging power p_i . We categorize the CSs as follows:

- slow: $p_i \leq 11$ kW,
- medium: $11 \text{ kW} < p_i \leq 30$ kW,
- fast: $p_i > 30$ kW.

We have performed a number of preprocessing actions on the provided data set. The first step was to group CSs at similar locations, for each group the fastest charger within that group

was considered. We then considered that CSs within a radius of $r_M = 100$ m form a cluster and if one CS belongs to two or more clusters, then all of them are merged. This reduction is based on the Haversine formula for computing the distance between each pair of nodes and assumes that the distances are symmetric. Merging all the CSs into a cluster produces a new CS that replaces the other CSs in the cluster. The cluster position is set as the average of the GPS coordinates of the CSs that comprise it, while its charging speed is set as the maximum among the CSs that comprise it. The final dataset is denoted by Γ . The final number of CSs is summarized in Tab. I.

Table I: Distribution of CSs for each country.

	Original # CSs	# CSs after grouping	# CSs after clustering
Germany	59 339	5 955	4 135
Italy	15 009	5 713	4 911
Switzerland	5 400	1 583	1 334
Austria	3 679	1 488	1 219
Liechtenstein	65	33	27
San Marino	34	17	15
Total	83 526	14 789	11 641

Using the post-processed database, we computed the distance and time matrix for each pair of CSs, obtained from multiple requests to the Open Source Routing Machine API (OSRM, [8]) server. The energy required by each arc was instead given by the product of the arc length and the average consumption per kilometer, as in [10].

The sets of required \mathcal{W}^R , and weakly mandatory time windows \mathcal{W}^M are given as input. Furthermore, we consider that tourism AWTs \mathcal{W}^T are also given as input. For $k \in \mathcal{W}^T$ a single CS location \mathcal{P}_k is given. To construct the set \mathcal{S}_k , the Haversine distance is computed by searching for CSs within a radius r_T centered in \mathcal{P}_k . The CSs with a distance less than r_T are included in \mathcal{S}_k . If no eligible nodes are present, the radius is iteratively increased by δ_T and the search is repeated, up to a maximum of \tilde{r}_T . If \mathcal{S}_k is still empty, the computation is resumed and an error informs that it is not possible to reach \mathcal{P}_k unless the EV is left more than \tilde{r}_T away. This process simulates the approach that a user needs to search for a CS near the location she wants to visit. If no CS is available at a reasonable distance from \mathcal{P}_k , then the user can decide to remove or change that tourism stop. For our experiments, we used $r_T = 2$ km, $\delta_T = 200$ m and $\tilde{r}_T = 4$ km.

Given the origin \mathcal{O} , the destination \mathcal{D} and the set of tourism stops \mathcal{W}^T , we construct the set of chargers \mathcal{S} and the set of arcs \mathcal{A} . Using OSRM, the optimal path without charging stops is computed and is used as a lower bound for **SPM**. All the CSs that are within a range of 5 km centered on the OSRM optimal route form the set \mathcal{S} . Finally, we construct \mathcal{A} as the set of all arcs (i, j) connecting nodes in $\mathcal{S}_{\mathcal{O}, \mathcal{D}}$.

In addition, we remove from \mathcal{S} all the nodes that have a distance from \mathcal{O} that is less than r^{min} , due to the fact that we want a solution with a small number of stops. Selecting one of those would have caused the EV to stop for just a few

kilometers from the origin point, which is not desirable. The same reasoning is applied to \mathcal{D} .

We also remove arcs that are going in the opposite direction with respect \mathcal{D} . More precisely, for each arc $(i, j) \in \mathcal{A}$, if by going from i to j the distance to \mathcal{D} is reduced, then (i, j) is kept, otherwise it is deleted. This process nearly halves the amount of edges included in \mathcal{A} .

Since the EV needs to respect the battery capacity Q and we want the total travel time to be small, we consider only the arcs (i, j) such that $r^{\min} \leq d_{ij} \leq r^{\max}$, where

$$r^{\max} := \lfloor (Q - q_{\min})/\eta \rfloor.$$

Finally, nodes that were not reachable from any other CS, as well as the corresponding arcs, are deleted.

B. Experiments and results

The codes were implemented in Python, using IBM ILOG CPLEX Optimization Studio 20.1. The tests ran on a single core of an Apple MacBook Pro with 8 core Apple M1 processor of 3.2 GHz, with 8 GB of LPDDR4 RAM.

The considered EV was a Škoda Enyaq iV 60, with a net battery capacity of $Q := 58 \text{ kWh}$ and a maximum average consumption of $\eta := 0.187 \text{ kWh/km}$ [3]. It has a maximum power charge $P := 40 \text{ kW}$, and we set the minimum required energy level q_{\min} to 15 kWh.

Two subsets of CSs were created: a small one, Γ_1 , with 650 CSs, used to compare the exact solution obtained with the MILP models with the A* search algorithms, and a larger one, Γ_2 , with 5 813 CSs, used to test the A* search. Both datasets are extracted with uniform probability from Γ , so we must guarantee that in each tourism stop there is at least one CS. We created a $5 \text{ km} \times 5 \text{ km}$ square centered in the coordinates of each tourism stop and uniformly extracted four CSs. Γ_1 and Γ_2 were obtained by selecting uniformly a certain amount of CSs from Γ and adding them to the ones selected for the tourism stops.

For both sets of CSs we use the same set of instances defined as trips. Since our CSs lay in a rectangular area that covers part of central Europe, those instances are chosen so that they fully lay in the same geographical area. We generate three main trips, with some variations, such as starting time, presence of tourism stops and minimum stopping times, presence or not of lunch (1 hour) and night (11 hours) ATWs. The ATW of lunch is [12:00, 13:30], while that of the night is [19:00, 22:30]. The instances have the following $\mathcal{O} - \mathcal{D}$ pairs:

- from Genoa to Zürich denoted by GeZu;
- from Livorno to Regensburg denoted by LiRe;
- Stuttgart to Ancona denoted by StAn

The remaining details are summarized in Tab. II. The name of the $\mathcal{O} - \mathcal{D}$ is followed by a running number to distinguish the instances. Overall, we created 20 instances.

We tested the MILP shortest path model, **SPM**, and maximum profit model, **MPM**, as well as both A* heuristics, the A* search algorithm for the **SPM**, **AsM**, and its variant for the maximum discount profit model, **AsDM**, for set Γ_1 . In addition, only the heuristics **AsM** and **AsDM** were applied to

Table II: Description of the instances

set Γ_2 . Then for all **AsDM** models we solved **SPM** imposing that the EV must use the arcs selected by the heuristic. CPLEX was unable to solve any instance in Γ_2 within one hour. We denote by GS_x^y (GT_x^y) the relative gap between the total score (trip time) of the models x and y . Also, to ease the notation, in the following we denote by **AsDM** $_{\mu_0}$ the application of **AsDM** for $\mu = \mu_0$, and use TS for the total score, TT for the trip time, and RT for the run time.

As seen in Tab. II, some instances describe the same trip, with different timings, and thus lead to the same set of unconstrained shortest optimal paths, and to the same set of CSs. For this reason, we subdivide the instances, and for both Γ_1 and Γ_2 extract the set of CSs related to each subdivision and store them. In this way, instances in the same subdivision use the same graph for all the models. In Tab. III we list the size for each subdivision.

Table III: Number of nodes and arcs for each instance.

Instances	Dataset Γ_1				Dataset Γ_2			
	Before		After		Before		After	
	Nodes	ArCs	Nodes	ArCs	Nodes	ArCs	Nodes	ArCs

StAn6 to StAn8	103	10506	73	629	819	669942	554	34542

We use the dataset Γ_1 to analyze the performance of the A* search with respect to the exact solution found. Initially we find the shortest path value T^{opt} of **SPM** and **AsM**. Then we compute the maximum relaxed time $T^{\text{max}} = T^{\text{opt}} + T^{\text{add}}$ and solve the **MPM** model. For the evaluation, we fix the value of T^{add} to 1h 30'. The result is then compared to the score gained

with **AsDM** for different values of the score multiplier μ , $\mu = 1, 2$. For the heuristic algorithms, we set $\beta := \{0, 1, 4\}$.

a) *Small dataset*: We solve the **MPM** model and apply the A* algorithm for $\mu = 2$. The results are in Tab. IV and V.

First, the solutions obtained with the A* search are refined using a MILP formulation. In particular, we create another **SPM** in which we set $x_{ij} = 1$ for each arc (i, j) selected in the final solution of **AsDM** for $\mu = 2$. The total trip times obtained by both approaches are quite similar. The results are summarized in Tab. IV and compared with the shortest path model **SPM**. The total trip time increases in average 3.3% when the refined **SPM** is applied, which is a small detour with respect to shortest path.

Table IV: Comparison of total trip time (in hours) between **SPM** and the refined **SPM** in Γ_1

ID	SPM	Ref. SPM	$GT_{\text{SPM}}^{\text{Ref. SPM}}$
	TT	TT	$\times 100$ [%]

StAn8	29.8	29.9	0.3
Average			3.3

In Tab. V we compare the total score gained and the run time of **MPM** and **AsDM** for $\mu = 2$. In average, the relative change between the maximum score computed with **MPM** and the one computed with **AsDM** there is an average of 11.9% worse scores with respect to the optimal solution found by **MPM**. This last value is quite large, with some instances having a relative change of over 25%. A possible approach to obtain better results may be to rely on different values of the parameter μ . The run time is quite low for all the models, but it is worth noting that we are considering the small graph created with the CSs in Γ_1 .

b) *Medium dataset*: We want to test the A* search algorithm for the medium dataset Γ_2 . We tested all the instances using only the heuristic approaches, **AsM** and **AsDM**. The results are reported in Tab. VI and VII. According to Tab. VI, we obtain an average increase of the total score with $\mu = 1$ with respect to $\mu = 2$. The difference is due to the fact that with $\mu = 2$ the shortest arcs become more important, even

Table V: Comparison of total score and run time (in sec.) between **MPM** and **AsDM** with $\mu = 2$ in Γ_1

with a lower score in the arrival node. The final solution might improve by tuning μ , also dynamically for each arc. The run time for the **AsM** model is quite high, with an average of 118.8sec for the trip from Livorno to Regensburg and of 81.4sec for the trip from Stuttgart to Ancona. If instead we analyze the **AsDM** model, we see a meaningful drop in the run time, with some exceptions. In particular, the instances that continue to have higher run times are the ones that have large time intervals without any TWs constraints. For instance, after the lunch break **StAn1** has no other TW that constrains the problem, so the research for a best bound solution is more time demanding.

The same holds for **LiRe1**, **LiRe2** and **StAn6**. Instead, **StAn8**, the instance with more TWs, is solved in less than 1 sec. in each discounted model. When the TWs are balanced along the trip, with not too many uncovered time intervals, the computation with the A* search is very fast, even in medium sized graphs. In Tab. VII we can see an average total trip time variation of less than 6.0% in the **AsDM** models with respect to the **AsM**.

V. CONCLUSIONS

We investigate the problem of finding a path for an EV performing a a long trip. The objective is to select CSs that better match the user preferences while respecting ATWs constraints.

We proposed an A* algorithm **AsM** for the shortest path version of our problem. We then proposed the **AsDM** algorithm which privileges POIs preferred by the user. This algorithm was quite fast in finding a shortest path solution with high total score. The algorithm performed fairly well with respect

to the exact solutions. This comparison was only possible on small instances, but the run times tend to increase with the size of the graph. If instead, the chosen trip has many TWs, then the computation is very fast even in medium sized graphs.

The run time of the MILP formulations increases exponentially in the size of the graph, so it can be computationally infeasible to solve even for medium size graphs. Both **AsM**

and **AsDM** solve this problem by storing only the promising states of the EV. However, the heuristics cannot manage real values of the additional charging time, so we must discretize those values using the set β . Solving again the **SPM** model with the arcs selected by the heuristics helps to optimize the charging times on the final solution.

Despite the promising results obtained by **AsM**, **AsDM**, there is potential for further improvements. More efficient heuristics can be developed to account for the potentials, leading to speeding up the A^* search algorithm. Such speeding ups may allow exploring more labels, yielding improved solutions.

Abstract—This paper aims to analyze longitudinal data, serial data related to different time points, in knowledge graphs. Knowledge graphs play a central role for linking different data. While multiple layers for data from different sources are considered, there is only very limited research on longitudinal data in knowledge graphs. However, knowledge graphs are widely used in big data integration, especially for connecting data from different domains. Few studies have investigated the questions how multiple layers and time points within graphs impact methods and algorithms developed for single-purpose networks. This manuscript investigates the impact of a modeling of longitudinal data in multiple layers on retrieval algorithms. In particular, (a) we propose a first draft of a generic model for longitudinal data in multi-layer knowledge graphs, (b) we develop an experimental environment to evaluate a generic retrieval algorithm on random graphs inspired by computational social sciences. We present a knowledge graph generated on German job advertisements comprising data from different sources, both structured and unstructured, on data between 2011 and 2021. The data is linked using text mining and natural language processing methods. We further (c) present two different shrinking techniques for structured and unstructured layers in knowledge based on graph structures like triangles and pseudo-triangles. The presented approach (d) shows that on the one hand, the initial research questions, on the other hand the graph structures and topology have a great impact on the structures and efficiency for additional data stored. Although the experimental analysis of random graphs allows us to make some basic observations we will (e) make suggestions for additional research on particular graph structures that have a great impact on the analysis of knowledge graph structures.

I. INTRODUCTION

KNOWLEDGE graphs have been shown to play an important role in recent knowledge mining and discovery, for example in the fields of computational social sciences, digital humanities, life sciences or bioinformatics. They also include single purpose networks (like social networks), but mostly they contain also additional information and data, see for example [1], [2], [3]. Thus, a knowledge graph can be seen as a multi-layer graph comprising different data layers, for example social data, spatial data, etc. In addition, scientists study network patterns and structures, for example paths, communities or other patterns within the data structure, see for example [4]. Very few studies have investigated the questions how multiple layers within graphs impact methods and algorithms

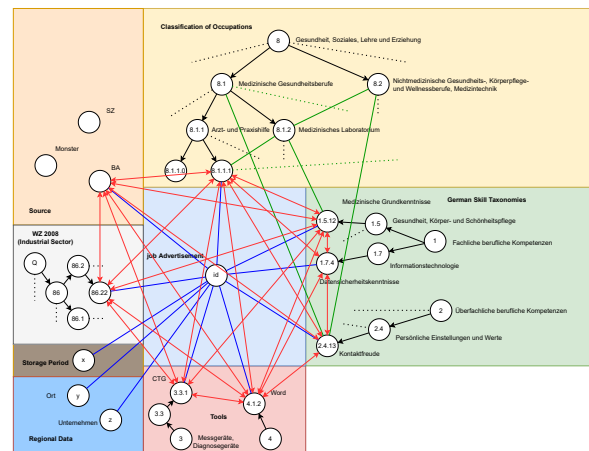

Fig. 1. Knowledge graph representation of German job ads, see Figure 1. In this case the red edges build the pseudo-triangles explaining the context of the job ad.

developed for single-purpose networks, see [5]. In addition, it is possible to store and analyze longitudinal data in knowledge graphs. This is an important topic in medical informatics, for example when working with longitudinal patient records. For example, in [6], the authors use a temporal query language on clinical knowledge graphs. Other authors like [7] use longitudinal patient records within a medical knowledge graph for predictive models. Longitudinal knowledge graphs are related to the versioning of knowledge graphs and other graph-based structures like ontologies. Although research started early on versioning RDF knowledge bases, see [8], only little research has been done on this field. Some attention was paid to the field of the evolution of data structures within information management, see for example [9], [10], [11], and the decentralized collaborative work on knowledge resources, see [12], [13]. Other researchers were interested in parallel world frameworks to analyze scenarios in knowledge graphs, see [14]. Nevertheless, a generic framework for modeling longitudinal data in knowledge graphs is still missing.

In this paper, we focus on an example use case from computational social sciences. In labor market research, ex-

tracking skill requirements from job advertisements (short: job ads) becomes a feasible approach to observe which skills are in demand by employers [15], [16], [17], [18]. Job ads are one way for a company to recruit new employees. Beside general information about the hiring company and the working conditions, they document the current skill needs on the labor market. For a longitudinal view on how skill demands develop, it is necessary to build a model which is capable of not only utilizing these data within a knowledge graph with contextual data, but also for efficient analysis.

We present a detailed overview of the knowledge graph representation in Figure 1. We give a detailed formal definition and overview in the next section.

The main research question of this paper is: How can we model longitudinal knowledge graphs on job ads for an efficient analysis of the development of skills while preserving all contextual data? In order to answer that question, this manuscript investigates both the impact of shrinking triangles in multiple layers and the runtime needed for this approach.

This paper is divided into five sections. The first section gives a brief overview of the research question, state of the art and related work. The second section describes the preliminaries and background. We will in particular introduce knowledge graphs and describe the knowledge graph models on job ads. In the third section, we present the experimental setting and the methods used. The fourth section is dedicated to experimental results and their evaluation. Our conclusions are drawn in the final section.

II. PRELIMINARIES

The term *knowledge graph* (sometimes also called a *semantic network*) is not clearly defined, see [19]. In [20], several definitions are compared, but the only formal definition was related to RDF graphs which does not cover labeled property graphs. However, a *knowledge graph* is a systematic way to connect information and data to knowledge.

Definition 1 (Knowledge Graph). *We define a knowledge graph as mixed graph $G = (E, R)$ with entities $e \in E = \{E_1, \dots, E_n\}$ coming from formal structures E_i , like ontologies.*

By using formal structures within the graph, we are implicitly using the model of a labeled property graph, see [21] and [22]. Here, nodes and edges form a heterogeneous set. Nodes and edges can be identified by using a single label or multiple labels, using a mapping $\lambda : V \cup E \rightarrow \Sigma$, where Σ denotes a set of labels. We need to mention that both concepts are equivalent, since graph databases use the concept of labeled property graphs.

Context is a widely discussed topic in text mining and knowledge extraction since it is an important factor in determining the correct semantic sense of unstructured text. In [23], Nenkova and McKeown discuss the influence of context on text summarization. Ambiguity is an issue for both common language words and those in scientific context. The challenge in this field is not only to extract such context data, but

TABLE I
DIFFERENT LAYERS WITHIN THE KNOWLEDGE GRAPHS OF GERMAN JOB ADS.

	Content	Size	Structure
E_1	Job Ads	ca. 600,000 per year	unstructured
E_2	Classification of Occupations	ca. 18,700	Taxonomy
E_3	Sources	1	unstructured
E_4	German Skill Taxonomy (AMS)	va. 600	Taxonomy
E_5	Tools	ca. 350,000	Taxonomy
E_6	Industrial Sectors	ca. 1,814	Taxonomy
E_7	Storage Period		unstructured
E_8	Regional Data		unstructured

also to be able to store this data for further natural language processing (NLP), like querying and discovery approaches, see for example [4].

In general, for a node $n \in V$, the neighborhood $N(n)$ contains all relevant contextual information. But usually information is best understood using information-triangles. Thus every two nodes $v, w \in N(n)$ form an implicit triangle v, n, w and when adding an additional edge (v, w) this forms a triangle K_3 , see Figure 1 for an illustration. Here, the additional edges that form pseudo-triangles are red.

Definition II.1 (Pseudo-Triangle). *Let $G = (E, R)$ be a knowledge graph and let $n, v, w \in G$ be three nodes in G . Moreover, let $n \in E_i$ for some i and let $v, w \in N(n)$. Then n, v, w form a pseudo-triangle in G .*

The knowledge graph on German job ads is build upon different corpora of job ads from multiple sources. In this paper, we will focus on a corpus from the German Federal Employment Agency. The corpus that we use to extract skills and tools contains approximately 600,000 job ads per year that were advertised from 2011 to 2021. In Table I we present the different knowledge graph layers.

Thus, combing Figure 1 and Table I, it appears that we are working on a knowledge graph $G = (V, E)$ with eight different layers, thus $G = E_1 \cup E_2 \cup \dots \cup E_8 \cup T_1 \cup I_1$ with the given data subsets E_1, \dots, E_8 and the text mining results T_1 and other data integrated in I_1 . We will now discuss how this knowledge graph can be connected with data from different years to build a longitudinal knowledge graph representation.

To test the efficiency of the analysis, we will focus on a very generic question: Given a structured layer which is not constantly changing (e.g. a taxonomy), how do the results on unstructured data (in our case: the job ads) evolve with respect to another structured layer (e.g. another taxonomy, for example tools or skills)? In other words: How can we efficiently retrieve data from a structured layer E_s ordered by another structured layer E_i when both are connected over time by different sets of unstructured data? For the sake of simplicity, we will define $E_s = E_4$ as skills retrieved by text mining and E_i as E_2 given by the classifications of occupations. Both sets are connected by the job ads.

III. METHOD

We can extend the knowledge graph with the information for one particular time point t , in our case for a year: $G^t = E_1^t \cup E_2^t \cup \dots \cup E_8^t \cup T_1^t \cup I_1^t$. With this, we can build a generic graph model comprising multiple times $T = \{t_1, \dots, t_m\}$: $G_T = G^{t_1} \cup G^{t_2} \cup C_{t_1, t_2} \cup G^{t_2} \cup G^{t_3} \cup C_{t_2, t_3} \cup \dots \cup G^{t_{m-1}} \cup G^{t_m} \cup C_{t_{m-1}, t_m}$

In this case, C_{t_i, t_k} comprises all edge relations from G^{t_i} to G^{t_j} . This contains relations like `isEqual` if two entities are equivalent or `isSuccessor` if an entity in G^{t_j} is the successor of an deprecated element in G^{t_i} .

Fig. 2. Merging maximal paths $P = p_1, \dots, p_m$ containing equal data in multiple years.

Thus, a first step to shrink the volume of the knowledge graph is to merge the multiple existence of elements in multiple years. Thus, we search for maximal paths $P = p_1, \dots, p_m$ in G_T where $p_i \in E_j \forall p_i \in P$. The edges between p_i and p_{i+1} are either `isEqual` or `isSuccessor` edges, see Figure 2. Thus for every edge $(p_i, p_{i+1}) \in C_{t_j, t_k}$ we can either merge p_i and p_{i+1} if they are the same (`isEqual`) or leave the `isSuccessor` edges. In our case we are in particular working on E_2 , the classification of occupations.

This can be done with depth-first search, see Algorithm 1, because we explicitly only use the directed subgraph induced by $R = G_T [C_{t_1, t_2} \cup C_{t_2, t_3} \cup \dots \cup C_{t_{m-1}, t_m}]$. The worst-case behavior is in $O(E(R) + V(R))$ and since every node p_i has at most $\Delta(E_2)$ neighbors in E_2 and at most $N(E_1)$ neighbors in E_1 the time complexity of merging the nodes is $O(\Delta(E_2) + N(E_1))$. Thus, the runtime of this step is linear, $O(n)$ in G_T . We denote the graph after step 1 with G_T^1 .

Algorithm 1 STEP-1

Require: Knowledge Graph G_T with layer (tree) E_x^t and mappings $C_{t_i, t_{i+1}}$ for all $t \in T = \{t_1, \dots, t_m\}$

Ensure: Shrunked G_T^1

$$M = N(\bigcup_{i=1, \dots, m} E_x^i) \cup E(\bigcup_{i=1, \dots, m-1} C_{t_i, t_{i+1}})$$

$$2: V = N(\bigcup_{i=1, \dots, m} E_x^i)$$

$$P = \emptyset$$

4: **for** every $v \in E_x^i$ with $v \in V \forall i \in \{1, \dots, m\}$ **do**

$p = \text{DFS}(M, v)$

6: $\text{del}(V, y) \forall y \in p$

$P.\text{add}(p)$

8: **end for**

return $G_T^1 = \bigcup_{i=1, \dots, \text{len}(P)} (p_i \in P)$

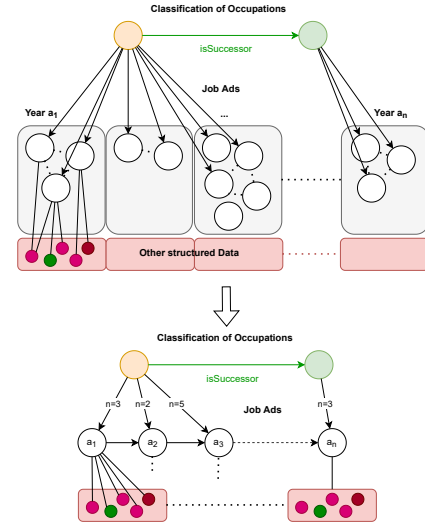

Fig. 3. Merging all job ads for a given year preserving the further links to other structured data.

In general we can make the following observations:

- Since the number of jobs in the classification schema does not increase dramatically, we can assume $N(E_2^t) \approx N(E_2^{t+1})$.
- Thus, even though a number of e_1 jobs may either be deprecated or are added as new items, the size of E_2^1 in G_T^1 is $\max_i N(E_2^i) + e_1 \in O(\max_i N(E_2^i))$.

In a next step, we can merge all job ads for a given year preserving the further links to other structured data. Thus for every time point t and every $v^t \in E_2^t$ we merge all nodes in $N = \{n^t \mid n^t \in N(v^t) \text{ and } n^t \in E_1^t\}$ to a meta node a_t and add an edge (v^t, a_t) with weight $|N|$, see Figure 3. These form pseudo-triangles in E_1 .

The runtime of this step is in $O(tN(E_1)N(E_2))$ and thus is quadratic, $O(n^2)$ in G_T , see Algorithm 2. We denote the changed graph after step 2 with G_T^2 and the new shrunked nodes in E_1 with E_1^2 .

Before continuing with a possible third step of shrinking graph structures, we should consider the theoretical results. Given the question, how the description of skills in job ads evolves in job classifications over the years, in the initial graph G_T we need to consider the following steps:

- Consider the evolution of any classifications v for all times $T = \{t_1, \dots, t_m\}$, runtime $O(m \max_i V(E_2^i))$.
- Consider all skills for any job ad in $N(v^t)$ for all times, runtime $O(V(E_1^t)V(E_4^t))$.

Thus, the average runtime is in $O(n^3)$. For the graph with shrunked pseudo-triangles this reduces to linear runtime:

- Consider any shrunked path p in E_2^1 , runtime $O(\max_i N(E_2^i))$.
- Consider all skills for all times, runtime $O(m)$.

With this third step we can reduce the data complexity, but while in step 1 we do not lose any relevant data, in step 2 we lose the information about specific job ads while preserving

Algorithm 2 STEP-2

Require: Knowledge Graph G_T with an unstructured layer E_x^t and a target layer E_y^t containing paths in P and mappings $C_{t_i, t_{i+1}}$ for all $t \in T = \{t_1, \dots, t_m\}$ and

Ensure: Shrunked G_T^2

$V = \emptyset$

2: $E'_x = \emptyset \forall t \in \{1, \dots, m\}$

$P = \square$

4: **for** every $p \in P$ in E_y^t **do**

for every $p_i \in P = \{p_1, \dots, p_z\}$ **do**

6: **for** every $t \in \{1, \dots, m\}$ **do**

$V' = N(p_i) \cap E_x^t$

8: **add** v' to E'_x

change all edges $(\hat{v}, u) \forall (\hat{v}, u) \in V'$ and $u \notin E_x$,
 $u \notin E_y$ to (v', u)

10: **end for**

12: **end for**

return $G_T^2 = (G_T \setminus E_x) \cup E'_x$

the information for a complete time set. Thus we can make the following observations:

- Structured data like taxonomies and ontologies can be shrunked without any data loss.
- Shrinking unstructured data in triangles or pseudo-triangles always goes along with data loss of particular data points while accumulated information might be preserved.
- Thus, it highly depends on the initial research question which layers and information can be shrunked to improve the runtime of algorithms.

For the given research question, steps 1-2 are the maximum reduction of the initial graph if considering the change for years.

IV. EXPERIMENTAL RESULTS

Our testing environment contains a random graph with m time points containing several graph layers. First, we have a random tree E_2^1 with 18,700 nodes and two probabilities p_p and p_d denoting a rate of a changing predecessor or a deleted node. These probabilities lead to m copies of E_2^1 and their mapping from one time point to the next as described in the previous section.

Second, we generate m times 600,000 random nodes in E_1^1, \dots, E_1^m with equal distributed mappings to E_2^1, \dots, E_2^m as described in the last section. In addition, these nodes receive random edges to 600 descriptive elements. Thus, our experimental setting is highly related to our real-world environment describes in the second section.

We used 50 instances to evaluate the runtime and performance of the algorithms presented in the last section. In Table II and Figure 4 we show the runtime of the two optimization steps. In general, we can see that both steps in average take 0.6 seconds.

TABLE II
RUNTIME OF STEP 1 AND STEP 2 IN SECONDS.

	Step 1	Step 2
Min	0.06	0.09
Max	0.79	0.24
Avg	0.45	0.13

TABLE III
RUNTIME OF RETRIEVAL ALGORITHM ON G_T AND G_T^2 IN SECONDS.

	G_T	G_T^2
Min	0.17	0.01
Max	1.01	0.02
Avg	0.58	0.01

In Table III and Figure 5 we show the runtime of the retrieval described in the last section. We can see that the runtime of both optimization steps is nearly the same as one retrieval on the initial graph G_T . This is not surprising, since the steps are quite similar. The retrieval on the optimized graph G_T^2 is much faster and at latest with the second run of a retrieval algorithm, we see a good improvement of runtime.

V. DISCUSSION AND OUTLOOK

This paper investigates the impact of longitudinal data in knowledge graphs. Knowledge graphs play a central role for linking different data. While multiple layers for data from different sources are considered, there is only very limited research on longitudinal data in knowledge graphs. We presented an experimental environment to evaluate one generic retrieval heuristic given different – both structured and unstructured – data layers. The result clearly shows that the graph structures and topology has a great impact on the efficient retrieval of additional data stored. The initial very generic question was: Given a structured layer which is not constantly changing (e.g. a taxonomy), how do the results on unstructured data (in our case: the job ads) evolve with respect to another structured layer (e.g. another taxonomy, for example tools or skills) evolve? In other words: How can we efficiently retrieve data from a structured layer E_s ordered by another structured layer E_i when both are connected over time by different sets of unstructured data? We specified three example layers to illustrate our optimization approach on (pseudo-)triangles and to evaluate the efficiency.

In particular, we propose a first draft of a generic model for longitudinal data in multi-layer knowledge graphs. This approach stores copies of the knowledge graph on multiple time points and the mapping between nodes in one and a following time point. Since some optimization can be done without losing data, e.g. step 1, we propose further research on a generic longitudinal data model to use these approaches when building the knowledge graph. Second, we develop an experimental environment to evaluate a generic retrieval algorithms on random graphs inspired by computational social sciences. This example was highly influenced by the boundary conditions given by the real-world problem, a knowledge

Fig. 4. Resulting runtimes of step 1 and step 2 in seconds.

Fig. 5. Resulting runtimes of retrieval algorithm on G_T and G_T^2 in seconds.

graph generated on German job advertisements comprising data from different sources, both structured and unstructured, on data between 2011 and 2021. The data is linked using text mining and natural language processing methods. In general, we present two different shrinking approaches for structured (step 1) and unstructured (step 2) layers in knowledge graphs based on graph structures like triangles and pseudo-triangles. Here, more research needs to follow. While we have argued that these approaches are generic and can be used for any content, further attention for triangles and pseudo-triangles is needed. They form a crucial factor both for understanding the data context and for efficient retrieval of these data.

The presented approach shows that on the one hand the initial research questions (what are the layers to shrink) and on the other hand the graph structures and topology have a great impact on the structures and efficiency for additional data stored. The experimental results show promising results, but further research is necessary to build a generic, time-efficient representation of longitudinal data in knowledge graphs.

Abstract—Cereals contribute significantly to humanity’s livelihood. They are a source of more food energy worldwide than any other group of crops. Their production contributes considerably to the total global anthropogenic greenhouse gas (GHGs) emissions. In this study we propose a basic bio-economic farm model (BEFM) solved with the help of Ant Colony Optimization (ACO) methodology. We aim to assess farm profits and risks considering various types of policy incentives and adverse weather events. The proposed model can be applied to any annual crop.

Index Terms—Agricultural System Modeling, Bio-economic farm model, Ant Colony Optimization, Metaheuristics

I. INTRODUCTION

CEREALS are essential for human nutrition and health. Their production accounts for a substantial amount of the greenhouse gas emission of the agricultural sector, which is in many cases directly affected by a changing climate. The policies of the European Union (EU) recognize these facts. The Farm to Fork Strategy is central to the efforts to decarbonize the economy outlined in the European Green Deal [14]. EU policy encourages agricultural producers to reconcile economic with environmental objectives. Apart from maintaining economic growth, competitiveness, and employment recent policies seek to optimize the use of scarce natural resources such as land and water, to reduce the use of chemical inputs and fertilizers, to promote integrated nutrient management and on- and off-farm biodiversity through sustainable intensification of agricultural systems. The Sixth Report (AR6) of the International Panel for Climate Changes (IPCC) [13], published in August 2021, states that “Each of the last four decades has been successively warmer than any decade that preceded it” (Paragraph A.1.2., page 6 in [13]).

An overview by Reidsma et al. (2018) identifies 202 studies conducted between 2007 and 2015 using bio-economic farm models (BEFMs) [1]. Recent prominent applications include the analysis of cotton production in Uzbekistan [2]. A stochastic dynamic optimization model by Spiegel et al. allows for the representation of managerial flexibility by adopting real options modeling techniques [3]. Another study by Spiegel et al. contributes towards the simultaneous appraisal of investment and managerial behavior and its environmental impacts. The usefulness of the method is demonstrated by an application to

a perennial biomass energy production system [4]. A second application to short rotation coppices can be found in the multi-objective optimization model of Rössert et al. [5]. An overview by Britz et al. determines the desirable features of a BEFM by comparing four generic template-based models selected based on preset criteria [6].

This paper proposes a decision-making system based on a BEFM that has the potential to exhibit many desirable features identified by literature. Cropland allocation is framed as a constrained profit maximization problem from the point of view of the farmer. Apart from the resource constraints the farmer is subjected to various policies and environmental influences. The optimization problem thus includes a lot of constraints and some uncertainties. We apply ACO methodology [7] to solve it. The model is calibrated for Bulgarian crop farms.

II. PROBLEM FORMULATION

The problem is framed as a microeconomics profit maximization problem. Farmers presumably maximize their profit every year to by allocating cropland to a specific annual crop and deciding how intensely to cultivate it. They consider various preconditions, such as various prices, price expectations, expenses, costs, taxes, fees, subsidies and, finally, the probability of an adverse events.

The system relying on profit maximization can be applied in the presence of one or more plots and several suitable for sowing crops. The system considers the expected price for each crop, the average yield for each crop for each of the plots. Included are the subsidies for the individual crops that the farmer can receive, as well as the costs for each of the crops related to tillage, planting, fertilization, crop cultivation, harvesting, etc., as well as the costs for each of the plots posed by rent, taxes and fees. Included is the probability of an adverse event reducing yields such as ozone pollution, cold winter, drought, etc. and a coefficient showing the reduction in yield if the event occurs.

The result of the optimization is a recommendation to the farmer with respect to the cropland allocation and the cultivation intensity so that the profit is maximized.

III. SOFTWARE AND DATA

Software implementing the decision-making system has been developed. The input parameters are: plots of land; crops for planting; minimum area for sowing crops, on each of the plots; expected price of every crop; subsidy per unit area for every crop; yield per unit area for every crop from every plot; estimated cost per unit area for crop (amount of tillage costs, seeds, fertilizers, chemicals, labor, overheads); costs per plot, independent of the crop sown (land lease, taxes, etc.); likelihood of an adverse event reducing the harvest (ozone pollution, drought, hail, pests, etc.); a coefficient showing the reduction in yield as an adverse event appears.

The decision-making system is calibrated using price and yield data provided by the Bulgarian Chamber of Agriculture. The used crops are the cereals most planted in Bulgaria (corn, sunflower, wheat, barley). The yield data refer to North-East Region in Bulgaria for the year 2018. The prices for crops, subsidies and costs are measured in Euro, while the land is measured in decares.

IV. ANT COLONY OPTIMIZATION ALGORITHM

Nature does not tolerate extravagance. It has millions of years of experience. It can teach us how to achieve maximum results with minimal effort. That is why methods with ideas from nature are so successful.

The ACO is a methodology, which is nature-inspired. It belongs to the group of metaheuristics. The method follows the real ants behavior when looking for food. Real ants use pheromone substance, to mark their path and to return back. Normally an ant moves in random fashion and when it comes across a previously laid pheromone it decides whether to follow it and reinforce it with an additional pheromone. So the more ants follow a given trail, the more attractive that trail becomes. Pheromone evaporates over time. Thus the pheromone level of less/not used paths decreases and they become less desirable later. It prevents the ants from following wrong and useless paths. Observations show that ants manage to find the shortest path between the nest and the food source using only the concentration of the pheromone, i.e. their collective intelligence.

A. Main ACO Algorithm

Problems with strict restrictions and a large number of parameters usually require a lot of computing resources. An option is to be applied some metaheuristics. They are more flexible and fast at the expense of accuracy [7].

For a first time, ant behavior is used for solving optimization problems by Marco Dorigo [8]. Later some modifications are proposed, mainly in pheromone updating rules [7]. The basic in ACO methodology is graph representation of the problem and simulation of ants behavior. The solutions are represented by paths in a graph and the aim is to find shorter path corresponding to given constraints. The requirements of ACO algorithm are as follows: Appropriate representation of the problem by a graph; Appropriate pheromone placement on the nodes or on the arcs of the graph; Suitable

problem-dependent heuristic function, which manage the ants to improve solutions; Pheromone updating rules; Transition probability rule, which specifies how to include new nodes in the partial solution; Appropriate algorithm parameters.

The transition probability $P_{i,j}$, is a product of the heuristic information $\eta_{i,j}$ and the pheromone trail level $\tau_{i,j}$ related to the move from node i to the node j , where $i, j = 1, \dots, n$.

$$P_{i,j} = \frac{\tau_{i,j}^a \eta_{i,j}^b}{\sum_{k \in \text{Unused}} \tau_{i,k}^a \eta_{i,k}^b}, \quad (1)$$

where Unused is the set of unused nodes of the graph.

The initial pheromone level is the same for all elements of the graph and is set to a positive constant value τ_0 , $0 < \tau_0 < 1$. After that at the end of the current iteration the ants update the pheromone level [7]. A node become more desirable if it accumulates more pheromone.

The main update rule for the pheromone is:

$$\tau_{i,j} \leftarrow \rho \tau_{i,j} + \Delta \tau_{i,j}, \quad (2)$$

where ρ decreases the value of the pheromone, which mimics evaporation in a nature. $\Delta \tau_{i,j}$ is a new added pheromone, which is proportional to the quality of the solution. For measurement of the quality of the solution is used the value of the objective function of the ants solution.

The first node of the solution is randomly chosen. With the random start the search process is diversifying and the number of ants may be small according the number of the nodes of the graph and according other population based metaheuristic methods. The heuristic information represents the prior knowledge of the problem, which is used to better manage the algorithm performance. The pheromone is a global history of the ants to find optimal solution. It is a tool for concentration of the search around best so far solutions.

B. ACO for Agricultural Modeling

ACO algorithm is a constructive method. Every ant constructs its solution, taking in to account the constraints. In our application an ant chooses first crop randomly between the crops for sowing and assign it to the randomly chosen possible plot. The assigned land is equal to the minimal lend for this crop. The next crop and plot is chosen applying probabilistic rule called transition probability. If on the chosen land this crop is assigned yet we increase the land with 1. If the number of assigned crops for all lends is less then the minimal number, than unassigned crops have two times higher probability to be assigned, or:

$$P_{i,j} = \begin{cases} \frac{\tau_{i,j}^a \eta_{i,j}^b}{\sum_{k \in \text{Unused}} \tau_{i,k}^a \eta_{i,k}^b} & \text{more crops or crop } i \text{ is assigned} \\ 2 \frac{\tau_{i,j}^a \eta_{i,j}^b}{\sum_{k \in \text{Unused}} \tau_{i,k}^a \eta_{i,k}^b} & \text{less crops, crop } i \text{ is'nt assigned} \end{cases} \quad (3)$$

We construct the following heuristic information:

$$\eta_{i,j} = PO \times Decr_{i,j} \times d_{i,j} \times P_i + (1 - PO) \times d_{i,j} \times P_i + (S_i - r1_{i,j}) \times N_{ij}$$

where PO is a probability for adverse event, $Decr_{i,j}$ is decrease of yield if adverse event appear, $d_{i,j}$ is output for crop i from land j , P_i is expected price of crop i , S_i is subsidy for crop i , $r1_{i,j}$ is expenses for crop i from land j , N_{ij} is the sown area of crop i on land j . Thus the adverse event and its influence is taken in to account. When the probability the adverse event to appear is more than 0, then the output of crop i decrease with coefficient $Decr$. For different crops this coefficient is different, because the adverse event influences different crops in different way. For example the corn and sunflower are more influenced by drought, than wheat and barley.

The used objective function is as follows:

$$F = \sum_{i=1}^n \sum_{j=1}^M PO \times Decr_{i,j} \times d_{i,j} \times P_i \times N_{ij} + (1 - PO) \times d_{i,j} \times P_i \times N_{ij} + (S_i - r1_{i,j}) \times N_{ij}$$

Thus the objective function takes in to account probability of adverse event, different expenses, prices of the crops and sown.

V. COMPUTATIONAL RESULTS AND DISCUSSION

Preparing test cases is a complex task. They need be as realistic as possible in order to draw the right conclusions, but also be able to show the qualities and capabilities of the proposed algorithm.

The proposed bio-economic farm model is tested on a test problems with following common parameters:

TABLE I: Test instances characteristics

Parameters	Value
plots of land	{100, 200}
crops	4
minimal area	10
minimal number of crops	4

The parameter settings of our ACO algorithm is shown in Table II and are fixed experimentally after several runs.

TABLE II: ACO parameter settings

Parameters	Value
Number of iterations	100
ρ	0.5
τ_0	0.5
Number of ants	20
a	1
b	1

Several test instances are prepared. The baseline of the bio-economic model refers to the situation without any subsidy or adverse event. Four scenarios are constructed to showcase the capabilities of the bio-economic model: a subsidy for barley amounting to 11 Euro per decare; with subsidy for both barley 11 Euro per decare and wheat 10 Euro per decare; an 80%

probability of drought that decreases corn and sunflower yields with a coefficient of 0.5 for corn and 0.7 for sunflower; a subsidy for barley 30 Euro per decare.

TABLE III: Baseline without any subsidy or adverse events

land	wheat	corn	sunflower	barley
Land1	0	10	90	0
Land2	10	140	40	10

When there is no adverse event and subsidy the corn and sunflowers are preferable because they are more profitable than the two other crops, Table III.

TABLE IV: Subsidy for barley 11 Euro per decare

land	wheat	corn	sunflower	barley
Land1	0	10	90	0
Land2	10	140	40	10

The situation is not changed when the subsidy of the barley is 11 Euro per decare, Table IV. It means that this subsidy is not effective as an incentive to make the barley attractive to the farmer.

TABLE V: Subsidy for barley 11 Euro per decare, for wheat 10 Euro per decare

land	wheat	corn	sunflower	barley
Land1	0	10	90	0
Land2	50	140	0	10

We observe that when the barley and wheat are subsidized the wheat becomes more attractive than the sunflower for the Land2, Table V. It means that a subsidy of 10 Euro per decare is sufficient to make the wheat more attractive.

TABLE VI: 80% probability for drought

land	wheat	corn	sunflower	barley
Land1	10	0	10	80
Land2	140	10	0	50

The drought influences only corn and sunflower yields, thus with a non-zero probability of drought the two other crops become more attractive while the income of the farmer is preserved, Table VI.

The last scenario envisions a larger subsidy for barley. We observe that the subsidy is effective as an incentive to make the barley attractive to the farmer, Table VII.

With these five examples we showcase the capabilities of the basic bio-economic farm model. In the baseline scenario, without any subsidy, the crops with the higher profit are more attractive to farmers. We show that subsidies can incentivize the farmers to alter behavior and stimulate the cultivation of crops that are not profitable in the market sense. We show how the potential for adverse weather events such as droughts can

TABLE VII: Subsidy for barley 30 Euro per decare

land	wheat	corn	sunflower	barley
Land1	0	10	90	0
Land2	10	140	0	50

influence profits by affecting yields and that the anticipating farmers adapt to it by changing the crops they sow as to maintain their profit level.

The proposed model showcases the influence of selected policies and adverse weather events on cropland allocation and can be adapted for any annual crop. The model can be extended to cover diverse other instruments such as subsidies, taxes, production quotas, guaranteed prices as well as regulations regarding the land management. It can also be extended to describe the production technology of the farmer in detail in particular with respect to the input and output requirements so that it is possible to include environmental considerations in the optimization problem, either as constraints or as desirable outcome of the optimization, e.g. achieving a specific soil carbon balance while maintaining agricultural profits or reducing the use of chemical inputs while maintaining a certain production quota.

This technological detail would also allow us to incorporate emission accounting in the model. This would give us the opportunity to quantify the amount of greenhouse gas (GHG) emissions that are consistent with the production level and the maximum profit. The model we propose can also be coupled to a crop growth simulation model for a more detailed representation of the nutrient balance in the soil or to a hydrological model to model the effects of an adoption of irrigation technology. Extensions are possible with respect to the time horizon of optimization even for annual crops to account for situations such as long-term contracts of the farmer with guaranteed prices. The risk-preferences of the farmer could be considered similar to different management options such as crop rotation. Management flexibility and long-term investment decisions could be incorporated.

VI. CONCLUSION

In this paper we propose a decision-making system based on a generic BEFM for annual crops, which has the potential to exhibit many desirable features of a BEFM identified by literature. The model is solved via Ant Colony Optimization methodology. We showcase the possibilities offered by our system by preparing various scenarios. The system can be used to assist farmers with cropland allocation, but also by the state and by the European administration to simulate the effects of technology adoption and for impact evaluation of policies. It will be further developed, thoroughly tested, and compared

to existing BEFM to validate the model results, but also to promote the development of an ecosystem of BEFM modelers.

A GPU approach to distance geometry in 1D: an implementation in C/CUDA

Simon B. Hengeveld* A. Mucherino,*

*IRISA, University of Rennes 1, Rennes, France.

simon.hengeveld@irisa.fr, antonio.mucherino@irisa.fr

Abstract—We present a GPU implementation in C and CUDA of a matrix-by-vector procedure that is particularly tailored to a special class of distance geometry problems in dimension 1, which we name “paradoxical DGP instances”. This matrix-by-vector reformulation was proposed in previous studies on an optical processor specialized for this kind of computations. Our computational experiments show that a consistent speed-up is observed when comparing our GPU implementation against a standard algorithm for distance geometry, called the Branch-and-Prune algorithm. These results confirm that a suitable implementation of the matrix-by-vector procedure in the context of optic computing is very promising. We also remark, however, that the total number of detected solutions grows with the instance size in our implementations, which appears to be an important limitation to the effective implementation of the optical processor.

I. INTRODUCTION

THE Distance Geometry Problem (DGP) asks whether a simple weighted undirected graph $G = (V, E, d)$ can be realized in the Euclidean space \mathbb{R}^K , with $K > 0$, so that the distance constraints

$$\forall \{u, v\} \in E, \quad \|x_u - x_v\| = d_{u,v},$$

are satisfied [5]. When this is the case, we say that the mapping $x : v \in V \rightarrow x_v \in \mathbb{R}^K$ is a *valid* realization of the graph G . Depending on the DGP application at hand, the vertices $v \in V$ can represent different kinds of *objects*, for which possible positions in \mathbb{R}^K are searched. The edge set E encodes the information about the distance between vertex pairs, and the numerical value of these distances is given by the associated weight. Notice that $\|\cdot\|$ is the Euclidean norm. We suppose that the available distance values are *exact*, i.e. extremely precise.

In this work, we focus our attention of DGPs in dimension 1. In 1979, Saxe proved that the DGP is NP-complete when K is set to 1 [10]. The main DGP application in this dimension is the clock synchronization problem: given a set of clocks (represented by the vertices $v \in V$), and a subset of offset measurements between pairs of clocks (encoded by the edges $\{u, v\} \in E$ and the associated weight $d_{u,v}$), the problem asks whether it is possible to know the precise time indicated by all clocks [11]. This problem is fundamental for the synchronization of events in distributed systems [1], [12], as for example in wireless sensor networks [14].

The Branch-and-Prune (BP) algorithm was proposed in [4] for a subclass of DGP instances that admit the discretization

of their search space. In the 1-dimensional case, this algorithm can be employed under the much weaker assumption that the graph G is connected [9]. In this case, in fact, a vertex order on V , which ensures that every vertex v has at least one predecessor u (exception made for the first vertex in the order), can be easily constructed [8]. This vertex order is indicated by the subscripts associated to the vertices in the discussion below.

We are interested in a particular subclass of DGPs in dimension 1: the class of *paradoxical* DGP instances [2]. These instances are represented by graphs G that are cycle graphs, for which a vertex order on its vertex set can be trivially identified. The paradoxical character of these instances is given by the two following observations. On the one hand, the construction of solutions to these instances appears to be relatively *easy*, because most vertices $v_k \in V$ only depend on one predecessor in the vertex order, so that, for each x_{k-1} , the two new positions $x_{k-1} - d_{k-1,k}$ and $x_{k-1} + d_{k-1,k}$ can be easily computed for v_k . Notice that this procedure allows us to build up a binary tree collecting, on each of its layers, the possible positions for each vertex v_k . On the other hand, however, the absence of any other distance information (apart the distance to the predecessor $d_{k-1,k}$) up to the layer n , where $n = |V|$, makes this class of instances actually *very hard*. In fact, it is only at layer n that the distance between the first vertex v_1 and the last vertex v_n can be exploited to select the only two valid realizations out of a set of 2^{n-1} potential solutions [6].

In this work, we consider the matrix-by-vector reformulation of paradoxical DGPs in dimension 1 (recently proposed in [2] for solving paradoxical DGP instances on a new optical processor) and we implement it on a GPU device. The presented computational experiments show a consistent speed-up when our GPU implementation is compared against the BP algorithm, as well as when the comparison is performed against the sequential implementation of the matrix-by-vector procedure itself. These results confirm therefore that the matrix-by-vector reformulation is promising in the context of optic computing. Our experiments also point out, however, a possible limit in the actual implementation of the optical processor.

The rest of this paper is organized as follows. In Section II, we will describe the matrix-by-vector reformulation of our paradoxical DGP instances in dimension 1. In Section III, we will present our GPU implementation for the matrix-by-

Fig. 1. The pattern given by the signs of the elements of the matrix M . In dark blue, the elements that have positive sign; in light gray the ones having negative sign. Notice that M is here transposed to let it better fit the page.

vector multiplication, which will benefit of some simplifications implied by the particular problem we aim to solve. We will present and discuss our computational experiments in Section IV, and finally draw our conclusions in Section V.

II. A MATRIX-BY-VECTOR REFORMULATION

When the BP algorithm mentioned in the Introduction is employed for the solution of paradoxical DGP instances in dimension 1 [9], a binary tree containing all possible vertex positions can be recursively constructed, and the valid realizations can be selected at the very end when positions are computed for the last vertex $v_n \in V$. Our paradoxical instances have the particularity of solely executing the branching phase of the algorithm until a leaf node of the tree is reached; it is only at this point that the pruning mechanism is invoked, where the only distance not used for branching, the distance related to the edge $\{1, n\}$, is verified. If the distance is satisfied by the current position for v_n , then the path from the tree root to the current node is a valid realization; it can be discarded otherwise.

As remarked in [2], it is possible to replace, for our paradoxical instances, the pruning phase occurring only at layer n with an additional branching phase, which is performed over the fictive vertex v_{n+1} that is introduced in the original graph. The fictive vertex is connected to its predecessor v_n by an edge having the same weight as the original edge $\{1, n\}$. The edge from v_1 to v_n is thereafter removed, breaking in this way the original cycle structure. The main reason for making this manipulation on G is that now the distance information is equally distributed over the vertices of the graph, and the solver of paradoxical instances can perform exactly the same operation when stepping from one vertex to its successor. In order to identify the valid realizations, it is finally necessary to verify that $x_1 = x_{n+1}$.

The introduction of the fictive vertex allows us to reformulate the paradoxical DGP in dimension 1 as a matrix-by-vector multiplication [2]. We introduce the matrix

$$M_{ij} = \begin{cases} -1 & \text{if } (i-1)/2^{j-1} \bmod 2 = 0, \\ 1 & \text{otherwise,} \end{cases}$$

and the vector $y_j = d_{j,j+1}$, which contains the distance information related to our paradoxical instance. Thus, the vector $r = My$ contains all possible positions x_{n+1} for all possible solutions. Notice that the index i varies from 1 to 2^n , whereas the index j varies from 1 to n . The feasible solutions to our paradoxical instances are the ones for which $r_i = 0$ (because x_1 is here implicitly set to 0).

We notice that performing the matrix-by-vector multiplication gives an answer to the original decision problem (does it exist a realization such that ...) but it does not directly provide the realizations, i.e. the sequences of positions on the real line for the vertices of G . In order to construct one selected valid realization, as for example the realization encoded by the i^{th} row of the matrix M , the value of each position x_k^i for the vertex $v_k \in V$ (we added a superscript to x to specify the matrix row) can be obtained by performing the following partial sum:

$$x_k^i = \sum_{j=1}^k M_{ij} y_j.$$

The next section describes an ad-hoc GPU implementation of this matrix-by-vector multiplication.

III. A GPU IMPLEMENTATION

Our GPU implementation does not perform *generic* matrix-by-vector multiplications. For this general problem, the reader can refer to some recent (see for example [7], [13]) and very recent (see [3]) publications on the topic. Differently from the cited papers, our implementation takes advantage of the structure of our matrix M to optimize the computations.

First of all, since the elements of our matrix M are either -1 or 1 , we can trivially “move” all distance values from the vector y to the matrix, by paying only attention to the sign to consider for each distance value when placed in a particular row of the matrix. We define therefore this new matrix:

$$M'_{ij} = \begin{cases} -d_{j,j+1} & \text{if } (i-1)/2^{j-1} \bmod 2 = 0, \\ d_{j,j+1} & \text{otherwise,} \end{cases}$$

from which the vector r can be simply computed by summing up all row elements:

$$r_i = \sum_{j=1}^n M'_{ij}.$$

As a consequence, our GPU implementation will only perform sums, and not products of real numbers.

Another important point in our implementation is the procedure to construct the matrix M' , and in particular for the choice of the sign for each matrix element. The rule given in the definition (involving the modulus operator) is simple to understand and to apply, but it can be computationally very expensive to perform for every element of the matrix. For our implementation, we found another, and more efficient, method to identify the sign of every matrix element.

Fig. 1 shows the sign distribution over the matrices M and M' : all positive elements correspond to the dark pixels, while all negative elements correspond to the light gray pixels. More than one pattern can be identified in these matrices, but one in particular turns out to be very useful for our GPU implementation. If in fact we interpret every gray pixel as a 0 (instead of a -1), whereas the dark pixels still represent 1's, then we can see every matrix row (notice that the matrix is transposed in Fig. 1) as the binary representation of integer numbers spanning from 0 to $2^n - 1$. Moreover, if we consider the big-endian convention for the bit ordering (which is, the less significant bit is on the left side, differently from our standard convention with decimal numbers), then the integer number at row i is simply the predecessor (in integer arithmetic) of the one at row $i + 1$, and it is the successor of the one at row $i - 1$. If the bits of an integer ℓ encode therefore the signs at row i , the bits of the integer $\ell + 1$ simply encode the signs at row $i + 1$.

In our GPU implementation, every thread is in charge of computing the sums for a subset of matrix rows. This subset forms a block of contiguous matrix rows, so that, once each thread has found out its starting value for ℓ , it simply needs to increase it by one unit per time for treating all subsequent rows. Naturally, all row blocks are supposed to have the same size in order to better exploit the power of the GPU device.

After the computation of every row sum, the thread verifies whether this sum is *close enough* to 0. In the case it is true, the thread keeps this information aside (in binary format) and it sends it back to the CPU at the end of the computations. Notice that this information is binary (a valid realization was found or not), because the symmetry properties [6] of our paradoxical instances indicate that the only chance to have two valid realizations treated by the same thread is when all matrix rows are assigned to one unique thread.

IV. COMPUTATIONAL EXPERIMENTS

This section presents some computational experiments where we compare the standard BP algorithm (see Introduction) against our matrix-by-vector procedure, executed both in sequential and in parallel. All programs¹ were written in C, and CUDA was employed for coding the computations on GPU. The experiments were performed on a workstation equipped with an Intel(R) Xeon(R) CPU E5-2609 v3 @1.90GHz, Nvidia GPU GeForce GTX TITAN X graphics card, and running Ubuntu Linux operating system. We compiled our programs with the version 5.4.0 of GCC, and with the version 9.0.176 of CUDA. In all experiments, our execution on GPU was launched with a thread grid comprising 64 blocks, having 512 threads each.

Table I presents some computational experiments where the BP algorithm is compared against the sequential and the parallel implementations of our matrix-by-vector procedure. We considered instances of size ranging from 20 to 32 which were randomly generated so that to satisfy the properties of paradoxical instances. The cardinality $|V|$ of the vertex sets is reported on the first column of the table. We omit to report the cardinality of the edge set E because it always corresponds to $|V|$ in our instances. The BP algorithm was run only on CPU; the matrix-by-vector procedure was run on both CPU (the sequential version) and GPU (the parallel version).

While it is expected (see Introduction and Section III) that every instance only admits two valid realizations, the second column of Table I shows that the number of solutions (#sols) found by the BP algorithm is larger, and it tends to increase with the instance size. Our interpretation for this phenomenon is that, the more the search space increases in size (exponentially with n), the more are the chances to find a realization that is *close enough* to feasibility. The verification of the final distance $d_{1,n}$ is performed with tolerance $\varepsilon = 10^{-4}$ in all experiments, which allows us to take into consideration the possible round-off error propagation. However, the use of this tolerance seems to enlarge *too much* the subset of realizations for which this final distance appears to be satisfied. We remark, however, that a generic tuning on the value of ε that would work for all instances is naturally not possible.

The third column of our table gives the time in seconds necessary for the BP algorithm to fully explore the search space of the given instances. To measure the time, we used the standard C `clock` function. Recall that the search space has size 2^{n-1} .

The fourth and fifth columns of Table I show the results obtained with the implementation of our matrix-by-vector procedure in sequential. While the number of found solutions does not change w.r.t those found by BP, we remark an increase on the computational time. This was expected, because the matrix-by-vector formulation does not exploit the fact that the computations necessary for a given solution can be partially reused for neighboring solutions (i.e. belonging to

¹The interested reader can find an extended version of this article on the online HAL open archive database, where code snippets are also included.

near matrix rows). This is the reason why the BP algorithm works differently. However, the independence of the matrix rows is an essential feature for our GPU implementation.

Finally, the last two columns of the table show the results obtained with our GPU implementation. We point out that we used the `float` primitive type for the distances and the positions (we did the same in the previous two C implementations, in order to obtain results as uniform as possible). We used `unsigned long` types to store the values of the integer ℓ (see Section III). Naturally, this choice limits the instance size n to 64, but has no impact on the experiments we have performed for this work (the decimal representation of 2^{64} is already a quite “large” integer, composed by 20 digits).

The computational time is significantly reduced, when compared to the sequential version of the matrix-by-vector procedure, as well as when the comparison is performed against the original BP algorithm. We notice, however, that the number of found solutions differs with the other implementations for the instances of larger size. This error is due to the way the GPU threads communicate their results to the CPU: this information is in fact binary (solution found / not found) because at most one solution per thread was initially expected to be identified. Apparently, during the computations, more than one solution was instead (wrongly) detected by the same thread, thus leading to a smaller final solution sum.

The reader may wonder why we have decided not to fix this “issue” in our CUDA implementation. Since our work is motivated by the optical processor mentioned in the Introduction, which is supposed to perform the calculations (although in an analog fashion) in a similar way, it seems important to us to point out this drawback of the implementation. This is actually a quite important limitation for the physical implementation of optical processor.

V. CONCLUSIONS

We have presented a GPU implementation of a matrix-by-vector procedure that is particularly tailored for the solution of paradoxical DGP instances in dimension 1. The idea to reformulate this problem as a matrix-by-vector multiplication comes from previous studies on an optical processor, which is specialized for this class of problems.

Our computational experiments show that our GPU implementation is already able to take advantage of the matrix-by-vector reformulation. On our randomly generated paradoxical instances, the pattern shown by our table of experiments is very regular: the GPU implementation is about 16 times faster than the standard BP algorithm. Naturally, much better speed-ups have been achieved on GPUs; in our case, however, the reformulation transforms the problem in a harder one (even if the complexity class remains the same). Nevertheless, the GPU implementation is still able “to do better” than the standard sequential algorithm.

In view of an implementation of the optical processor in [2], we remark that it is likely to suffer of the same effect on the increased number of detected solutions that we have

observed in our computational experiments. This opens new challenging for the conception and development of this kind of alternative computing devices.

Acknowledgments

We are grateful to Caroline Collange for the fruitful discussions and for the authorization to use one of the machines of her research group to perform our computational experiments.

We are also thankful to the three reviewers that provided very helpful comments on this paper. Unfortunately, for the lack of space (this paper was from the beginning meant to be a short contribution), we could not consider all of them in the final version. However, we intend to deposit an extended version of this paper, including some additional details about our CUDA implementation, on the HAL open archives.

This work is partially supported by the international project MULTIBIOSTRUCT funded by the ANR French funding agency (ANR-19-CE45-0019).

Abstract—The protein structure prediction problem is one of the most important bioinformatics problems. Computational methods can be used to approach this problem and *de novo* methods are able to generate protein structures without the need of having known similar structures to the predicted protein. These methods transform the prediction problem into an optimization problem, using optimization models that combine different energy functions and high-level information. These models usually have only a single optimization objective. However, it is known that this single objective optimization approach may harm the optimization search due to the existence of conflicts between the different terms that compose the optimization objective. The proposed model has three objectives: energy function, secondary structure, and contact maps. A multi-objective Biased Random-Key Genetic Algorithm (BRKGA) with online parameter control, named MOBO, is proposed as the optimizer. The final predictor comprises two phases of the MOBO algorithm and selects a final structure using the MUFOLD-CL clustering method. Results obtained demonstrated that the proposed predictor generated highly competitive results with the literature.

I. INTRODUCTION

PROTEINS are base molecules present in living organisms [1]. They are responsible for many biological functions, and understanding their mechanisms is important to better understand how organisms work. One application of this knowledge about proteins is in the biomedicine and pharmaceuticals areas [2], where novel proteins could be developed to combat particular types of diseases.

The Protein Structure Prediction (PSP) problem has the objective of determining the spatial structure of proteins, using the amino acid sequence of a protein as its main input. Although these structures can be determined using classical laboratory methods, such as Nuclear Magnetic Resonance (NMR) or X-ray crystallography [3], they have a considerable cost and are time-consuming. An alternative method is the use of computational resources to simulate these structures.

Recently, the AlphaFold, the deep learning algorithm developed by DeepMind, achieved highly promising results in the CASP13 and CASP14 competition [4]. The AlphaFold combines features derived from homologous templates and from multiple sequence alignment to generate the predicted structure. Nevertheless, AlphaFold has some drawbacks, such as the bias to the PDB database, and the heavy dependency on high-computational efforts for training their model [5]. Also, given the number of possible natural and artificial protein structures, it is currently unfeasible to rely on template-based methods to predict any unknown structure with consistent quality. As such, the PSP is still considered to be an open problem. So far, there is no viable general solution to this challenging problem. In this way, metaheuristics can be a faster option to the problem even though achieved results are not the same as AlphaFold.

In the literature, there are many computational methods proposed as possible approaches to the PSP problem [6], [7]. Among these methods, some works further explore the use of specific types of protein structure information [8], [9].

For a more general solution to this problem, one possible way is to use methods that do not rely on databases. One class of methods that do not employ known structure information are the *ab initio* methods. These methods work by generating structures using some evaluation function, which guides the optimization towards the optimal structure. Different from other types of methods, these methods only need as input the amino acid sequence to work [3].

While it is possible to work with pure *ab initio* methods, which utilize only information provided by the amino acid sequence, their results may be unfeasible given inaccuracies of currently employed energy functions. One way to deal with this issue is to utilize high-level information about the protein structure, such as secondary structure and contact map information. *Ab initio* methods that employ this type of information are called *de novo* methods. This work employs *de novo* methods instead of pure *ab initio*.

All this information related to the PSP problem can be described in an objective function. However, combining multiple information in a single objective function is not always optimal. It is known that some of the terms that compose an energy function, such as the bonded and non-bonded energies, are in conflict [10]. These conflicts indicate that optimizing one particular function term may not optimize the others. Hence, it is interesting to separate conflicting terms in different objectives. The separation of conflicting terms creates a multi-objective model, whose final solution is a set of non-dominating solutions [11]. This set, also called the *Pareto set*, represents possible solutions for the mathematical model.

As the optimization result of a multi-objective problem is a set of non-dominating solutions [11], it may be necessary to employ a decision-making method to select a single final solution from this set. As each non-dominated solution represents some trade-off among all objectives, it is not always trivial to choose a singular solution. To assist this selection, decision-making methods can be employed to filter the non-dominated set and identify the most promising solutions based on some desired properties.

This work is an extension of a previous study [12]. The previous work proposed the use of the Biased Random-Key Genetic Algorithm (BRKGA) method as an optimizer for a *de novo* multi-objective optimization model of the PSP problem. The present work brings some contributions compared to the previous publication:

- Online parameter control strategies were incorporated, creating the new version called MOBO. The main objective of this change is to reduce the number of parameters that the user must define to use the optimizer effectively. This change makes it possible to dedicate more time to problem modeling than parameter tuning.
- The MUFOLD-CL was employed as decision-maker in the Pareto set. The generated clusters were analyzed to determine the distance between the best solution found by the optimizer and the solution selected by the decision-maker.

II. BACKGROUND

A. Proteins and Protein Structure Prediction

Proteins are biomolecules composed of amino acids linked by peptide bonds. The amino acids are molecules composed of a central carbon, called α -carbon, that is connected to an amino group (NH), a carboxyl group (CO), a hydrogen molecule (H), and a side chain [1]. The side chain is a variable group unique to each type of amino acid. The molecular structure of each amino acid is the same, changing only the side chain, which gives its identity.

The structure of a generic amino acid can be seen in Figure 1. These amino acids connect between themselves through the peptide bonds, created by the combination of the carboxyl and amino group [1]. A point of interest in this figure is the three dihedral angles (Φ , Ψ , and Ω), which are important for computational representation of the protein structures.

Fig. 1: Chemical structure of an amino acid

1) *Computational representation*: There are several ways to represent a protein structure computationally. The most direct would be to maintain complete information on all the atoms and interactions of the structure. However, this type of representation can be computationally expensive given the large number of atoms and interactions of a single protein structure [3].

One interesting computational representation of protein structures uses only the backbone and side chain torsion angles of each amino acid. Instead of maintaining the entire atomic structure of each amino acid, algorithms may use only the ϕ , ψ , and ω backbone angles and the χ side chain angles. These angles can be seen in Figure 1. By using these angles, the final three-dimensional structure can be uniquely determined.

2) *Structure prediction*: Computational methods can be used to generate protein structures. One class of such methods are the *ab initio* methods, which do not use information from known protein structures [3]. These methods use physical energy functions to guide the generation of protein structures, using only the amino acid as necessary input. As such, *ab initio* methods effectively transform the PSP problem into an optimization problem.

Besides the computational representation of a protein structure, defining a function to evaluate these structures is also necessary. As *ab initio* methods generally perform searches in the space of structures, it is necessary to select a suitable evaluation function. Regarding accuracy, the most optimal choice would be an evaluation function representing the natural energy function. However, such realistic energy functions are computationally expensive [2].

Other types of information can be incorporated into the evaluation function to enhance the search process. Although pure *ab initio* methods do not use information from known structures, it may be beneficial to use this type of information, if available. There are different types of high-level information that can be added to the evaluation function, such as *secondary structure prediction* and *contact maps*. When an *ab initio* method incorporates information other than the energy function, it is called a *de novo* method [3].

B. Biased Random-Key Genetic Algorithm

The Biased Random-Key Genetic Algorithm (BRKGA) [13] is an optimization method of the evolutionary algorithms class. It is a variation of the genetic algorithm in which only the selection and crossover routines are used to evolve solutions [13]. Initially, all individuals are initialized uniformly at random. Each generation, pairs of individuals are selected and combined through a biased uniform crossover operator, where one parent is an elite solution, and the other is a non-elite. A new population is formed by a fraction of the most-fit solutions of the current generation, a fraction of randomly and uniformly generated solutions, and the remaining individuals are the offspring generated through the crossover operation. There is no explicit mutation operator in this algorithm, but an implicit mutation can be simulated through the crossover of a random individual with a non-random individual.

The main aspect of the BRKGA is the clear separation of the problem-dependent and independent parts. Other notable aspects are elitism as a core mechanism for the evolution and the generation of random solutions instead of applying mutation to offspring solutions.

The problem-independent codification is composed of real numbers in the $[0, 1]$ interval, decoded into a problem-specific solution using a decoding function, and evaluated by a fitness function. This way, the algorithm's main structure is standardized for all problems, with only the decoding and fitness functions needing to be developed. This standardization simplifies the algorithm structure by removing the necessity of developing complex solution encodings and various genetic operators, such as crossover or mutation operators.

Similar to other evolutionary algorithms, the BRKGA has a set of parameters that need to be defined. These parameters are the number of iterations (N_{it}), population size (p), elite fraction (p_e), random individuals fraction (p_m), and crossover probability (c_{pr}). Due to the standardized structure of the algorithm, the crossover operator is fixed.

III. RELATED WORK

One of the initial works in the area of multi-objective PSP was [10]. In this pioneering study, the authors proposed a multi-objective model for the PSP problem, decomposing the CHARMM energy function into two objectives: bonded and non-bonded energies. They demonstrated that these energies were in conflict, and combining them in a single objective would harm the optimization. To optimize the model, they used the IPAES algorithm and also employed a decision-making step to select a final structure by using the method of *knees*.

Other works followed this approach of breaking the energy function into bonded and non-bonded energies [14], [15], [16], [17], [18]. Most works approaching the multi-objective PSP employed some evolutionary algorithm [14], [15], [16], [19], [20], [18], [21]. Regarding the protein structure representation, most works employed the full atomic structure [14], [15], [16], [22], [21], although some preferred the centroid representation [19], [20], [18].

Considering the extra information that can be added to complement the energy function, there are several possibilities. Some works employ structural information that energy functions may not capture accurately, such as solvent terms [15], [16], [22], compactness [19], and hydrogen bonding [19], [20]. Also, high-level information that can be predicted was explored, such as protein fragments [19], [20], secondary structures [14], [15], [16], [17], [19], [22], [18], [21], and contact maps [19], [20], [22].

As the complete solution of multi-objective problems is a set of non-dominated solutions, selecting a single final solution from this set may be necessary. Several works employ some decision-making criteria to select the final optimized solution. Popular methods include the *knees* method [10], [23], [14] and clustering-based methods [15], [17], [17], [16], [21]. One promising clustering method for protein structures is the MUFOLD-CL method, which was employed in recent works for the multi-objective PSP problem [17], [21].

IV. PROPOSED MODEL

A multi-objective Biased Random-Key Genetic Algorithm (BRKGA) with online parameter control is proposed, named MOBO. In the present work, proteins are modeled with the Rosetta framework¹ using the full-atom with centroid backbone representation [24], where the side chain is simplified as a centroid. The ϕ , ψ , and ω angles model each amino acid. These angles are in the $[-180, 180]$ domain, except for the ω angle, whose optimal value can be either 180° or 0° [10]. In this work, the ω angle is restricted to 180° , as both values are equally optimal. Figure 2 shows how an amino acid sequence can be coded as a list of angles.

Fig. 2: Protein structure representation as a list of torsion angles.

The optimization model for the PSP problem is composed of 3 objectives, shown in Expressions (1)-(3):

$$\min \text{score4}(\vec{x}) \quad (1)$$

$$\max SS(\vec{x}) \quad (2)$$

$$\max CM(\vec{x}) \quad (3)$$

The \vec{x} vector represents a protein structure coded as a list of angles with size $2L$, where L is the length of the amino

¹<https://www.rosettacommons.org/software>

acid sequence of the protein. The angle list is mapped into a protein structure before being evaluated by each objective function. Expression (1) is the *score4* energy function from the Rosetta framework [24] and is used to evaluate the protein structure.

Expression (2) refers to secondary structure information predicted by the PSIPRED [25] server ². This prediction was performed excluding homologous proteins. Equation (4) details the evaluation, where for each amino acid x_i , the *pSS* function will return the predicted probability for the current secondary structure manifested, determined with the DSSP program [26], which assigns secondary structure to proteins structures. Hence, protein structures with the most probable secondary structures are benefited.

$$SS(\vec{x}) = \sum_i^L pSS(x_i) \quad (4)$$

Expression (3) refers to contact map information predicted by the RaptorX [27] server ³. This prediction was performed by removing homologous proteins. Two atoms are considered in contact if their distance is less than the cutoff distance. Equation (5) describes how each contact is evaluated for a given protein structure.

For each contact c_i in the L -best list, the pair of amino acids c_i^1 and c_i^2 from this contact is verified. If their distance, $d(c_i^1, c_i^2)$, is less than the cutoff value (8\AA), the pair is said to be in contact, and a term equal to the predicted probability of this contact is summed. Otherwise, this probability term is decreased exponentially due to the cutoff value's distance, allowing slight deviations from the cutoff to be considered. Protein structures that exhibit the most probable contacts are rewarded using this objective function.

$$CM(\vec{x}) = \sum_i^L \begin{cases} p_i & \text{if } d(c_i^1, c_i^2) \leq 8 \\ \frac{p_i}{e^{d(c_i^1, c_i^2) - 8}} & \text{otherwise} \end{cases} \quad (5)$$

As global optimizer, the multi-objective BRKGA is employed [12]. The proposed algorithm uses the base structure of the original BRKGA [13] and can be applied to any multi-objective problem that can be approached with evolutionary algorithms. The main modifications were to allow the algorithm to optimize multi-objective problems. Modifications were made to the problem-independent parts to achieve multi-objective optimization. The elitist selection operator from NSGA-II [28] was used to generate the elite part of the population.

An archive (set of solutions) is maintained and updated at each generation. This archive has the same size as the population, and it is updated using the non-dominated sorting with crowding. At the end of the algorithm, the archive is returned and contains the best Pareto set found. However, it may also contain dominated solutions as the best Pareto set may not occupy the entire archive.

A. Parameter control

There are several types of parameter control in evolutionary algorithms [29]. This work employs an adaptive online parameter control by simple rules to control and guide the optimizer. The information utilized to guide the search is the population diversity defined in Equation (6):

$$Div(P) = \frac{\sum_{x,y \in P} d_{norm}(x,y)}{|P| * (|P| - 1)} \quad (6)$$

where x and y are individuals from population P , and d_{norm} is the normalized Euclidean distance metric, defined by:

$$d_{norm}(\vec{x}, \vec{y}) = \frac{d(\vec{x}, \vec{y})}{N} \quad (7)$$

where $d(\vec{x}, \vec{y})$ is the Euclidean distance and N is a normalization factor representing the solution space diagonal. This distance is a genotypic diversity metric, that is, it measures the diversity in the problem-independent part of the algorithm. This work will not incorporate fitness information in the parameter control, as the definition of fitness is different for a multi-objective optimizer, and concepts such as best and mean fitness are not trivially defined.

The algorithm is modified to control and increase diversity in the population to incorporate diversity information. In the original BRKGA method, the crossover probability p_{cr} is defined as a parameter of the algorithm and should have a value in the range $(0.5, 1)$. In this work, the crossover parameter is modified to be a uniformly random value in the range $(0.5, 1)$, removing the complexity of defining an optimal value for this parameter and minimizing the impact in the diversity. This value is generated for each crossover operation.

Another modification is the introduction of two diversity control values: the diversity fraction (p_d) and the exploration diversity threshold (δ). These values are used to control the generation of the elite part of the population. The diversity fraction indicates the fraction of the elite part that should be diversified. The exploration diversity threshold is used to indicate the minimum distance between two diversified solutions during the exploration part of the search.

The set P_d of diversified elite solutions is defined as:

$$P_d = \{ \forall \vec{x} \in P_d \mid \Delta(\vec{x}) \geq \delta \} \quad (8)$$

where $\Delta(\vec{x})$ is defined as:

$$\Delta(\vec{x}) = \min_{\substack{\vec{y} \in P_d \\ \vec{x} \neq \vec{y}}} d_{norm}(\vec{x}, \vec{y}) \quad (9)$$

where d_{norm} is the normalized Euclidean distance expressed by Equation (7). This definition of diversified individuals spreads the solutions through the space. Incorporating this diversification in the elite part allows the algorithm to explore the best solutions in different parts of the search space.

Given the population of size p , $E = p \times p_e$ is the size of the elite part of the population and $E_d = E \times p_d$ is the size of the diversified elite. With P_s as the sorted population, the elite part P_e is generated by the following steps:

- While $|P_e| < E$, do:
 - 1) If $|P_d| < E_d$, then:
 - a) If exists $\vec{x}_i \in P_s$ that can be inserted in P_d , then select \vec{x}_i with lowest index i .
 - b) Else, from P_s select \vec{x}_i with greatest Δ
 - c) Insert selected \vec{x}_i in P_d and P_e
 - d) Remove selected \vec{x}_i from P_s
 - 2) Else:
 - a) From P_s select \vec{x}_i with lowest index i
 - b) Insert selected \vec{x}_i in P_e
 - c) Remove selected \vec{x}_i from P_s

The parameter control is performed by dividing the optimization procedure into two phases: exploration and exploitation. The algorithm generates diversified solutions in the exploration phase to search the entire solution space. The algorithm increases the evolutionary pressure in the exploitation phase by favoring the best solutions found. By properly controlling the algorithm parameters, it is possible to balance global and local searches.

To balance between exploration and exploitation, each phase runs for $N_{it}/2$ iterations. For both phases, the parameters p_e and p_m are initially set to 0.25. With these values, half of the population is composed of offspring. With $p_e = 0.25$, it also means that each elite individual should on average generate two offspring each generation.

This initial value was defined empirically. The following initial values and ranges for each parameter were also defined empirically. Although these values may not always be optimal, they are reasonable and straightforward enough to be used as base values.

The exploration phase initializes the optimization process. The diversification parameters p_d and δ are used to explore the search space. The diversification fractions starts as $p_d = 0$, and is modified in steps of $k = 0.01$. This parameter is updated during the exploration phase to keep the population diversity $Div(P)$ above δ . If the current $Div(P) < \delta$, p_d is increased by k . Otherwise, p_d is decreased by k . The parameter p_d is kept in the range $[0, 0.5]$, diversifying at most half of the elite part.

If the $Div(P)$ is still below δ when $p_d = 0.5$, then the parameter p_m is also modified. The parameter is kept in the range $[0.25, 0.5]$ and is updated using step k . By increasing the random part of the population, the diversity of the population is increased. At the maximum value of $p_m = 0.5$, half of the population is uniformly randomly generated each iteration. Also, only 1/4 of the population is offspring, with each elite individual generating on average one offspring and each non-elite parent being on average 2/3 of the time a random individual.

The exploration diversity threshold δ is used to define the diversity of the exploration phase. The user can define it as an algorithm parameter. However, the value 0.4 should be reasonable, in general, and is used as the default value for this parameter. This value was selected due to the nature of uniformly randomly generated solutions and global search.

Considering this, δ is set to 0.4 by default. With this value, the population of the exploration phase has the property of being similar to a uniform distribution without losing the generation of reasonable solutions. Although, in general, it should not be necessary to change this value, in some cases, it can be interesting to lower the parameter to limit the exploration.

In the exploitation phase, the algorithm eliminates the diversity parameters. The parameter p_m is reset to the initial value 0.25 if modified during the exploration. The only parameter modified during this phase is the elite fraction p_e .

The algorithm forces the search to converge to the best solution found during this phase. To increase the convergence, the parameter p_e is increased in the range $[0.25, 0.5]$, using step k . At the maximum value of $p_e = 0.5$, half of the population is composed of elite solutions, and each elite individual will generate, on average, one offspring.

Considering the modifications proposed, the parameters p_e , p_m and c_{pr} are no longer user-defined. The only parameters that still need to be defined are the number of iterations N_{it} and the population size p . The exploration diversity threshold δ can also be defined if necessary.

This proposed parameter control aims to find a reasonable balance between usability complexity and optimization efficiency. The proposed control does not guarantee the selection of optimal values for every problem. However, it should select reasonable values for any general optimization, as it uses the generic concept of exploration and exploitation. Although the algorithm may not execute the most optimal search for some specific problem, the decreased number of parameters allows the user to focus more on the problem modeling and less on the calibration of the algorithm.

B. Parallelism

To increase the scalability of the algorithm, a master-slave model was developed using CPU threads. During fitness evaluation, the master thread divides the population into equal-sized chunks and distributes them to other threads. More formally, considering a number t of threads (e.g., the number of processors), the master will divide the population into chunks of size p/t . Each thread will evaluate the fitness of individuals in its chunk, effectively reducing the processing time of fitness evaluation, which is usually the most time-consuming step of the optimizer.

C. Codification and fitness

The fitness for the multi-objective model of the PSP is a tuple (F_1, F_2, F_3) , where F_1 , F_2 , and F_3 are the objectives defined by the Expressions (1)-(3), respectively. The decoder function is a function that will receive a coded solution $x = (x_1, x_2, x_3, \dots, x_n)$, where n is the size of an encoded chromosome, which is problem-specific, and each x_i is in the domain $[0, 1]$. The decoder should map this chromosome into a problem-specific solution, which will then be evaluated by the fitness function.

In this work, two decoders are used in two different algorithm executions. The first decoder, named fragment decoder, takes an $F = L/9$ -sized chromosome, with L being the amino acid sequence length, and maps it into an angle list by inserting fragments of size nine. Each of these fragments is a continuous sequence of nine amino acids extracted from some known protein structure.

For each amino acid in the protein to be predicted, 200 fragments of size nine were generated using the Robetta server⁴. These fragments were predicted excluding homologous proteins. As the fragments are size nine, each selected fragment contributes nine pairs of ϕ and ψ angles in the solution. The torsion angles ϕ and ψ are extracted from each fragment and used to build the solution.

In the fragment decoder, each variable of the chromosome x (candidate solution) is used to select a fragment from the list of 200 fragments of an amino acid. The x_i variable represents a fragment f_i that starts on the amino acid with position $p_i = 9 \times (i - 1) + 1$ in the protein sequence. The inserted fragment f_i is the one with position $\lceil 200 \times x_i \rceil$ in the fragment list of amino acid p_i . Figure 3a shows the decoding process.

The second decoder, named residue decoder, takes an L -sized chromosome y and maps it into an angle list by extracting the ϕ and ψ angles from each variable. The y_i variable is mapped into torsion angles ϕ_i and ψ_i by using 14 digits as scale, where the first 7 digits are used to generate ϕ_i and the remaining 7 are used to generate ψ_i . If $D_i = \{d_1, d_2, \dots, d_7\}$ are the 7 digits used to generate ϕ_i , the angle ϕ_i can be defined as $\phi_i = -180 + 360 \times r$ where $r = 0.d_1d_2\dots d_7$ (the ψ angle is defined similarly). Figure 3b exemplifies this decoding process.

D. Predictor

The predictor first applies the MOBO with the fragment decoder, MOBO/FRAG, to predict protein structures. This algorithm will search the structure space using fragments, generating valid low-resolution structures. Then, the MOBO with the residue decoder, MOBO/RES, optimizes the initial archive of solutions.

Using the archive from MOBO/FRAG as the initial population, the MOBO/RES can refine the results and increase their resolution. The archive returned by the MOBO/RES is the predicted set of protein structures. Then, a decision-making step is applied to select the final predicted protein structure. To accomplish that, the MUFOLD-CL method [30] is used to cluster the final set.

The MUFOLD-CL works by first estimating potential cluster representatives (center of a cluster) using a structural difference metric. These representatives are then used to cluster the remaining structures, also using this metric. Finally, after all clusters are formed, new representatives are selected for each cluster using a structural similarity metric that is able to describe more accurately the center of a cluster [30]. The representative structure of the largest group is returned as the predicted structure of the proposed method.

⁴<http://old.rosetta.org/>

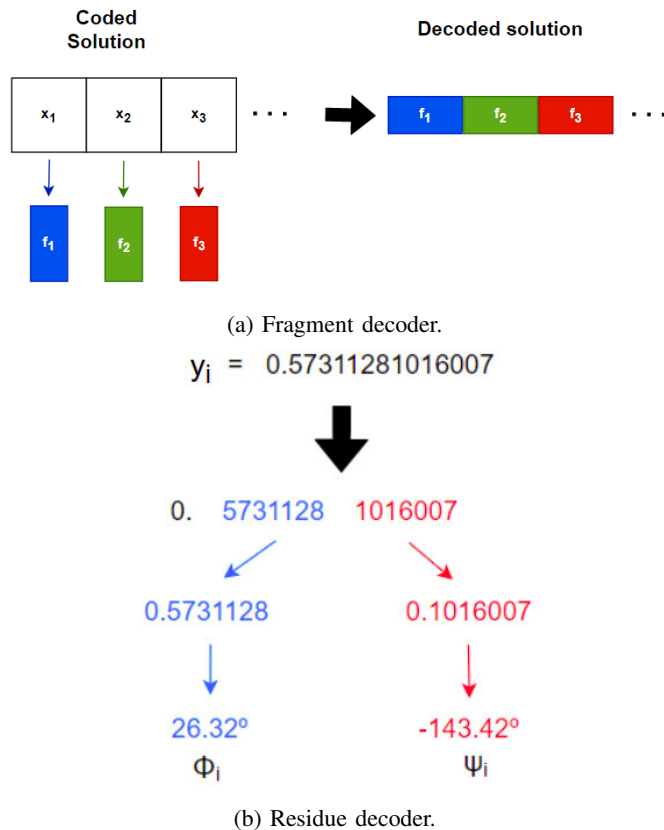

Fig. 3: MOBO decoders

A diagram with a visualization of the complete predictor can be seen in Figure 4. In this diagram, the primary input is the amino acid sequence. The secondary structure, contact map, and fragment information are generated from this sequence. This information is used to feed the optimizer, which starts with MOBO/FRAG method. This method generates an archive of solutions, used as the initial population for the second method, MOBO/RES. The output of the second method is the optimizer output. This output is also an archive of solutions, used as input for the clustering method MUFOLD-CL. The final structure is then selected from the largest cluster found.

V. EXPERIMENTS, RESULTS & ANALYSIS

Table I shows the protein set employed in the experiments. All proteins were taken from the RCSB database⁵, with the exception of proteins T0868, T0900, T0968s1, and T1010, which were taken from the CASP competition⁶. An amount of 20 proteins with different sizes and different types of secondary structures were selected.

The Root Mean Square Deviation (RMSD) metric was utilized to measure the quality of the predicted structures. The RMSD measures the distance of atoms between two superimposed structures, with lower values indicating higher similarity structures [31]. The distance is taken considering

TABLE I: Proteins utilized in the experiments

the C_α atoms (protein backbone) and can be mathematically defined as:

$$RMSD(\vec{a}, \vec{b}) = \sqrt{\frac{\sum_{i=1}^L d(a_i, b_i)^2}{L}} \quad (10)$$

where L is the number of residues (amino acids), \vec{a} and \vec{b} are two superimposed structures, and $d(a_i, b_i)$ returns the Euclidean distance (in angstroms) between the atoms a_i and b_i . The best and average values (with standard deviation) were measured for all proteins.

All the experiments were executed 20 times for statistical validation. The proposed predictor was implemented using C++17, and experiments were performed on an Ubuntu 18.04 system with an Intel Xeon E7-8860 @ 80x 2.26GHz and 1TB

RAM. The utilized system has a NUMA architecture [32] with four nodes, each node with 20 cores (10 physical and 10 virtual).

The experiments were conducted using the number of iterations $N_{it} = 1000$ and the population size $p = 500$. Both MOBO/FRAG and MOBO/RES use the same values, resulting in 1,000,000 fitness evaluations. However, the MOBO/RES also defines the exploration diversity threshold as $\delta = 0.25$. This definition occurs to limit the exploration of new solutions in the MOBO/RES, whose objective is to refine the solutions found by the MOBO/FRAG. These parameters were empirically defined.

A. Predictor performance analysis

The first experiment compared the results obtained by MOBO against the previous work [12]. The previous algorithm has the same structure as MOBO, including the diversity modifications, but uses static parameters defined before the algorithm execution. The ANOVA test with 95% confidence interval was performed to validate the statistical difference between the result of the MOBO and the previous algorithm. From the results obtained, both algorithms obtained statistically same results in all 20 proteins. As one objective of using online parameter control strategies is to reduce the usability complexity of the algorithm, the MOBO algorithm has an advantage over the previous work with fewer parameters to be adjusted. Therefore, the use of parameter control is validated reducing the number of parameters to be tuned from 6 to 2. The only parameters that still need to be defined are the number of iterations N_{it} and the population size p .

In the following, three types of results are analyzed considering the proposed MOBO predictor:

- Best value of the final archive: $MOBO_{BEST}$;
- Average value of the final archive: $MOBO_{MEAN}$; and
- Value from the structure selected with MUFOLD-CL: $MOBO_{CL}$.

This analysis was performed to verify the overall quality of generated archive and the quality of the solution selected with MUFOLD-CL. Although it is not expected that the decision-maker will always select the best-generated structure, it should at least select a structure with quality higher than the average generated structure.

Comparisons with predictors from the literature were also conducted, which can be seen in Table II. For the Rosetta *de novo* protocol, the set of proteins was predicted locally. The results of the other predictors were extracted directly from their respective works.

The predictor proposed in [21] uses the MUFOLD-CL to select a final solution from the optimized set of structures. In [17], a hierarchical clustering method is used for this purpose. In [18], a single final solution was not selected, using the best solution generated by the algorithms for evaluation instead.

The overall results are shown in Table III. The table compares each protein with the results of all methods. The best and average values from other works were utilized, if available. Missing results are marked with '-' in the table.

The ANOVA test with 95% confidence interval was performed to validate the statistical difference between the result of the proposed predictor MOBO (with MUFOLD-CL) and the other predictors. At the end of Table III, an extra row (B/S/W) was added to summarize the result of this test. B represents the number of proteins where the competing method was statistically better than the proposed predictor, and the W is the number of times where the competing method was statistically worse than the proposed predictor. S is the number of proteins where there was no statistical difference between the results of the competing method and the proposed predictor.

TABLE II: Compared methods

Reference	Algorithm	Function evaluations
[21]	MODE-K	100,000 (10^5)
[18]	NSGA-II GDE3 DEMO	1,000,000 (10^6)
[17]	MOPSO	100,000 (10^5)
Rosetta	<i>de novo</i> protocol	1,000,000 (10^6)
Proposal	MOBO	1,000,000 (10^6)

Considering the best solution found on all executions, the MOBO was able to generate the best solution for almost all proteins except for 1ACW (Rosetta), 1GB1 (Rosetta), 1ZDD (DEMO), and 2P81 (MODE-K). The quality of the solutions found using MUFOLD-CL was not far from the best solution generated by the MOBO. It seems that, on average, the distance between the best solution and the MUFOLD-CL solution is between 1 and 3 Å.

Overall, the solutions selected by the MUFOLD-CL are better than the other methods. The MOBO with MUFOLD-CL selected better solutions most of the time when compared with NSGA2, GDE3, DEMO, and Rosetta.

Considering the best and mean values of the MOBO, the MUFOLD-CL was always worst than the best and almost always similar to the mean. These results make sense, as the MUFOLD-CL is a clustering method and selects as the final result the center of the largest cluster. As this center is similar to all the other structures of the cluster, and the largest cluster is selected, it is expected that the results are close to the mean of the final frontier.

1) *Predicted structures visualization*: The visualization of the predicted structures can be seen in Figure 5. In this figure, the best solution predicted by the MOBO with MUFOLD-CL is in red, while the native structure is in blue. The structures were overlapped using the α -carbons. This overlap displays the quality of the predicted structures.

It is possible to see that the α -helices of the proteins were accurately predicted, in general. This behavior can be seen in the structures of 1AB1, 1BDD, 1CRN, 1ENH, 1GB1, 1ROP, 1ZDD, and 2MR9. However, for some α proteins, the algorithm was unable to generate accurate helices. This can be observed in 2KDL and 2P81, which are small α proteins with poor predictions. This divergence of quality is probably due to the secondary structure and contact map information predicted for these proteins. If the input information has poor

quality, it is expected that the output structure will be equally bad.

It is also possible to see in this visualization that one difficult part is the prediction of β -sheets. These structures are harder to predict than the α -helices, and proteins of the class β are usually the ones with the lowest prediction quality. This difficulty can be observed both in simpler proteins, such as 1DFN, and in the more complex, such as 1ALY and 1HHP.

VI. CONCLUSION AND FUTURE WORK

The PSP problem is one of the most important open problem in biology. As proteins are a core biological macromolecule, understanding their structure and functionality is essential to understanding complex biological processes. For this purpose, computational methods are employed to build and simulate protein structures.

Among possible methods to approach the PSP problem, multi-objective optimization shows great potential. Being able to simultaneously optimize multiple conflicting objectives, these methods can optimize complex mathematical models. Due to this, recent works in the literature have invested multi-objective optimization for the PSP problem.

The results obtained by the proposed approach demonstrated that the predictor with the decision-making step is highly competitive with other works from the literature. Although the predictor is consistently able to predict α -helices, the

prediction of β -sheet is unstable, with proteins of the β class having considerably lower quality when compared with proteins of the α class.

It is possible to define some improvements in the proposed

work. Multiple predictors could be used to reduce the inaccuracy of predicted information in the optimization. By using the information of different predictors, it is possible to reduce bias and combine the best information from each source. This combination of multiple data sources may increase the effectiveness of secondary structures and contact maps in the prediction of tertiary structures.

Also, the prediction of β should be more thoroughly researched. Other types of information could be added to the optimization model with the objective of increasing the quality of β -sheets in protein predictions. By focusing on this weak point, the overall effectiveness of the predictor should increase not only for β proteins but also for all proteins in general.

Another line of work is to further improve the search algorithm itself. This work presents a simple online parameter control that is able to select reasonable values. However, more complex techniques could be employed, such as the use of fuzzy systems to incorporate expert information about the problem that is being optimized. Also, local search could be implemented to further specialize the proposed algorithm for the optimization of protein structures.

Abstract—This paper introduces the **Team Orienteering Problem with Time Windows and Variable Profits (TOPWPVP)**, which is a variant of the classical **Orienteering Problem (OP)** and an **NP-hard optimization problem**. It consists in determining the optimal route for a vehicle to traverse to deliver to a given set of nodes (customers), where each node has a predefined time window in which the service must start (in case this node is visited), and the vehicle may spend an amount of time given by a predefined interval so that the profit collected at this node depends on the time spent. We first propose a mathematical model for the **TOPTWVP**, then propose an algorithm based on **Iterated Local Search** to solve modified benchmark instances. The results show that our approach can solve difficult instances with good quality.

I. INTRODUCTION

THE Orienteering Problem (OP) [1] is a combinatorial optimization and integer programming problem whose goal is to obtain the optimal route for a vehicle to traverse to deliver to a given set of customers. The objective is to maximize the total score collected from visited (selected) nodes. The Team OP (TOP) [2] is one of the most studied variants of the OP, where the route for several vehicles must be computed. When a time window is established for each node so that the service at a particular node has to start within a predefined time window, a new variant, called (Team) Orienteering Problem with Time Windows ((T)OPTW) [3], is defined. Another variant is the orienteering problem with variable profit (OPVP) [4] and its generalization, the team orienteering problem with variable profit (TOPVP) [5]. In this case, the profit collected at each node depends on the number of times a node is visited or on the continuous amount of time spent at a given node.

In this paper, we combine the TOPTW and the TOPVP to come up with the **Team Orienteering Problem with Time Windows and Variable Profit (TOPTWVP)**. Specifically, each node has a predefined time window in which the service must start (in case this node is visited) and the vehicle may spend an amount of time given by a predefined interval so that the profit collected at this node depends on the time spent.

This extension of the TOPTW and the TOPVP is especially interesting to applications of the vehicle routing problems

This work has been partially supported by the Spanish MINECO project TIN2017-88476-C2-1-R, the AVI project SmartTur+ECO INNEST/2021/233 and the EU project TAILOR 952215.

such as the routing of a reconnaissance vehicle [6], which has the option of staying longer at a location to gather more information and the route planning may depend on time windows when it is safer to perform this reconnaissance task; or the the Tourist Trip Design Problems [7], where a longer stay at a location may provide a higher satisfaction (profit) to the visitor and the visits must be scheduled taking into account the opening times of attractions. For example, the work in [8], [9] and [10] use a modified version of the TOPTWVP which allow the tourist to define some travel-style preferences, such as if they prefer to visit a few or many places or if they prefer to enjoy some free time during the trip. In order to consider these travel-style preferences, each visit is assigned a duration interval so that each visit finally takes the most appropriate time to fit into the tourist preferences.

In general, TOPTWVP tries to model a more realistic situation, where locations can only be visited within specific time windows and where staying longer (also within a given interval) may report a higher profit.

The main contributions of this paper are the following:

- We introduce a mathematical model for the TOPTWVP.
- Due to the limitation of solving large instances, we then propose a heuristic based on Iterated Local Search (ILS).
- We perform experiments with the ILS algorithm on instances for the Solomon benchmark.
- We compare the solutions with respect to several Key Performance Indicators (KPIs): score, number of visits, waiting time (idle time in the route), and execution time.

The remainder of this paper is as follows. The problem description and the mathematical model is detailed in Section II. Section III describes the proposed algorithm based on ILS. Section IV reports numerical experiments performed on benchmark instances. Finally, in Section V, we summarize the main achievements and future works.

II. TOP WITH TIME WINDOWS AND VARIABLE PROFIT

The input values in the **TOPTWVP** are the following:

- a set of nodes $N = \{1, \dots, |N|\}$, where nodes 1 and $|N|$ represent the start and end nodes
- a number of routes M and total time budget per route T_{max}
- For each node $i \in N$:

- a travel time t_{ij} from node i to j , known for all vertices
- a non-negative profit P_i , i.e. the maximum profit collected when visiting a node; P_1 and $P_{|N|}$ are 0
- a time window $[O_i, C_i]$, which indicates that a visit to a node can only start during this time window
- a service time interval $[minD_i, maxD_i]$, i.e. the minimum and maximum amount of time that can be spent at a node

The goal of the TOPTWVP is to determine M routes, each limited by T_{max} , that visit a subset of N within the respective time windows, during a service time in the interval duration and that maximize the total collected profit. The TOPTWVP can be formulated as an integer programming model with the following decision variables:

- $x_{ijm} = 1$, if in route m , a visit to node i is followed by a visit to node j ; 0, otherwise
- $y_{im} = 1$, if node i is visited in route m ; 0, otherwise.
- s_{im} is the start of the service at node i in route m
- d_{im} is the service time (duration) at node i in route m

And the following constraints:

$$\sum_{m=1}^M \sum_{j=2}^{|N|} x_{1jm} = \sum_{m=1}^M \sum_{i=1}^{|N|-1} x_{i|N|m} = M \quad (1)$$

$$\sum_{m=1}^M y_{km} \leq 1; \forall k = 2, \dots, (|N| - 1) \quad (2)$$

$$\sum_{i=1}^{|N|-1} x_{ikm} = \sum_{j=2}^{|N|} x_{kjm} = y_{km}; \quad \forall k = 2, \dots, (|N| - 1); \forall m = 1, \dots, M \quad (3)$$

$$O_i \leq s_{im} \leq C_i; \forall i = 1, \dots, |N|; \forall m = 1, \dots, M \quad (4)$$

$$s_{im} + d_{im} + t_{ij} - s_{jm} \leq L(1 - x_{ijm}); \quad \forall i, j = 1, \dots, |N|; \forall m = 1, \dots, M \quad (5)$$

$$minD_i \leq d_{im} \leq maxD_i; \forall m = 1, \dots, M \quad (6)$$

Constraints 1 establish that each route starts from node 1 and ends in $|N|$. Constraints 2 ensure that each node can only be visited at most once in all routes. Constraints 3 ensure the connectivity of each route. Constraints 4 force that the service starts within the time window for each route. Constraints 5 ensure the timeline of the route (L is a large constant, that can be equal to T_{max}), explicitly considering the variable duration of the service. Constraint 6 guarantees that the service time is within the corresponding interval of duration.

$$Maximize \sum_{m=1}^M \sum_{i=2}^{|N|-1} P_i d_{im} y_{im} \quad (7)$$

The maximization function 7 establishes that the profit of the final plan not only depends on whether a node is visited or not but also it depends on how long a node is visited. Without loss of generality, in this definition of the TOPTWVP, we assume that each time unit spent at the node collects P_i . Therefore, the total score of a visited node i results from the product of the profit P_i and the time spent at a node d_{im} (in a route m).

Since the TOPTW and TOPVP are NP-hard, the TOPTWVP is also NP-hard. Both dealing with time windows and with an interval of possible service times makes this problem harder to solve. We have performed some experiments (not shown in this paper due to space restrictions) that prove that our implementation of this mathematical model is able to solve only small instances. Moreover, as some works referred to in this paper also state, in general, variations of TOP problems with a significant number of nodes are solved with heuristic approaches, and exact algorithms are only feasible for problems with a small number of nodes. For this reason, the following section introduces a heuristic approach to solve the TOPTWVP.

III. HEURISTIC APPROACH TO TOPTWVP

The more successful heuristic approaches for both the TOPTW and TOPVP are based on the ILS algorithm ([11],[12],[5]). Specifically, in this work, we take the ILS implementation for solving the TOPTW given in [11] and [12] and adapt some steps in order to consider the variable profit.

The general scheme of the ILS is shown in Algorithm 1. In a nutshell, this algorithm constructs an initial feasible solution (Construction), which is further improved by Iterated Local Search (ILS). ILS comprises the components LocalSearch, Perturbation and AcceptanceCriterion. We refer the reader to [11] and [12] for further details in the ILS implementation. In this section, we only focus on the modifications introduced to solve the specific TOPTWVP.

Apart from the input data and decision variables detailed in the previous section, we also keep the following data for each node, to reduce the time devoted to checking the feasibility of a route, thus making the algorithm more efficient [11]:

- $arrive_{im}$: arriving time to a node. If $arrive_{im} \in [O_i, C_i]$, then the arriving time and the start time s_{im} take the same value.
- $wait_{im}$: waiting time to visit a node because the arriving time $arrive_{im}$ is previous to the opening time O_i .
- $MaxShift_{im}$: maximum time that a visit can be delayed so that the route is still feasible, i.e. it keeps track of how much a certain visit can be shifted in time, without violating any time window in the route.

Regarding the Construction process, the first solution only contains the start node or depot, as initial and final nodes. Then, a set F with all feasible candidate nodes that can be visited is generated. All possibilities of inserting an unscheduled node in position p of route m are examined. To check the feasibility of inserting node j between nodes i and k , we

Algorithm 1 ILS(N, M)

```

1:  $S_0 \leftarrow \text{Construction}(N, M)$ 
2:  $S_0 \leftarrow \text{LocalSearch}(S_0, N^*, N', M)$ 
3:  $S^* \leftarrow S_0$ 
4:  $\text{NoImprovement} \leftarrow 0$ 
5: while TimeLimit has not been reached do
6:    $S_0 \leftarrow \text{Perturbation}(S_0, N^*, N', M)$ 
7:    $S_0 \leftarrow \text{LocalSearch}(S_0, N^*, N', M)$ 
8:   if  $S_0$  better than  $S^*$  then
9:      $S^* \leftarrow S_0$ 
10:     $\text{NoImprovement} \leftarrow 0$ 
11:   else
12:      $\text{NoImprovement} \leftarrow \text{NoImprovement} + 1$ 
13:   end if
14:   if  $(\text{NoImprovement} + 1) \bmod \text{ThresholdImpr} = 0$ 
15:     then
16:        $S_0 \leftarrow S^*$ 
17:     end if
18: end while
19: return  $S^*$ 

```

compute Shift_{jm} , which is time added or reduced when a new node is inserted or removed in a route:

$$\text{Shift}_{jm} = t_{ij} + \text{wait}_{jm} + d_{jm} + t_{jk} - t_{ik}$$

where: $\text{wait}_{jm} = \max(0, O_j - \text{arrive}_{jm})$ and $\text{arrive}_{jm} = s_{im} + d_{im} + t_{ij}$. Therefore, it is feasible to insert a node j between nodes i and k in route m if $\text{Shift}_{jm} \leq \text{wait}_{km} + \text{MaxShift}_{km}$. In the TOPTWVP, the service time d_{jm} is not a value known a priori. Therefore, to perform the calculations above, it is necessary to compute an estimate of the service time, which is based on using all the available time without causing infeasibility in the route:

$$d_{jm} = \max(\min D_j, \min(\max D_j, MS')), \text{ where :}$$

$$MS' = \text{wait}_{km} + \text{MaxShift}_{km} - t_{ij} - \text{wait}_{jm} - t_{jk} + t_{ik}$$

The set F contains all the feasible candidate nodes; one of these nodes i is selected according to the attractiveness of the insertion, which is computed as P_i^2 / Shift_i . Once a node i is selected, it is inserted in the corresponding route and position, and S_0 , N' , and N^* are updated accordingly. The service time d_{im} for the selected node is set to the estimate computed above. Consequently, the value of arrive_{jm} , wait_{jm} , s_{jm} , Shift_{jm} and MaxShift_{jm} of the subsequent nodes is also updated. Additionally, MaxShift_{jm} of the previous nodes is also recomputed. The construction process of the first solution is terminated when $F = \emptyset$, that is, when no more feasible candidate nodes are found. This solution will be further improved by the ILS.

Our LocalSearch procedure is composed by the same six local search moves described in [12], and we add a new move that modifies the service time of some nodes. These seven local search moves are applied in three stages. The first stage contains the moves Swap1, Swap2, 2-Opt and Move which

Algorithm 2 IncreaseServiceTime(S_0, M)

```

1: for each route  $m \in M$  do
2:   while  $\exists i : \text{MaxShift}_{im} > 0$  do
3:      $G = \{i : \text{MaxShift}_{im} > 0\}$ 
4:     for  $i \in G$  do
5:        $\Delta_{im} \leftarrow \min(\text{MaxShift}_{im}, \max D_i - d_{im})$ 
6:     end for
7:      $n^* = \text{argmax}_{i \in G} (P_i * \Delta_{im})$ 
8:      $d_{n^*m} \leftarrow d_{n^*m} + \Delta_{n^*m}$ 
9:     for each node  $j$  in route  $m: s_{jm} > s_{n^*m}$  do
10:      Update( $\text{arrive}_{jm}, s_{jm}, \text{Shift}_{jm}, \text{MaxShift}_{jm}$ )
11:    end for
12:    for each node  $k$  in route  $m: s_{km} \leq s_{n^*m}$  do
13:      Update( $\text{MaxShift}_{km}$ )
14:    end for
15:  end while
16: end for
17: return  $S_0$ 

```

restructure the current solution trying to decrease the travel total cost, thus increasing the unused time budget.

The second stage, named IncreaseServiceTime, consists of a new move aiming to enlarge some nodes' service time, thus increasing the total score. Specifically, Algorithm 2 is applied. Once the first stage has been executed, and at least one move has been applied, a restructured solution with an increased unused time budget is obtained; that is, some idle time can be used to increase the service time of specific nodes. Therefore, our aim at this moment is to find a node whose service time can be enlarged and, consequently, the solution profit improves. Algorithm 2 describes this process. For each route, we build the set G with the nodes whose service time can be increased (line 3) because they have a positive MaxShift. Then, this increment in the service time is computed for each node in G (lines 4-6), and the node n^* with the highest increment in the score is selected (line 7). The new service time d_{n^*m} is computed and, hence, the value of arrive_{jm} , wait_{jm} , s_{jm} , Shift_{jm} and MaxShift_{jm} of the subsequent nodes and the value of MaxShift_{jm} of the previous nodes are also recomputed.

The third stage in the LocalSearch procedure contains the moves Insert and Replace, focused on increasing the profit. Finally, for both the Perturbation and AcceptanceCriterion components of ILS, in our implementation, we follow the same scheme as [12].

IV. EXPERIMENTS

This section shows the experiments performed in order to validate our algorithm to solve the TOPTWVP problem for $m = 1$ and $m = 2$. A set of 56 TOPTW Solomon (set c) instances of vehicle routing problems with time windows were selected (<https://unicen.smu.edu.sg/oplib-orienteeering-problem-library>) and adapted to the TOPTWVP by adding the interval of service time; in particular, \min_D was set to the service time indicated in the original problems,

whereas max_D is set to $min_D + 30$. For comparison, we have executed a TOPTW implementation with the original Solomon instances (where the service time coincides with min_D), denoted as **Min** and with these same instances where the service time is set to max_D , denoted as **Max**. Table I show the results for score, number of visited nodes, waiting time and execution time for one and two routes, when executing the two baselines **Min** and **Max** and our implementation **Var**; columns under **AVG** show the average value among the ten runs of our ILS solving the TOPTWVP for each instance and columns under **MAX** show the maximum value of these ten runs.

For the **score**, in the case of the **AVG** results, **Max** obtains a higher score in 21 instances for one route and 25 for two routes. On average, **Var** obtains a higher score than **Max** with one route, whereas **Max** gets a better score than **Var** with two routes (although the difference is smaller). Regarding **MAX** results, the solution with **Var** is the one that provides the highest score in many problems, except in 16 instances out of 56 for one route and 24 for two routes, where **Max** obtains a higher score. **Min** is always quite far from the other two approaches, as expected.

Regarding the **number of visits**, the **Var** approach (almost) always include few more visits in the routes for instances solved with one and two routes. In the case of **Max**, fewer nodes tend to be incorporated as they have a longer duration.

The **waiting time** is defined as the sum of the waiting time of all visits, that is, the idle time in the routes. **Var** obtains routes with less waiting time than **Max** for one route: for **AVG** results, **Var** obtains routes with less waiting time in 26 instances versus 14 instances where **Max** obtains routes with less waiting time. However, for two routes, the results are more similar (26 versus 24 instances). Looking into the individual solutions, we have observed that, in many cases, this worsening of the waiting time is due to an improvement in the score, because the maximization function only considers the score and not the waiting time. That is, it is prioritized to include shorter visits that provide a higher score, although it may imply having idle time in the route waiting for the start time of the time window.

The **execution time** corresponds to the time required to find the best solution, although each execution takes all the given time. It can be observed that **Var** always needs longer to obtain a solution since an additional dimension is being introduced by having to work with an interval for the duration of the service time. This makes the problem more complicated, and it is reflected in the time needed to find a solution.

V. CONCLUSIONS

This paper has introduced the Team OP with Time Windows and Variable Profits where each node has a predefined time window in which the service must start (if visited), and the vehicle may spend an amount of time given by a predefined interval so that the profit collected at this node depends on the time spent. We have proposed a mathematical model for solving the TOPTWVP, and an ILS algorithm to solve modified benchmark instances. The results show that our

	Score		Num. Visits		Waiting Time		Exec. Time	
	m=1	m=2	m=1	m=2	m=1	m=2	m=1	m=2
AVG								
Min	21039,39	34748,93	24,34	47,81	6,77	9,04	485,39	615,44
Max	26523,71	46150,14	11,69	23,29	5,97	6,75	269,83	513,86
Var	26813,11	46031,54	12,63	25,44	3,60	7,43	701,07	792,21
MAX								
Min	21316,07	35104,82	24,34	48,58	4,31	6,88	562,30	679,10
Max	26907,86	46726,43	11,69	23,80	4,64	5,20	339,02	547,01
Var	27330,80	46948,29	12,71	25,75	2,94	7,26	715,62	760,83

TABLE I: Summary of score, number of visits, waiting time and execution time of the ILS algorithm with **Min**, **Max** and **Var** for $m = 1$ and $m = 2$

approach can solve difficult instances with good quality. When compared with two baselines **Min** and **Max**, our approach is, in general, obtaining better scores and also better values in other KPIs, such as the number of visits and the waiting time.

As future work, we are developing new procedures to handle the variable profit with the aim of improving the execution time. Moreover, we are working on a new variant of TOPTWVP that allows defining a custom waiting time so that it can also be considered in the optimization function.

Abstract—In this paper, we investigate a *subcaterpillar isomorphism* that is a problem, for a rooted labeled caterpillar P and a rooted labeled tree T , of determining whether or not there exists a subtree in T which is isomorphic to P . Then, we design two algorithms to solve the subcaterpillar isomorphism for a caterpillar P and a tree T in (i) $O(p + tDh\sigma)$ time and $O(Dh)$ space and in (ii) $O(p + tD\sigma)$ time and $O(D(h + H))$ space, respectively. Here, p is the number of vertices in P , t is the number of vertices in T , h is the height of P , H is the height of T , σ is the number of alphabets for labels and D is the degree of T . Furthermore, we give experimental results of the two algorithms for artificial data and real data.

I. INTRODUCTION

THE PATTERN matching for tree-structured data such as HTML and XML documents for web mining or DNA and glycan data for bioinformatics is one of the fundamental tasks for information retrieval or query processing. As such pattern matching for *rooted labeled unordered trees* (a tree, for short), a *subtree isomorphism* is the problem of determining, for a *pattern tree* P and a *text tree* T , whether or not there exists a subtree of T which is isomorphic to P . It is known that the subtree isomorphism can be solved in $O(p^{1.5}t/\log p)$ time [10], where p is the number of vertices in P and t is the number of vertices in T . On the other hand, it cannot be solved in $O(t^{2-\varepsilon})$ time for every ε ($0 < \varepsilon < 1$) under SETH [1].

In this paper, we focus on *subcaterpillar isomorphism* that is a subtree isomorphism when P is a *rooted labeled caterpillar* (a *caterpillar*, for short) (cf., [3]). The caterpillar is an unordered tree transformed to a rooted path after removing all the leaves in it. The caterpillar provides the structural restriction of the tractability of computing the *edit distance* [8] and *inclusion problem* [7] for unordered trees.

It is known that the problem of computing the edit distance between unordered trees is MAX SNP-hard [11]. This statement also holds even if two trees are binary, the maximum height is at most 3 or the cost function is the unit cost function [2], [4]. On the other hand, we can compute the edit distance between caterpillars in $O(n + H^2\sigma^3)$ time in the general cost function and $O(n + H^2\sigma)$ time under the unit cost function, where n is the total number of vertices of the two caterpillars, H is the maximum height of the two caterpillars and σ is

the number of alphabets for labels in the two caterpillars [8]¹.

It is known that the inclusion problem of determining whether or not a text tree T achieves to a pattern tree P by deleting vertices in T is NP-complete [6]. This statement also holds even if P is a caterpillar [6]. On the other hand, if both P and T are caterpillars, then we can solve the inclusion problem in $O(p + t + (h + H)\sigma)$ time, where h is the height of P and H is the height of T [7]².

In this paper, we design two algorithms to solve the subcaterpillar isomorphism in (i) $O(p + tDh\sigma)$ time and $O(Dh)$ space and (ii) $O(p + tD\sigma)$ time and $O(D(h + H))$ space, respectively. Here, D is the degree of T . Since there may exist many matching positions that match P in T when P is much smaller than T , the above algorithms also output all of such positions. Hence, under the assumption that $p < t$, $h \ll t$ and $h < H$, the algorithm (i) runs in $O(tD\sigma)$ time and $O(Dh)$ space and the algorithm (ii) runs in $O(tD\sigma)$ time and $O(DH)$ space.

Note that both algorithms do not use the maximum cardinality matching algorithm for bipartite graphs [5], which is essential for the subtree isomorphism algorithm [10]. Also we cannot apply the proof of the SETH-hardness in [1] when a pattern tree P is a caterpillar.

Furthermore, by implementing the algorithms (i) and (ii), we give experimental results of the two algorithms for artificial data and real data. Then, we confirm that, whereas the algorithm (ii) is faster than the algorithm (i) as same as the theoretical results for artificial data of which number of matching positions is large, the algorithm (i) is faster than the algorithm (ii) for real data.

II. PRELIMINARIES

A *tree* is a connected graph without cycles. For a tree $T = (V, E)$, we denote V and E by $V(T)$ and $E(T)$. We sometimes

¹The time complexity represented in [8] is $O(H^2\lambda^3)$ time and $O(H^2\lambda)$ time, where λ is the maximum number of leaves in the two caterpillars. Since $O(\lambda^3)$ and $O(\lambda)$ in them are corresponding to the time complexity of computing the multiset edit distances under the general and the unit cost functions (cf. [9]), we can replace λ with σ , by storing the labels occurring in the leaves. Also, in order to compare the time complexity of this paper, we add $O(n)$ as the initialization of the algorithm, containing the above storing.

²The time complexity represented in [7] is $O((h + H)\sigma)$ time. In order to compare the time complexity of this paper, we add $O(p + t)$ as the initialization of the algorithm.

denote $v \in V(T)$ by $v \in T$. A *rooted tree* is a tree with one vertex r chosen as its *root*, which we denote by $r(T)$.

For each vertex v in a rooted tree with the root r , let $UP_r(v)$ be the unique path from v to r . The *parent* of $v (\neq r)$, which we denote by $par(v)$, is its adjacent vertex on $UP_r(v)$ and the *ancestors* of $v (\neq r)$ are the vertices on $UP_r(v) \setminus \{v\}$. We denote $u < v$ if v is an ancestor of u , and we denote $u \leq v$ if either $u < v$ or $u = v$. The parent and the ancestors of the root r are undefined. We say that u is a *child* of v if v is the parent of u , and u is a *descendant* of v if v is an ancestor of u . We denote the set of all children of v by $ch(v)$. Two vertices with the same parent are called *siblings*. A *leaf* is a vertex having no children and we denote the set of all the leaves in T by $lv(T)$. We call a vertex that is not a leaf an *internal vertex*.

For a rooted tree $T = (V, E)$ and a vertex $v \in T$, the *complete subtree of T at v* , denoted by $T(v)$, is a rooted tree $S = (V', E')$ such that $r(S) = v$, $V' = \{w \in V \mid w \leq v\}$ and $E' = \{(u, w) \in E \mid u, w \in V'\}$.

The *height* $h(v)$ of a vertex v is defined as $|UP_r(v)| - 1$ and the *height* $h(T)$ of T is the maximum height for every vertex $v \in T$. The *degree* $d(v)$ of a vertex v is the number of the children of v , and the *degree* $d(T)$ of T is the maximum degree for every vertex in T .

We say that a rooted tree is *ordered* if a left-to-right order among siblings is given; *Unordered* otherwise. For a fixed finite alphabet Σ , we say that a tree is *labeled over Σ* if each vertex is assigned a symbol from Σ . We denote the label of a vertex v by $l(v)$, and sometimes identify v with $l(v)$. In this paper, we call a rooted labeled unordered tree over Σ a *tree*, simply.

In this paper, we often represent a rooted labeled unordered tree as a rooted labeled *ordered* tree under a fixed order of siblings. Then, for a rooted labeled ordered tree T , a vertex v in T and its children v_1, \dots, v_i , the *postorder traversal* of $T(v)$ is obtained by first visiting $T(v_k)$ ($1 \leq k \leq i$) and then visiting v . The *postorder number* of $v \in T$ is the number of vertices preceding v in the postorder traversal of T .

Definition 1: Let T and S be trees.

- 1) We say that T is a *subtree* of S , denoted by $T \preceq S$, if T is a tree such that $V(T) \subseteq V(S)$ and $E(T) = \{(v, w) \in E(S) \mid v, w \in V(T)\}$.
- 2) We say that T and S are *isomorphic*, denoted by $T \simeq S$, if $T \preceq S$ and $S \preceq T$.
- 3) We say that T is a *subtree isomorphism* of S , denoted by $T \trianglelefteq S$, if there exists a tree $S' \preceq S$ such that $T \simeq S'$.

In this paper, we deal with a *subtree isomorphism problem* of P for T whether or not $P \trianglelefteq T$ for trees P and T . We call P a *pattern tree* and T a *text tree*. Then, the following theorem holds.

Theorem 1 (Shamir & Tsur [10]): Let P and T be trees where $p = |P|$ and $t = |T|$. Then, the problem of determining whether or not $P \trianglelefteq T$ is solvable in $O(p^{1.5}t/\log p)$ time.

As the restricted form of trees, we introduce a *rooted labeled caterpillar* (a *caterpillar*, for short) as follows.

Definition 2: We say that a tree is a *caterpillar* (cf. [3]) if it is transformed to a rooted path after removing all the leaves in it. For a caterpillar C , we call the remained rooted path a *backbone* of C and denote it by $bb(C)$.

It is obvious that $r(C) = r(bb(C))$ and $V(C) = V(bb(C)) \cup lv(C)$ for a caterpillar C , that is, every vertex in a caterpillar is either a leaf or an element of the backbone.

III. ALGORITHMS FOR SUBCATERPILLAR ISOMORPHISM

In this section, we focus on a *subcaterpillar isomorphism* that is a subtree isomorphism when P is a caterpillar. In other words, we focus on the problem of whether or not $P \trianglelefteq T$ for a caterpillar P and a tree T . Throughout of this section, we refer $p = |P|$, $t = |T|$, $h = h(P)$, $H = h(T)$, $D = d(T)$ and $\sigma = |\Sigma|$.

For a pattern caterpillar P , we refer the backbone of P to a sequence $\langle v_1, \dots, v_n \rangle$ such that $(v_i, v_{i+1}) \in E(P)$ and $v_n = r(P)$. We denote the children of v_i by $ch(v_i)$.

On the other hand, for a text tree T , we refer the vertices in T to w_1, \dots, w_m in postorder traversal. We denote the height of w_j by $h(w_j)$ and the set of children of w_j by $ch(w_j)$.

Let P be a pattern caterpillar and T a text tree such that $P \trianglelefteq T$. Also let $P' \preceq T$ be a subcaterpillar in T such that $P \simeq P'$ and $bb(P') = \langle v'_1, \dots, v'_n \rangle$, where $v'_n = r(P')$. Then, we call the postorder number j such that $v'_1 = w_j$ in T a *matching position* of P in T .

Example 1: Consider a pattern caterpillar P and a text tree T in Figure 1. Here, the number assigned to every vertex in T denotes the postorder number. Also v_i denotes the backbone. Then, $\{6, 8, 16\}$ is the set of all the matching positions of P in T . The corresponding backbones to P in T are $\langle 6, 8, 9 \rangle$, $\langle 8, 9, 18 \rangle$ and $\langle 16, 17, 18 \rangle$.

Fig. 1. A pattern caterpillar P and a text tree T in Example 1.

To design the algorithm to determine subcaterpillar isomorphism, we use a *multiset* of labels in order to compare two sets of vertices. A *multiset* on Σ is a mapping $S : \Sigma \rightarrow \mathbb{N}$. For a set V of vertices, we denote the multiset of labels occurring in V by \tilde{V} . Then, it is necessary for the subcaterpillar isomorphism to check whether or not $ch(v_i) \subseteq ch(w_j)$ for $v_i \in bb(P)$ and $w_j \in T$. It is realized to check $\left(\widetilde{ch(v_i)} \right) (a) \leq \left(\widetilde{ch(w_j)} \right) (a)$ for every $a \in \Sigma$ in $O(\sigma)$ time (cf. [9]).

Then, we design the algorithm SUBCATISO in Algorithm 1 to determine whether or not $P \trianglelefteq T$. Here, the algorithm SUBCATISO output all of the matching positions if $P \trianglelefteq T$. Then, it holds that no matching point is output if $P \not\trianglelefteq T$.

```

procedure SUBCATISO( $P, T$ )
  /*  $P$  : caterpillar such that  $bb(P) = \langle v_1, \dots, v_n \rangle$  */
  /*  $T$  : tree consisting of vertices  $w_1, \dots, w_m$  in postorder
  traversal */
1  for  $i = 1$  to  $n - 1$  do  $match[i] \leftarrow \emptyset$ ;
2  for  $j = 2$  to  $m$  do
3    if  $h(w_{j-1}) = h(w_j) + 1$  then
4      /*  $w_j = par(w_{j-1})$  */
5      for  $i = n - 1$  downto  $1$  do
6        if  $match[i] \neq \emptyset$  then
7          foreach  $k \in match[i]$  do
8            if  $h(w_k) = h(w_j) + i$  then
9              /*  $w_j = par(w_k)$  */
10              $match[i] \leftarrow match[i] \setminus \{k\}$ ;
11             if  $l(v_{i+1}) = l(w_j)$  and
12              $ch(v_{i+1}) \subseteq ch(w_j)$  then
13               if  $i + 1 = n$  then output  $k$ ;
14               else
15                  $match[i + 1] \leftarrow$ 
16                  $match[i + 1] \cup \{k\}$ ;
17             if  $l(v_1) = l(w_j)$  and  $ch(v_1) \subseteq ch(w_j)$  then
18               if  $n = 1$  then output  $j$ ;
19               else  $match[1] \leftarrow match[1] \cup \{j\}$ ;

```

Algorithm 1: SUBCATISO.

Example 2: We apply the algorithm SUBCATISO to the pattern caterpillar P and the text tree T in Example 1 in Figure 1. The if-sentence in line 3 works just internal vertices.

- 1) For $j = 6$, since $l(v_1) = a = l(w_6)$ and $ch(v_1) = \{a, b, c\} = ch(w_6)$, 6 is stored to $match[1]$ and then $match[1] = \{6\}$.
- 2) For $j = 8$, since $match[1] \neq \emptyset$, set k to $6 \in match[1]$. Since $h(w_6) = 3 = h(w_8) + 1$, $match[1]$ is changed to \emptyset . Since $l(v_2) = a = l(w_8)$ and $ch(v_2) = \{a, b\} \subseteq ch(w_8)$, 6 is stored to $match[2]$ and then $match[2] = \{6\}$. Also since $ch(v_1) = \{a, b, c\} = ch(w_8)$, 8 is stored to $match[1]$ and then $match[1] = \{8\}$.
- 3) For $j = 9$, since $match[2] \neq \emptyset$, set k to $6 \in match[2]$. Since $h(w_6) = 3 = h(w_9) + 2$, $match[2]$ is changed to \emptyset . Since $l(v_3) = a = l(w_9)$ and $ch(v_3) = \{a, b\} = ch(w_9)$, 6 is output. Also since $match[1] \neq \emptyset$, set k to $8 \in match[1]$. Since $h(w_8) = 2 = h(w_9) + 1$, $match[1]$ is changed to \emptyset . Since $l(v_2) = a = l(w_9)$ and $ch(v_2) = \{a, b\} \subseteq ch(w_8)$, 8 is stored to $match[2]$ and then $match[2] = \{8\}$.
- 4) For $j = 16$, since $ch(v_1) = \{a, b, c\} = ch(w_{16})$, 16 is stored to $match[1]$ and then $match[1] = \{16\}$.
- 5) For $j = 17$, since $match[1] \neq \emptyset$, set k to $16 \in match[1]$. $match[1]$ is changed to \emptyset . Since $l(v_2) = a = l(w_{17})$ and $ch(v_2) = \{a, b\} \subseteq ch(w_{17})$, 16 is stored to $match[2]$ and then $match[2] = \{8, 16\}$.
- 6) For $j = 18$, since $match[2] \neq \emptyset$, set k to 8 and 16. For $k = 8$, since $h(w_8) = 2 = h(w_{18}) + 2$, $match[2]$

is changed to $\{16\}$. Since $l(v_3) = a = l(w_{18})$ and $ch(v_3) = \{a, b\} \subseteq ch(w_{18})$, 8 is output. Also, for $k = 16$, since $h(w_{16}) = 2 = h(w_{18}) + 2$, $match[2]$ is changed to \emptyset . As the same reason, 16 is output.

Hence, the set of all the matching positions of P in T is $\{6, 8, 16\}$. As summarising, Table I illustrates the transition of $match[i]$ for the algorithm SUBCATISO.

TABLE I
THE TRANSITION OF $match[i]$ FOR THE ALGORITHM SUBCATISO.

	$j = 6$	$j = 8$	$j = 9$	$j = 16$	$j = 17$	$j = 18$
$match[1]$	6	8	\emptyset	16	\emptyset	\emptyset
$match[2]$	\emptyset	6	8	8	8, 16	\emptyset
output			6			8, 16

Theorem 2: Let P be a caterpillar and T a tree. Then, the algorithm SUBCATISO correctly outputs all of the matching positions of P in T in $O(p + tDh\sigma)$ time and $O(Dh)$ space.

Proof: First, we show the correctness of the algorithm SUBCATISO. The matching point of P in T is the internal vertices of T . Then, the algorithm SUBCATISO first stores the candidate j of the matching point corresponding to v_1 to $match[1]$ if $l(v_1) = l(w_j)$ and $ch(v_1) \subseteq ch(w_j)$ (line 14). Then, for the current j , the algorithm SUBCATISO removes the candidate k from $match[i]$ if w_j is an ancestor of w_k (line 8) and stores k to $match[i + 1]$ if $l(v_{i+1}) = l(w_j)$, $ch(v_{i+1}) \subseteq ch(w_j)$ and $i < n - 1$ (line 12). If $i = n - 1$, then the algorithm SUBCATISO outputs k (line 10).

Hence, every output k at line 10 satisfies that $l(v_i) = l(par^{i-1}(w_k))$ and $ch(v_i) = ch(par^{i-1}(w_k))$ for every i ($1 \leq i \leq n$), where $par^0(v) = v$ and $par^{i+1}(v) = par(par^i(v))$. As a result, the algorithm SUBCATISO outputs all of the matching points of P in T .

Next, consider the complexity of the algorithm SUBCATISO. As preprocessing, it is necessary to store $ch(v_i)$ for v_i in P and $ch(w_j)$ for internal vertex w_j in T in $O(p)$ time and $O(t)$ time, respectively. Also it is necessary to initialize $match$ in $O(h)$ time. For the for-loop between lines 2 and 12 in the algorithm SUBCATISO, the line 3 works at just internal vertices in T . Since $n = h$ and $|match[i]| \leq D$ ($1 \leq i \leq n - 1$), the foreach-loop between lines 6 and 12 is iterated at most $O(hD)$ times. Since we can check $ch(v_{i+1}) \subseteq ch(w_j)$ in $O(\sigma)$ time, the algorithm SUBCATISO executes the foreach-loop is $O(hD\sigma)$ time. Then, the for-loop is executed in $O(tDh\sigma)$ time. Hence, the total running time of the algorithm SUBCATISO is $O(p + t + h + tDh\sigma) = O(p + tDh\sigma)$ time. The total space is the space spent by the array $match[i]$ for every i ($1 \leq i \leq n - 1$), which is bounded by $O(Dh)$. ■

In order to reduce the searching time in $match[i]$ for every i ($1 \leq i \leq n - 1$) of the algorithm SUBCATISO, we design another algorithm SUBCATISO2 in Algorithm 2.

The main difference between the algorithms SUBCATISO and SUBCATISO2 is that the index i accessed to the array $match$ is determined by $height[h_{j-1}]$ without accessing to $match[i]$ for every i ($1 \leq i \leq n - 1$).

```

procedure SUBCATISO2( $P, T$ )
  /*  $P$  : caterpillar such that  $bb(P) = \langle v_1, \dots, v_n \rangle$  */
  /*  $T$  : tree consisting of vertices  $w_1, \dots, w_m$  in postorder
  traversal */
  1 for  $i = 1$  to  $n$  do  $match[i] \leftarrow \emptyset$ ;
  2 for  $j = 1$  to  $m$  do  $current(j) \leftarrow 0$ ;
  3 for  $h = 1$  to  $h(T) - 1$  do  $height[h] \leftarrow \emptyset$ ;
  4 for  $j = 2$  to  $m$  do
  5    $h_j \leftarrow h(w_j)$ ;  $h_{j-1} \leftarrow h(w_{j-1})$ ;
  6   if  $h_{j-1} = h_j + 1$  then
  7     /*  $w_j = par(w_{j-1})$  */
  8     foreach  $k \in height[h_{j-1}]$  do
  9        $height[h_{j-1}] \leftarrow height[h_{j-1}] \setminus \{k\}$ ;
 10      if  $h(w_k) = h_j + current(k)$  then
 11        /*  $w_j = par(w_k)$  */
 12         $i \leftarrow current(k)$ ;
 13         $match[i] \leftarrow match[i] \setminus \{k\}$ ;
 14         $current(k) \leftarrow 0$ ;
 15        if  $l(v_{i+1}) = l(w_j)$  and
 16         $ch(v_{i+1}) \subseteq ch(w_j)$  then
 17          if  $i + 1 = n$  then output  $k$ ;
 18          else
 19             $match[i + 1] \leftarrow$ 
 20             $match[i + 1] \cup \{k\}$ ;
 21             $height[h_j] \leftarrow height[h_j] \cup \{k\}$ ;
 22             $current(k) \leftarrow i + 1$ ;
 23
 24      if  $l(v_1) = l(w_j)$  and  $\widetilde{ch}(v_1) \subseteq \widetilde{ch}(w_j)$  then
 25        if  $n = 1$  then output  $j$ ;
 26        else
 27           $match[1] \leftarrow match[1] \cup \{j\}$ ;
 28           $height[h_j] \leftarrow height[h_j] \cup \{j\}$ ;
 29           $current(j) \leftarrow 1$ ;

```

Algorithm 2: SUBCATISO2.

Example 3: We apply the algorithm SUBCATISO2 to the pattern caterpillar P and the text tree T in Example 1 in Figure 1. Then, Table II illustrates the transitions of $match[i]$ and $height[j]$ for the algorithm SUBCATISO2.

TABLE II
THE TRANSITIONS OF $match[i]$ AND $height[j]$ FOR THE ALGORITHM SUBCATISO2.

	$j = 6$	$j = 8$	$j = 9$	$j = 16$	$j = 17$	$j = 18$
$match[1]$	6	8	\emptyset	16	\emptyset	\emptyset
$match[2]$	\emptyset	6	8	8	8, 16	\emptyset
<i>output</i>			6			8, 16
$height[1]$	\emptyset	\emptyset	8	8	8, 16	\emptyset
$height[2]$	\emptyset	6, 8	\emptyset	16	\emptyset	\emptyset
$height[3]$	6	\emptyset	\emptyset	\emptyset	\emptyset	\emptyset

- 1) For $j = 6$, by lines 3 and 13, 6 is stored to $match[1]$ and $height[3]$, and $current(6)$ is set to 1.
- 2) For $j = 8$, by lines 6 and 7, 6 is selected as $k \in height[3]$. Since $h(w_6) = 3 = 2 + 1 = h_8 + current(6)$, 6 is deleted from $match[1]$. By line 13, 6 is stored to $match[2]$ and $height[2]$, and $current(6)$ is set to 2. By line 18, 8 is stored to $match[1]$ and $height[2]$, and

$current(8)$ is set to 1.

- 3) For $j = 9$, by lines 6 and 7, 6 and 8 are selected as $k \in height[2]$. For $k = 6$, by line 9, i is set to $2 = current(6)$ and 6 is deleted from $match[2]$. By lines 13 and 14, 6 is output. Also, for $k = 8$, by line 9, i is set to $1 = current(8)$ and 8 is deleted from $match[1]$. By line 13, 8 is stored to $match[2]$ and $height[1]$, and $current(8)$ is set to 2.
- 4) For $j = 16$, by lines 3 and 13, 16 is stored to $height[2]$ and $match[1]$, and $current(16)$ is set to 1.
- 5) For $j = 17$, by lines 6 and 7, 16 is selected as $k \in height[2]$. By line 9, i is set to $1 = current(16)$ and 16 is deleted from $match[1]$. By line 13, 16 is stored to $match[2]$ and $height[1]$, and $current(8)$ is set to 2.
- 6) For $j = 18$, by lines 6 and 7, 8 and 16 are selected as $k \in height[1]$. For $k = 8$, by line 9, i is set to $2 = current(8)$ and 8 is deleted from $match[2]$. By lines 13 and 14, 8 is output. Also, for $k = 16$, by the same reason, 16 is output.

Theorem 3: Let P be a caterpillar and T a tree. Then, the algorithm SUBCATISO2 correctly outputs all of the matching positions of P in T in $O(p + tD\sigma)$ time and $O(D(h + H))$ space.

Proof: The difference between the algorithms SUBCATISO and SUBCATISO2 is the usage of $current$ and $height$ without accessing to $match[i]$ for every i ($1 \leq i \leq n - 1$).

For the selected $k \in height[h_{j-1}]$ at line 7, $current(k)$ is the already processed index i as v_i ($1 \leq i \leq n - 1$). Then, if w_k satisfies the condition at line 13, then $current(k)$ is updated to $i + 1$ at line 17.

On the other hand, for the current j in the for-loop at line 4 and for $k \in height[h_{j-1}]$ at line 7, k is deleted from $height[h_{j-1}]$ at line 8. If $h(w_k) = h_j + current(k)$ at line 9, then h_j is the corresponding height to v_i such that $i = current(k)$. Then, k determines the index i at line 10 to access the array $match[i]$. Furthermore, if v_{i+1} satisfies the condition at line 13, then k is stored to $match[i + 1]$ and $height[h_j]$, and $current(k)$ is updated to $i + 1$.

Hence, the algorithm SUBCATISO2 correctly accesses the array $match[i]$ for every i ($1 \leq i \leq n - 1$). Then, by Theorem 2, the algorithm SUBCATISO2 is correct.

Next, consider the complexity of the algorithm SUBCATISO2. The preprocessing time is $O(p + t)$ from the proof of Theorem 2. It is necessary to initialize $current(j)$ and $height[h]$ in $O(t)$ and $O(H)$, respectively. The foreach-loop between lines 7 and 18 is iterated in $O(D)$ time since $|height[h_{j-1}]| \leq D$, and then the foreach-loop is executed to $O(D\sigma)$ time. Since the for-loop between lines 4 and 22 is executed to $m = t$ time, the total running time of the algorithm SUBCATISO2 is $O(p + t + t + H + tD\sigma) = O(p + tD\sigma)$. The total space of the algorithm SUBCATISO2 is the space spent by the arrays $match[i]$ for every i ($1 \leq i \leq n - 1$) and $height[h]$ for every h ($1 \leq h \leq h(T) - 1$), which is bounded by $O(D(h + H))$. ■

Theorems 2 and 3 imply the following corollary.

Corollary 1: Let P be a caterpillar and T a tree such that $p < t$, $h \ll t$ and $h < H$. Then, the algorithm SUBCATISO determines whether or not $P \trianglelefteq T$ in $O(tD\sigma)$ time and $O(Dh)$ space. Also the algorithm SUBCATISO2 determines whether or not $P \trianglelefteq T$ in $O(tD\sigma)$ time and $O(DH)$ space.

IV. EXPERIMENTAL RESULTS

In this section, we give experimental results of the algorithms SUBCATISO and SUBCATISO2 for both the artificial data and the real data. Here, the computer environment is that OS is Ubuntu 18.04.4, CPU is Intel Xeon E5-1650 v3 (3.50GHz) and RAM is 3.8GB.

A. Artificial data

First, in order to investigate the efficiency of the algorithm SUBCATISO2, we adopt a *binary caterpillar* P_k with height k and the unique label, which is a caterpillar such that every internal vertex has just two children, and a *complete binary tree* T_{2k} with height $2k$ and the unique label, which is a tree such that every internal vertex has just two children and the height of every leaf is just $2k$. It is obvious that $P_k \trianglelefteq T_{2k}$.

Note that the algorithm SUBCATISO2 is more efficient than the algorithm SUBCATISO when the number of the matching points of P in T are large. Then, Table III illustrates the running time of the algorithms SUBCATISO and SUBCATISO2 for P_k and T_{2k} and the number (#match) of matching points of P_k for T_{2k} for $4 \leq k \leq 11$.

TABLE III
THE RUNNING TIME (MSEC.) OF THE ALGORITHMS SUBCATISO AND SUBCATISO2 FOR P_k AND T_{2k} AND THE NUMBER (#MATCH) OF MATCHING POINTS OF P_k FOR T_{2k} FOR $4 \leq k \leq 11$.

P_k	T_{2k}	SUBCATISO	SUBCATISO2	#match
P_4	T_8	4	3	248
P_5	T_{10}	23	21	1,008
P_6	T_{12}	115	98	4,064
P_7	T_{14}	585	473	16,320
P_8	T_{16}	3,256	2,331	65,408
P_9	T_{18}	21,493	12,126	261,888
P_{10}	T_{20}	181,978	67,697	1,048,064
P_{11}	T_{22}	1,579,043	417,140	4,193,280

Table III shows that the algorithm SUBCATISO2 is faster than the algorithm SUBCATISO for P_k and T_{2k} when k is larger.

The number of the matching points of P_{k+1} is about 4 times of those of P_k . On the other hand, the running time of P_8 (resp., P_9 , P_{10} , P_{11}) by the algorithm SUBCATISO is about 5.5 times (resp., about 6.5 times, about 8.5 times, about 8.7 times) of that of P_7 (resp., P_8 , P_9 , P_{10}). Also the running time of P_8 (resp., P_9 , P_{10} , P_{11}) by the algorithm SUBCATISO2 is about 5 times (resp., about 5.2 times, about 5.6 times, about 6.2 times) of that of P_7 (resp., P_8 , P_9 , P_{10}).

B. Real data

Next, we give experimental results for caterpillars and trees in real data. We deal with data for N-glycans and all-

glycans from KEGG³, CSLOGS⁴, dblp⁵ and TPC-H, Auction, Nasa, Protein and University from UW XML Repository⁶. In particular, we deal with the largest 51,546 trees (1%) in dblp (refer to dblp_{1%}). As pattern caterpillars, we deal with non-isomorphic caterpillars in TPC-H, caterpillars obtained by deleting the root in Auction and non-isomorphic caterpillars obtained by deleting the root in Nasa, Protein, and University. Note that we use all the trees as text trees in TPC-H, Auction, Nasa, Protein and University.

Table IV illustrates the information of such caterpillars and trees. Here, #, n , d and h are the number of caterpillars and trees, the average number of vertices, the average degree and the average height.

TABLE IV
THE INFORMATION OF CATERPILLARS AND TREES.

	caterpillars				trees			
	#	n	d	h	#	n	d	h
N-glycans	514	6.40	1.84	4.22	2,124	11.06	2.07	5.38
all-glycans	7,984	4.74	1.49	3.02	10,683	6.38	1.65	3.59
CSLOGS	41,592	5.84	3.05	2.20	59,691	12.93	4.48	3.42
dblp _{1%}	51,395	21.29	20.21	1.04	51,546	21.29	20.18	1.04
SwissProt	6,804	35.10	24.96	2.00	50,000	59.54	31.33	2.76
TCP-H	8	8.63	7.63	1.00	86,805	14.46	13.46	1.00
Auction	259	4.29	3.00	0.71	37	31.00	12.00	3.00
Nasa	33	7.27	5.15	1.64	2,435	195.74	21.53	5.76
Protein	5,150	4.97	3.63	1.16	262,525	81.15	23.27	4.99
University	26	1.35	0.35	0.19	6,739	22.52	11.75	2.31

Then, Table V illustrates the total and average running time (msec.) of the algorithms SUBCATISO and SUBCATISO2 applying to data in Table IV by regarding caterpillars as pattern caterpillars and trees as text trees. Here, #cat denotes the number of pattern caterpillars and #tree denotes the number of text trees. Also the average running time is obtained by dividing the total running time by the total number of pairs, that is, (#cat) × (#tree).

TABLE V
THE TOTAL AND AVERAGE RUNNING TIME (MSEC.) OF THE ALGORITHMS SUBCATISO AND SUBCATISO2 APPLYING TO DATA IN TABLE IV.

	#cat	#tree	SUBCATISO		SUBCATISO2	
			total	ave.	total	ave.
N-glycans	514	2,142	53,969	0.0490	55,638	0.0505
all-glycans	7,894	10,683	1,353,490	0.0159	1,521,891	0.0178

⁵<http://dblp.uni-trier.de/>

⁶<http://aiweb.cs.washington.edu/research/projects/xmltk/xmldata/www/repository.html>

pairs, and the total and average number (#match) of matching points when $P \trianglelefteq T$.

TABLE VI

THE NUMBER ($\#(P \trianglelefteq T)$) OF PAIRS SUCH THAT $P \trianglelefteq T$ AND ITS RATIO, AND THE TOTAL AND AVERAGE NUMBER (#MATCH) OF MATCHING POINTS WHEN $P \trianglelefteq T$.

	#cat	#tree	$\#(P \trianglelefteq T)$		#match	
			total	ratio (%)	total	ave.
N-glycans	514	2,142	58,128	5.277	96,729	1.664
all-glycans	7,894	10,683	983,163	1.153	1,625,099	1.653
CSLOGS	41,592	59,691	3,201,441	0.129	3,201,441	1.000
dblp _{1%}	51,395	51,546	364,237,724	13.749	364,238,110	1.000
SwissProt	6,804	50,000	20,259,951	5.955	34,465,633	1.701
TCP-H	8	86,805	86,805	12.500	86,805	1.000
Auction	259	37	5,476	57.143	5,476	1.000
Nasa	33	2,435	17,850	22.214	42,687	2.391
Protein	5,150	262,525	2,413,404	0.179	2,515,642	1.042
University	26	6,739	9,260	5.285	9,260	1.000

In contrast to Table III, Table V shows that the algorithm SUBCATISO is faster than the algorithm SUBCATISO2 for real data like as Corollary 1. One of the reasons is that the number of the matching points for real data is much smaller than that for artificial data. In fact, Table VI shows that the average number of matching points for real data when $P \trianglelefteq T$ is less than 2.

Table V also shows that the average running time of both algorithms for Nasa is largest and that for SwissProt is next largest for all the data. The reason is that both the average number of vertices of text trees in Table IV and the average number of matching points in Table VI are larger than other data.

Table VI shows that, for CSLOGS, TCP-H, Auction and University, the number of the matching point is always exactly one when $P \trianglelefteq T$. Then, for the other data as N-glycans, all-glycans, dblp_{1%}, SwissProt, Nasa and Protein, Table VII illustrates the histograms of the number of matching points and the maximum value (max) of matching points when $P \trianglelefteq T$.

TABLE VII

THE HISTOGRAMS FOR THE NUMBER OF MATCHING POINTS AND THE MAXIMUM VALUE (MAX) OF MATCHING POINTS FOR N-GLYCANS, ALL-GLYCANS, DBLP_{1%}, SWISSPROT, NASA AND PROTEIN WHEN $P \trianglelefteq T$.

#match	N-glycans	all-glycans	dblp _{1%}	SwissProt	Nasa	Protein
1	29,909	640,541	364,237,418	13,589,834	10,209	2,344,390
2	20,869	195,221	253	3,828,308	2,692	51,684
3	4,432	72,597	40	1,422,806	3,558	9,862
4	2,804	39,496	6	598,676	590	3,882
5	114	16,172	0	295,015	265	1,394
6	0	9,799	7	161,599	150	1,160
7	0	4,297	0	100,317	99	425
8	0	1,998	0	64,968	59	298
9	0	1,211	0	47,901	48	97
≥ 10	0	1,858	0	150,527	180	212
max	5	21	6	79	1,178	32

Table VII shows that the number of cases whose matching points are more than 1 for SwissProt is largest and that for

all-glycans is next largest for all the data. On the other hand, the maximum value of matching points for Nasa is extremely largest and that for SwissProt is next largest for all the data.

V. CONCLUSION

In this paper, we have investigated the *subcaterpillar isomorphism* and designed two algorithms SUBCATISO running in $O(p + tDh\sigma)$ time and $O(Dh)$ space and SUBCATISO2 running in $O(p + tD\sigma)$ time and $O(D(h + H))$ space, where $p = |P|$, $t = |T|$, $h = h(P)$, $H = h(T)$, $D = d(T)$ and $\sigma = |\Sigma|$. Also we give experimental results for artificial data and real data.

Then, as same as Theorems 2 and 3, we have confirmed that the algorithm SUBCATISO2 is faster than the algorithm SUBCATISO for artificial data whose number of the matching points of P in T are large. On the other hand, we have confirmed that the algorithm SUBCATISO is faster than the algorithm SUBCATISO2 for real data. One of the reason is that the running time of using the array $height[h]$ in the algorithm SUBCATISO2 cannot be absorbed like as Corollary 1 when the number of the matching points is not large.

The reason why we cannot apply the SETH-hardness to subcaterpillar isomorphism is that a caterpillar has a unique backbone. Then, it is a future work to extend a caterpillar to a tree with the bounded number of backbones, in order to avoid to the SETH-hardness of subtree isomorphism [1]. Also it is a future work to extend the algorithms in this paper to *unrooted* subcaterpillar isomorphism like as [10].

Abstract—The N -NEH+ algorithm is one of the most efficient construction algorithms for solving the permutation flow-shop problem with the makespan criterion. It extends the well-known NEH heuristic with the N -list technique. In this paper, we propose the Starting Point (SP) method that employs a new strategy for using the N -list technique. The SP method allows to obtain an algorithm that is a combination of NEH and an N -list-based algorithm. Extensive numerical experiments on the standard set of Taillard’s and VRF benchmarks show that the SP method significantly improves the results (average relative percentage deviation) of the NEH and N -NEH+ algorithms.

I. INTRODUCTION

THE permutation flow-shop problem (PFSP) is one of the most famous combinatorial optimization problems in the industry. It can be defined as follows: given two finite sets of m machines $\{M_1, \dots, M_m\}$ and n jobs $\{J_1, \dots, J_n\}$, each of which should go through all the m machines in the same order, the goal is to find the ordering of jobs that minimizes the assumed goal function (makespan, total tardiness, flow time, cost, energy consumption, etc.).

The PFSP with makespan criterion, commonly referred to as $Fm|prmu|C_{\max}$ [1], which is our main concern, is undoubtedly the most frequently investigated scheduling problem. Garey and Johnson [2] have shown that $Fm|prmu|C_{\max}$ is NP-hard if $m \geq 3$. Therefore, various heuristic algorithms have been developed to solve this problem. One of the most popular algorithms for solving $Fm|prmu|C_{\max}$ is the $\mathcal{O}(n^3m)$ NEH construction heuristic proposed by Nawaz, Enscore and Ham [3]. Since 1983 NEH has been commonly regarded as the best heuristic for solving $Fm|prmu|C_{\max}$, and many attempts have been made to improve it. Taillard [4] proposed the so-called *acceleration technique* that reduces the asymptotic time complexity of NEH to $\mathcal{O}(n^2m)$. New criteria were proposed for the initial job classification, e.g., in [5], [6], [7]. The problem of tie-breaking (i.e., how to choose among different subsequences with the same best partial makespan) was considered, e.g., in [8], [9], [10]. One of the most efficient modifications of NEH is the N -NEH+ algorithm recently proposed by Puka et al. [11] which, roughly speaking, combines the NEH heuristic with the N -list technique [11].

This study was conducted under a research project funded by a statutory grant of the AGH University of Science and Technology in Kraków for maintaining research potential.

In this paper, we propose the Starting Point (SP) method that is based on a new strategy of using the N -list technique. The extensive numerical experiments on the standard Taillard’s and VRF benchmarks show that the SP method can significantly improve the results of the N -NEH+ algorithm.

II. STARTING POINT METHOD

The general scheme of the NEH algorithm for solving $Fm|prmu|C_{\max}$ is presented in Algorithm 1.

Algorithm 1 NEH algorithm for solving $Fm|prmu|C_{\max}$

Initial phase: Sort n jobs in non-increasing order of their total processing time and put them into the initial list of jobs $L = \{1, \dots, n\}$.

Insertion phase: Schedule the first job and remove it from L
for $k = 2, \dots, n$ **do**

Insert the job k in the place that minimizes the partial makespan among the k possible ones

Remove job k from the list.

end for

Ruiz and Maroto [12] compared NEH with 25 heuristics for solving PFSPs and it turned out that NEH performed the best both with respect to the quality of the results and the running time. It is no wonder then that a lot of studies on the improvements of NEH performance have been published in the scientific literature.

One of the most efficient NEH-based algorithms for solving $Fm|prmu|C_{\max}$ is the N -NEH+ algorithm [11]. It relies on multiple run of the N -NEH algorithm (see Algorithm 2) that extends NEH with the N -list technique. More specifically, N -NEH+ runs N -NEH for the length of the N -list ranging in the interval $[0, N]$, where $N \leq n - 1$ is the parameter of the N -NEH+ algorithm, and takes the best result of all runs. Let us note that if $N = 1$ (i.e., the N -list technique is not used) the N -NEH+ algorithm is equivalent to NEH.

The Starting Point method proposed in this paper, presented in Algorithm 3, is based on the following strategy: the first N' (N' is a parameter of the SP method) steps are performed as in NEH, and the remaining steps are performed with the use of the N -list technique. For example, given a problem with $n = 100$ and $N' = 0.2n$, the first 20 jobs will be scheduled as in NEH and the remaining 80 jobs as in N -NEH.

Algorithm 2 N -NEH algorithm for solving $Fm|prmu|C_{max}$

Initial phase: Sort n jobs in non-increasing order of their total processing time and put them into the list L .

Insertion phase: Initialize the partial sequence $S = \{1\}$.

Initialize the list L_N of N candidate jobs and remove the respective jobs from L .

for $k = 2, \dots, n$ **do**

Evaluate each job in L_N , put the best job in the respective place in S and remove this job from L_N .

if $L \neq \emptyset$ **then**

Append the first job from L to L_N and remove this job from L .

end if

end for

Algorithm 3 SP method for solving $Fm|prmu|C_{max}$

Initial phase: Sort n jobs in non-increasing order of their total processing time and put them into the list L .

Insertion phase: Initialize the partial sequence $S = \{1\}$.

for $k = 2, \dots, \alpha$ **do**

Insert the job k at the place that minimizes the partial makespan among the k possible ones.

end for

Initialize the list L_N of N candidate jobs and remove the respective jobs from L .

for $k = \alpha + 1, \dots, n$ **do**

Evaluate each job in L_N , put the best job in the respective place in S and remove this job from L_N .

if $L \neq \emptyset$ **then**

Append the first job from L to L_N and remove this job from L .

end if

end for

For the purposes of this work, the Starting Point method will be denoted as $SP(N')N(N)$, where N' is a parameter of the SP method and N is the length of the N -list. Additionally, $SP+(N')N(N)$ will be used to denote the method that relies on running $SP(n')N(N)$ with n' ranging in the interval $[0, N']$; the result of the $SP+(N')N(N)$ method is the best result out of all runs. Similarly, $SP+(N')N+(N)$ will be used to denote the method that runs the $SP(n')N(n')$ method with n' ranging in the interval $[0, N']$ and n'' ranging in the interval $[1, N]$. Let us note that the $SP(0)N$ -NEH+ algorithm (0 means that the SP method is not used) is equivalent to the N -NEH+ algorithm, whereas $SP(N')N+(1)$ is equivalent to NEH.

Since the optimal solution is not known for some instances, the results obtained by a given algorithm are compared with the best solution known so far. The average relative percentage deviation (ARPD) of an algorithm is given as

$$ARPD = \frac{1}{I} \sum_{i=1}^I (C_{max,i} - Best_i) / Best_i, \quad (1)$$

where I is the number of instances, $C_{max,i}$ is the solution

of the algorithm on the instance i , and $Best_i$ is the best solution known so far for this instance. Additionally, for many computed instances, the computational effort of the evaluated algorithm is measured by using the average CPU time (ACPU) given as:

$$ACPU = \left(\sum_{i=1}^I CPU_i \right) / I, \quad (2)$$

where CPU_i is the CPU time of the algorithm on instance i .

The computational experiments that aim to verify the performance of the $SP+(N')N+(N)$ method are presented in the next section. The performance of the method is assessed by using ARPD and ACPU measures.

III. COMPUTATIONAL EXPERIMENT

The performance of the $SP(N')N+(N)$ and $SP+(N')N+(N)$ algorithms (with Taillard's acceleration) was verified on two benchmarks: Taillard's benchmark with 120 instances [13], and VRF benchmark with 240 Small (S) and 240 Large (L) instances [14]. The algorithm was implemented in C# and all the computations were carried out on a computer with two Intel Xeon E5-2660 v4 CPUs (14 cores, each with 2.0 GHz base clock speed).

The results of $SP(N')N+(N)$ (Table I) show that the use of the N -list technique after performing N' steps of insertion phase of NEH can improve the results of the N -NEH+ algorithm, i.e., the $SP(N')N+(N)$ method can outperform N -NEH+. However, if N' is too large ($N' > 0.3n$), the probability of obtaining worse results is greater than in the case of $N' = 0$. The most interesting results are obtained for $N' = 0.1n$ and $N' = 0.2n$. However, it should be noted that improving the results is not possible for all lengths of the N -list.

The results of $SP+(N')N+(N)$ (Table II) show that the greatest decrease in the ARPD values can be observed for smaller values of N' . It can also be observed that for $N' = 0.1n$, the average improvement of N -NEH+ results is 5.9% and for $N' = 0.3n$, the average decrease in the ARPD value is greater than 11.6%. For all the considered benchmarks, a regularity regarding the effectiveness of using the $SP+(N')N+(N)$ method can also be noticed: the longer the N -list, the higher the average percentage decrease in the ARPD value.

From Table III it can be concluded that the larger N' , the shorter computational time of the $SP(N')N+(N)$ algorithm. The computational time also decreases when increasing the length of the N -list. The average decrease in computational time between $SP(0)N+(2)$ (i.e., $N+(2)$) and $SP(0.9n)N+(2)$ ranges from 14% to 16%, and the average decrease in computational time between $SP(0)N+(16)$ (i.e., $N+(16)$) and $SP(0.9n)N+(16)$ ranges from 63% to 69%. Table IV shows that the computational time of $SP+(N')N+(N)$ increases both with N and N' , however the increase with N is much faster.

The ARPD and ACPU values are also shown in Figures 1–3, where the y -axis represents ARPD and x -axis represents ACPU (in logarithmic scale) of the $SP+(N')N+(N)$, NEH

and N -NEH+ algorithms. As can be seen from the figures, for all benchmarks, it is difficult to indicate the parameters for which the SP+ method is dominated by other algorithm. In most cases, the usage of $SP+(N')N+(2)$ does not allow obtaining non-dominated results. The results for the remaining parameters form the Pareto front.

Table V presents the comparison of the APRD and ACPU values of the selected algorithms for solving $Fm|prmu|C_{max}$ (cf. [15]). It is not hard to see that these results confirm the good performance of the $SP+(N')N+(N)$ algorithm. This means that the new strategy of delaying the usage of the N -list allows to improve the results of N -NEH+ and makes the $SP+(N')N+(N)$ even more competitive with FRB algorithms [16]. One may argue that in most cases the $SP+(N')N+(N)$ algorithm is more time consuming than FRB algorithms; however, you should keep in mind that $SP+(N')N+(N)$ is (unlike FRB) a construction algorithm, and what is more, it allows you to obtain the entire population of solutions, not just one solution as in the case of FRB.

IV. CONCLUSION

This work proposes a Starting Point method that improves N -list technique-based algorithms for solving the permutation flow-shop problem with makespan criterion. The general idea behind the proposed method is to delay the usage of the N -list technique. The extensive numerical experiments on the standard Taillard's and VRF benchmarks show that for both benchmarks the Starting Point method significantly improves the results of the N -NEH and N -NEH+ algorithms. According to the best knowledge of the authors, the analyzed $SP+(N')N+(N)$ algorithm allows obtaining the best results among the results of existing construction algorithms. It is also worth noting that, unlike the more efficient FRB algorithm (which is not construction algorithm), the $SP+(N')N+(N)$

Fig. 1. APRD vs. ACPU (in logarithmic scale) of $SP+(N')N+(N)$ algorithm on Taillard's instances.

algorithm can return not just one but multiple complete rankings. This issue is important because the results of the $SP+(N')N+(N)$ algorithm may be used as the initial population for genetic algorithms. The last important aspect of the $SP+(N')N+(N)$ algorithm is the ease of parallelization of the computations (e.g., for different values of N' and N). For example, the computation time of $SP+(0.3n)N(N)$ run is parallel on 4 cores (one core = one N' value), is equal to the computational time of N -NEH for the same length of the N -list. At the same time, the improvement in the APRD value for different benchmarks ranges from 6.8% to even 17.2%.

Abstract—In this paper we solve a variant of the multi-hop influence maximization problem in social networks by means of a hybrid algorithm that combines a biased random key genetic algorithm with a graph neural network. Hereby, the predictions of the graph neural network are used with the biased random key genetic algorithm for a more accurate translation of individuals into valid solutions to the tackled problem. The obtained results show that the hybrid algorithm is able to outperform both the biased random key genetic algorithm and the graph neural network when used as standalone techniques. In other words, we were able to show that an integration of both techniques leads to a better algorithm.

I. INTRODUCTION

Social networks form part of our daily lives. Whether a person is an artist or an engineer, a student or an academic, young or old, or a spartan troll, the person most likely is embedded in one or more social networks. People use social networks to communicate through audiovisual media or text messages, to help others, or even to attack them. In other words, people *influence* other people, either in a positive or in a negative way. Note that the world’s leading technology companies invest huge amounts of money in advertising in social networks. For any social network it is essential to be aware of the transmission of information and its impact.

The identification of a group of users who can influence as many people as possible is a problem called influence maximization (IM). This problem was defined by Kempe et al. in 2003 [1]. By solving the IM problem, a set of adequate people can be identified, for example, for spreading the news about a certain product on a social network. In this way, the dissemination of the product can be supported and eventually maximized. The IM problem has been studied, for example, in the context of dealing with emerging negative opinions [2], social advertising [3], and influence maximization on Twitter for marketing campaigns [4]. Also, different variations of the IM problem have been studied. One example concerns the case of social networks that have a diversity of communities, which implies that there are different types of users who can influence in different ways [5]. Another example is the one of trying to maximize influence in time-evolving social networks [6].

A social network can be viewed as a (directed) graph in which the users are the nodes and user interactions are modeled by arcs. Furthermore, the propagation of influence is often simulated by models such as the independent cascade (IC) model and the linear threshold (LT) model, which might be deterministic or probabilistic. In any case, both models consider one-hop coverage, that is, if a person is covered depends exclusively on its direct neighbors. Although it is common to consider one-hop coverage models in IM problems, the interaction in social networks may also be of multi-hop nature [7].

In this paper we tackle a variant of the IM problem which can be seen as a variant of the classical minimum dominating set problem (MDSP) in a directed graph $G = (V, A)$. In the MDSP, the task is to identify a set of nodes $U \subseteq V$ of minimum cardinality such that for each node $v \in V$ the following holds: either (1) $v \in U$, or (2) it exists at least one node $v' \in U$ such that $(v', v) \in A$, where (v', v) is the directed arc from v' to v . In other words, the classical MDSP considers one-hop coverage. In contrast, in the problem tackled in this paper—known as the multi-hop influence maximization problem (k - d DSP)— d -hop coverage is considered. More specifically, in the k - d DSP the task is to find a set $U \subseteq V$ of cardinality k such that the set $C_U \subseteq V$ of nodes that are covered (or influenced) by U is of maximal cardinality. Hereby, a node v forms part of C_U —that is, v is said to be covered (or influenced) by U —if there exists a node $v' \in U$ such that the shortest directed path from v' to v consists of at most d arcs. As an example, consider Figure 1, where $k = 2$ and the two nodes with a purple color form part of set U , that is, $U = \{v_4, v_5\}$. In case $d = 1$ it holds that $C_U = \{v_4, v_5, v_3, v_6, v_7\}$ because v_3, v_6 and v_7 are in 1-hop distance from a node in U . In other words, the objective function value of U is 5. In case $d = 2$, $C_U = \{v_4, v_5, v_3, v_6, v_7, v_2, v_8, v_{11}\}$ and the objective function value of U would be 8. Finally, in case $d = 3$, $C_U = V$ and the objective function value would be 11.

For a large-scale graph, such as a large social network, exact solutions to the k - d DSP are costly to compute. Therefore, researchers have focused on heuristic and on machine learning

Fig. 1. **Multi-hop influence process.** Given is a directed graph with 11 nodes and 12 arcs (top). Let us assume the k - d DSP is solved with $k = 2$. The two purple nodes (v_4 and v_5) form part of the example solution U . If $d = 1$ (bottom left) then nodes $\{v_3, v_7, v_6\}$ are 1-hop covered by U . If $d = 2$ (bottom center) then nodes $\{v_2, v_3, v_7, v_8, v_6, v_{11}\}$ are 2-hop covered by U . Finally, if $d = 3$ (bottom right), then all remaining nodes of the graph are 3-hop covered by U .

techniques for solving this problem (see Section II). In this paper, we present a novel hybrid algorithm to solve k - d DSP. This algorithm is obtained through an integration of (1) a new graph neural network (GNN) called graph inverse attention network (GRAT) that incorporates the influence of the neighbourhood into the feature embedding of each node [8], and (2) a biased random key genetic algorithm (BRKGA) [9]. More specifically, the information provided by the GNN is used in the BRKGA as greedy information. Our algorithm is evaluated on real-world networks with up to 500.000 nodes and 1 million arcs. Experimental results prove that our hybrid method is at least as good as the two individual techniques in most cases. Therefore, our method is another example for the successful integration of a GNN framework with a metaheuristic to boost the metaheuristics' performance.

The article is organized as follows. Section II introduces prior and related work. In Section III, we provide a more technical description of the k - d DSP. In Section IV, we present our hybrid approach. In Section V, we compare and analyze our hybrid algorithm on real-world data sets. Finally, Section VI concludes the work with some discussions on the utilized type of hybridization.

II. RELATED WORKS

As mentioned before, most of the works on influence maximization (IM) in social networks make use of the independent cascade (IC) and the linear threshold (LT) diffusion models for calculating the influence of solutions. Chen et al. [10], [11] present a fined-tuned heuristic for generating scalable solutions

to the IM problem and an improved runtime in comparison to previous approaches. Jung et al. [12] provide an even faster heuristic for the application to large graphs. Goyal et al. [13] added Monte Carlo simulation in order to obtain an improved heuristic.

Multi-hop influence is a way of measuring the influence of a group of people (set of nodes) in IM problems that has been studied recently. Nguyen et al. [14] proposed a heuristic which takes into account the probability of each node in the network for contributing to a high influence spread. However, the proposed algorithm is only evaluated on small graphs of less than 30.000 nodes. With respect to large graphs, Nguyen et al. [15] presented an alternative heuristic that consists of three phases: pre-optimization to reduce the size of the graph, a construction phase to build a k -dominating set, and post-optimization by removing redundant nodes from the set. This algorithm improves in speed over the one from [16]. However, by doing so it sacrifices performance for a reduction of computation time.

Recently, machine learning techniques have entered the scene to solve combinatorial problems [17]. An early example is S2V-DQN, which is a general reinforcement learning (RL) framework for combinatorial optimization problems in graphs proposed by Khalil et al. [18]. It uses graph neural networks (GNNs) for graph embedding with partial solutions and a *deep Q-network* (DQN) for node selection. This framework is more and more used by the community working with learning techniques for combinatorial optimization.

In the same line, FASTCOVER is a very recent unsupervised

learning framework for solving the k -dDSP by Ni et al. [8]. It uses a multi-layer GNN known as *graph reversed attention network* (GRAT) for generating for each node of a given graph a probability to belong to the optimal solution. The output of FASTCOVER are the k nodes with the highest probability. The authors of [8] show that FASTCOVER outperforms the existing heuristics.

III. PROBLEM DEFINITION

Many optimization problem in social networks can be formalized by modeling the social network as a directed graph $G = (V, A)$, where V is the set of nodes and A is the set of directed arcs present in the graph. This is also the case for the multi-hop influence maximization problem tackled in this paper, denoted by k -dDSP.

The most important concept in this context is the one of the *influence* $I_d(u) \subseteq V$ of a node $u \in V$, which depends on two things:

- 1) Parameter $d \geq 1$, which is part of the problem input.
- 2) A distance measure $dist(u, v)$ between nodes. In the context of this paper, $dist(u, v)$ is defined as the length—in terms of the number or arcs—of the shortest directed path from u to v in G .

With this we can provide the definition of $I_d(u)$ as follows:

$$I_d(u) := \{v \mid dist(u, v) \leq d\} \quad (1)$$

In other words, $I_d(u)$ is the set of all nodes of G that can be reached from u by means of a directed path with at most d arcs. We say that u influences (or covers) all nodes from $I_d(u)$. This definition can naturally be extended to sets of nodes in the following way:

$$I_d(U) := \bigcup_{u \in U} I_d(u) \quad \forall U \subseteq V \quad (2)$$

That is, $I_d(U)$ is the set of all nodes of G that are influenced by at least one node from U .

Valid solutions to the k -dDSP are all sets $U \subseteq V$ such that $|U| \leq k$, that is, any valid solution may consists of at most k nodes. The goal of the k -dDSP is to find a valid solution $U^* \subseteq V$ such that $|I_d(U^*)| \geq |I_d(U)|$ for all valid solutions U to the problem. In other words, the objective function value of a valid solution U is $|I_d(U)|$. In technical terms,

$$\begin{aligned} \max_{U \subseteq V} & |I_d(U)| \\ \text{s.t.} & |U| \leq k \end{aligned} \quad (3)$$

Finally, note that the k -dDSP was proven to be NP-hard in [8], [19].

IV. METHODOLOGY

In this section, we present a novel hybrid algorithm that emerges from the integration between a BRKGA and a GNN framework for solving the k -dDSP in social networks. To begin, we briefly introduce both methods individually. Then we present the developed hybridization strategy.

Algorithm 1 The pseudo-code of BRKGA

Require: a directed graph $G = (V, E)$

Ensure: values for params. $p_{size}, p_e, p_m, prob_{elite}, seed$

```

1:  $P \leftarrow \text{GENERATEINITIALPOPULATION}(p_{size}, seed)$ 
2:  $\text{EVALUATE}(P)$  ▷ dependent part (greedy)
3: while computation time limit not reached do
4:    $P_e \leftarrow \text{ELITESOLUTIONS}(P, p_e)$ 
5:    $P_m \leftarrow \text{MUTANTS}(P, p_m)$ 
6:    $P_c \leftarrow \text{CROSSOVER}(P, p_e, prob_{elite})$ 
7:    $\text{EVALUATE}(P_m \cup P_c)$  ▷ dependent part (greedy)
8:    $P \leftarrow P_e \cup P_m \cup P_c$ 
9: end while
10: return Best solution in  $P$ 

```

A. Biased Random Key Genetic Algorithm

We implemented a Biased Random Key Genetic Algorithm (BRKGA), which is a well-known GA variant for combinatorial optimization. In general, a BRKGA is problem-independent because it works with populations of individuals that are vectors of real numbers (random keys). The problem-dependent part of each BRKGA deals with the way in which individuals are translated into solutions to the tackled problem. The problem-independent pseudo-code of BRKGA is provided in Algorithm 1.

In the following, we first describe the independent or generic part of the algorithm. It starts by invoking function $\text{GenerateInitialPopulation}(p_{size}, seed)$, which generates a population P formed by p_{size} individuals. In case $seed = 0$, all p_{size} individuals are randomly generated. Hereby, each individual $\pi \in P$ is a vector of length $|V|$, where V is the set of nodes from the input graph. For this purpose, the value at position i of π , denoted by $\pi(i)$, is chosen uniformly at random from $[0, 1]$, for all $i = 1, \dots, |V|$. In case $seed = 1$, only $p_{size} - 1$ individuals are randomly generated. The last individual is obtained by defining $\pi(i) := 0.5$ for all $i = 1, \dots, |V|$. Next, the individuals from the initial population are evaluated. This means, each individual $\pi \in P$ is transformed into a valid solution U_π to the k -dDSP, and the value $f(\pi)$ of π is defined as follows: $f(\pi) := |U_\pi|$. The transformation of individuals to valid solutions is discussed below.

Then, at each iteration of the algorithm, the operations to be performed are as follows. First, the best $\max\{\lfloor p_e \cdot p_{size} \rfloor, 1\}$ individuals are copied from P to P_e in function $\text{EliteSolutions}(P, p_e)$. Second, a set of $\max\{\lfloor p_m \cdot p_{size} \rfloor, 1\}$ so-called mutants are generated and stored in P_m . These mutants are random individuals generated in the same way as the random individuals from the initial population. Finally, a set of $p_{size} - |P_e| - |P_m|$ individuals are generated by crossover in function $\text{Crossover}(P, p_e, prob_{elite})$ and stored in P_c .

Each such individual is generated as follows: (1) an elite parent π_1 is chosen uniformly at random from P_e , (2) a second parent π_2 is chosen uniformly at random from $P \setminus P_e$, and (3) an offspring individual π_{off} is generated on the basis of π_1 and

π_2 and stored in P_c . In the context of the crossover operator, value $\pi_{off}(i)$ is set to $\pi_1(i)$ with probability $prob_{elite}$, and to $\pi_2(i)$ otherwise. After generating all new offspring in P_m and P_c , these new individuals are evaluated in function `Evaluate()`; see line 7. Note that the individuals in P_e are already evaluated. Finally, the population of the next generation is determined to be the union of P_e with P_m and P_c .

The evaluation of an individual (see lines 2 and 7 of Algorithm 1) is the problem-dependent part of our BRKGA algorithm. The function that evaluates an individual is often called the *decoder*. In our case, we make use of a simple greedy heuristic which is based on the intuition that nodes with a higher degree (number of neighbors) are more likely to have a high influence than nodes with a lower degree. Hereby, the set of neighbors $N(v_i)$ of a node $v_i \in V$ is defined as follows: $N(v_i) := \{v_j \in V \mid (v_i, v_j) \in A\}$, that is, neighbors of v_i are only those nodes that can be reached via a directed arc from v_i . The greedy value $\phi(v_i)$ of each $v_i \in V$ is defined as follows:

$$\phi(v_i) := |N(v_i)| \cdot \pi(i) \quad (4)$$

In other words, the greedy value of a node v_i is obtained by multiplying the degree of v_i with the numerical value found at position i of the individual to be translated into a solution. Subsequently, solution U_π is obtained by adding the k nodes with the highest greedy values.

Note that, in Section IV-C, greedy function ϕ will be modified in order to obtain a hybrid algorithm.

B. Graph Neural Network Framework

The general objective of a graph neural network (GNN) [20]–[22] is to automatically find patterns in data. In contrast to more classical deep learning techniques, GNNs directly work on graphs. Therefore, they can be used to make predictions about nodes, arcs, or subgraphs without the need for unnecessary transformations of the graph. The crucial idea of GNNs is to iteratively update so-called node representations by combining the representations of a nodes' neighbors with its own representation. Given a graph $G = (V, A)$, $H^l \in \mathbb{R}^{|V| \times C}$ are node attribute matrices, one for each layer $l \in \{0, 1, \dots, L\}$ of the GNN. Note that C is hereby the number of chosen features. Each line in such a matrix is a representation for the respective node. The final goal of a GNN is to learn competent node representations in these matrices.

In order to adapt/train the representations to be useful for a specific task, there are two actions that are successively performed at each GNN layer: (1) *Aggregate*, which aggregates all the information from the neighbors of each node, and (2) *Combine*, which updates the node representations by combining the aggregated information from the neighbors with the current node representation. Based on this, the general framework of a GNN can be specified as follows:

$$\begin{aligned} a_v^l &= \text{AGGREGATE}^l \{ H_u^{l-1} : u \in N(v) \} \\ H_v^l &= \text{COMBINE}^l \{ H_v^{l-1}, a_v^l \} \end{aligned}$$

where $N(v)$ is the set of neighbors of node v . H^K is the node representation matrix for each layer. Once the training process finishes, the final representations can be used for making predictions.

A GNN can be trained, for example, in order to make predictions about the probability of each node to belong to the optimal solution of the k -dDSP. In fact, as mentioned already in the section on related work, such a GNN approach was recently presented in [8]. This GNN—called FASTCOVER (FC)—is an unsupervised GNN framework. FC can be characterized as follows: (1) the features of all nodes are embedded as vector spaces, and the direction of each arc is reversed, (2) a multi-layer GNN known as *graph reversed attention network* (GRAT) assigns each node to its value within $[0, 1]$, and (3) the representations of the GNN are optimized in the training stage through a differentiable loss function over all nodes scores.

The GRAT layer is the heart of FC. In particular, in contrast to a standard *graph attention network* (GAT) [23], the so-called attention mechanism is integrated at the origin nodes instead of the destination nodes. The central idea is that the nodes with more influence are likely to receive a stronger reward. This means a higher probability of getting a potential score.

C. The Hybrid BRKGA Algorithm

Our hybrid algorithm—henceforth called BRKGA+FC—starts with two offline steps. Given a network in which the k -dDSP must be solved, first, all node probabilities are extracted from the trained FC model; note that the prior training process is described in the next section. This probability is denoted by $p_i \in (0, 1]$ for each $v \in V$. Then, the original greedy function $\phi()$ from Eq. 4 is replaced by the following one that incorporates the node probabilities extracted from FC:

$$\phi_{FC}(v_i) := |N(v_i)| \cdot \pi(i) \cdot p_i \quad \forall v_i \in V \quad (5)$$

The hypothesis is that good/correct predictions will bias the algorithm towards the area in the search space in which an optimal solution is located, or, at least, solutions of very high quality. Moreover, we expect the probabilities obtained from FC to undo the bias introduced by the degree of a node, which might sometimes be misleading. The integration process is also shown in Figure 2.

V. EXPERIMENTAL EVALUATION

This section is divided into three parts. First, we will describe the preparation of the data for training and evaluation, and the parameter tuning procedure. Then, the experimental setting and the numerical results of three algorithms will be presented (FC, BRKGA, and BRKGA+FC). In this context note that FC can, of course, be used as a standalone technique by simply adding the k nodes with highest probabilities to the solution. Finally, we will analyse the algorithms graphically by means of so-called search trajectory networks.

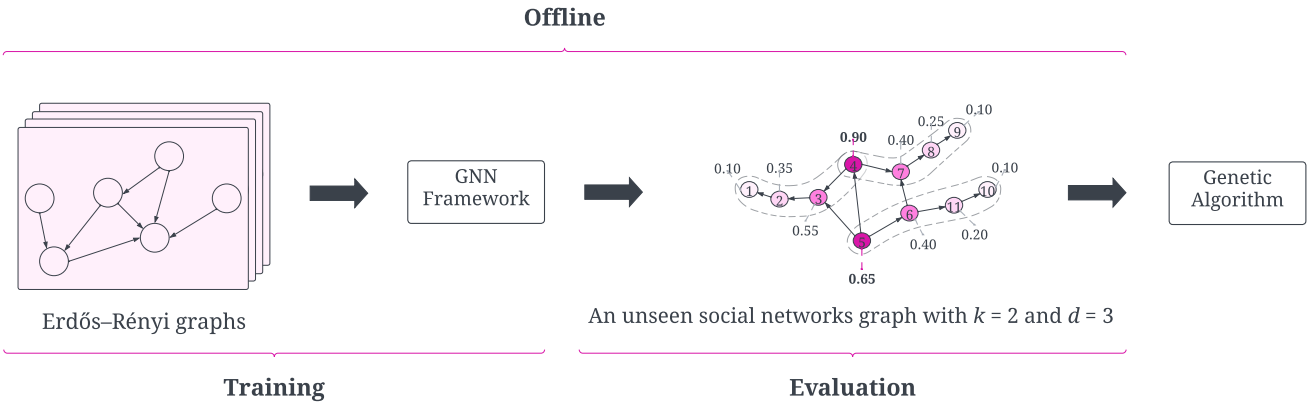

Fig. 2. **Hybridization Process.** The integration of BRKGA with FC starts with two offline steps concerning FC as follows. The training phase begins by using 15 random graphs (Erdős–Rényi). This provides us with a trained version of FC (called GNN Framework in the graphic). Then, the social network in which the k - d DSP is to be solved is presented to FC, which returns probabilities for all nodes of the network to belong to the optimal solution. Finally, the final phase consists of integrating these probabilities into the BRKGA (called Genetic Algorithm in the graphic).

TABLE I
TUNING CONFIGURATION. FINAL PARAMETER SETTING FOR BRKGA AND BRKGA+FC (FOR $k \in \{32, 64, 128\}$)

Parameters	Tuning domain	BRKGA			BRKGA+FC		
		k			k		
		32	64	128	32	64	128
P_{size}	[50, 250]	113	162	132	183	198	137
P_e	[0.1, 2.0]	0.17	0.24	0.25	0.19	0.22	0.2
P_m	[0.3, 5.0]	0.27	0.22	0.14	0.3	0.21	0.21
$prob_{elite}$	[0.01, 0.1]	0.6	0.59	0.58	0.57	0.67	0.67
$seed$	{0, 1}	0	0	0	1	1	1

A. Data Preparation and Tuning Process

We decided to execute experiments for three different values of k , that is, $k \in \{32, 64, 128\}$. For this reason we trained 3 different FC models, one for each value of k . Figure 3 illustrates that each model uses the fixed-parameter $d = 1$. In other words, the same FC model is used for applications of FC and BRKGA+FC for all $d \in \{1, 2, 3\}$. This was done for reducing the computational burden. Nevertheless, in the analysis of the final results we will see that this had some influence on the quality of the node probabilities extracted from the FC models, that is, these probabilities seem to loose accuracy with a growing value of d .

The three FC models (for each value of k) were trained as follows. First, we used 15 Erdős–Rényi graphs [24] with 4000 nodes each, similar to what is presented by the authors of [8]. After the training phase, the probabilities for all 19 social networks used later for the final experimental evaluation are extracted (for each value of $d \in \{1, 2, 3\}$) and stored in text files.

In order to ensure a fair experimental evaluation, both BRKGA and BRKGA+FC were tuned for each value of k

using 10 test graphs. In particular, we used Erdős–Rényi graphs¹ with $n = 25.000$ nodes and an arc probability of $p = 10/n$. The tuning was done using a well-known tool called *irace* [25]. The considered parameter domains together with their finally chosen values are provided in Table I. Note that the number of nodes (25.000) of the test graphs corresponds to approximately the average number of nodes in the networks used for the final experimental evaluation (presented in Section V-B). The size of the tuning graphs is reasonable because the population size parameter in BRKGA is highly dependent on the size of the graphs. In the case of FC, we do not modify the parameters and the configuration as described in [8].

Note that the training phase of FC and the parameter tuning procedure for BRKGA and BRKGA+FC were performed with random graphs to maintain generality.

B. Experimental Evaluation

In this subsection, we apply all three approaches—FC, BRKGA and BRKGA+FC—to 19 real-world social networks from the SNAP library [26]. Each of these networks is a directed, unweighed graph. The sizes of these graphs are provided in Table II (columns $|V|$ and $|A|$).

We use three different values of $k \in \{32, 64, 128\}$. Also for d , the multi-hop influence parameter, we used three different values: $d \in \{1, 2, 3\}$. Note that $k = 64$ was used for the experimental evaluation on social networks of FC [8]. In order to provide a broader experimentation and analysis we also considered two additional values of k : a smaller one (32) and a larger one (128). The reason to not consider values of d greater than 3 is that we were not able to observe substantial differences to the case $d = 3$.

¹Instances can be downloaded from the repository <https://github.com/camilochs/genetic-algorithm-with-gnn>

TABLE II

NUMERICAL RESULTS OBTAINED BY FC, THE BRKGA, AND OUR HYBRID ALGORITHM BRKGA+FC ON 19 WELL-KNOWN SOCIAL NETWORKS. FOR EACH NETWORK THE ALGORITHMS WERE APPLIED FOR $d \in \{1, 2, 3\}$ AND $k \in \{32, 64, 128\}$. FOR $k = 32$ BRKGA+FC WINS IN 73% OF THE CASES; FOR $k = 64$ IN 71%; AND FOR $k = 128$ IN 66%.

Instance	V	E	Distance	$k = 32$			$k = 64$			$k = 128$

As FC is a deterministic approach (at least for what concerns the use of the model after training), it was applied exactly once to each of the 19 networks, for each combination of k and d . On the contrary, both BRKGA and BRKGA+FC were applied 30 times to each network and combination of k and d . As a computation time limit of BRKGA and BRKGA+FC we used 900 CPU seconds for each run. All experiments were performed on machines with an Intel(R) Xeon(R) Silver 4210 CPU @ 2.20GHz. The FC framework uses Python 3 and our implementations of BRKGA and BRKGA+FC were coded in C++.

In Table II we compare the results of FC with the average results of BRKGA and BRKGA+FC over 30 runs. The following observations can be made:

- Generally, both BRKGA and BRKGA+FC outperform FC which, in turn, was shown in [8] to outperform the existing heuristics for solving the k -dDSP. The only exceptions are 1 case with $k = 64$ and 9 cases with $k = 128$. This suggests that the performance of FC (when compared to the BRKGA versions) improves with an increasing value of k .
- Even though BRKGA generally outperforms FC, the

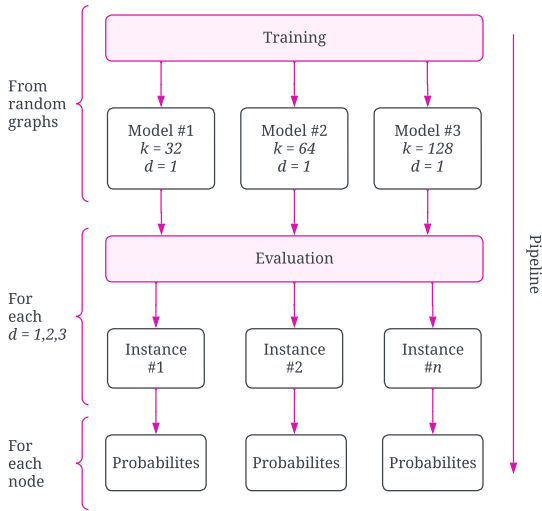

Fig. 3. **Data preparation and pipeline.** The pipeline starts by training three FC models, one for each $k \in \{32, 64, 128\}$. Random graphs (Erdős–Rényi) were used for this purpose. Next, the evaluation of the FC models is performed for each of the 19 instances (social networks), for each value of parameter $d \in \{1, 2, 3\}$. Finally, the obtained probabilities (FC output) are exported and stored in text files.

hybrid algorithm BRKGA+FC generally benefits from the use of the probability information extracted from FC for the translation of individuals into solutions. This advantage of BRKGA+FC over BRKGA is greatest for the smallest value of d (that is, $d = 1$). In this case BRKGA+FC outperforms BRKGA in 73% of all cases.

- The worst performance of BRKGA+FC is obtained for $k = 32$ and $d = 3$ (47% of superiority). This may be due to two possible reasons: (1) FC might find it difficult to detect pattern for rather small values of k ; (2) all our FC models were trained for $d = 1$, which might suggest that our results could be improved by specifically training FC for each value of d .

Summarizing, we can say that making use of information from the GNN framework FC within our BRKGA clearly improves the algorithm.

C. Analysis

There are cases when our hybrid algorithm does not perform as expected. This is the case when the results are similar to the ones of BRKGA, or when they are even worse than the ones of BRKGA. In an attempt to analyse such cases we used the Search Trajectory Networks (STNs) tool from [27], which allows to visualize the trajectories of algorithms in the search space. Moreover, it lets us compare the behavior of more than one metaheuristic. For this analysis we chose three network corresponding to three different cases as outlined in Figure 4. The obtained graphics allow to make the following observations.

- 1) Figure 4 (a). This is a case in which the hybrid algorithm BRKGA+FC does not perform well in comparison to BRKGA. We can see in the graphic that both algorithms are clearly focused on different areas of the search space. In particular, BRKGA is attracted by a certain area of the search space. Nevertheless, the best solution found (red dot), even though it belongs to this part of the search space, it is not close to the area of attraction (see the two larger grey triangles). One hypothesis is that the probabilities provided by the graph neural network framework (FC) for this instance are rather misleading.
- 2) Figure 4 (b). In this case, the performance of both algorithms is comparable. Again, the two algorithm version are focused on different areas of the search space. This time there is a minimal overlap between two of the algorithm trajectories (see the light gray dot in the middle of the graphic). Interestingly, even though both algorithms find a best solution of the same quality, these two solutions are clearly different to each other (see the two red dots).

However, as mentioned before, in a majority of cases BRKGA+FC outperforms BRKGA. Such a case is visualized in the graphic of Figure 4 (c). It can be observed that the trajectory of BRKGA+FC is more bounded and, therefore, it is not dispersed in the search space as it occurs for BRKGA. Moreover, the best solution is found in the area of the search space that attracts BRKGA+FC. This means that, in this case, the information provided by the FC is very useful.

VI. CONCLUSION AND FUTURE WORK

In this work we have devised a hybrid algorithm combining a biased random key genetic algorithm with a graph neural network called FASTCOVER. This was done in the context of an NP-hard combinatorial optimization problem dealing with the maximization of influence spreading in social networks. In particular, our hybrid algorithm makes use of the recommendations provided by FASTCOVER (in the form of probabilities) for translating individuals to valid solutions to the tackled problem. The results have shown that, in a majority of the cases, our hybrid algorithm outperforms both its individual algorithmic components: the biased random key genetic algorithm and FASTCOVER. The experimental evaluation of our approaches was done in the context of 19 real-world social networks.

One opportunity to advance this type of hybridization is to address other problems using a similar integration methodology, especially taking the recent progress of graph representation learning into account.

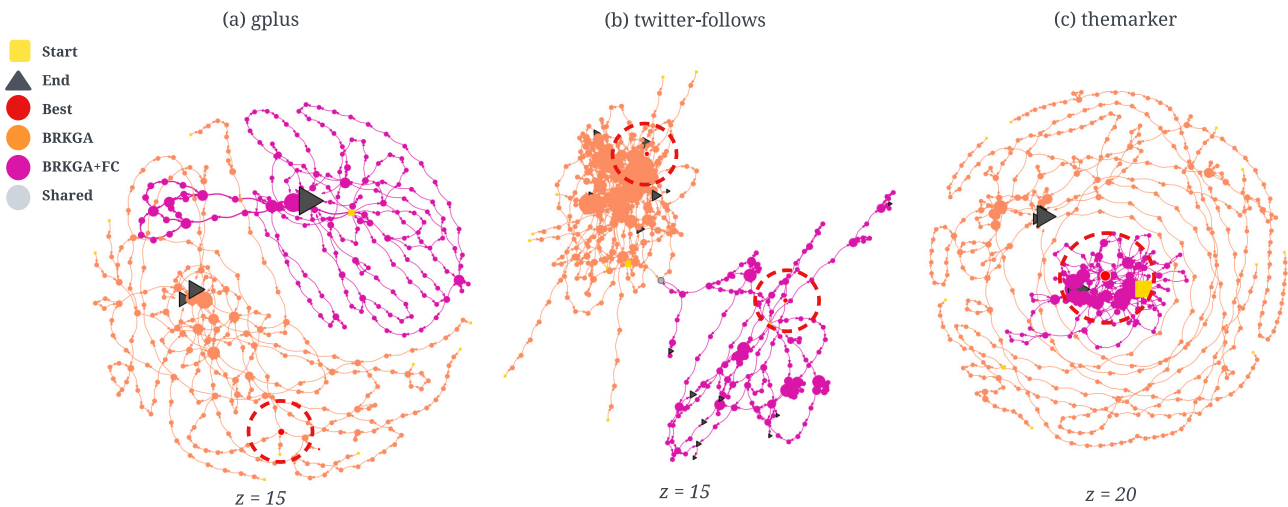

Fig. 4. Search trajectory analysis concerning BRKGA and BRKGA+FC. The three graphics show 10 executions (trajectories) of BRKGA (orange) and BRKGA+FC (pink) for three instances (gplus, twitter-follows, and themarker). The value of z indicates the degree of search space partitioning used to generate the graphics (see [27]). Yellow squares indicate the start of trajectories, while gray triangles indicate their ends. Also, light gray circles indicate that both algorithms passed through this location of the search space, while red circles indicate the best solutions found. (a) A case in which BRKGA is able to outperform BRKGA+FC (gplus). (b) A case in which BRKGA and BRKGA+FC achieve similar results (twitter-follows). (c) A case in which BRKGA+FC outperforms BRKGA (themarker). For each graphic we used the force-directed layout based on physical analogies, not relying on any assumptions about the structure of the networks.

Abstract—An instance of a weighted Stackelberg load balancing game is given by a set of identical machines, a set of variable-length jobs and a parameter $0 \leq \alpha \leq 1$. A centralized authority, denoted *the leader*, selects a subset of the jobs whose total length is at most an α -fraction of the total length and determines their assignment on the machines. After the controlled jobs are assigned, the remaining jobs join the schedule. They act selfishly, each determining its own assignment.

Our work combines theoretical and experimental results for this setting. We suggest various heuristics for the leader and analyze their performance.

I. INTRODUCTION

IN RESOURCE allocation applications, a set of resources is used by a set of clients (users). For example, in job-scheduling applications, servers process jobs; in communication or transportation networks, traffic is routed on network links. In some settings, the users are assigned to the different resources by a centralized authority. The centralized authority is aware of all clients' requests and can utilize the system in the best possible way. Other resource allocation applications lack a central authority and are managed by multiple strategic users, whose individual payoff is affected by the assignment of other users. As a result, game theory has become an essential tool in the analysis of resource-allocation services. In the corresponding game, every client is a selfish player who aims at maximizing his own utilization.

In this work, we consider systems in which the two models are combined. That is, some of the users obey a central authority and some are selfish. The goal of the system is to assign the centrally controlled users such that the total system performance is optimized. We formulate this goal as an optimization problem via *Stackelberg games*, in which one player, corresponding to the centralized authority, acts as a *leader* and the rest of the players, corresponding to the selfish users, as *followers*. The problem is then to compute a strategy for the leader (a Stackelberg strategy) that cause the followers to react in a way that is as good as possible for the social utility.

We focus on load balancing games in job scheduling systems. The users are jobs having variable weights and the resources are machines. Every job should be assigned on a single machine. The cost of a job depends on the total load on its machine and the social cost is given by the load on the most loaded machine. In centralized systems, this load

balancing scenario is the well-studied *minimum Makespan* problem. It was well-studied also as a game where all the jobs are selfish, however, it has not been studied in an environment with a mixed type of jobs. All previous works on Stackelberg strategies consider non-atomic (splittable) players – every player has a neglected load and the total load can be distributed among the machines in an arbitrary way. Thus, our work initiate the study of Stackelberg strategies for weighted singleton congestion games.

Our goal is to develop Stackelberg strategies that guarantee load balancing and a low social cost. We will consider several different models, depending on the different capabilities of the leader.

In our model, the leader can select the jobs it controls and its power is given by a parameter $0 \leq \alpha \leq 1$, such that it can select any subset of jobs whose total load is at most an α fraction of the total load.

As we show, in some instances, the leader should better exploit its power only partially and let more jobs select their strategy selfishly. Intuitively, this is due to the fact that the leader acts first and its assignment is irrevocable.

The scenarios we propose to study arise in real life applications that provide service to a mixture of independent and controlled clients. For example, several companies suggest computing services on shared machines for private users (using cloud services) as well as local computation tasks. Similarly, in routing problems, some users obey and consult a navigation app, while others don't. The navigation app acts as a leader that determines the decisions (selected path) of some of the clients.

A. Notation and Problem Statement

A load balancing game is given by $G = (\mathcal{J}, \mathcal{M}, \{p_j\} \forall j \in \mathcal{J})$, where \mathcal{J} is a set of n jobs, \mathcal{M} is a set of m machines, p_j is the *weight* (also denoted *size*) of job j . In unweighted games, all the jobs have the same unit size, that is, $\forall j, p_j = 1$.

A Stackelberg load balancing game is given by (G, α) , where G is a load balancing game and $0 \leq \alpha \leq 1$ denotes the maximal fraction of the load controlled by the leader.

Let A be the set of jobs controlled by the leader. Let $P = \sum_{j \in A} p_j$. We have that $\sum_{j \in A} p_j \leq \alpha P$. A profile of a game is a *schedule* $s = \langle s_1, \dots, s_n \rangle \in M^n$ describing the machines on

which the jobs are assigned¹. If $j \in A$ then s_j is determined by the leader and if $j \in \mathcal{J} \setminus A$, then s_j is selected by player j .

For a machine $i \in \mathcal{M}$, the *load* on i in s , denoted $L_i(s)$, is the total size of the jobs assigned on machine i in s , that is, $L_i(s) = \sum_{\{j|s_j=i\}} p_j$. When s is clear from the context, we omit it. It takes p_j time-units to process job j on machine i . As common in the study of job-scheduling games, we assume that all the jobs assigned on the same machine are processed in parallel and have the same cost, defined as the machine's completion time. Formally, the cost of job j in profile s is $C_j(s) = L_{s_j}(s)$. The players that control jobs act selfishly, trying to minimize the cost of the job they control. The leader is trying to optimize some global objective function. Note that if $A = \mathcal{J}$ then all the jobs are controlled by the leader and we have a classical job scheduling problem.

The leader applies its strategy first and determines an assignment for the players in A . Afterwards, the players in $\mathcal{J} \setminus A$ join this partial schedule, each selecting selfishly an assignment for its job. The jobs assigned by the leader cannot change their assignment. The selfish jobs may change their assignment in response to other jobs' assignments.

For a profile s , a job $j \in \mathcal{J} \setminus A$ and a machine $s'_j \neq s_j$, let (s_{-j}, s'_j) denote the profile obtained from s by replacing the strategy of job j by s'_j . That is, the profile resulting from a migration of job j from machine s_j to machine s'_j . A profile s is a *pure Nash equilibrium* (NE) if no selfish job can benefit from unilaterally deviating from its strategy in s to another strategy; i.e., for every job $j \in \mathcal{J} \setminus A$ and every machine s'_j it holds that $C_j(s_{-j}, s'_j) \geq C_j(s)$. The cost of a schedule is defined to be the maximal completion time of a job, also known as *the Makespan* of the schedule, that is, $cost(s) = \max_{j \in \mathcal{J}} C_j(s)$.

It is well known that decentralized decision-making may lead to sub-optimal solutions from the point of view of society as a whole. For a game G , let $S(G)$ be the set of feasible profiles of G . We denote by $OPT(G)$ the cost of a social optimal (SO) solution; i.e., $OPT = \min_{s \in S(G)} cost(s)$. We quantify the inefficiency incurred due to self-interested behavior according to the *price of anarchy* (PoA) [16] and *price of stability* (PoS) [1], [20] measures. The PoA is the worst-case inefficiency of a pure Nash equilibrium, while the PoS measures the best-case inefficiency of a pure Nash equilibrium. Formally,

Definition 1.1: Let \mathcal{G} be a family of games and let G be a game in \mathcal{G} . Let $\Upsilon(G)$ be the set of pure Nash equilibria of the game G . Assume that $\Upsilon(G) \neq \emptyset$.

- The *price of anarchy* of G is the ratio between the *maximal* cost of a NE and the social optimum of G . That is, $PoA(G) = \max_{s \in \Upsilon(G)} cost(s)/OPT(G)$. The *price of anarchy* of the family of games \mathcal{G} is $PoA(\mathcal{G}) = \sup_{G \in \mathcal{G}} PoA(G)$.

We now define the inefficiency measure of a Stackelberg game.

¹In this paper, we only consider *pure* strategies. Unlike mixed strategies, pure strategies may not be random or drawn from a distribution.

Definition 1.2: Let $\langle \mathcal{G}, \alpha \rangle$ be a family of Stackelberg games where \mathcal{G} is a family of games and let G be a game in \mathcal{G} . Let $\Upsilon(G, \alpha)$ be the set of pure Nash equilibria of the game $\langle G, \alpha \rangle$. Assume that $\Upsilon(G, \alpha) \neq \emptyset$.

- The *price of anarchy* of $\langle G, \alpha \rangle$ is the ratio between the *maximal* cost of a NE and the social optimum of G . That is, $PoAL(G, \alpha) = \max_{s \in \Upsilon(G, \alpha)} cost(s)/OPT(G)$. The *price of anarchy* of the family of Stackelberg games $\langle \mathcal{G}, \alpha \rangle$ is $PoAL(\mathcal{G}, \alpha) = \sup_{G \in \mathcal{G}} PoAL(G, \alpha)$.

B. Related Work

The two extreme cases, of $A = \mathcal{J}$ and $A = \emptyset$ are well studied. The case $A = \mathcal{J}$ is the classical minimum makespan problem, while the case $A = \emptyset$ is the classical load balancing game.

The minimum makespan problem is an NP-hard problem and has a rich collection of approximation algorithms. For identical machines, the simple greedy List-scheduling (LS) algorithm [10] provides a $(2 - \frac{1}{m})$ -approximation to this problem. A bit better approximation ratio of $(\frac{4}{3} - \frac{1}{3m})$ is guaranteed by the Longest Processing Time (LPT) algorithm [11]. A PTAS for the minimum makespan problem on identical machines is given in [12]. For related machines (with various speeds), List-scheduling guarantees $\Theta(m)$ -approximation [4] and a PTAS is presented in [6].

Load balancing *game* consist of a set of jobs (players) and a set of machines. Each job is controlled by a selfish agent who aims to minimize his cost - given by the load on the machine it is assigned to ([21]). The concept of the price of anarchy (PoA) was introduced by Koutsoupias and Papadimitriou in [16]. They proved that the price of anarchy of job scheduling games is $2 - \frac{1}{m}$. In [7], Finn and Horowitz presented an upper bound of $2 - \frac{2}{m+1}$ for the price of anarchy in load balancing games with identical machines. Czumaj and Vöcking [5] gave tight bounds for related machines that grow as the number of machines grows.

Other related work consider Stackelberg strategies for resource allocation games with identical players and non-decreasing latency functions which can vary between the resources. In these games, the leader is characterized by the fraction $\alpha \in [0, 1]$ of the players it controls and an optimal allocation can be computed in polynomial time. Our model differs from the previous studies as we do not assume the players to have identical weight or strategy space, hence, the leader is characterized by the specific set of players it controls and calculating a socially optimum assignment is an NP-hard problem.

For routing games on parallel networks for with non-decreasing latency functions, it is known that computing an optimal Stackelberg strategy is NP-hard. There are two known approximation algorithms for the case of splittable (non-atomic) symmetric games with non-decreasing latency functions presented by Roughgarden in [18]; The *Scale* strategy which simply employs the optimal configuration scaled by the fraction of coordinated players. The best bound known for *Scale* PoA is $\frac{4}{3} - \frac{X}{3}$ where $X = \frac{(1-\sqrt{1-\alpha})(3\sqrt{1-\alpha}+1)}{2\sqrt{1-\alpha}+1}$

[13]. The *LLF* (Largest Latency First) strategy presented by Roughgarden in [18] assigns the controlled players to the largest cost strategies in the optimal configuration. The best known upper bound, achieved by Karakostas and Kolliopoulos [13], is equal to $\frac{4}{3}$ for $\alpha \leq \frac{1}{3}$ and $\frac{2(1-\alpha^2)}{2-\alpha-\sqrt{4\alpha-3\alpha^2}}$ for $\alpha > \frac{1}{3}$.

Subsequently, Kumar and Marathe [17] presented a fully polynomial-time approximation scheme for the problem of computing an optimal Stackelberg configuration on parallel links with polynomial latencies. Stackelberg routing in arbitrary networks is studied in [2].

The work mostly related to our study considers games with unsplittable (atomic) flows with non-decreasing latency functions. In these games, different machines may have different latency functions, that are not necessarily linear. The players are identical, but they do have a non-splittable constant size. Thus, the problem of calculating the optimal assignment is polynomially solvable, contrary to our model. Fotakis [8] studied *LLF* and a randomized version of *Scale* and gave upper and lower bounds for them. He also introduced the Stackelberg strategy λ -Cover which assigns to every resource either at least λ or as many coordinated players as the resource has in the social optimum. Finally, he also gave upper bounds for strategies obtained by combining λ -Cover with either *LLF* or *Scale* and upper bounds for games played on parallel links.

Vittorio and Vinci [3] then presented improved bounds for the three Stackelberg strategies studied by Fotakis [8]. For *LLF* they showed *PoA* of exactly $\frac{20-11\alpha}{8}$ for $\alpha \in [0, \frac{4}{7}]$ and $\frac{4-3\alpha+\sqrt{4\alpha-3\alpha^2}}{2}$ for $\alpha \in [\frac{4}{7}, 1]$. For λ -Cover they showed that the *PoA* is for affine functions is $\frac{4\lambda-1}{3\lambda-1}$ and $1 + \frac{4\lambda+1}{4\lambda(2\lambda+1)}$ for linear ones. Finally, for *Scale* they give a bound of $1 + \frac{(1-\alpha)(2h+1)}{(1-\alpha)h^2+\alpha h+1}$, where h is the unique positive integer such that $\alpha \in [r_L(h), r_U(h)]$, with $r_L(h) = \frac{2h^2-3}{2(h^2-1)}$, $r_U(h) = \frac{2h^2+4h-1}{2h(h+2)}$ and $r_L(1) = 0$.

To the best of our knowledge our work is the first to consider a model with unsplittable variable size jobs.

C. Our Results

Let $\langle G, \alpha \rangle$ be a Stackelberg load balancing game. The leader aims to minimize the makespan of the schedule achieved after the addition of selfish jobs. We consider two questions:

- 1) How should the leader choose the jobs it controls?
- 2) How should it schedule them on the machines?

In Section II, we present results for games with two job sizes, that is, for all $j \in \mathcal{J}$, $p_j \in \{1, p\}$. First, in Section II-A we characterize the social optimum in these instances in leader-free settings. In Section II-B, we consider settings where the leader must exploit all of its power and we show that it may result with a worst schedule than a NE in a leader-free environment. In Section II-C we show that when $\alpha \geq \min\{\frac{n_1}{p}, \frac{n_p p}{p}\}$ the leader can guarantee an optimal NE. Furthermore, we show that for every $\alpha \geq 0$, for every game G with two job sizes, $PoAL(G, \alpha) \leq 1 + \frac{p-1}{OPT(G)}$.

In Section III, we analyze the *PoAL* as a function of α and compare it to the *PoA* in a leader-free game. We show that for $\alpha < \frac{1}{m+1}$, $PoAL(\mathcal{G}, \alpha) = PoA(\mathcal{G})$. We also show a lower

bound of $\alpha \geq \frac{1}{m}$ from which we can guarantee $PoAL(\mathcal{G}, \alpha) < PoA(\mathcal{G})$. Furthermore, we present and analyze two strategies for choosing and scheduling the controlled jobs.

In Section IV, we present the leader's heuristics for both choosing the controlled jobs and assigning them to machines. In Section V we present our experimental results.

We conclude in Section VI, where we summarize the work and suggest some directions for future work. Due to space constraints, some of the technical proofs are omitted.

II. INSTANCES WITH TWO JOB SIZES $\{1, p\}$

In this section, we consider the class \mathcal{G}_2 of game instances with only two different job sizes, w.l.o.g., 1 and p . Formally, $G \in \mathcal{G}_2$ if there exists a constant $p > 1$ such that $\forall j \in \mathcal{J}$, $p_j \in \{1, p\}$. We denote by ℓ -job a job of size ℓ . Let n_1 and n_p denote the number of 1-jobs and p -jobs, respectively. It is easy to see that LPT algorithm is optimal for any $G \in \mathcal{G}_2$.

A. Social Optimum in Leader-Free Games

We first provide some simple observations regarding the social optimum and leader-free games in \mathcal{G}_2 .

First, we denote r_G to be the number of machines with exactly $\lceil \frac{n_p}{m} \rceil$ p -jobs on them on a LPT schedule. Thus, $r_G = n_p \bmod m$ when $\frac{n_p}{m} \notin \mathbb{N}$ and there are $m - r_G$ machines with $\lfloor \frac{n_p}{m} \rfloor$ p -jobs. Also, let $h = \lfloor \frac{n_p}{m} \rfloor$, meaning, $n_p = hm + r_G$.

Proposition 2.1: For every load balancing game $G \in \mathcal{G}_2$,

$$OPT(G) = \begin{cases} \lceil \frac{n_p}{m} \rceil p & \text{if } n_1 \leq (m - r_G)p \text{ and } n_p > 0 \\ \lfloor \frac{p}{m} \rfloor & \text{otherwise} \end{cases}$$

Proof: Consider an optimal LPT schedule of $G \in \mathcal{G}_2$. If $n_p > 0$ then LPT first schedules all the p -jobs in a balanced way. The makespan after this stage is $\lceil \frac{n_p}{m} \rceil p$. For the makespan to remain $\lceil \frac{n_p}{m} \rceil p$, the number of 1-jobs must be at most $(m - r_G)p$, since otherwise, $\frac{n_1 + n_p p}{m} > \lceil \frac{n_p}{m} \rceil p$. If $n_1 > (m - r_G)p$, then the number of 1-jobs is sufficient to perfectly balance the load on the machines, up to a gap of 1, hence, the resulting schedule has a makespan of $\lfloor \frac{p}{m} \rfloor$. ■

Proposition 2.2: For every load balancing game $G \in \mathcal{G}_2$, if $PoA(G) > 1$, then in every sub-optimal NE s , every machine a with $L_a(s) > OPT(G)$ processes only p -jobs.

Proof: Let $G \in \mathcal{G}_2$ such that $PoA(G) > 1$. Let s be a NE of G such that $cost(s) > OPT(G)$. Let a be a machine with $L_a(s) > OPT(G)$. By the pigeonhole principle, there must be a machine b for which $L_b < OPT(G)$. Hence, $L_a(s) > L_b(s) + 1$. Machine a processes only p -jobs, as otherwise, any 1-job on machine a would benefit from migrating to machine b , contradicting the stability of s . ■

Next, we characterize instances for which every NE is optimal. First, we calculate some useful values. Denote $G \in \mathcal{G}_2$ to be a game with $n_1 > (m - r_G)p$. In order to calculate the value of $OPT(G)$ we take s to be an LPT schedule which we know is optimal. Each machine has at least h p -jobs on it and there are $m - r_G$ machines with exactly h which has exactly $(m - r_G)p$ 1-jobs scheduled on them since $OPT(G) > \lceil \frac{n_p}{m} \rceil$. Thus, we have n_p p -jobs and $(m - r_G)p$ 1-jobs in order to have all the machines with load of $\lceil \frac{n_p}{m} \rceil$. Hence, there are

more $n_1 - (m - r_G)p$ 1-jobs in \mathcal{J} and the maximal load they reach is $\lceil \frac{n_1 - (m - r_G)p}{m} \rceil$. Denote this value to be B_G and we get in total $OPT(G) = \lceil \frac{P}{m} \rceil = \lceil \frac{n_p}{m} \rceil + B_G$.

For some schedule s' if there is a machine i with $L_i(s') > OPT(G)$ then it must be that there are only p -jobs on i . The number of p -jobs on i is $\lceil \frac{n_p}{m} \rceil + \lfloor \frac{B_G}{p} \rfloor + 1$, meaning, the number of p -jobs that fits in a machine with load $OPT(G)$ and additional 1 p -job. We denote the number of p -jobs on i to be C_G . Using the above definitions, we can characterize instances for which every NE is optimal (proof omitted).

Proposition 2.3: For every load balancing game $G \in \mathcal{G}_2$, $PoA(G) = 1$ iff at least one of the following conditions holds:

- 1) $n_p \leq 1$
- 2) $OPT(G) = \lceil \frac{n_p}{m} \rceil p$
- 3) $OPT(G) > \lceil \frac{n_p}{m} \rceil p$ and $n_1 < (-n_p - C_G) \bmod m - 1$ or $C_G p > \lfloor \frac{(n_p - C_G)p + n_1}{m - 1} \rfloor + p$ or $(n_p p - 1)(m - 1) \leq n_1$

B. The Leader Controls Maximal Load from αP

In this section we assume that the leader must fully exploit its power, that is, the leader must control a subset of jobs whose total size is maximal among subsets of total size at most αP . We assume that the leader has the computational power to identify such a subset. In particular, if there exists a subset of the jobs with total size αP , then the leader must control such a subset. A game in which the leader must control such a subset is denoted $\langle G, = \alpha \rangle$.

The definition of PoAL is adjusted to fit this case as follows:

Definition 2.1: Let $\langle \mathcal{G}, = \alpha \rangle$ be a family of Stackelberg games, and let $G \in \mathcal{G}$. Let $\Upsilon(G, = \alpha)$ be the set of pure Nash equilibria of the game $\langle G, = \alpha \rangle$. Assume that $\Upsilon(G, = \alpha) \neq \emptyset$.

- The *price of anarchy* of $\langle G, = \alpha \rangle$ is the ratio between the maximal cost of a NE and the social optimum of G . That is, $PoAL(G, = \alpha) = \max_{s \in \Upsilon(G, = \alpha)} cost(s) / OPT(G)$. The *price of anarchy* of the family of Stackelberg games $\langle \mathcal{G}, = \alpha \rangle$ is $PoAL(\mathcal{G}, = \alpha) = \sup_{G \in \mathcal{G}} PoAL(G, = \alpha)$.

We first show that controlling the maximal possible load may not always minimize the PoAL.

Proposition 2.4: There exists a game $G \in \mathcal{G}_2$ and $0 \leq \alpha \leq 1$ such that $PoAL(G, = \alpha) > PoA(G)$.

Proof: Let G be a weighted Stackelberg load balancing game with $m = 2$, $p = 4$, $n_p = 3$ and $n_1 = 2$ and let $\alpha = \frac{5}{14}$. Let $\mathcal{J} = \{j_1 \dots j_5\}$ where $p_1 = p_2 = p_3 = 4$ and $p_4 = p_5 = 1$.

We have $P = 14$, thus, the leader must control jobs of total size 5. This implies that the leader controls one 4-job and one 1-job. W.l.o.g. the leader controls jobs j_1 and j_4 . Figure 1(a) presents an optimal schedule of \mathcal{J} . $OPT(G) = 8$ and by Proposition 2.1 $PoA(G) = 1$. We show that $PoAL(G, = \alpha) > 1$. If the leader schedules both of the jobs on the same machine, w.l.o.g., on machine m_1 , then a possible NE is depicted in Figure 1(b). We have $L_1(s) = 9$ and $L_2(s) = 5$. The only job that may benefit from a migration is the 1-job on m_1 . However, this job was assigned by the leader and cannot change its assignment.

If the leader schedules each of the two controlled jobs on a different machine, w.l.o.g., $s_1 = 1$ and $s_4 = 2$, then a possible NE is a one where j_2, j_3 are scheduled on m_1 and j_5 on m_2 . We have, $L_1(s) = 9$ and $L_2(s) = 5$ as depicted in Figure 1(c). The only job that may benefit from a migration is the 1-job on m_1 . However, this job was assigned by the leader and cannot change its assignment.

Hence, $PoAL(G) = \frac{9}{8} > 1 = PoA(G)$. ■

Fig. 1. $PoAL(G) > PoA(G)$. (a) optimal and worst case schedule with only selfish jobs, (b),(c) possible NE profiles with controlled jobs

We show that there is no constant $\alpha < 1$ such that controlling α of the total load is sufficient to guarantee an optimal assignment.

Theorem 2.5: For every $\epsilon > 0$ and every $p > 1$, there exists a load balancing game $G \in \mathcal{G}_2$ such that $PoAL(G, = \alpha) \geq 1 + \frac{1}{p}$ for $\alpha \geq 1 - \epsilon$.

Proof: Given ϵ, p , let $m \geq 3$ be an integer such that $\frac{2p-1}{m} \leq \epsilon$ and let $\epsilon' = \frac{2p-1}{pm}$. Let G be a game on m machines. Let $n_1 = p$ and $n_p = m - 1$. Thus, $P = pm$. Since the leader controls a fraction $1 - \epsilon'$ of the total load and $\epsilon'P = 2p - 1$, it must be that the leader does not control exactly one p -job and $p - 1$ 1-jobs, that is, A consists of a single 1-job and $m - 2$ p -jobs.

In every optimal schedule for G , all the machines have load p . Specifically, on $m - 1$ machines there is one p -jobs and on one machines there are p 1-jobs. Thus, $OPT(G) = \lceil \frac{P}{m} \rceil = p$.

In order to achieve an optimal solution, the leader must schedule the jobs in A in a sub-assignment of an optimal schedule, since otherwise it cannot be completed to an optimal schedule. We show that the leader cannot schedule the jobs of A such that any stable addition of the selfish jobs is optimal.

The only possible assignment for the leader, is to schedule $m - 2$ p -jobs on $m - 2$ machines and the single 1-job on another machine. After the assignment of A , there is an empty machine. A possible stable assignment of the selfish jobs is produced by adding one p -job to the machine with load 1 and assigning the $p - 1$ 1-jobs on the empty machine. (see Figure 2)

In this case, it is easy to see that the resulting schedule is stable against deviations of the selfish jobs, thus, the resulting schedule has cost $p + 1$ and $PoAL = 1 + \frac{1}{p}$. ■

Fig. 2. The only optimal Stackelberg strategy of the controlled (shaded) jobs and a possible non-optimal stable completion of the assignment by the selfish (light) jobs.

C. Games with Optional Control

As shown in section II-B, forcing the leader to fully exploit its power may be harmful. We therefore consider next the more flexible and reasonable setting in which the leader may choose the amount of load it controls out of the maximal allowed fraction α .

Theorem 2.6: For every game $\langle G, \alpha \rangle$ with $G \in \mathcal{G}_2$ and $\alpha \geq \min\{\frac{n_1}{P}, \frac{n_p p}{P}\}$ it holds that $PoAL(G, \alpha) = 1$.

Proof: Let $G \in \mathcal{G}_2$. If $\alpha \geq \frac{n_p p}{P}$, the leader may choose to control all of the p -jobs and none of the 1-jobs. If $\alpha \geq \frac{n_1}{P}$, it can choose to control all of the 1-jobs. The leader would schedule the controlled jobs in a sub-assignment of an optimal schedule. Since all of the selfish jobs have the same size, they will complete the assignment in a balanced schedule, which is optimal. ■

Theorem 2.7: For every $\alpha \geq 0$ and $G \in \mathcal{G}_2$, $PoAL(G, \alpha) \leq 1 + \frac{p-1}{OPT(G)}$.

Proof: Let $G \in \mathcal{G}_2$ be a weighted Stackelberg load balancing game. Assume that the leader assigns the controlled jobs in a sub-assignment of an optimal schedule. We show that for any completion of this sub-assignment to a NE, s , it holds that $cost(s) \leq OPT(G) + p - 1$.

Assume by contradiction that there is a machine m_i with $L_i(s) \geq OPT(G) + p$. By Proposition 2.2 the only selfish job on m_i are p -jobs. Also, since the leader schedule the jobs in a sub-optimal assignment then there is at least one selfish job j on m_i . By the pigeonhole principle there is a machine $m_{i'}$ with $L_{i'} < OPT(G)$. Thus, j would benefit from migrating to $m_{i'}$ and s is not stable. ■

III. INSTANCES WITH ARBITRARY JOB SIZES

Algorithm 1 presents a strategy for the leader, given the job sizes and the fraction of load $0 \leq \alpha < 1$ that the leader may control. Recall that $P = \sum_j p_j$. Thus, the leader may choose to assign any subset of jobs of total load at most αP . We assume that the leader has unlimited computational power, in particular, it may solve NP-hard problems.

Algorithm 1 - A strategy for assigning the controlled jobs on m machines

- 1: Sort the jobs such that $p_1 \geq \dots \geq p_n$
- 2: Let k be the maximal index for which $\sum_{j \leq k} p_j \leq \alpha P$.
- 3: Assign the k first jobs in a way that minimizes the maximal load on a machine.

Claim 3.1: Algorithm 1 gives a $(1 + \frac{1 - \frac{1}{m}}{1 + \lfloor \frac{k}{m} \rfloor})$ -approximation.

Proof: The analysis is similar to the analysis of the PTAS for the minimum makespan problem [9]. Let s' be the schedule

of the k longest jobs and let s denote the NE profile after the selfish jobs join. If $cost(s') = cost(s)$ then s is optimal for G . Otherwise, $cost(s) \geq OPT(G)$.

Let j be the job determining $cost(s)$. Since s is NE, every machine has load of at least $cost(s) - p_j$. Therefore, $P \geq m(cost(s) - p_j) + p_j$. Also, since the jobs are sorted in nonincreasing order of processing times, we have that $p_j \leq p_{k+1}$ and therefore, $P \geq m \cdot cost(s) - (m-1)p_{k+1}$. Furthermore, a lower bound for the optimal solution is a perfectly balanced schedule, thus, $OPT(G) \geq \frac{P}{m}$, which implies that $cost(s) \leq OPT(G) + (1 - \frac{1}{m})p_{k+1}$.

Next we bound p_{k+1} in terms of $OPT(G)$. To obtain such a bound, consider the $k+1$ longest jobs. In an optimal schedule, some machine is assigned at least $\lceil \frac{k+1}{m} \rceil \geq 1 + \lfloor \frac{k}{m} \rfloor$ of these jobs. Since each of these jobs has processing time at least p_{k+1} , we conclude that $OPT(G) \geq (1 + \lfloor \frac{k}{m} \rfloor)p_{k+1}$, which implies that $p_{k+1} \leq \frac{OPT(G)}{1 + \lfloor \frac{k}{m} \rfloor}$ and finally,

$$cost(s) \leq OPT(G) \left(1 + \frac{1 - \frac{1}{m}}{1 + \lfloor \frac{k}{m} \rfloor}\right)$$

Our next results identify the threshold fraction α , such that controlling less than fraction α may not be helpful at all while controlling at least fraction α is guaranteed to be beneficial.

Theorem 3.2: If $\alpha < \frac{1}{m+1}$ then $PoAL(G, \alpha) = PoA(G)$.

Proof: Recall that $PoA(G) = 2 - \frac{2}{m+1}$. We show that there exists a game G for which $PoAL(G, \alpha) = 2 - \frac{2}{m+1}$ for every $\alpha < \frac{1}{m+1}$.

Given m , the set of players in G consists of $m^2 - m$ jobs of size 1 and two jobs of size m . Thus, $P = m^2 + m$. $OPT(G) = m + 1$ achieved by assigning the two long jobs on different machines and balance the load with the unit jobs.

Assume the leader controls a fraction $\alpha < \frac{1}{m+1}$ of the load. Thus, it controls load less than m , implying that it controls at most $m-1$ unit jobs. Therefore, after the leader schedules the controlled jobs, there is an empty machine m_1 .

In a possible NE schedule s the two m -jobs are assigned on m_1 and all of the unit jobs are balanced on the remaining machines, each having load m .

We show that s is NE. Clearly, none of the unit jobs on machine $i \neq 1$ may benefit from a migration since $L_i(s) = m$ and $L_1(s) = 2m$. Moreover, since for every $i \neq 1$ $L_i(s) = m$ and there are only two m -jobs scheduled on m_1 , they will not benefit from a migration.

Therefore, for any $\alpha < \frac{1}{m+1}$ we have a NE s with $cost(s) = 2m$. Thus, $PoAL(G, \alpha) = \frac{2m}{m+1}$. ■

In order to show that controlling a fraction $\alpha \geq \frac{1}{m-1}$ guarantees a reduced equilibrium inefficiency, we characterize instances that achieve the worst PoA. We first show that every optimal solution must be perfectly balanced and then that there are at least m relatively short jobs.

Claim 3.3: For every game G with $PoA(G) = \frac{2m}{m+1}$, $OPT(G) = \frac{P}{m}$.

Proof: Let G be a game with $PoA(G) = \frac{2m}{m+1}$ and let $r = \frac{OPT(G)}{m+1}$. Let s be a schedule such that $cost(s) = 2mr$. Therefore, there is a machine M_a with $L_a(s) = 2mr$.

Assume by contradiction that $OPT(G) > \frac{P}{m}$, thus, $P < r(m^2 + m)$ then $\sum_{i \neq a} L_i(s) < r(m^2 - m)$. Therefore, there is a machine $b \neq a$ with $L_b < rm$. Also, since $L_a(s) = 2mr$ and $OPT(G) = r(m+1)$ it must be that M_a processes at least two jobs and the shortest job on M_a has size at most rm . By migrating to M_b , the shortest job on M_a will reduce its cost below $2rm$, contradicting the stability of s . ■

Theorem 3.4: If $\alpha \geq \frac{1}{m}$ then $PoAL(\mathcal{G}, \alpha) < 2 - \frac{2}{m+1}$.

Theorem 3.5: If the leader controls m jobs, $PoAL(\mathcal{G}) < PoA(G)$.

Proof: Let G be a load balancing game with $PoA(G) = 2 - \frac{2}{m+1}$ and $m \geq 3$ and let s be the schedule for which $cost(s) = (2 - \frac{2}{m+1})OPT(G)$. Denote i to be a machine with $L_i(s) = cost(s)$. Also, $L_i(s) - OPT(G) = (2 - \frac{2}{m+1})OPT(G) - OPT(G) = (1 - \frac{2}{m+1})OPT(G)$ and for $m \geq 3$ we get $L_i(s) - OPT(G) \geq \frac{OPT(G)}{2}$. Since $L_i(s) > OPT(G)$ there must be a machine i' with $L_{i'}(s) < OPT(G)$. Therefore, i contains two jobs with $p_j > \frac{OPT(G)}{2}$, since otherwise, s is not NE.

Moreover, there are at most m jobs with $p_j > \frac{OPT(G)}{2}$ since otherwise, for every schedule s' there must be a machine i' with $L_{i'}(s') > OPT(G)$ and the optimal value of G can not be achieved. Contradicting the definition of $OPT(G)$.

Let A be the group of jobs with $p_j > \frac{OPT(G)}{2}$. If the leader controls A , since $|A| \leq m$, it may schedule each job on a different machine. Let s' be the resulted schedule s' after the selfish jobs reach NE.

We show that the schedule s' is a NE for a game with all selfish jobs. Assume there is a job j scheduled on machine a that may benefit from a migration. Then since all of the jobs with $p \leq \frac{opt(G)}{2}$ are satisfied, it must be that $p_j > \frac{OPT(G)}{2}$ and there is a machine b with $L_b(s') < \frac{OPT(G)}{2}$. Also, machine b has an additional job j' scheduled on it, since otherwise j is the only job on a and it may not benefit from a migration. It must be that $p_{j'} \leq \frac{OPT(G)}{2}$ since the leader scheduled all of the larger jobs on distinct machines. Thus, j' may benefit by migrating to b . Contradicting the stability of the jobs with sizes smaller than $\frac{OPT(G)}{2}$.

Since s' is a NE then it must be that $cost(s') \leq (2 - \frac{2}{m+1})OPT(G)$. Also, we showed that in every NE with cost $(2 - \frac{2}{m+1})OPT(G)$ it must be that there is a machine with two jobs larger than $\frac{OPT(G)}{2}$. Thus, since s' does not satisfy the condition, $cost(s') < (2 - \frac{2}{m+1})OPT(G)$. ■

Algorithm 2 presents a strategy for the leader, given a fraction α , which is the load of jobs the leader control.

Algorithm 2 - A strategy for finding an approximation for a schedule with m machines

- 1: Sort the jobs such that $p_1 \geq \dots \geq p_n$
 - 2: Assign the k first jobs such that $\sum_{i=1}^k p_i \leq \alpha P$ in First-Fit with limit of C^* .
-

Theorem 3.6: For every $\alpha \leq \frac{m}{m+1}$, Algorithm 2 gives $PoAL(\mathcal{G}, \alpha) \geq 2 - \frac{2}{m+1}$.

Proof: Given m , let G be a game for which the set of players in G consists of m jobs of size m and m jobs of size 1. Thus, $OPT(G) = m+1$ is achieved in a balanced schedule and $PoA(G) = 2 - \frac{2}{m+1}$. Let $\alpha \leq \frac{m}{m+1}$ be the fraction of controlled load. Therefore, the leader controls at most $m-1$ jobs with size m .

If $C^* \geq 2m$, if the leader controls only one job, then the cost after the selfish jobs join may be the worst case. Otherwise, the leader assigns at least two m -jobs on a machine. in both case $cost(s) \geq 2m$ and $PoAL(G, \alpha) \geq 2 - \frac{2}{m+1}$.

If $C^* < 2m$ the leader assigns only one m -job on at most $m-1$ machines. Let M_1 be one of those machines. In a possible NE schedule s a selfish m -job is assigned on M_1 , the selfish m -jobs are assigned on different machines and all of the unit jobs are assigned on a single machine. Therefore, each machine having load m except M_1 , with $L_1(s) = 2m$. Thus, $PoAL(G, \alpha) = 2 - \frac{2}{m+1}$. ■

IV. OUR HEURISTICS

In this section we describe the heuristics we have designed and implemented. An instance in our experiments is characterized by a set of jobs, a number of machines and two different heuristics. The first defines the leader's strategy and depends on the fraction of load it controls and the second defines the selfish players behaviour. We describe each of these two classes of heuristics separately.

A. Leader's Strategy

A leader's strategy consists of two steps: (i) Choosing the controlled jobs, (ii) Scheduling the controlled jobs. In this section we describe the heuristics we propose for these steps. Note that the leader's strategy is independent of the selfish jobs' behaviour, however, the leader may benefit and adjust its heuristic if it is known in advance how the selfish jobs will act after it is done assigning the controlled jobs.

1) *Choosing the Controlled Jobs:* Given a fraction $0 \leq \alpha \leq 1$, the leader needs to choose the jobs it controls. Recall that $P = \sum_j p_j$. Given $0 \leq \alpha \leq 1$, the leader may control jobs of total load at most αP . We implemented three simple heuristics. In the first heuristic, denoted *Pick Smallest*, the leader sorts the jobs in non-decreasing order of size and adds jobs according to this order as long as their total size is at most αP .

In the second heuristic, the leader sorts the jobs in non-increasing order. For choosing the controlled jobs there are two options: it may choose the largest jobs prefix of this sorted set whose total size is at most αP and stop when the next job can not fit, we denote this heuristic *Pick Largest - Stop*, or it may add jobs according to the sorted order and skip jobs whose addition will make the total load more than αP , we denote this strategy *Pick Largest - Skip*.

For example, assume the jobs sizes are $\{1, 2, 3, 4\}$ and let $\alpha = \frac{1}{2}$. Using *Pick Smallest*, the leader controls jobs of sizes $\{1, 2\}$, in *Pick Largest - Stop*, it controls only the job of size 4 and in *Pick Largest - Skip* it controls jobs of sizes $\{4, 1\}$.

2) *Leader's Scheduling Strategy*: Given the set of controlled jobs, the leader's next mission is to schedule them on the machines. We assumed the leader has limited computational power, meaning, it cannot solve *NP*-hard problems and in particular, it cannot calculate an optimal schedule for the jobs.

The first algorithm we implemented returns an LPT schedule. Meaning, the leader first sorts the controlled jobs in a non-increasing order. Next, it assigns one job at a time to a least loaded machine. We denote this heuristic *Leader's LPT*.

The second algorithm uses the bin packing algorithm *First Fit*. We denote this heuristic *Leader's FF*. The bin packing problem is an optimization problem, in which items of different sizes must be packed into a finite number of bins or containers, each of a fixed given capacity, in a way that minimizes the number of bins used. First Fit algorithm packs each item into the first bin where it fits, possibly opening a new bin if the item cannot fit into any currently open bin.

We consider the machines as bins and the jobs as items. Let $L = \frac{\sum_{j \in \mathcal{J}} p_j}{m}$. Clearly, L is a lower bound on *OPT*. In our heuristics, the bins' capacity is determined to be γL for different values of $\gamma \in \{0.9, 1, 1.1\}$. The leader sorts the job on non-increasing order and then uses First Fit with the chosen bins capacity to schedule the controlled jobs on the machines. If some job cannot fit into any machine without an overflow beyond γL (this may happen if α is relatively large), then the jobs is assigned on a lightly loaded machine.

B. Selfish Player's Strategies

The selfish players behaviour also has significant impact on the results. We considered two methods according to which the selfish players reach a NE.

In the first method the selfish players are added to the game sequentially, each added to a least loaded machine at that time.

The jobs are considered in LPT order. We denote this strategy *Player's LPT*. We claim that in this case, after adding the selfish players, the schedule is stable against deviation of the selfish players. The proof of the following claim follows from the analysis of LPT for classical load balancing games [21].

Claim 4.1: LPT algorithm for non-empty machines produces a NE for the selfish jobs.

In the second method the jobs are added greedily in arbitrary order and then we use *Best Response Dynamics (BRD)*. The best response dynamics is one of the most elementary methods in game theory. Using Round Robin according to the jobs assignment order. Each player at its turn tries to improve its state. If there is a machine for which the player may benefit from a migration, it will migrate to a most beneficial option. Otherwise, it stays on the same machine. The algorithm stops when non of the players has a beneficial migration. It is known that BRD algorithm converges to a NE when starting the algorithm with empty machines. The discussed case of adding players to non-empty machines is a sub-problem of it and achieves NE similarly.

V. EXPERIMENTAL RESULTS

Our instances consist of 20 machines and 100 jobs. It is common to use exponential times for job processing times as it is often a good approximation of service times [19]. In order to work with integers, we used geometrical distribution and chose parameter 0.13 which provides instances with mostly small jobs, with an amount of larger jobs that allows many combinations of equilibrium with different makespan values. Diversity of job sizes and relatively low loads, enables a good comparison between different heuristics.

The random jobs generator may create jobs whose size is larger than the optimal makespan, calculated by $\frac{\sum_{j \in \mathcal{J}} p_j}{m}$. We address these jobs as outliers. The presence of such jobs hurts the comparison of the different heuristics, since they may cause that an instance will have the same makespan for all strategies. By scheduling one such long job on a machine, non of the selfish jobs may benefit by choosing this machine. In order to emphasis the differences between the different heuristics, we remove the outliers using the following method. We note that on average 1 – 2 jobs were removed from each instance.

Algorithm 3 - Removing outliers

- 1: Calculate $avgLoad(G) = \frac{\sum_{j \in \mathcal{J}} p_j}{m}$
 - 2: Remove every job $j \in \mathcal{J}$ with $p_j > avgLoad(G)$.
 - 3: Repeat steps 1, 2 while some job was removed.
-

In the following sections we present our experimental results. These results were obtained by running our heuristics on the same 100 instances, each consisting of 100 players and 20 machines. For each instance we calculated the lower bound, $L = \sum_j p_j / M$, on the optimal makespan. For each experiment we present in the diagrams the average makespan scaled by L . For example, if the average makespan in all the runs performed in some experiment is $1.2L$ then the corresponding bar in the figure has height 1.2. Since $L \leq OPT$, this ratio is an upper bound on the price of anarchy.

A. Choosing the Controlled Jobs

In this section, we present our results for the comparison of the first part in the leader's strategy. Specifically, we compare how the performance is affected by the fraction of load controlled by the leader and the different heuristics for choosing the leader's controlled jobs. We consider all the possible combinations of leader and selfish players strategies. Recall that *Leader's FF* algorithm schedules each job on the first machine where it fits with limit of $\gamma \frac{\sum_{j \in \mathcal{J}} p_j}{m}$ on the totals' machine load for $\gamma \in \{0.9, 1, 1.1\}$, possibly starting to schedule on a new machine if the job cannot fit into any currently open machine. In the experiment described below, we fixed $\gamma = 1$ as a representative case for the strategy.

Fig. 3. Comparing jobs choosing strategies for Leader's FF with BRD

Fig. 4. Comparing jobs choosing strategies for Leader's FF with Player's LPT

Fig. 5. Comparing jobs choosing strategies for Leader's LPT with BRD

Fig. 6. Comparing jobs choosing strategies for Leader's LPT with Player's LPT

Figures 3,4,5 and 6 present the differences between the

possible leader's strategies for choosing controlled jobs for every possible combination of considered strategies for the leader and selfish players. The figures present the PoA (y axis) as a function of α for every strategy.

First, we can conclude that *Pick Smallest* provides the worst results for all α values and heuristics. As shown in the figures, the PoA increases with α , meaning that the leader's control hurts the social cost.

In contrast, we can also conclude that for the other two strategies *Pick Largest - Skip* and *Pick Largest - Stop*, as α increases, the final schedule is better and the leader reduces the makespan in average by factor 1.16, 1.11, 1.08 if it controls 0.3, 0.5, 0.7 fraction of the load respectively. Other than that, the difference between both strategies is minor, with a slight advantage to the *Pick Largest - Stop* strategy in most of the cases.

B. Leader's Scheduling Strategy

In this section we discuss the optimal strategy we recommend the leader to apply on the controlled jobs. The best strategy may differ between the amount of load the leader controls, the selfish players behaviour or other parameters we examine.

The experiments that consider the selection of the controlled jobs, reported in section 5.1, reveal that *Pick Largest - Stop* has the best performance, thus, we use it in the following experiments.

1) *Leader's First Fit*: Our next experiments analyze the influence of the parameter γ in the *Leader's FF* strategy. Recall that the *Leader's FF* strategy schedules the controlled jobs using *First Fit* algorithm with machine capacity of $\gamma \sum_j \frac{p_j}{m}$ for $\gamma > 0$. We applied this strategy with $\gamma \in \{0.9, 1, 1.1\}$. These values were chosen since we aim to have approximate PoA closer to 1; if we choose a low γ value, the selfish players may determine the makespan since larger jobs may join non-empty machines.

If we choose higher γ value, then already the jobs assigned by the leader may cause a high makespan. On the other hand, this leaves more empty machines for the selfish jobs and potentially prevents them from reaching load higher than $\gamma \sum_j \frac{p_j}{m}$ on the remaining machines.

Figures 8 and 7 present the approximated PoA with regards to the discussed options for γ parameter and the controlled fraction α achieved with $\alpha \in \{0.3, 0.5, 0.7\}$ and $\gamma \in \{0.9, 1, 1.1\}$. In the experiments described in Figure 7 the selfish jobs join and perform BRD. In the experiments described in Figure 8 they are added using LPT rule.

Fig. 7. Comparing γ parameter for *Leader's FF* strategy with *BRD*

Fig. 8. Comparing γ parameter for *Leader's FF* strategy with *Selfish LPT*

As presented in Figure 7, when the selfish players use *Player's BRD* strategy, for every fraction α , the best performance is achieved when $\gamma = 1$. For $\gamma = 0.9$ we have significantly worst result for $\alpha \in \{0.3, 0.5\}$, but better than $\gamma = 1.1$ for $\alpha = 0.7$. This difference is explainable since the leader have the most significant control for this α and both approximated PoA results values are below 1.1 and for $\gamma = 1.1$ the leader schedules as much as it can near the load of $1.1 \sum_j \frac{p_j}{m}$ which ensured result near 1.1. In contrast to $\gamma = 0.9$ which allowed lower results.

On the other hand, for *Player's LPT* in Figure 8 we get consistent results for all α values. We get the worst results for the value $\gamma = 0.9$. Next, we have $\gamma \in \{1, 1.1\}$ with close results, with a minor advantage to $\gamma = 1.1$.

2) *Leader's Strategy*: We conclude with experiments that compare the leader's strategy choice with regards to the selfish players behaviour. Based on the results of these previous experiments, in all the experiments we report in this section, the controlled jobs are chosen using *Pick Largest - Stop* and for *Leader's FF* we use parameter $\gamma = 1$. In the experiments presented bellow, we compared which leader's strategy gives better results with respect to the applied player's strategy for every α choice.

Fig. 9. Comparing leader's possible strategies for *Player's BRD*

Fig. 10. Comparing leader's possible strategies for *Player's LPT*

The results shown in both Figures 9 and 10, imply that for $\alpha = 0.3$ we get better makespan when using *Leader's FF* strategy. On the other hand, for larger α we get that *Leader's LPT* perform better. Moreover, we can conclude that when the selfish players use BRD, the difference between the makespans resulting from the two leader's strategy are more significant comparing to games in which the selfish players are added by LPT.

Another interesting result we can infer from these experiments, is the difference between the results for selfish players behaviour. For all α values and leader's strategy choice, we get much lower makespans when the selfish players use BRD.

VI. CONCLUSIONS

In this work we examined the potential influence of a leader who control a subset of the jobs in load balancing games. The leader assigns the jobs it controls and the other jobs then select their assignments in a selfish way. We present theoretical as well as experimental results answering several questions regarding the advantages and disadvantages of controlling a fraction of the load. We have designed and implemented several heuristics for possible strategies the leader may apply when choosing the jobs to control and when scheduling them on the machines.

In the theoretical results, we proved that if the leader is obligated to control a maximal amount of the given fraction, the resulting schedule may be worse than a NE schedule in a leader-free environment. On the other hand, for a setting in which the leader may choose to exploit only part of its power, we presented tight bounds on the fraction α of the controlled load that may improve the game cost. Additionally,

we presented several relations between the common $PoA(\mathcal{G})$ measure and the $PoAL(\mathcal{G}, \alpha)$ measure which we defined.

Our experiments show that controlling the largest jobs in a game is the best strategy for the leader, while controlling the smallest jobs may cause significant damage. In fact controlling no job may be better than controlling only small ones. One of the main conclusions that resulted from the experiments is that controlling a larger fraction of the load improves the game cost when controlling the larger jobs.

We have observed that when using the heuristic *Leader's FF*, the performance is significantly influenced by the choice of the capacity to which the machines are loaded. Let $L = \sum_j \frac{p_i}{m}$, then for a parameter γ , the leader adds jobs to machine in a First-Fit matter, where each job is added to the first machine whose addition will result in total load at most γL . In general, the best result achieved for this strategy is when $\gamma = 1$. Although, if the selfish players scheduling strategy is known to be LPT, then filling the machines up to capacity $1.1L$ results is slightly better outcomes. Also, for large α values the results for all γ values are very close, but on the other hand for low α we can definitely conclude that we should not use γ less than 1. Future work on this algorithm may find more characteristics for choosing the γ value.

Another conclusion we can infer, is that knowing the selfish player's behaviour in advance may be helpful for the leader. Similarly, the strategy choice depends also on α - the fraction of controlled jobs. In general, for both selfish players methods it holds that the *Leader's LPT* strategy gives the best results, but if it is known that the selfish players acts in BRD and the controlled fraction is low we may consider using *Leader's FF*.

For future work it may be interesting to improve the *Leader's FF* strategy and characterize the jobs that the leader should choose specifically for using this heuristic. *Leader's FF* is a heuristic in which the leader assigns the controlled jobs on a subset of the machines and leave some of the machines empty for the selfish jobs. We believe that additional algorithms using this approach should be considered and analyze and may perform even better than *Leader's FF*. Also, it may be interesting to get inspiration from additional known approximation algorithms for the minimum makespan problem as we did with *Leader's LPT* which is based on the algorithm presented in [7].

In the theoretical side, we believe that there are many interesting open problems in this setting. For example, analyzing weighted Stackelberg games of congestion games with non-singelton strategy space, non symmetric singelton games, or games with non-uniform resources, that is, machines with different speeds. Also, in our settings the leader has unlimited computational power, meaning, it is able to solve NP-hard problems. It will be interesting to have results for a leader with a limited computational power. Another interesting direction

is to analyze the consequences of controlling a specific given subset of jobs $A \subseteq \mathcal{J}$ instead of a fraction α of the load.

Abstract—Here we propose for the first time a temporal intuitionistic fuzzy extension of the Hungarian method for solving the Travelling Salesman Problem (TIFHA-TSP) based on intuitionistic fuzzy logic and index matrices theories. The time for passing a given route between the settlements depends on different factors. The expert approach is used to determine the intuitionistic fuzzy time values for passing the routes between the settlements. The rating coefficients of the experts take the times into account. We are also developing an application for the algorithm’s provision to use it on a real case of TIFHA-TSP.

I. INTRODUCTION

HAMILTON [11] defined the travelling salesman problem (TSP). The Hungarian algorithm (HA) was described by Kuhn in 1955 [6]. In today’s dynamic environment, some of the parameters of this problem are unclear and rapidly changing. Traditional optimisation methods are not easily applicable to this problem. The use of intuitionistic fuzzy logic proposed by Atanassov [8] as an extension of Zadeh’s fuzzy (F) logic [12] allows us to model uncertainty. The TSP and related problems have been solved through various techniques, including meta-heuristic algorithms [1]. FTSP with trapezoidal and triangular fuzzy costs has been solved in [2], [14] using the fuzzy Hungarian method. An improved Hungarian method is described in [15] for FTSP. The optimal solution of triangular intuitionistic FTSP is found [10] using the fuzzy HA. From the literature review we can see that optimal solutions in uncertainty are found only with triangular IF parameters, which are a special case of IF sets. Here we will extend our previous implementation of an IF Hungarian method [16], [19] by using temporal IF pairs and index matrices [9] to find the solution for the TSP at a certain moment in time to fulfil delivery requests. We will denote this approach as Temporal IF HA for the TSP (TIFHA-TSP). We are also in the process of developing a software application for the provision of TIFHA-

TSP and with its help we apply TIFHA-TSP in a real case. The experts’ ratings are taken into account in a way similar to [8]. The rest of this work contains the following sections: Section II describes the definitions of index matrices (IMs) and temporal intuitionistic fuzzy pairs (TIFPs). In Section III, we describe TIFHA-TSP and software for its implementation, and then apply it to a real case. Section IV marks some conclusions and some aspects for future research.

II. TIFP AND INDEX MATRICES

In this section, we will recall the definitions of temporal intuitionistic fuzzy pairs (TIFPs) and index matrices (IMs), as well as some operations and relations with them from [3], [9].

2.1. Temporal Intuitionistic Fuzzy Pair (TIFP)

Let $T = \{t_1, \dots, t_g, \dots, t_f\}$ be a fixed time-scale. A TIFP has the form of $\langle a(t), b(t) \rangle$, where $a, b: T \rightarrow [0, 1]$ and $a(t) + b(t) \leq 1$ for $t \in T$. With two TIFPs $x = \langle a, b \rangle$ and $y = \langle c, d \rangle$ there are different definitions of conjunction and disjunction [3], [16]. We will modify subtraction this way:

$$x(t) - y(t) = \begin{cases} \langle 0, 1 \rangle & \text{if } a = b \text{ \& } c = d \\ \langle a, b \rangle & \text{if } c = 0 \text{ \& } d = 1 \\ \langle \max(0, a - c), \min(1, b + d, 1 - a + c) \rangle & \text{otherwise} \end{cases}$$

Let $R_{\langle a(t), b(t) \rangle} = 0.5(2 - a(t) - b(t))(1 - a(t))$ following [5]. Then, as per [8], [19]:

$$x(t) \geq_R y(t) \text{ iff } R_{\langle a(t), b(t) \rangle} \leq R_{\langle c(t), d(t) \rangle}. \quad (1)$$

A TIFP x is named as “temporal intuitionistic fuzzy false pair” (TIFFalseP) if and only if $\inf a(t) \leq b(t)$, while x is named as “false pair” (TFalseP) iff $a(t) = 0, b(t) = 1$.

2.2. Temporal Intuitionistic Fuzzy Index Matrix (TIFIM)

We remind the definition of a TIFIM [9]

$$A(T) = [K, L, T, \{\langle \mu_{k_i, l_j, t_g}, \nu_{k_i, l_j, t_g} \rangle\}],$$

$t_g \in T$	l_1	...	l_n
k_1	$\langle \mu_{k_1, l_1, t_g}, \nu_{k_1, l_1, t_g} \rangle$...	$\langle \mu_{k_1, l_n, t_g}, \nu_{k_1, l_n, t_g} \rangle$
\vdots	\vdots	...	\vdots
k_m	$\langle \mu_{k_m, l_1, t_g}, \nu_{k_m, l_1, t_g} \rangle$...	$\langle \mu_{k_m, l_n, t_g}, \nu_{k_m, l_n, t_g} \rangle$

(2)

where \mathcal{S} be a fixed set of indices, $(K, L, T \subset \mathcal{S})$, and its elements are TIFP. T is a some fixed temporal scale and its element $t_g (g = 1, \dots, g, \dots, f)$ are time-moments.

Work is supported by the Asen Zlatarov University through project Ref. No. NIX-449/2021 “Index matrices as a tool for knowledge extraction”.

The operations with TIFIMs, such as transposition, addition, termwise multiplication, projection, substitution, internal subtraction, aggregated global internal operation, aggregation and index type operations, are given in [9], [17], [18], [19].

III. AN OPTIMAL TEMPORAL IF HA FOR THE TSP

This section describes a type of temporal intuitionistic fuzzy TSP to find the the fastest route to fulfilling all delivery requests to certain sites with temporal intuitionistic fuzzy data. The IFTSP has the following description:

The seller must visit m settlements $K = \{k_1, \dots, k_i, \dots, k_m\}$ at time t_f . He wants to start from a certain settlement, visit each settlement once and then return to his starting point. The time c_{k_i, l_j, t_f} (for $1 \leq i, j \leq m, i \neq j$) for switching from settlement k_i to l_j at a particular moment t_f are given TIFPs, depending on the peak hours of the day, the condition of the roads, the road conditions, etc. factors. The ratings of the experts $\{r_1, \dots, r_s, \dots, r_D\}$ in the form of TIFPs are defined on the basis of their participation in $\lambda_s(t_f) (s = 1, \dots, D)$ evaluating time procedures respectively before a particular moment t_f and were reflected in the final assessment of the travel time from one point to another. Our aim is to choose the visiting sequence of the settlements so that its total time is minimal.

A. An Optimal Temporal Intuitionistic Fuzzy HA for TSP

Let us be given the following TIFIMs, in accordance with the problem: The initial IM C , which consisting the time for passing the road from settlement k_i to settlement l_j at the current moment t_f has the form:

$$C[K, L, t_f] = \begin{matrix} & t_f & \dots & l_n & & R \\ \begin{matrix} k_1 \\ \vdots \\ k_m \\ Q \end{matrix} & \dots & \langle \mu_{k_1, l_n, t_f}, \nu_{k_1, l_n, t_f} \rangle & \dots & \langle \mu_{k_m, R, t_f}, \nu_{k_m, R, t_f} \rangle \\ & \ddots & \vdots & & \vdots \\ & \dots & \langle \mu_{k_m, l_n, t_f}, \nu_{k_m, l_n, t_f} \rangle & \dots & \langle \mu_{Q, R, t_f}, \nu_{Q, R, t_f} \rangle \end{matrix},$$

where t_f is a current moment, $K = \{k_1, k_2, \dots, k_m, Q\}$, $L = \{l_1, l_2, \dots, l_n, R\}$ and for $1 \leq i \leq m, 1 \leq j \leq n : \{c_{k_i, l_j, t_f}, c_{k_i, R, t_f}, c_{Q, l_j, t_f}\}$ are TIFPs. The time $c_{k_i, k_i, t_f} = \langle \perp, \perp \rangle$ (for $1 \leq i \leq m$). We can see, that $|K| = m + 1$ and $|L| = n + 1$;

$$X[K^0, L^0, t_f, \{x_{k_i, l_j, t_f}\}],$$

where $K^0 = \{k_1, k_2, \dots, k_m\}$, $L^0 = \{l_1, l_2, \dots, l_n\}$ and for $1 \leq i \leq m, 1 \leq j \leq n$:

$$x_{k_i, l_j, t_f} = \begin{cases} \langle 1, 0 \rangle, & \text{if the salesman travels from } k_i\text{-th} \\ & \text{settlement to } l_j\text{-th settlement at } t_f (k_i \neq l_j) \\ \langle \perp, \perp \rangle, & \text{if } k_i = l_j \\ \langle 0, 1 \rangle, & \text{otherwise.} \end{cases}$$

The auxiliary matrices in the algorithm have the forms:

- 1) $S(t_f) = [K, L, \{s_{k_i, k_j, t_f}\}]$, such that $S = C$.
- 2) $D[K^0, L^0, t_f]$ where for $1 \leq i \leq m, 1 \leq j \leq n$:

$$d_{k_i, l_j, t_f} \in \{1, 2\},$$

if the element s_{k_i, l_j, t_f} of S is crossed out with 1 or 2 lines respectively;

$$3) RC[K^0, e_0, t_f] = \begin{matrix} & t_f & e_0 \\ \begin{matrix} k_1 \\ \vdots \\ k_m \end{matrix} & \begin{matrix} rc_{k_1, e_0, t_f} \\ \vdots \\ rc_{k_m, e_0, t_f} \end{matrix} \end{matrix},$$

where $K^0 = \{k_1, k_2, \dots, k_m\}$ and for $1 \leq i \leq m$: rc_{k_i, e_0, t_f} is equal to 0 or 1, depending on whether the k_i -th row of K^0

of the matrix S is crossed out;

$$4) CC[r_0, L^0, t_f] = \begin{matrix} t_f & l_1 & \dots & l_j & \dots & l_n \\ r_0 & cc_{r_0, l_1, t_f} & \dots & cc_{r_0, l_j, t_f} & \dots & cc_{r_0, l_n, t_f} \end{matrix},$$

where $L^0 = \{l_1, l_2, \dots, l_n\}$ and for $1 \leq j \leq m$: cc_{k_i, l_j, t_f} is equal to 0 or 1, depending on whether the l_j -th row of L^0 of the matrix S is crossed out. Let us $rc_{k_i, e_0, t_f} = cc_{r_0, l_j, t_f} = 0$. In the beginning of the algorithm, the initial IM $C[K, L, t_f]$, which consists of the time evaluations $c_{k_i, l_j, t_f} = \langle \mu_{k_i, c_j, t_f}, \nu_{k_i, c_j, t_f} \rangle$ for passing the road from settlement k_i to settlement l_j at a current moment t_f are constructed by application of similar expert approach, described in [3], [8], [19]. The experts $E = \{d_1, \dots, d_s, \dots, d_D\}$ (for $s = 1, \dots, D$) are evaluated the time for passing the road from settlement k_i to settlement l_j at a current moment t_f as a TIFP $\{c_{k_i, l_j, d_s, t_f}\}$, interpreted as the degrees of perception (a positive time evaluation that the expert is more likely to accept for passing the road of the d_s -th expert for the k_i -th settlement to the l_j -th settlement divided by the *max-min* evaluation of time) and non-perception (a negative time evaluation for passing the road of the d_s -th expert from the k_i -th settlement to the l_j -th settlement divided by the *max-min* evaluation of time) of time evaluation for passing the road of the d_s -th expert from the k_i -th settlement to the l_j -th settlement at a current time t_f .

The hesitation degree $\mu_{k_i, l_j, d_s, t_f} = 1 - \mu_{k_i, l_j, d_s, t_f} - \nu_{k_i, l_j, d_s, t_f}$ corresponds to the uncertain evaluation of the time for passing the road of the d_s -th expert from the k_i -th settlement to the l_j -th settlement at a current time moment t_f . If the optimistic (pessimistic) scenario is obtained, then the maximum (minimum) degree of membership μ_{k_i, l_j, d_s, t_f} , proposed by the experts, will be the time evaluation for passing the road from the k_i -th settlement to the l_j -th settlement at a current time t_f . The degree of non-membership of the time evaluation for passing the road from the k_i -th settlement to the l_j -th settlement at a current time t_f is calculated as 1-(minimum) maximum degree of membership, proposed by the experts.

The index matrix interpretation of the described process for creating of the IM C is as follows:

A TIFIMs $C^s(t_f)[K, L, t_f, \{c_{s k_i, l_j, t_f} = \langle \mu_{k_i, l_j, t_f}, \nu_{k_i, l_j, t_f} \rangle\}]$ is created with the dimensions $K = \{k_1, k_2, \dots, k_m\}$, $L = \{l_1, l_2, \dots, l_n\}$ at a particular moment t_f for each expert $d_s (s = 1, \dots, D)$, where $K = \{k_1, k_2, \dots, k_m\}$, $L = \{l_1, l_2, \dots, l_n\}$ and the element $\{c_{s k_i, c_j, t_f}^s\}$ is the time evaluation for passing the road of the d_s -th expert from the k_i -th settlement to the c_j -th settlement at a current time t_f .

Let the ordinal coefficient $r_s(t_f)$ of each expert ($s \in D$) is defined by an TIFP $\langle \delta_s(t_f), \varepsilon_s(t_f) \rangle$, which elements can be interpreted respectively as his degree of competence and of incompetence at a current time t_f . Then the IM

$$C(t_f)[K, L, t_f, \{c_{k_i, l_j, t_f}\}] = r_1 C^1(t_f) \oplus_{(\#_q)} r_d C^d(t_f) \dots \oplus_{(\#_q)} r_D C^D(t_f),$$

$\forall k_i \in K, \forall l_j \in L, \forall s \in D, 1 \leq q \leq 3$ is constructed and it contains the final time evaluation for passing the road from the k_i -th settlement to the l_j -th settlement at a current time t_f .

If we use $\#_1^* = \langle \min, \max \rangle$, then the decision maker accepts super pessimistic scenario, with $\#_2^* = \langle \text{average}, \text{average} \rangle$ the decision maker assumes averaging scenario and with $\#_3^* =$

(\max, \min) he proposes super optimistic scenario for the time evaluation between the settlements.

The steps of TIFHA-TSP approach are as follows:

Step 1. This step checks the problem balance requirement according to [6]. For this aim, the algorithm compares the number of rows with the number of columns in C .

Step 1.1. If the number of rows is greater than the number of columns, then a dummy column $l_{n+1} \in \mathcal{L}$ is entered in the matrix C , in which all time evaluations $c_{k_i, l_{n+1}}$ ($i = 1, \dots, m$) are equal to $\langle 1, 0 \rangle$; otherwise, go to the *Step 1.2*. For this purpose, the following operations are executed:

– we define the IM $C_1[K/\{Q\}, l_{n+1}, t_f], \{c_{1, k_i, l_{n+1}, t_f}\}$, whose elements are equal to $\langle 1, 0 \rangle$;

– the new cost matrix is obtained by:

$C := C \oplus_{(\max, \min)} C_1; s_{k_i, l_j, t_f} = c_{k_i, l_j, t_f}, \forall k_i \in K, \forall l_j \in L$, Go to *Step 2*.

Step 1.2. If the number of columns is greater than the number of rows, then a dummy row $k_{m+1} \in \mathcal{K}$ is entered in the time matrix, in which all time evaluations are equal to $\langle 1, 0 \rangle$. Similar operations to those in *Step 1.1*. are performed. Let us create IM $S = [K, L, \{s_{k_i, l_j}\}]$ such that $S = C$.

Step 2. In each row k_i of K of S , the smallest element is found among the elements s_{k_i, l_j, t_f} ($j = 1, \dots, n$) and it is subtracted from all elements s_{k_i, l_j, t_f} for $j = 1, 2, \dots, n$.

Go to *Step 3*.

Step 2.1. For each row k_i of K of S , the smallest element is found and is recorded as the value of the element s_{k_i, R, t_f} :

for $i = 1$ to m , for $j = 1$ to n

$\{AGIndex_{\min_R, (\mathcal{L})}(pr_{k_i, L, t_f} S) = \langle k_i, l_{v_j}, t_f \rangle\}$;

If the minimum elements are more than one, then one of them is chosen arbitrary.

We create S_1 and S_2 : $S_1[k_i, l_{v_j}, t_f] = pr_{k_i, l_{v_j}, t_f} S$;

$S_2 = \left[\perp; \frac{R}{l_{v_j}}; \perp; \perp \right] S_1$; $S := S \oplus_{(\#_q)} S_2$, where $1 \leq q \leq 3$.

Step 2.2. The smallest element s_{k_i, l_{v_j}, t_f} is subtracted from the elements s_{k_i, l_j, t_f} ($j = 1, \dots, m$). Let us create IM $B = pr_{K, R, t_f} S$.

for $i = 1$ to m , for $j = 1$ to n

If $s_{k_i, l_j, t_f} \neq \perp$, then $\{IO_{-(\max, \min)}(\langle k_i, l_j, t_f, S \rangle, \langle k_i, R, t_f, B \rangle)\}$.

Step 3. For each index l_j of L of S , the smallest element is found among the elements s_{k_i, l_j, t_f} ($i = 1, \dots, m$) and it is subtracted from all elements s_{k_i, l_j, t_f} , for $i = 1, 2, \dots, m$ at a particular moment t_f . Go to *Step 4*. Similar operations to those in *Step 2*. are executed. They are presented in [16].

Step 4. At this step are crossed out all elements s_{k_i, l_j, t_f} for $\langle k_i, l_j, t_f \rangle \in \{Index_{(\max v), k_i/l_j}(S)\}$ or equal to $\langle 0, 1 \rangle$ in S with the minimum possible number of lines (horizontal, vertical or both). If the number of these lines is m , go to *Step 6*. If the number of lines is less than m , go to *Step 7*.

This step introduces IM $D[K^0, L^0, t_f]$, which has the same structure as the IM X . We use to mark whether an element in S is crossed out with a line.

If $d_{k_i, l_j, t_f} = 1$, then s_{k_i, l_j, t_f} is covered with one line;

if $d_{k_i, l_j, t_f} = 2$, then s_{k_i, l_j, t_f} is covered with two lines.

The IMs $CC[r_0, L^0]$ and $RC[K^0, e_0]$ reflect whether the element is covered by a line in a row or column in the S matrix.

for $i = 1$ to m , for $j = 1$ to n

If $s_{k_i, l_j, t_f} = \langle 0, 1 \rangle$ (or $\langle k_i, l_j, t_f \rangle \in Index_{(\max v), k_i/l_j}(S)$) and $d_{k_i, l_j, t_f} = 0$, then $\{rc_{k_i, e_0, t_f} = 1$; for $i = 1$ to m $d_{k_i, l_j} = 1$; $S_{(k_i, \perp, t_f)}\}$.

If $s_{k_i, l_j, t_f} = \langle 0, 1 \rangle$ (or $\langle k_i, l_j, t_f \rangle \in Index_{(\max v), k_i}(S)$) and $d_{k_i, l_j, t_f} = 1$, then $\{d_{k_i, l_j, t_f} = 2$; $cc_{r_0, l_j, t_f} = 1$;

for $j = 1$ to n $d_{k_i, l_j, t_f} = 1$; $S_{(\perp, l_j, t_f)}\}$.

Then we count the covered rows and columns in CC and RC :

$Index_{(1)}(RC) = \{\langle k_{u_1}, e_0, t_f \rangle, \dots, \langle k_{u_i}, e_0, t_f \rangle, \dots, \langle k_{u_x}, e_0, t_f \rangle\}$;

$Index_{(1)}(CC) = \{\langle r_0, l_{v_1}, t_f \rangle, \dots, \langle r_0, l_{v_j}, t_f \rangle, \dots, \langle r_0, l_{v_y}, t_f \rangle\}$.

If $\text{count}(Index_{(1)}(RC)) + \text{count}(Index_{(1)}(CC)) = m$, then go to *Step 6*, otherwise to *Step 5*.

Step 5. We find the smallest element in the IM S that it is not crossed by the lines in *Step 4*, and subtract it from any uncovered element of S , and we add it to each element, which is covered by two lines. We return to *Step 4*.

The operation $AGIndex_{\min_R, (\mathcal{L})}(S) = \langle k_x, l_y, t_f \rangle$ finds the smallest element index of the IM S . The operation $IO_{-(\max, \min)}(\langle S \rangle, \langle k_x, l_y, t_f S \rangle)$ subtract it from any uncovered element of S . Then we add it to each element of S , which is crossed out by two lines:

for $i = 1$ to m , for $j = 1$ to n

{if $d_{k_i, l_j, t_f} = 2$, then $S_1 = pr_{k_x, l_y, t_f} C$;

$S_2 = pr_{k_i, l_j, t_f} C \oplus_{(\#_q)} \left[\frac{k_i}{k_x}, \frac{l_j}{l_y}, t_f \right] S_1$; $S := S \oplus_{(\#_q)} S_2$;

if $d_{k_i, l_j, t_f} = 1$ or $d_{k_i, l_j, t_f} = 2$ then $S := S \oplus_{(\#_q)} pr_{k_i, l_j, t_f} C$;

Go to *Step 4*.

Step 6. Here we search each row until we find a row-wise exactly single element, which is a TIFFalseP. We mark this pair to make the assignment, then cross out all elements lying in the respective column. If there lie more than one unmarked TIFFalseP in any column or row, then choose one of them arbitrary and cross out the remaining elements in its row or column. We repeat until no unmarked elements are left in the reduced IM. Then each row and column of S has exactly one marked TIFFalseP. If the solution does not satisfy the route conditions, adjustments need to be made to the assignments with minimum increase to the total cost [14]. The optimal solution $X_{opt}[K^0, L^0, \{x_{k_i, l_j, t_f}\}]$ is found where the elements $\langle 1, 0 \rangle$ in X correspond to the marked elements in S .

{for $i = 1$ to m , for $j = 1$ to n

if $(\langle k_i, l_j, t_f \rangle \in Index_{(\max v), k_i/l_j}(S))$ and $d_{k_i, l_j, t_f} \neq 3$, then $x_{k_i, l_j, t_f} = \langle 1, 0 \rangle$;

for $i = 1$ to m $d_{k_i, l_j, t_f} = 3$

for $j = 1$ to n $d_{k_i, l_j, t_f} = 3$ };

The optimal time evaluation for X_{opt} at a particular moment t_f is:

$$AGIO_{\oplus(\#_q)} \left(C(\{Q\}, \{R\}) \otimes_{(\#_q)} X_{opt} \right),$$

$\forall k_i \in K, \forall l_j \in L, 1 \leq q \leq 3$ in a pessimistic scenario $q = 1$. If we want an optimistic result, we can use 3 in place of 1.

Step 7. The old rank coefficients of the experts, involved in the evaluation process are changed by [8]:

$$= \begin{cases} \left\langle \frac{\delta(t_f)\lambda+1}{\lambda+1}, \frac{\varepsilon(t_f)\lambda}{\lambda+1} \right\rangle, & \text{if the expert has assessed correctly} \\ \left\langle \frac{\delta(t_f)\gamma}{\lambda+1}, \frac{\varepsilon(t_f)\lambda}{\lambda+1} \right\rangle, & \text{if the expert had not given any estimation} \\ \left\langle \frac{\delta(t_f)\lambda}{\lambda+1}, \frac{\varepsilon(t_f)\lambda+1}{\lambda+1} \right\rangle, & \text{if the expert has assessed incorrectly} \end{cases} \quad (3)$$

The complexity of the HA as used here is comparable with that of the standard Hungarian method [7], [13]. To explore the effect of TIFHA-TSP on various input data, we are currently developing a software tool that implements the algorithm. It reads a file containing the matrix of time evaluations and performs the steps stated above. It is written in C++ and uses the *IndexMatrix* template class [4] with TIFPs. Several operations had to be adjusted, most significantly the IFP and TIFP subtraction operation, which will now return a false pair $\langle 0,1 \rangle$ of the two operands are equal, and subtracting a false pair from another (T)IFP will result in no change.

B. A Real Case Study of TIFHA-TSP

In this section, we demonstrate TIFHA-TSP with a real case study in a shipping company for a day of the week in Bulgaria. The carrier needs to visit 4 settlements and wants to make a cyclical route passing all of them. The evaluation TIFPs are given by experts with ratings $\{\langle 0.9,0.05 \rangle, \langle 0.8,0.05 \rangle, \langle 0.95,0.05 \rangle\}$ defined on the basis of their participation in 10 ($s = 1, \dots, D$) past procedures respectively in the days before t_f . The initial evaluation time IM $C[K, L, t_f]$ incorporating the ratings of the experts is:

$$\begin{matrix} \left. \begin{matrix} t_f & l_1 & l_2 & l_3 & l_4 & R \\ k_1 & \langle \perp, \perp \rangle & \langle 0.72, 0.09 \rangle & \langle 0.55, 0.2 \rangle & \langle 0.45, 0.45 \rangle & \langle \perp, \perp \rangle \\ k_2 & \langle 0.57, 0.23 \rangle & \langle \perp, \perp \rangle & \langle 0.7, 0.15 \rangle & \langle 0.61, 0.1 \rangle & \langle \perp, \perp \rangle \\ k_3 & \langle 0.67, 0.15 \rangle & \langle 0.4, 0.28 \rangle & \langle \perp, \perp \rangle & \langle 0.7, 0.05 \rangle & \langle \perp, \perp \rangle \\ k_4 & \langle 0.83, 0.05 \rangle & \langle 0.75, 0.1 \rangle & \langle 0.65, 0.13 \rangle & \langle \perp, \perp \rangle & \langle \perp, \perp \rangle \\ Q & \langle \perp, \perp \rangle & \langle \perp, \perp \rangle & \langle \perp, \perp \rangle & \langle \perp, \perp \rangle & \langle \perp, \perp \rangle \end{matrix} \right\} \end{matrix}$$

After application of the software utility, described in the section (III), we get the following results:

Step 1. $m = n$, therefore the problem is balanced.

Step 2. - 3. In each row k_i of K of S , the smallest element is found among the elements s_{k_i, l_j, t_f} ($j = 1, \dots, n$) and it is subtracted from all elements s_{k_i, l_j, t_f} for $j = 1, 2, \dots, n$. For each index l_j of L of S , the smallest element is found among the elements s_{k_i, l_j, t_f} ($i = 1, \dots, m$) and it is subtracted from all elements s_{k_i, l_j, t_f} , for $i = 1, 2, \dots, m$ at a particular moment t_f . The form of the IM $C(t_f)$ is

$$\left. \begin{matrix} \begin{matrix} l_1 & l_2 & l_3 & l_4 & R \\ k_1 & \langle \perp, \perp \rangle & \langle 0.27, 0.54 \rangle & \langle 0.1, 0.65 \rangle & \langle 0, 1 \rangle & \langle 0.45, 0.45 \rangle \\ k_2 & \langle 0, 1 \rangle & \langle \perp, \perp \rangle & \langle 0.13, 0.38 \rangle & \langle 0.04, 0.33 \rangle & \langle 0.57, 0.23 \rangle \\ k_3 & \langle 0.27, 0.43 \rangle & \langle 0, 1 \rangle & \langle \perp, \perp \rangle & \langle 0.3, 0.33 \rangle & \langle 0.4, 0.28 \rangle \\ k_4 & \langle 0.18, 0.18 \rangle & \langle 0.1, 0.23 \rangle & \langle 0, 1 \rangle & \langle \perp, \perp \rangle & \langle 0.65, 0.13 \rangle \\ Q & \langle 0, 1 \rangle & \langle 0, 1 \rangle & \langle 0, 1 \rangle & \langle 0, 1 \rangle & \langle \perp, \perp \rangle \end{matrix} \end{matrix} \right\}$$

Step 4. At this step are crossed out all elements s_{k_i, l_j, t_f} equal to $\langle 0,1 \rangle$ in S with the minimum possible number of lines. Since each row and each column contain exactly one false pair, we will cross out all four rows. The test for the optimality is satisfied (the number of lines = $m = n = 4$). Step 5 does not apply, because there are no uncrossed elements.

The next steps will give us the final results.

In **Step 6**, we find that the optimal route is: $A \rightarrow D \rightarrow C \rightarrow B \rightarrow A$ and in an optimistic scenario it will take the optimal time of travelling with degree of membership 0.65 and degree of non-membership 0.13, forming the IFP $\langle 0.65, 0.13 \rangle$. In a pessimistic scenario, the optimal time IFP is $\langle 0.4, 0.45 \rangle$.

Step 7. The new ranking coefficients of the experts are equal respectively to $\{\langle 0.91, 0.05 \rangle, \langle 0.81, 0.05 \rangle, \langle 0.95, 0.05 \rangle\}$, because their evaluations are intuitionistic fuzzy correct.

IV. CONCLUSION

In the study, we defined TIFHA-TSP, a temporal intuitionistic fuzzy extension of the Hungarian method for solving the TSP using the IF logic and IMs concepts. The developed software, which implements this TIFHA-TSP approach, is applied to a real case in a shipping company at a certain time. In the future, the research will continue with the development of TIFHA-TSP so that it can find the optimal solution of the IFTSP, where the initial data have saved in extended TIFIMs [9] and also with a software for its implementation.

Abstract—The selection of the most suitable franchisee applicant in an uncertain environment in a particular moment of time is a key decision for a franchisor and the success of a franchising business. In this work, for the first time, we describe a problem for choosing the optimal candidate for the franchise chain and algorithm for a solution in terms of temporal intuitionistic fuzzy pairs and index matrices as a means for data analysis in uncertain conditions over time. We also use our software utility to demonstrate the proposed algorithm and to apply the decision support approach to a franchisee selection for the largest fast food restaurant chain in Bulgaria.

I. INTRODUCTION

Franchising is an effective business strategy for entering new markets. The franchisor grants the right to its franchisees to use the brand, the business concept, and the products or services within a specific time frame [1]. The concept of fuzzy [10] and intuitionistic fuzzy logic [6], provides such a tool for creating an optimal algorithm for choosing a franchisee in conditions of ambiguity. The studies [12], [13] present fuzzy franchisee selection models using an Analytic Hierarchy Process (AHP) and neural networks.

In [16], we presented an optimal interval-valued intuitionistic fuzzy multicriteria decision-making problem in outsourcing and a software utility for its solution. We have also introduced in [19] an intuitionistic fuzzy approach (IFIMFr) to select the most suitable candidates for franchising in a patisserie using the theory of index matrices (IMs, [5]). The aim of the paper is to expand the IFIMFr approach so that it can be applied to temporal intuitionistic fuzzy data [3]. The work uses our custom programs to implement the proposed algorithm and to apply it to the largest fast food restaurant chain in Bulgaria. The remainder of our study includes 4 sections: Section II describes some definitions and properties of temporal intuitionistic fuzzy IMs and pairs. Section III describes a problem for choosing the optimal franchise candidate and algorithm

for solution in terms of temporal IFPs an IMs as a means for uncertain data analysis over time and the basic characteristics of our software utility. Section IV sets out the conclusions and aspects for future research.

II. DEFINITION AND PROPERTIES OF TEMPORAL INTUITIONISTIC FUZZY IMs AND PAIRS

Let us briefly give the definitions of temporal intuitionistic fuzzy IMs and TIFPs and some of their properties [3].

2.1. Temporal Intuitionistic Fuzzy Pair (TIFP)

Let $T = \{t_1, \dots, t_g, \dots, t_f\}$ be a fixed time-scale. A TIFP is in the form of $\langle \mu(t), \nu(t) \rangle$, where $\mu(t)$ and $\nu(t)$ are interpreted as degrees of membership and non-membership, $\mu, \nu : T \rightarrow [0, 1]$ and $\mu(t) + \nu(t) \leq 1$ for $t \in T$. Let us have two TIFPs $x = \langle \mu(t), \nu(t) \rangle$ and $y = \langle \rho(t), \sigma(t) \rangle$. Then, we recall some basic operations [3] with two TIFPs.

$$\begin{aligned} x(t) \wedge_1 y(t) &= \langle \min(\mu(t), \rho(t)), \max(\nu(t), \sigma(t)) \rangle \\ x(t) \vee_1 y(t) &= \langle \max(\mu(t), \rho(t)), \min(\nu(t), \sigma(t)) \rangle; \\ x(t) \wedge_2 y(t) &= x(t) + y(t) = \langle \mu(t) + \rho(t) - \mu(t) \cdot \rho(t), \nu(t) \cdot \sigma(t) \rangle \end{aligned} \quad (1)$$

Let $R_{\langle a(t), b(t) \rangle} = 0.5 \cdot (2 - a(t) - b(t)) \cdot (1 - a(t))$ following [4]. Then, as per [6], [20]:

$$x(t) \geq_R y(t) \text{ iff } R_{\langle a(t), b(t) \rangle} \leq R_{\langle c(t), d(t) \rangle}. \quad (2)$$

2.2. Three-Dimensional Temporal Intuitionistic Fuzzy Index Matrices (3-D TIFIM)

A 3-D TIFIM [5] $A(T) = [K, L, T, \{\langle \mu_{k_i, l_j, t_g}, \nu_{k_i, l_j, t_g} \rangle\}]$

$$= \begin{array}{c|ccc} t_g \in T & l_1 & \dots & l_n \\ \hline k_1 & \langle \mu_{k_1, l_1, t_g}, \nu_{k_1, l_1, t_g} \rangle & \dots & \langle \mu_{k_1, l_n, t_g}, \nu_{k_1, l_n, t_g} \rangle \\ \vdots & \vdots & \dots & \vdots \\ k_m & \langle \mu_{k_m, l_1, t_g}, \nu_{k_m, l_1, t_g} \rangle & \dots & \langle \mu_{k_m, l_n, t_g}, \nu_{k_m, l_n, t_g} \rangle \end{array}, \quad (3)$$

where \mathcal{S} be a fixed set of indices, $(K, L, T \subset \mathcal{S})$, and its elements $\langle \mu_{k_i, l_j, t_g}, \nu_{k_i, l_j, t_g} \rangle$ are TIFPs. T is a fixed temporal scale and its elements $t_g (g = 1, \dots, g, \dots, f)$ are time moments.

In [5], [17], [18], operations with 3-D TIFIMs, analogous to those with the classical matrices were introduced, but there are also specific ones such as projection, substitution, aggregation operations, internal subtraction of IMs' components, term-wise multiplication and subtraction. Let us recollect some operations with an application in temporal IFIMFr.

Aggregation operation by one dimension [17]: Let us have

Work is supported by the Asen Zlatarov University through project Ref. No. NIX-449/2021 "Index matrices as a tool for knowledge extraction".

two TIFPs $x = \langle a, b \rangle$ and $y = \langle c, d \rangle$ and $(1 \leq q \leq 3)$. An aggregation operation by one dimension is

$$\alpha_{K, \#_q}(A(T), k_0) = \begin{array}{c|ccc} t_g & l_1 & \dots & l_n \\ \hline k_0 & \#_q^m \langle \mu_{k_i, l_1, t_g}, \nu_{k_i, l_1, t_g} \rangle & \dots & \#_q^m \langle \mu_{k_i, l_n, t_g}, \nu_{k_i, l_n, t_g} \rangle \end{array} \quad (4)$$

If we use $\#_1^* = \langle \min(a(t), c(t)), \max(b(t), d(t)) \rangle$ we perform a super pessimistic aggregation operation, with $\#_2^* = \langle \text{average}(a(t), c(t)), \text{average}(b(t), d(t)) \rangle$ we have an averaging aggregation operation, and with $\#_3^* = \langle \max(a(t), c(t)), \min(b(t), d(t)) \rangle$ we perform a super optimistic aggregation operation.

Projection: Let $W \subseteq K$, $V \subseteq L$ and $U \subseteq H$. Then, $pr_{W, V, U}A(T) = [W, V, U, \{\langle R_{pr, q_s, e_d}, S_{pr, q_s, e_d} \rangle\}]$, where for each $k_i \in W, l_j \in V$ and $t_g \in U$, $\langle R_{pr, q_s, e_d}, S_{pr, q_s, e_d} \rangle = \langle \mu_{k_i, l_j, t_g}, \nu_{k_i, l_j, t_g} \rangle$.

A Level Operator for Decreasing the Number of Elements of TIFIM: Let $\langle \alpha(t), \beta(t) \rangle$ is an TIFP, then according to [9] $N_{\alpha(t), \beta(t)}^>(A(T)) = [K, L, T, \{\langle \rho_{k_i, l_j, t_g}, \sigma_{k_i, l_j, t_g} \rangle\}]$, where

$$= \begin{cases} \langle \rho_{k_i, l_j, t_g}, \sigma_{k_i, l_j, t_g} \rangle & \text{if } \langle \rho_{k_i, l_j, t_g}, \sigma_{k_i, l_j, t_g} \rangle > \langle \alpha(t), \beta(t) \rangle \\ (0, 1) & \text{otherwise} \end{cases} \quad (5)$$

III. AN OPTIMAL TEMPORAL INTUITIONISTIC FUZZY ALGORITHM FOR SELECTION OF THE MOST ELIGIBLE FRANCHISEE (OTIFAFr)

This section proposes an OTIFAFr, used the concepts of IMs and TIFPs. Let us formulate the optimal problem as follows:

A large franchise has decided to turn to experts to select the best franchisee candidate for expanding its brand. The franchise candidates for studied brand v_e need to be evaluated by the experts. The experts assess the IF priorities pk_{c_j, v_e, t_f} of the criteria c_j in the evaluation system of the franchise chain v_e at a particular moment t_f . The IF ratings of the experts are defined on the basis of their participation in previous franchise evaluation procedures and given to the experts at a time t_f . All candidates for a franchisee have been evaluated by the experts at a particular moment t_f and their evaluations ev_{k_i, c_j, d_s, t_f} at a current moment t_f are temporal intuitionistic fuzzy data. The estimations of the same applicants from previous evaluation procedures are given as elements of TIFIM at time points $t_1, \dots, t_g, \dots, t_{f-1}$. The aim of the problem is to select the most eligible franchisee for this brand.

A. An Optimal Temporal Intuitionistic Fuzzy Algorithm for Assignment of a Franchisee

The procedure of OTIFAFr includes the following steps:

Step 1. The team of experts needs to evaluate the candidates for the brand v_e according to the approved criteria in the company at a particular moment t_f . The estimations of the $d_s (1 \leq s \leq D)$ expert are described by the TIFP $ev_{k_i, c_j, d_s, t_f} = \langle \mu_{k_i, c_j, d_s, t_f}, \nu_{k_i, c_j, d_s, t_f} \rangle$ by criterion $c_j (1 \leq j \leq n)$ for the the k_i -th $(1 \leq i \leq m)$ candidate at a particular moment t_f . Expert assessments are uncertain due to galloping inflation and the existing pandemic. The data values are transformed into TIFPs as demonstrated in [3], [20]. The TIFP $\{ev_{k_i, c_j, d_s, t_f}\}$ presents the degrees of perception (the positive evaluation of the d_s -th expert for the k_i -th candidate by the c_j -th criterion divided by the (maximum-minimum) evaluation) and non-perception (the

negative evaluation of the d_s -th expert for the k_i -th candidate by the c_j -th criterion divided by the (maximum-minimum) evaluation) of the d_s -th expert for the k_i -th candidate by the c_j -th criterion at a particular moment t_f . The hesitation degree $\mu_{k_i, c_j, d_s, t_f} = 1 - \mu_{k_i, c_j, d_s, t_f} - \nu_{k_i, c_j, d_s, t_f}$ corresponds to the uncertain evaluation of the d_s -th expert for the k_i -th candidate by the c_j -th criterion at a particular moment t_f .

The experts have the opportunity to include assessments for the same candidates from the previous evaluation procedures at time points $t_1, \dots, t_g, \dots, t_{f-1}$. A TIFIM $EV_s[K, C, T, \{ev_{k_i, c_j, d_s, t_g}\}]$ is built with the dimensions $K = \{k_1, k_2, \dots, k_m\}$, $C = \{c_1, c_2, \dots, c_n\}$ and $T = \{t_1, t_2, \dots, t_f\}$ for each expert $d_s (s = 1, \dots, D)$:

$$EV_s[K, C, T, \{ev_{k_i, c_j, d_s, t_g}\}] = \begin{array}{c|ccc} t_g \in T & c_1 & \dots & c_n \\ \hline k_1 & \langle \mu_{k_1, c_1, d_s, t_g}, \nu_{k_1, c_1, d_s, t_g} \rangle & \dots & \langle \mu_{k_1, c_n, d_s, t_g}, \nu_{k_1, c_n, d_s, t_g} \rangle \\ \vdots & \vdots & \ddots & \vdots \\ k_m & \langle \mu_{k_m, c_1, d_s, t_g}, \nu_{k_m, c_1, d_s, t_g} \rangle & \dots & \langle \mu_{k_m, c_n, d_s, t_g}, \nu_{k_m, c_n, d_s, t_g} \rangle \end{array},$$

where $K = \{k_1, k_2, \dots, k_m\}$, $C = \{c_1, c_2, \dots, c_n\}$, $T = \{t_1, t_2, \dots, t_f\}$ and the element $\{ev_{k_i, c_j, d_s, t_g}\}$ is the estimate of the d_s -th expert for the k_i -th candidate by the c_j -th criterion at a particular moment t_g . Let us apply the α_T -th aggregation operation (4) to find the aggregated evaluation of the d_s -th expert $(s = 1, \dots, D)$ for the k_i -th candidate for the period T .

The result IM $\alpha_{EV_s(T), \#_q}$ has the form

$$\alpha_{EV_s(T), \#_q} = \begin{array}{c|ccc} d_s & \dots & c_n \\ \hline k_1 & \dots & \#_q^f \langle \mu_{k_1, c_n, d_s, t_g}, \nu_{k_1, c_n, d_s, t_g} \rangle_{g=1} & \dots \\ \vdots & \ddots & \vdots & \ddots \\ k_m & \dots & \#_q^f \langle \mu_{k_m, c_n, d_s, t_g}, \nu_{k_m, c_n, d_s, t_g} \rangle_{g=1} & \dots \end{array},$$

where $1 \leq q \leq 3$ depending on whether the pessimistic, averaging or optimistic scenarios are accepted in the process of decision making in the franchise chain. Then we create aggregated TIFIM $EV[K, C, E, \{ev_{k_i, c_j, d_s, t_f}\}]$ with the evaluations of all experts for all candidates by all criteria:

$$EV(t_f) = \alpha_{EV_1, \#_q}(T, d_1) \oplus_{(max, min)} \dots \oplus_{(max, min)} \alpha_{EV_D, \#_q}(T, d_D) \quad (6)$$

Then we go to Step 2.

Step 2. Let the present score coefficient $r_s(t_f)$ of each expert $(s \in E)$ is defined by an TIFP $\langle \delta_s(t_f), \varepsilon_s(t_f) \rangle$, which elements can be interpreted respectively as his degree of competence and of incompetence at a particular moment t_f . Then is created the IM $V(t_f)[K, C, E, \{v_{k_i, c_j, d_s, t_f}\}]$

$$= r_1 pr_{K, C, d_1, t_f} EV \oplus_{(max, min)} r_2 pr_{K, C, d_2, t_f} EV \dots \oplus_{(max, min)} r_D pr_{K, C, d_D, t_f} EV.$$

The IM $EV(t_f) := V(ev_{k_i, l_j, d_s, t_f} = v_{k_i, l_j, d_s, t_f}, \forall k_i \in K, \forall l_j \in L, \forall d_s \in E)$ contains the final score of each franchise candidate at a particular moment t_f .

The total assessment of the k_i -th candidate on the c_j -th criterion at a particular moment $t_f \notin E$ is calculated by an application of the α_E -th aggregation operation as follows

$$R(h_0) = \alpha_{E, \#_q}(EV(t_f), h_0) = \left\{ \begin{array}{c|ccc} c_j & h_0 & & \\ \hline k_1 & \#_q^D \langle \mu_{k_1, c_j, d_s, t_f}, \nu_{k_1, c_j, d_s, t_f} \rangle & & \\ \vdots & \vdots & & \\ k_m & \#_q^D \langle \mu_{k_m, c_j, d_s, t_f}, \nu_{k_m, c_j, d_s, t_f} \rangle & & \end{array} \right\}_{c_j \in C}, \quad (7)$$

where $(1 \leq q \leq 3)$.

If we use $\#_1^* = \langle \min, \max \rangle$, then we accept super pessimistic aggregation operation, with $\#_2^* = \langle \text{average}, \text{average} \rangle$ we assume averaging aggregation operation and with $\#_3^* = \langle \max, \min \rangle$ we accept super optimistic aggregation operation for the assessment of the applicant.

If the franchise chain has a requirement for the candidates, so that their total score is not less than a predetermined TIFP $\langle \alpha(t_f), \beta(t_f) \rangle$, then in this case it is necessary to apply the level operator (5) to TIFIM B to remove from the ranking candidates who do not meet this requirement. Go to *Step 3*.

Step 3. This step creates a TIFIM $PK(h_0)$ with the coefficients determining the importance of the evaluation criteria for the franchisor v_e at a particular moment t_f by :

$$PK(h_0)[C, v_e, h_0, \{pk_{c_j, v_e, h_0}\}] = \begin{array}{c|c} h_0 & v_e \\ \hline c_1 & pk_{c_1, v_e, h_0} \\ \vdots & \vdots \\ c_j & pk_{c_j, v_e, h_0} \\ \vdots & \vdots \\ c_n & pk_{c_n, v_e, h_0} \end{array},$$

Then we calculate the evaluation TIFIM

$$B(h_0)[K, v_e, h_0, \{b_{k_i, v_e, h_0}\}] = R(h_0) \odot_{(\circ, *)} PK(h_0),$$

containing the total estimates of the k_i -th candidate (for $1 \leq i \leq m$) at a particular moment t_f for the brand v_e , where $\langle \circ, * \rangle$ is an operation from (4). Go to *Step 4*.

Step 4. At this step we choose the most optimal franchisee for v_e by using the aggregation operation by $K - \alpha_{K, \#_q}(B(h_0), k_0)$ using pessimistic, average or optimistic scenarios

$$\alpha_{K, \#_q}(B(h_0), k_0) = \begin{array}{c|c} & v_e \\ \hline k_0 & \begin{array}{c} m \\ \#_q \\ \langle \mu_{k_i, v_e, h_0}, \nu_{k_i, v_e, h_0} \rangle \end{array} \end{array}, \quad (8)$$

where $k_0 \notin K, 1 \leq q \leq 3$. Go to *Step 5*.

Step 5. After finding the most effective franchisee, we will optimize the evaluation system for the next procedures using the intercriteria method (ICrA, [7], [8], [14]).

Let $\langle \alpha, \beta \rangle$ is an TIFP. The criteria C_k and C_l are in:

- $\langle \alpha(t_f), \beta(t_f) \rangle$ -positive consonance at a particular moment t_f , if $\mu_{C_k, C_l}(t_f) > \alpha(t_f)$ and $\nu_{C_k, C_l}(t_f) < \beta(t_f)$;
- $\langle \alpha(t_f), \beta(t_f) \rangle$ -negative consonance at a particular moment, if $\mu_{C_k, C_l}(t_f) < \beta(t_f)$ and $\nu_{C_k, C_l}(t_f) > \alpha(t_f)$;
- $\langle \alpha(t_f), \beta(t_f) \rangle$ -dissonance at a particular moment t_f , otherwise.

ICrA is applied over the matrix $R(h_0)$ to find the criteria, which are in a consonance. More complex criteria are reduced from the evaluation franchise system using the IM reduction operation over $R(h_0)$. Go to *Step 6*.

Step 6. This step obtains the new rank coefficients of the experts. Let the expert d_s ($s = 1, \dots, D$) has participated in γ_s evaluation procedures for the selection of a franchisee, on the basis of which his score $r_s(t_f) = \langle \delta_s(t_f), \varepsilon_s(t_f) \rangle$ is determined, then after his participation in the next procedure, his new score

$$\langle \delta_s^{(t_f+1)}, \varepsilon_s^{(t_f+1)} \rangle \text{ will be changed by [6]:} \begin{cases} \langle \frac{\delta(t_f)\gamma+1}{\gamma+1}, \frac{\varepsilon(t_f)\gamma}{\gamma+1} \rangle, & \text{if the expert has assessed correctly} \\ \langle \frac{\delta(t_f)\gamma}{\gamma+1}, \frac{\varepsilon(t_f)\gamma}{\gamma+1} \rangle, & \text{if the expert had not given any estimation} \\ \langle \frac{\delta(t_f)\gamma}{\gamma+1}, \frac{\varepsilon(t_f)\gamma+1}{\gamma+1} \rangle, & \text{if the expert has assessed incorrectly} \end{cases} \quad (9)$$

The complexity of OTIFAFr algorithm is $O(Dm^2n^2)$ [15]. For the application of the OTIFAFr algorithm, we will use an updated version of the C++ utility we previously developed for the IFIMOA and IVIFIMOA algorithms. As we outlined before [2], [16], it is based on a template class which allows us to replace its type with any C++ type or class that implements basic comparison and arithmetic operators. This has allowed us to use the same code for both IFPs (as we will do here) and IVIFPs (as we have done in [16], [21]). The program is command-line based. It expects the following input arguments: a 3-D TIFIM of the experts' evaluations, a matrix of the experts' rating coefficients and a matrix of the weight coefficients of each criterion for each service. The expert evaluations can be given either directly as an index matrix of IFPs, or as a matrix of mark intervals. For the latter case, the first argument of the program must be "interval" followed by the lowest and highest possible mark that an expert can give [21].

B. An Application of OTIFAFr to the Largest Fast Food Restaurant Chain in Bulgaria

In this section, the proposed OTIFAFr model from Sect. III-A is demonstrated with a real case study for choosing a franchisee for the largest fast food restaurant chain in Bulgaria. The optimal problem is defined below: The largest fast food restaurant chain in Bulgaria has given a decision to expand its business through the selection of a franchisee. The franchisor decides to invite a team of 3 experts to evaluate the 3 candidates at a particular moment t_f . The evaluation system consists of 4 groups of criteria: C_1 - owner profitability and business experience level; C_2 - brand marketing and franchise brand development concept; C_3 - opportunities to quickly start a franchise and actively participate in the management of the restaurant and C_4 - restaurant traffic management and parking options, strategic location of the restaurant and successful traffic management around it with provided parking opportunities. Each criteria has priority coefficient as TIFPs pk_{c_j, v_e, t_f} according to their importance from the franchisor's point of view at a current moment t_f . The experts' ratings are defined by TIFP $\{r_1(t_f), r_2(t_f), r_3(t_f)\}$ at a particular moment t_f . In the final ranking we admit only candidates with an overall score higher than $\langle 0.6, 0.01 \rangle$ Now we need to optimally rank the candidates and select the most eligible one.

Solution of the problem:

Step 1. At this step, we create the expert evaluation TIFIM $EV[K, C, E, \{es_{k_i, c_j, d_s}\}]$ with the estimates of the d_s -th expert for the k_i -th candidate by the c_j -th criterion (for $1 \leq i \leq 3, 1 \leq j \leq 4, 1 \leq s \leq 3$) and its form is:

$$\begin{array}{c|cccc} d_1 & c_1 & c_2 & c_3 & c_4 \\ \hline k_1 & \langle 0.4, 0.2 \rangle & \langle 0.3, 0.4 \rangle & \langle 0.7, 0.1 \rangle & \langle 0.3, 0.4 \rangle \\ k_2 & \langle 0.2, 0.7 \rangle & \langle 0.5, 0.3 \rangle & \langle 0.5, 0.4 \rangle & \langle 0.5, 0.3 \rangle \\ k_3 & \langle 0.5, 0.1 \rangle & \langle 0.2, 0.6 \rangle & \langle 0.3, 0.3 \rangle & \langle 0.7, 0.1 \rangle \\ \hline d_2 & c_1 & c_2 & c_3 & c_4 \\ \hline k_1 & \langle 0.5, 0.3 \rangle & \langle 0.2, 0.6 \rangle & \langle 0.8, 0.0 \rangle & \langle 0.4, 0.4 \rangle \\ k_2 & \langle 0.3, 0.7 \rangle & \langle 0.4, 0.4 \rangle & \langle 0.7, 0.1 \rangle & \langle 0.7, 0.0 \rangle \\ k_3 & \langle 0.4, 0.3 \rangle & \langle 0.4, 0.5 \rangle & \langle 0.2, 0.6 \rangle & \langle 0.5, 0.3 \rangle \\ \hline d_3 & c_1 & c_2 & c_3 & c_4 \\ \hline k_1 & \langle 0.2, 0.6 \rangle & \langle 0.3, 0.6 \rangle & \langle 0.5, 0.3 \rangle & \langle 0.5, 0.3 \rangle \\ k_2 & \langle 0.2, 0.7 \rangle & \langle 0.4, 0.5 \rangle & \langle 0.3, 0.5 \rangle & \langle 0.6, 0.1 \rangle \\ k_3 & \langle 0.4, 0.4 \rangle & \langle 0.3, 0.6 \rangle & \langle 0.4, 0.5 \rangle & \langle 0.5, 0.4 \rangle \end{array}$$

Step 2. The rating coefficients of the experts at t_f are: $\{r_1(t_f), r_2(t_f), r_3(t_f)\} = \{(0.7, 0.05), (0.6, 0.05), (0.8, 0.05)\}$.

The TIFIM $V(t_f)[K, C, E, \{v_{k_i, c_j, d_s, t_f}\}]$, which contains the final score of each franchisee at a current moment t_f , is constructed by

$$V(t_f) = r_1 pr_{K,C,d_1,t_f} EV \oplus_{(max,min)} r_2 pr_{K,C,d_2,t_f} EV \oplus_{(max,min)} \oplus_{(max,min)} r_3 pr_{K,C,d_3,t_f} EV(t_f); EV(t_f) := V(t_f) \quad (10)$$

Then we apply the operation $\alpha_{E, \#_q}(EV, h_0) = R[K, C, h_0]$

h_0	c_1	c_2	c_3	c_4
k_1	$\langle 0.3, 0.24 \rangle$	$\langle 0.24, 0.3 \rangle$	$\langle 0.49, 0.05 \rangle$	$\langle 0.4, 0.34 \rangle$
k_2	$\langle 0.18, 0.72 \rangle$	$\langle 0.35, 0.34 \rangle$	$\langle 0.42, 0.15 \rangle$	$\langle 0.48, 0.05 \rangle$
k_3	$\langle 0.35, 0.15 \rangle$	$\langle 0.24, 0.53 \rangle$	$\langle 0.32, 0.34 \rangle$	$\langle 0.49, 0.15 \rangle$

to calculate the aggregated value of the k_i -th applicant about c_j -th criterion at a current moment $h_0 \notin D$, where $\#_q$ is equal to 1, 2 or 3 depending on whether the pessimistic, averaging or optimistic scenarios are chosen. The franchise chain has a requirement for the candidates, so that their total score is not less than a predetermined TIFP $\langle 0.6, 0.01 \rangle$. The level operator (5) is applied to the TIVIFIM B and it is established that all candidates meet this requirement.

Step 3. At this step, a TIFIM $PK(h_0)$ of the weight coefficients of the assessment criterion according to its antecedence is created from the franchisor v_e :

$$PK(h_0)[C, v_e, t_f, \{pk_{c_j, v_e, h_0}\}] = \begin{array}{c|c} h_0 & v_e \\ \hline c_1 & \langle 0.8, 0.1 \rangle \\ c_2 & \langle 0.7, 0.1 \rangle \\ c_3 & \langle 0.5, 0.2 \rangle \\ c_4 & \langle 0.7, 0.1 \rangle \end{array}$$

$$\text{and } B = R \odot_{(\circ,*)} PK = \begin{array}{c|c} h_0 & v_e \\ \hline k_1 & \langle 0.656, 0.0148 \rangle \\ k_2 & \langle 0.661, 0.0136 \rangle \\ k_3 & \langle 0.669, 0.0142 \rangle \end{array}$$

Step 4. The optimistic aggregation operation $\alpha_{K, \#_3}(B, k_0)$ finds that k_3 is the optimal franchisee for the franchise chain of fast food restaurants in Bulgaria v_e with the maximum degree of acceptance (d.a.) 0.669 and the minimum degree of rejection (d.r.) 0.0142 in an optimistic scenario, in a pessimistic scenario – k_1 with the minimum d.a. 0.656 and the maximum d.r. 0.0148. The closest to the average scenario is k_2 with the d.a. 0.661 and the d.r. 0.0136.

Step 5. At this step, we apply the ICRA with $\alpha = 0.8$ and $\beta = 0.10$ over $R(h_0)$. The conclusion is that the evaluation system in the chain is optimized.

The results, obtained from the ICRA application [11], are in the form of IM in $\mu - \nu$ view result matrix:

	c_1	c_2	c_3	c_4
c_1	\perp	$\langle 0.33, 0.48 \rangle$	$\langle 0.62, 0.29 \rangle$	$\langle 0.57, 0.29 \rangle$
c_1	$\langle 0.33, 0.48 \rangle$	\perp	$\langle 0.52, 0.29 \rangle$	$\langle 0.57, 0.19 \rangle$
c_1	$\langle 0.62, 0.29 \rangle$	$\langle 0.52, 0.29 \rangle$	\perp	$\langle 0.67, 0.19 \rangle$
c_1	$\langle 0.57, 0.29 \rangle$	$\langle 0.57, 0.19 \rangle$	$\langle 0.67, 0.19 \rangle$	\perp

Step 6. At last step, the experts' assessments are correct from the point of view of IF logic [6] and their new rating coefficients are equal to $\{(0.82, 0.05), (0.64, 0.05), (0.81, 0.05)\}$.

IV. CONCLUSION

In the study, we have defined the OTIFAFr procedure for selection of the most suitable franchisee over temporal IF evaluations. A software implementation of the proposed algorithm was presented and the decision making procedure

applied for a franchisee selection. In the future, the study will continue with the development of OTIFAFr approach, so that it can be applied over the data, saved in extended TIFIMs [5] and also with software for its implementation.

Data Mining Competition

THE topic of this year's data mining competition is the prediction of the costs related to the execution of forwarding contracts. The data sets made available to participants will contain many years of history of orders appearing on the transport exchange, along with details such as the type of order, basic characteristics of the shipped goods (e.g., dimensions, special requirements), as well as the expected route that a driver will have to cover. The task for the competition participants will be to develop a predictive model that will assess the actual cost of individual orders as accurately as possible. Such a model will be used in the future to support Freight Forwarders in selecting profitable contracts.

The sponsor of the competition is Control System Software

– a software company that has been delivering solutions for the Transportation, Spedition, and Logistics industry for 20 years. Attractive prizes are provided for the competition participants:

- 1,000 USD for the winning solution (+ the cost of one FedCSIS 2022 registration)
- 500 USD for the 2nd place solution (+ the cost of one FedCSIS 2022 registration)
- 250 USD for the 3rd place solution (+ the cost of one FedCSIS 2022 registration)

Moreover, Control System Software may award an additional prize (250 USD + the cost of one FedCSIS 2022 registration) to the team that develops the most practical solution to the task.

KnowledgePit Meets BrightBox: A Step Toward Insightful Investigation of the Results of Data Science Competitions

Abstract—We discuss the benefits of integrating the KnowledgePit data science competition platform with the BrightBox technology aimed at diagnostics of machine learning models embedded within complex software systems. We briefly recall the history of international challenges held at KnowledgePit and we also discuss in what sense such technologies as BrightBox can be helpful during the post-challenge analysis. In particular, we show how to combine solutions submitted by the competition participants in order to obtain even more accurate predictions. The discussed functionalities are of significant importance for the sponsors and organizers of data science / machine learning online contests because they support adoption of submissions while designing ultimate solutions of real-world problems.

Index Terms—Data science competitions; machine learning; model stacking; KnowledgePit platform; BrightBox technology

I. INTRODUCTION

KNOWLEDGE Pit¹ is an online platform for organizing data science / machine learning (ML) challenges. Its architecture was first presented in [1] and since then, it has been improving continually. Currently, KnowledgePit puts together the functionalities of a typical competition platform – such as Kaggle² – with additional tools that make it possible for the competition sponsors and organizers to investigate the submitted solutions with respect to their *true* usefulness in the corresponding real-life decision problems. These tools are available thanks to integrating KnowledgePit with BrightBox – the technology developed by QED Software³ for the purpose of assessing the decision models basing on the analysis of mistakes that they are making [2]. In this paper, we discuss one of such functionalities – designed at the border of KnowledgePit and BrightBox – which lets us create better models by mixing solutions acquired from the competition participants.

The paper is organized as follows: In Section II, we recall the main ideas behind KnowledgePit and, as an illustration, we report the history of the KnowledgePit contests held in cooperation with the FedCSIS conference series. Analogously, Section III introduces the main ideas behind BrightBox, with a special emphasis on its contributions into the KnowledgePit’s

functionality. Section IV refers to the data science challenge which was associated with this year’s FedCSIS conference⁴. Besides describing the competition itself, we include here some KnowledgePit-supported visualizations that can be helpful for sponsors and organizers. In Section V, we explain our aforementioned idea of mixing the competition solutions and report the experimental results obtained for the challenge outlined in Section IV. Section VI concludes the paper.

II. THE HISTORY OF KNOWLEDGE PIT

The platforms such as Kaggle attract thousands of data scientists to participate in challenges aiming at solving real-life problems. Such challenges not only address specific problems but often facilitate innovative applications of ML algorithms. On the one hand, they are appealing to those for whom competitive challenges can be a source of new interesting research topics. They can also be an attractive addition to academic courses for students who are interested in practical applications. On the other hand, setting up a public data science competition is a form of outsourcing a given task to the community [3]. It can be beneficial to the sponsors and organizers who set up the contest, as it is an inexpensive approach to solve the problem that they are after [4].

Accordingly, it should not be surprising that the scope of our own platform – KnowledgePit – shifted during the years from organizing smaller, mostly student-focused challenges and projects to international data science competitions. Although KnowledgePit still hosts several student competitions for ML-related university courses every year, the most prestigious events are those prepared for big industry clients and partners, in association with international conferences [5], [6].

One may say that our competitions grew together with recognition of the FedCSIS conferences. Together with the one reported in Section IV [7], there have been already nine challenges held at KnowledgePit in cooperation with FedCSIS. The series started in 2014 with the *AAIA’14 Data Mining Competition: Key Risk Factors for Polish State Fire Service* [8]. Other competition topics included the recognition of firefighters’ activities based on inertial sensor readings [9], predicting seismic activity in coal mines [10], predicting video

This research was co-funded by the Polish National Centre for Research and Development in frame of project MAZOWSZE/0198/19.

⁴<https://knowledgepit.ai/fedcsis-2022-challenge/>

game winners based on game logs [11], marking hair follicles on microscopic images⁵, predicting win-rates of custom card decks in collectible card games [12], [13], and predicting typical patterns in network device workloads [14]. All of these competitions were highly successful. With more than 1,300 participating teams and several thousands of submitted solutions, they significantly contributed to solving important real-life challenges. They also provided us with a comprehensive survey on the state-of-the-art ML approaches in the related fields, such as time series forecasting [15], feature extraction [16], as well as prediction model ensembling [17].

III. KNOWLEDGEPIT MEETS BRIGHTBOX

During its journey, KnowledgePit had to evolve to fit the needs of our industrial partners. One of the most significant needs has been related to the post-competition analysis of the submitted solutions. With this regard, it was possible to meet the industry expectations thanks to integrating KnowledgePit with the aforementioned BrightBox technology.

As highlighted in Section I, BrightBox is a software technology which assesses decision models (aimed at classification, regression, prediction, etc.) basing on their mistakes (i.e. differences between their outputs and the observed ground truth). Its main application field is in diagnostics of ML models deployed within complex systems [18]. Its methods have deep roots in the theory of rough sets [19]. A diagnosed model is approximated by the rough-set-based surrogate models – the ensembles of so-called approximate decision reducts [20]. Then, particular cases are investigated by looking at their neighborhoods – the groups of other cases that are classified similarly by the surrogate reducts (i.e. objects that fit the same rules induced by reducts [21]). If a mistake that happened for a given case often repeats in its neighborhood, then it is likely that the diagnosed model was not trained correctly for such objects from the beginning. As another example, if the neighborhood is almost empty (i.e.: the diagnosed object seems to be classified by different rules than objects observed before), then BrightBox can conclude that the model seems to find itself in a new situation. Such hints are useful from an operational viewpoint when it comes to rebuilding ML models as parts of the aforementioned complex systems.

Although it was a non-trivial effort to adapt the default settings of BrightBox to the specifics of a data science competition platform (for instance, we had to address different scenarios of the access to the diagnosed models' behavior on the training data), it enabled us to extend basic KnowledgePit's functionalities (such as the analysis of trends in the quality scores or survey-based summaries of commonly applied ML techniques) with in-depth diagnostics of individual submissions. Since BrightBox does not require a direct access to the diagnosed models, it can be applied to construct the above-discussed surrogate models that approximate submitted solutions and allow reasoning about their properties. For example, it allows to approximate feature importance coefficients of

⁵<https://knowledgepit.ai/esensei-challenge/>

Fig. 1: Exemplary visualizations of one of solutions from challenge [5]. Points on the upper plot correspond to cases from the test data and their color reflects prediction errors. The lower plot shows approximated (using BrightBox) feature importance for the model used to create the analyzed submission. An experimental evaluation showed that the Spearman correlation between the approximated feature importance values and the actual values estimated for the model was ≈ 0.7 .

models used to create the submissions (see Figure 1). It can also provide insightful information on types of errors committed by models, and similarities between solutions submitted by competition participants. Prototype implementations of some selected functionalities provided by the BrightBox technology have been already tested in our previous competitions [5], [22].

IV. FEDCSIS 2022 CHALLENGE

As mentioned in Section II, FedCSIS 2022 hosted the ninth KnowledgePit competition associated with the FedCSIS series. We use this competition as an illustration how KnowledgePit works, as well as a prerequisite for the discussion in Section V. We refer to [7] for more details about this particular contest. The best solutions submitted by its participants are described in [23] (1st place), [24] (2nd), [25] (3rd), and [26] (4th).

The task was to predict the execution costs of so-called forwarding contracts. The data about contracts was provided by the competition sponsor – a company that develops decision

Fig. 2: The final scores of all solutions that reached less than 0.2 RMSE. The most successful teams are specially highlighted.

TABLE I: Top results of the FedCSIS 2022 Challenge [7]. Both preliminary and final scores reflect the RMSE measure.

rank	team name	preliminary	final	#submissions
1	Dymitr [23]	0.1398	0.1383	619
2	Cyan [24]	0.1402	0.1391	181
3	hieuvq [25]	0.1396	0.1407	159
4	Lord of the ML [26]	0.1434	0.1420	147
5	baseline [7]	0.1491	0.1475	-

TABLE II: The RMSE results of the solution stacking methods on the final test set. The simple solution averaging and the weighted solution averaging are included as a reference.

ensemble	final	#solutions
<i>average - best solution of top 5 teams</i>	0.1361	5
<i>weighted average - best solution of top 5 teams</i>	0.1360	5
<i>average - best solution of top 8 teams</i>	0.1366	8
<i>weighted average - best solution of top 8 teams</i>	0.1367	8
<i>LASSO reg. (opt. λ) best solution of each team</i>	0.1344	8
<i>average - top 28 solutions</i>	0.1358	28
<i>weighted average - top 28 solutions</i>	0.1358	28
<i>LASSO reg. (opt. λ) all solutions</i>	0.1339	28

support and optimization systems in the transportation, spedition, and logistics areas. That company was highly interested in a deeper analysis of the submitted solutions with respect to their potential deployment within the designed systems.

For the evaluation purposes, the data was divided into the training set (330,055 historical contracts) and test set (72,452 newer contracts). The data was carefully anonymized, but it

was done in such a way that its analytical value is not lost (see also our other competitions [5]). Given a regression nature of the considered prediction task, we selected one of typical evaluation measures – the root mean square error (RMSE). However, let us note that sometimes specifying a measure that truly reflects a real-life decision problem is not easy [27].

The competition was conducted in a standard way including: (i) the online preliminary evaluation on an unknown subset of the test data (the participants submit solutions for the full test set but preliminary evaluation is done on a subset which is unknown to them), (ii) the associated public leaderboard (only preliminary results are shown during the competition), and (iii) the final evaluation on the full test set (which is calculated after the competition is closed, after the participants select their final solutions to be evaluated, and only if they submit to KnowledgePit the reports that describe their solutions).

Table I displays the top results. Let us note that the preliminary and final rankings are different. Actually, the solution at the 3rd final place would be the best one if only preliminary scores were taken into account. Such cases are specially worth investigating with the usage of the BrightBox technology.

Table I shows also the baseline solution – the model that we prepared by ourselves prior to the contest’s beginning [7]. In this challenge, only four teams exceeded the baseline score (though sometimes it may be even less, see e.g. [14]). Figure 2 displays the history of all submissions of those teams.

V. MIXING THE SOLUTIONS

Due to a large number of submitted solutions and the fact that most of the best-performing teams used some advanced ensembling methods to compute their final predictions [23],

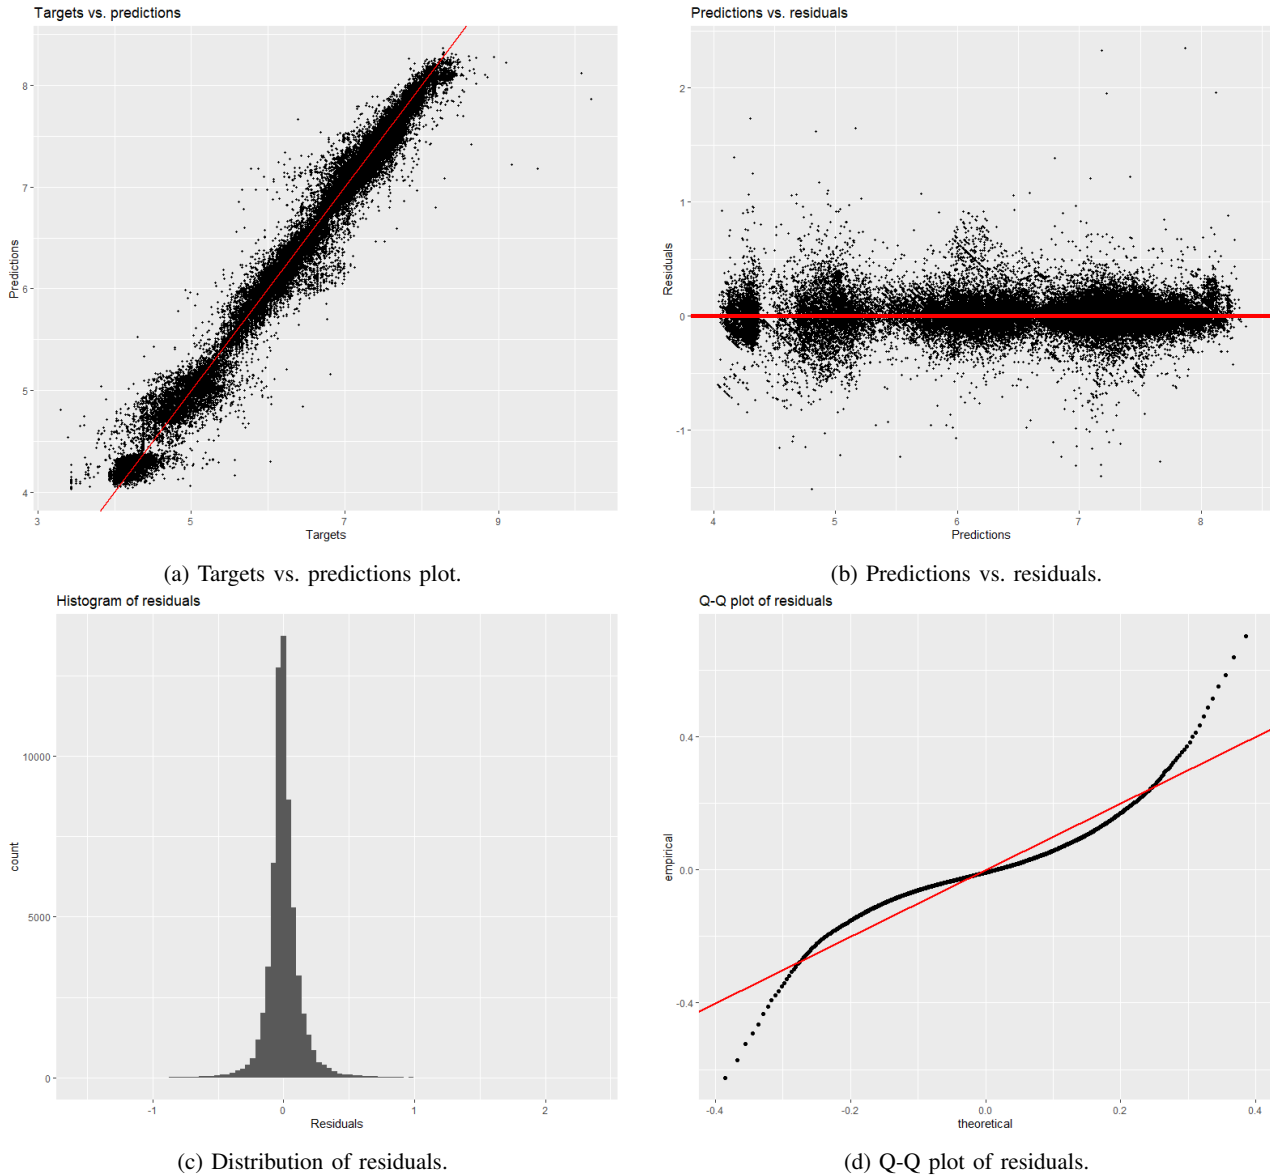

Fig. 3: Visual quality analysis of the ensemble model obtained using the considered solution mixing methodology. The top-left plot shows the relation between ground truths and predictions for test cases. The top-right scatter plot visualizes residuals with regard to predictions. The bottom-left plot shows the distribution of residuals on test cases, and the bottom-right plot shows the relation between theoretical quantiles of the Gaussian distribution and the empirical quantiles of the residuals.

[24], [25], [26], we decided to check how accurate the predictions could be if we mix submissions from different teams. In this way, not only could we verify which solutions are the most influential and potentially worth deploying, but also we could get a better insight into where the limit to prediction quality is when working with this type of the data.

To create the ensemble of submissions, we used the post-competition data analytics tools provided by KnowledgePit thanks to its integration with BrightBox (see also [22]). We compared the results of the LASSO regression-based model stacking [28] to simple model averaging methods. We also

investigated two ensembling scenarios. In the first one, we used all correctly formatted submissions. In the second one, we restrained the submissions to those with the best score in the preliminary evaluation from each team. In both cases, we trained the logistic regression model with LASSO regularization on predictions for the competition's preliminary evaluation set. Then, we verified the performance of each ensemble on the same final test set as all individual submissions.

We tuned the regularization parameter λ of the LASSO regression using the cross-validation technique, following the

guidelines taken from the `glmnet` package⁶. We chose λ for which the validation loss was lowest. Table II shows the results for the obtained ensembles. As a reference, we include the results obtained using simple averaging of the best solutions from top 5 teams (solutions [23], [24], [25], [26] and the baseline model), and the results of weighted averaging in which the weights correspond to the preliminary scores. We also include results obtained for the simple averaging, and weighted averaging when the number of used solutions corresponds to the optimal selection of the λ value.

The ensemble that achieved the best RMSE was trained on all submissions. It had non-zero coefficients for 28 solutions submitted by nine different teams. All of those coefficients were positive. The highest total impact on predictions had the submissions of *hieuwq* (0.321), followed by *Lord of the ML* (0.189), *Cyan* (0.156), and *Dymitr* (0.151). The combined impact of the remaining teams was less than 0.187.

We analyzed residuals of the resulting predictions. Figure 3 depicts their distribution across the test data. The top-left plot 3a shows the relation between ground-truth targets and predictions for test cases from the FedCSIS 2022 Challenge. It can be seen that they are aligned along the diagonal (the red line) with relatively few outlying cases. Similarly, in the top-right part of Figure 3 there is a scatter plot of residuals with regard to predictions of the ensemble. It shows that the residuals are not evenly distributed and there are a few prediction ranges with slightly larger magnitude (variance) of prediction errors. Both of those plots also show that the ensemble is nearly unbiased. This observation was confirmed – the mean difference between the ground truths and the predictions is nearly zero, i.e., -0.00027 . However, the distribution of residuals is not Gaussian. Such a hypothesis was rejected with high confidence using the Shapiro-Wilk test⁷. This can also be seen in Figures 3c and 3d. The distribution of residuals has long tails and the frequency of high error values is far from the theoretical quantile values of the Gaussian distribution. This observation suggests that the considered ensemble model could be further improved. Herein, a thorough BrightBox-based investigation of the morphology of mistakes made by each of the aforementioned 28 solutions can be helpful.

VI. CONCLUSIONS

We discussed the idea of organizing online data science competitions, with some examples taken from our own experience. We referred to KnowledgePit – our competition platform which, besides standard functionalities, includes some advanced analytical and visualization tools. We paid a special attention to the BrightBox technology which is used by KnowledgePit to approximate and diagnose solutions submitted by the competition participants. One of the methods which can be used within the resulting KnowledgePit-BrightBox environment, refers to mixing different solutions together, which leads toward more efficient ML models, as well as additional insights with regard to particular submissions.

⁶<https://cran.r-project.org/web/packages/glmnet/glmnet.pdf>

⁷https://en.wikipedia.org/wiki/Shapiro-Wilk_test

Consequently, in order to provide even more value to the future competition sponsors, we are extending KnowledgePit’s functionalities to utilize a broader range of XAI tools for the purpose of advanced post-challenge research. We also believe that such functionalities can be useful from an education perspective, whereby KnowledgePit may be considered as a platform for assessing and improving the data science competencies at universities, as well as in companies.

We also plan to continue integration of KnowledgePit with BrightBox. In particular, we are going to develop better tools for inter-competition analysis of individual platform users. Such functionality would help us to monitor the progress and skill development of participants. It could also provide value to our industrial partners who often look for potential skilled employees. In this context, KnowledgePit could be used by our partners as a tool that facilitates the recruitment of researchers for projects related to the competition topics, and for the evaluation of job candidates. Actually, QED Software is already using KnowledgePit for such evaluations.

Abstract—We discuss the international competition *FedCSIS 2022 Challenge: Predicting the Costs of Forwarding Contracts* that was organized in association with the FedCSIS conference series at the KnowledgePit platform. We explain the scope and outline the results obtained by the most successful teams.

Index Terms—Data mining competitions; costs of forwarding contracts; KnowledgePit platform

I. INTRODUCTION

TRANSPORTATION and logistics are among the most influential sectors in the global economy. It is their capacity that determines whether the commodities will reach the end customers. Moreover, the cost of transportation has a direct impact on the prices of essential goods. According to the European Union’s Science Hub¹, production expenses among European Union companies consist of up to 15% of transportation and warehousing fees. Hence, appropriate decisions of freight forwarders – individuals involved in the overall arrangement of transportation services – remain vital. The *FedCSIS 2022 Challenge* is an attempt to address this issue.

Freight forwarders commonly use their expert intuition to decide whether to accept or reject a contract. It allows them to arrive at accurate choices, though underneath it is a complex process. The contract cost is affected by, but not limited to, the size of transported goods, their weight, fuel prices and, most importantly, the contract route. Various countries are likely to have significantly different transit-related costs. Furthermore, outlier contracts such as hazardous freight or those requiring additional safeguarding are particularly hard to handle. The motivation for the competition was the presumption that machine learning (ML) can make efficient use of this data.

The paper is organized as follows: Section II reviews the literature on ML in freight forwarding tasks. Section III outlines the objective of the competition and gives some details about the data. Section IV describes the baseline solution that we prepared for the competition purposes. Section V reports the winning solutions. Section VI concludes the paper.

II. ANALYSIS OF RELATED LITERATURE

The income of the freight forwarder is largely based on a commission from the profit of successfully finding transportation services for the cargo that needed moving. Freight forwards operate on online freight exchanges, such as Timocom², Trans.eu³ or Teleroute⁴, seeking the most profitable contracts for which they can find a transportation service. The accurate transportation cost prediction is one of the key problems that need to be solved by freight forwarders to be successful. The importance of managing forwarders’ information is discussed in [1], while [2] analyzes other factors impacting the financial effectiveness of managing transportation logistics.

An interesting topic is the prediction of the future freight demand [3], which would enable freight forwarders to balance risk and expected income. Other ML-based approaches focus on finding estimated time of arrival (ETA) or predict fuel consumption. In [4] a random forest is used to predict ETA for intermodal transportation (i.e. including sea and/or railway transport). In [5], [6] random forests and support vector machines are also used to predict fuel consumption in order to monitor and prevent fuel fraud. A recent review [7] summarizes the aspects of freight forwarding and transportation, whereby ML approaches have been utilized up to now.

Meanwhile, factors other than time and fuel consumption influencing transportation costs, especially in data-driven ML approaches, have not been thoroughly studied. However, [8], [9] propose expert models to calculate such transportation costs. Moreover, [10] proposes a statistical model and analyzes the impact of various factors on the estimated cost. While [11] also takes into account risk factors for the ocean transportation costs. Finally, [12] tried to solve the problem of cost prediction using artificial neural networks. However, as in most of the mentioned studies, these results were based only on small data sets or expert surveys. We believe that providing research community with a more comprehensive data will prove crucial for finding new factors that impact the accuracy of predicting transportation cost for forwarding contracts.

III. FEDCSIS 2022 CHALLENGE OUTLINE

The challenge was launched at the KnowledgePit platform⁵ on March 1, 2022, and the submission system was opened until

²<https://www.timocom.co.uk/smart-logistics-system/freight-exchange>

³<https://www.trans.eu/en/carriers/>

⁴<https://teleroute.com/en-en/>

⁵<https://knowledgepit.ai/fedcsis-2022-challenge/>

May 27, 2022. We refer to [13] for more information about KnowledgePit, as well as about the previous KnowledgePit competitions that have quite a long tradition at FedCSIS.

The data used this year was provided by the competition sponsor, i.e. Control System Software – a Polish software company that is specializing in solutions for the Transportation, Spedition, and Logistics industry. The task for participants was to predict execution costs of forwarding contracts described in the available test data. An accurate prediction model for this task could be used in future to support freight forwarders.

A. Data preparation

The data sets that were made available in our competition describe an over six-year history of contracts accepted by a large Polish transportation company. The main data was composed of two separate tables. The first one contained basic information about the contracts, and the second one described the main sections of the planned routes associated with each contract. The first column in both tables, i.e. *id_contract*, stored identifiers that allow matching records between them. Additionally, the second column in the first table (the main data file), i.e. *expenses*, contained information about the actual prediction target values. A short description of the remaining data attributes from both tables was also made available in separate files. Finally, an additional data table containing historical wholesale prices of fuel was provided.

Since the data came from a real transportation company, all sensitive information had to be scrambled prior to publishing. All identifiers were removed or encoded by random strings. Geo-location data related to key points on the routes was modified. Instead of original values, we used the Nominatim service⁶ to generate coordinates of the central points in the corresponding post code areas. In the published data, the original geographical coordinates are changed into the generated ones. Some of the characteristics of trucks and trailers were transformed into indicators. Finally, the fuel prices and the target values (the contract execution costs) were rescaled.

For the purpose of the evaluation, the data was divided into separate training and test data tables. The training data contained approximately five-year history of the accepted contracts, and the test set was composed of the data collected in the last year (between Nov. 1, 2020 and Nov. 23, 2021). In total, training data stored information about 330,055 contracts described by 36 attributes, and the total number of route parts was 1,189,654 (the route data table had 60 attributes). The empirical distribution of the target expenses looked like a mixture of a few Gaussians, with the mean value 6.3735 and standard deviation 1.059. The histogram of target values is presented on Figure 1. The test data contained 72,452 contracts, and the corresponding route data consisted of 325,222 entries.

B. Evaluation procedure

The evaluation procedure for our competition was typical to challenges held at KnowledgePit [14], [15]. Competitors submitted solutions as text files with each line containing a single prediction for the corresponding test instance. The quality of submissions was evaluated online. We used RMSE as the

Fig. 1: The target expenses values in the training data set.

error measure. The preliminary score of each submission was computed on a small subset of the test records. Approximately 10% of test data was used for the preliminary evaluation. The best preliminary result for each team was published on the public leaderboard. The final evaluation was performed after the competition's completion using the remaining part of the test instances. Those results were then published online too. Only the teams which submitted a short report describing their approach were qualified for the final evaluation.

IV. COMPETITION BASELINE

To give a reference to competitors, we prepared and submitted at the very beginning predictions of our own baseline model. To construct it, we first analyzed the available data and identified features that could be useful. We divided the data preprocessing task into stages. At each stage, we extracted different types of features describing the contracts from the available data tables. This part of the model preparation process (i.e. feature extraction [16], [17]) proved to be crucial to the performance of the resulting prediction model.

Firstly, we processed the main data table. After consulting with domain experts, we identified categorical features that could have predictive value. For each of such features, we narrowed its set of possible values to those which appeared in at least 1% of training data. All other non-missing values were changed to *other*. After this transformation, we used two types of encoding. The selected features were one-hot encoded. Additionally, we created a numeric version of the categorical features by transforming each value into the mean *expenses* of contracts from the training data with that value. Overall, we applied this transformation to features *id_payer*, *id_currency*, *direction*, *load_size_type*, *contract_type*, *id_service_type*, *first_load_country*, *last_unload_country*, *route_start_country*, *route_end_country*, *prim_train_line*, *prim_ferry_line*, *route_start_month*, and *route_end_month*.

In the second stage, data from the route tables was processed. Again, the filtration of rare categorical values was performed. After that, for each contract we performed projections of aggregated *km*, *km_haversine*, and *kg_current* values on the values of selected categorical features. We added those

⁶<https://nominatim.org/>

Fig. 2: Estimated feature importance for the baseline model.

Fig. 3: Activity of participants by means of daily submissions.

projections as new features describing individual contracts. We also constructed a few dozen of other auxiliary features, such as the total number of steps without a load, the number of steps performed by external contractors, the average ratio between the current weight and the length of the route part, etc.

Finally, we added time features (e.g. month number, quarter, whether the contract will be executed through the week-end), fuel prices at the route beginning, and truck features (e.g. average size of the required trucks during the route). In total, we defined 585 numeric features describing the contracts.

We constructed the prediction model using the XGBoost library [18]. We did not focus on the hyperparameter tuning. We used a small portion of the training data as a validation set and experimentally checked several settings. The final model was heavily regularized, i.e. the learning rate was set to 0.01, $\alpha = \lambda = 1$, and subsampling was used on both instances and columns. The total number of used trees was 2,500, and the maximum depth of trees was set to 8. Figure 2 shows the estimation of feature importance in the resulting model. In the competition, our model had the fifth score with the preliminary RMSE value 0.1491 and the final result 0.1475.

V. COMPETITION RESULTS

The challenge was taken up by 130 teams from 24 countries. The teams came e.g. from Poland (76), India (14), and the USA (4). There were 1,927 solutions submitted. Figure 3 shows activity of competitors expressed in terms of the number of daily submissions. It shows that the number of daily

Fig. 4: RMSE (final test set) of solutions of the best teams.

submissions remained stable in the first half of the competition. Teams increased their activity in the second half, reaching the peak in the last week. Solutions submitted during the last 3 days of the competition account for nearly 24% of all solutions. This shows that the competition between participants continued until the last moment. In Table I, we present the final ranks, scores, and the number of submissions of the best performing teams. Figure 4 follows with more details about the teams that eventually managed to exceed our baseline solution.

As in previous KnowledgePit competitions, feature extraction was a crucial step. The solutions of the best-performing teams were preceded by in-depth data analysis and processing. The well-established approach of a feature selection preceded by a feature generation was the most common. Feature generation methods ranged from simple statistics to a manual selection of feature combinations and regex-based information extraction from text describing temperature requirements.

Every team that exceeded the baseline used gradient boosting methods (XGBoost [18], LightGBM [19] or CatBoost [20]) and model ensemble techniques. The winners’ solution puts emphasis on choosing suitable ensemble methods and model diversification, whereby their two proposed approaches focus on the diversity of the models’ hyperparameters and the level of disagreement of the models’ output. Both approaches were used in the final solution. The decision of their final model ensemble was the average of the models’ predictions on two

subsets with different features. The runner-up team used the model stacking approach (i.e. ridge regression trained on top of gradient boosted trees' outputs). On the other hand, the team that finished third conducted a forecast post-processing that aimed to predict a trend in the contract costs. That forecast was used to adjust the predictions of the final model.

VI. CONCLUSIONS

We presented an international data mining competition related to a vital problem in the transportation and logistic industry, i.e. predicting the execution costs of forwarding contracts accepted by a freight company. We described the competition scope and available data sets, and we proposed a baseline model for the task. We also discussed the most successful solutions proposed by the participants.

The competition was a successful event, with 130 registered teams from 24 countries. The most accurate solutions were largely dominated by gradient boosting models implemented in popular libraries, such as XGBoost, and LightGBM. They were typically combined with feature extraction techniques in the data preprocessing phase. Moreover, a few teams decided to mix several models trained on different parts of data, and their final solutions were generated using an ensemble.

Reducing transportation expenses by selecting optimal contracts, or by identifying the most costly factors can decrease the price of production of many goods including those purchased on a daily basis. We believe that our competition contributed to the discussion on the estimation of forwarding contract costs. The solutions developed by participants, and outcomes of future research may pronouncedly influence the decision-making process of transportation and logistics companies. By providing the research community with a large-scale data set, we hope to accelerate the advances in this area.

Abstract—The industrial machine learning applications today involve developing and deploying MLOps pipelines to ensure the versatile quality of forecasting models over an extended period, simultaneously assuring the model's accuracy, stability, short training time, and resilience. In this study, we present the ML pipeline conforming to all the abovementioned aspects of models' quality formulated as a constrained multi-objective optimization problem. We also provide the reference implementation on state-of-the-art methods for data preprocessing, feature extraction, dimensionality reduction, feature and instance selection, model fitting, and ensemble blending. The experimental study on the real data set from the logistics industry confirmed the qualities of the proposed approach, as the successful participation in an international data competition did.

Index Terms—XGBoost, Dimensionality reduction, Ensemble blending, Feature selection, Feature extraction, MOO, MCDA, Logistics

I. INTRODUCTION

MACHINE learning (ML) algorithms are widely used within decision-support [1] or recommender systems [2] in many branches of the industry, like fast-moving consumer goods (FMCG) [3], e-commerce [4], logistics [5], or even hard-coal mining [6]. However, as ML models continue to run in production environments for an extended period, new expectations and concerns have also arisen. Some time ago, data scientists were expected to deliver a fine-tuned model, today, attention is paid to building ML operations (MLOps) pipelines responsible for continuous monitoring and ensuring the quality of the developed models during their functioning [7], [8]. It is also worth paying attention to the ongoing shift in the quality assurance of models' predictions, which are no longer limited to optimizing a single measure, such as accuracy or root mean square error (RMSE). It should cover more models' characteristics like stability [9], resilience [10], or interpretability [11].

The fundamental task of data analysis is to represent the data accordingly to the investigated problem. The selection of appropriate criteria for assessing the quality of generated predictions is no less important. The choice of such measure primarily depends on the nature of the problem, e.g., there are different ones for classification and regression. The quality measure we choose in the model optimization process will have a crucial impact on its performance. Once decided, we

can rely on AutoML meta-learning to ignite a versatile exploration of several learning algorithms meanwhile optimizing their parameters, which, however, is very costly and time-consuming [12]. Whereas, over-optimizing a single measure in many applications is simply unnecessary. In particular, further tuning a model of sufficient quality may lead to overfitting, increase complexity, and reduce interpretability, not to mention the longer learning time and the increased cost of computing resources. Furthermore, in many cases, optimizing a single quality measure is insufficient. Reaching the optimal regression model according to the RMSE, which meanwhile is vulnerable to data deficiencies (e.g., unavailability of selected attributes), is pointless. One of the ways we may address those concerns is to refer to the multi-objective optimization (MOO) [13]. However, as the result of MOO, we do not end up with a single solution but many Pareto optimal models. Selecting the best one is still a complex and time-consuming task related to the multi-criteria decision aiding (MCDA) [14].

In response to the above expectations and challenges, let us present the ML pipeline for training forecasting models that allows optimizing not only a single quality measure, such as RMSE, accuracy, or F1-score, but also taking into account the robustness and resilience of the ensemble blended. The developed pipeline assumes that during the training procedure, the goal is not to optimize the model over days to achieve even a minimal quality improvement on a single error measure but to adhere to many business expectations possibly fast. Accordingly, we define the task as a MOO and adapt ϵ -constrained scalarization for the investigated criteria [14]. By referring to quality thresholds that correspond directly to business expectations, we could significantly limit the time of model fitting (from days to seconds), which obviously determines the lower cost of cloud computing resources [15]. Furthermore, the adopted principle of building a model on random subsets of attributes and rows allows to achieve a variety of different models within an ensemble [16], [17]. Such an approach to training set selection enables a very straightforward parallelization of the learning procedure and hence provides significant acceleration of computation [18].

Yet another material aspect of the developed solution is the proposed feature extraction mechanism. The method is composed of several steps. Firstly, we combine available data sources into one flat file and aggregate the one-to-many relations with the common *SELECT . . . GROUP BY SQL-*

Research co-funded by Polish National Science Centre (NCN) grant no. 2018/31/N/ST6/00610.

based approach to extract some generic statistics. Later, we use feature extraction methods like one-hot encoding and ordinal coding to obtain a numerical representation of the data. This way, we achieve a sparse data representation, which poses a big problem for the boosting tree algorithms by impacting the quality of their cuts on the attributes. Such a situation imposes the construction of deeper trees, making generalization difficult and leading to over-fitting. Therefore, after encoding a given feature, we apply one of the most popular dimensionality reduction methods - principal component analysis (PCA) - to use the first few components.

To show the particular qualities of our solution, we present a case study in the logistics industry for predicting costs associated with forwarding contracts. For this purpose, we used three data sets from the machine learning contest organized on the KnowledgePit.ml platform [19], which we combined together, preprocessed, and analyzed with the developed solution. In the conducted research, we assume that the acceptable level of the prediction error measured with the RMSE measure should not exceed 2.5% of the average cost of forwarding contracts in data that corresponds to RMSE of approx 0.17. We also assume the robustness threshold of 0.02, understood as the maximal acceptable difference of RMSE achieved by the model on the training and validation set during the training procedure. Furthermore, we set the resilience threshold so the constructed ensemble should consist of at least 10 models. This way, we could provide reliable forecasts even if some of the models within the ensemble became unreliable and could impair the overall prediction quality of the ensemble. Such a situation may occur in production environments, e.g., due to a software error or unavailability of the critical attributes for this model.

The main contributions of this paper are as follows:

- 1) The ML pipeline considering various aspects of models' quality formulated as a constrained multi-objective optimization problem.
- 2) The complete reference implementation of the ML pipeline providing methods for preprocessing, feature extraction, dimensionality reduction, feature and instance selection, model fitting, and ensemble blending.
- 3) The experimental study on the real data set from the logistics industry that confirmed several qualities of the proposed approach, including small prediction error (RMSE), robustness to over-fitting, fast computing time, and resilience.

The rest of the paper is organized as follows. In Section II, we review the related literature. Section III provides a complete reference for the developed ML pipeline. In Section IV, we describe in detail the experiments conducted in this study including the description of the data, experimental setup, and the results. Finally, in Section V, we draw conclusions and suggest possible future research directions.

II. RELATED WORKS

Due to the general availability and affordability of cloud services [15], and the proven effectiveness of machine learning

[5], [17], modern enterprises massively automate their processes and optimize decision-making with intelligent use of the collected data [3]. This trend is beneficial to many industries, including supply management and logistics [20]. Let us pay special attention to international freight transportation, which is related to moving goods between countries and may involve many stakeholders: shippers, carriers, forwarders, third-party logistics services, and customs of two or more countries for each movement [21]. In this context, machine learning is seen as one of the primary enablers for the dynamic development of enterprises, allowing for apt data-driven decisions, including route planning, travel time prediction, vehicle scheduling, estimated time of arrival, and foremost accurately predicting costs related to the execution of forwarding contracts [22], [23].

We can model this task as a regression of the forwarding contract costs conditioned by the attributes of orders, such as the type of order, basic characteristics of the shipped goods (e.g., dimensions, special requirements), and the expected route that a driver will have to cover. Among the ML algorithms commonly applied to solve the regression problems, we may point out eXtreme gradient boosting trees (XGBoost), deep neural networks, or support vector machines [21], [24]. Considering the industry specifics and the dynamics of changes in the business and technological environment, the developed data-driven decision-making system should promptly adapt to changes and operate reliably even in the event of data deficiencies. One of the ways to simultaneously address several potentially conflicting concerns is multi-objective optimization (MOO) [13].

Classically, MOO problems are often solved using scalarization techniques. In brief, scalarization means that the objective functions are aggregated (or reformulated as constraints), and then a single-objective problem is solved [25]. However, this method requires defining the perfect balance between objectives' importance. Another possibility to solve such a problem is to rely on Pareto front (PF) methods. For instance, the ϵ -constraint approach can obtain a set of PF solutions by keeping only one objective and subdividing the others into several segments with some thresholds. Here, we do not end up with a single solution but potentially many models, and selecting the optimal one requires further effort [14]. In the proposed framework, we refer to ϵ -constraint filtering, but instead of choosing a single model, we blend the ensemble of several solutions [17]. This way, we not only avoid the multi-criteria decision task but also introduce the additional resilience level to our solution [10].

Among the popular ensembling techniques, we may mention random forest and XGBoost. These approaches of blending tree models minimize the regression (or decision) trees' tendency of overfitting, hence, ensuring better robustness and stability [9], [24]. The stability, RMSE, and resilience can be further improved by ensuring that the trained models in the final ensemble are relatively different from each other. One way to do this is to train models on diverse subsets of objects and attributes [17]. The training set selection, complemented by parallelization of computation, can lead to better general-

ization and minimize the overall training latency [16], [18]. It is usually essential to ingest several diverse data sources to provide adequately rich data representation with many different attributes. However, models such as XGBoost or deep neural networks operate on numerical features, whereas in most databases, we will also find some other data types.

A typical approach, in this case, would be to apply feature extraction, in particular, to encode each feature in numerical form [26]. One of the weaknesses of this approach may be the creation of a very sparse data representation related to the one-hot encoding of categorical features, which in turn can have a negative impact on tree models' performance.

Furthermore, as the number of features increases, the model training takes far more time and consumes more resources. There are many methods allowing to project or embed the data into a lower-dimensional space while retaining as much information as possible, just to mention independent component analysis, multidimensional scaling, or principal component analysis (PCA) [26]. The central idea of PCA is to reduce the dimensionality retaining as much as possible of the variation present in the data [27]. In the proposed framework, we refer to all the above-mentioned techniques. Furthermore, putting the things together, we propose the end-to-end ML pipeline adhering to the ML operations paradigm that ensures the solution's quality over time.

III. SOLUTION OVERVIEW

The developed ML pipeline consisted of several stages related to data ingestion, preprocessing, extending representation, reducing dimensionality, robust model training, and resilient ensemble blending. The first step in the developed pipeline is data ingestion and integration. Next, we perform data cleansing, encoding categorical variables to the numeric form, extracting some custom characteristics from text columns, imputing missing values, and conducting further feature extraction (FE) [18], [28].

FE addresses the problem of finding the most compact and informative data representation and is fundamental for every

ML pipeline. The importance of proper data representation was aptly identified by *Pedro Domingos*: “At the end of the day, some machine learning projects succeed, and some fail. What makes the difference? Easily the most important factor is the features used”. Using more relevant data sources and better knowledge representation may have a crucial impact on the final model quality. Therefore we plan to further extend the developed FE methods by introducing histogram-based feature engineering [29]. Among other relevant, recently reported approaches that could be in the future implemented in our ML framework, we may indicate embedding selected statistics from survival analysis or features derived from deep learning methods into data representation [5], [30].
